Figure 33.2 A typical survival curve for rodents.

statistical power and allow for expected mortality during the experiment (reviewed in Miller and Nadon, 2000). Figure 33.2 illustrates the need for excess animals when an experiment will require the animals to be maintained for some time. If the age of the animals puts them near the top of the mortality phase of the survival curve (arrowhead), few will die during the experimental period. But if the age of the animals puts them in the middle of the mortality phase (arrow), significantly more animals are needed to allow for the anticipated mortality. It is also important when comparing two different strains to compare biological age instead of chronological age. F344 × BN F1 male rats have a median lifespan of 34 months while F344 male rats have a median lifespan of 24 months. Comparing 24-month-old rats of the two strains would have them in very different points in their biological age. These concerns are covered in more detail in Chapter 4 of this book.

### Resources

Getting started in the use of animal models to study biogerontology can be challenging, but there are many resources available to assist in this endeavor. The NIA supports many resources designed to provide the raw materials for studies into the process of normal aging and the prevention, progression and treatment of age-related diseases. Table 33.6 provides web URLs for NIA resources relating to animal models, as well as three informational resources: the Mouse Genome Informatics site, the Mouse Phenome Database, and the Rat Genome Database. The latter resources are valuable repositories of information crucial to deciding on the optimal strain for experimental purposes.

### ACKNOWLEDGMENTS

The author deeply appreciates the critical review of the manuscript by Dr. Huber Warner and his support of the development of the NIA resources program, and the helpful discussions with Dr. Richard Miller.

# Life Extension in the Dwarf Mouse

Andrzej Bartke

*Dwarf mice are remarkably long-lived. Congenital deficiency of growth hormone (GH), prolactin, and thyroid-stimulating hormone (TSH) due to mutations at the Pit1 or Prop1 loci, as well as GH resistance due to targeted disruption of the GH receptor gene lead to major increase in both average and maximal lifespan. Prolonged longevity of Snell dwarf (Pit1dw), Ames dwarf (Prop1df), and GHRKO mice is associated with a major extension of "health span" and multiple symptoms of delayed aging. Suspected mechanisms of prolonged longevity of hypopituitary and GH resistant mice include reduced peripheral levels of IGF-1 and insulin, enhanced sensitivity to insulin actions, reduced generation of reactive oxygen species, enhanced antioxidant defenses and stress resistance, and delayed onset of fatal neoplastic and nonneoplastic disease. Although negative correlation of body size and longevity applies to genetically normal mice and to other species, it remains to be determined whether reduced GH signaling delays aging in all mammals. However, the ability of reduced IGF-1/insulin signaling to prolong longevity applies broadly and perhaps universally.*

## Introduction

The realization that growth hormone (GH), insulin-like growth factor 1 (IGF-1), and insulin play important roles in the control of mammalian aging is a relatively recent development. In 1996, it was reported that hypopituitary Ames dwarf mice live significantly longer than their normal siblings (Brown-Borg *et al.*, 1996). These animals have primary deficiency of GH, prolactin (PRL), and thyroid-stimulating hormone (TSH) with secondary suppression of circulating levels of IGF-1, insulin, and thyroid hormones (details and references in the next section of this chapter). Soon afterwards, Kimura *et al.* (1997) demonstrated that mammalian IGF-1 receptor and insulin receptor genes exhibit significant homology to the *daf-2* gene in a round worm, *Caenorhabditis elegans* (*C. elegans*), a key gene in the signaling pathway that controls aging and longevity in this species. Research results reported during the next few years provided evidence for prolonged longevity in another mouse mutant deficient in GH, PRL, and TSH, and in mice with various spontaneous or induced mutations affecting

only the somatotrophic (GH/IGF-1) axis. Moreover, several genes involved in the control of aging in yeast, *C. elegans* and the fruit fly *Drosophila melanogaster* were shown to be homologous to genes related to IGF-1 and insulin signaling in mammals (reviews in Guarente and Kenyon, 2000; Tatar *et al.*, 2003). The picture that emerges from these studies is that an ancient pathway widely conserved during evolution is involved in the control of aging in organisms from distant taxonomic groups and that in mammals this pathway is represented by IGF-1 and insulin, by their receptors, and by proteins that become activated after these receptors bind the corresponding ligands.

In this chapter, we will list key characteristics of mice in which mutation of a single gene related to GH synthesis or action is associated with a significant extension of longevity. We will also review mechanisms which are suspected of mediating the effects of altered somatotrophic signaling on aging and longevity, and briefly discuss controversies surrounding the relationship of GH to aging. Finally, we will provide some information on the husbandry and breeding of long-lived mutant dwarf mice.

## Origin and Characteristics of Snell Dwarf and Ames Dwarf Mice

In laboratory stocks of house mice (*Mus musculus*), several spontaneous mutations cause hereditary dwarfism. The first mutation with a major impact on growth and adult body size was described by George Snell three quarters of a century ago (Snell, 1929). This mutation was originally named dwarf, genetic symbol *dw*, but subsequently was referred to by various names including Snell-Bagg dwarf mice and Snell-Smith mice and is now known as Snell dwarf, Snell dwarf mouse or Snell dwarf (*dw*) mutant of the Pituitary factor1 (*Pit1*) gene, *Pit1<sup>dw</sup>*. Snell dwarfism is due to a recessive autosomal mutation of the *Pit1* gene located on chromosome 16 (Li *et al.*, 1990). Animals homozygous for this mutation appear to be normal at birth, but their growth soon begins to lag behind their normal *+/+* and *dw/+* siblings and they reach approximately 1/3 of the adult body weight of normal mice. Early studies of Snell dwarf mice demonstrated that these animals lack GH- and TSH-producing

cells in the pituitary, are GH deficient and hypothyroid, and readily grow in response to injected GH (reviewed in Grüneberg, 1952; Bartke, 1979a). Reciprocal transplants of anterior pituitaries between dwarf and normal animals provided clear evidence that hormonal deficits and reduced growth in these animals are due to inherited anomalies in the pituitary rather than to altered hypothalamic control of pituitary function (Carsner and Rennels, 1960). Subsequent studies resulted in the demonstration that in addition to deficiency of GH and TSH, Snell dwarf mice also lack PRL (Bartke, 1965; reviewed in Bartke, 1979b).

Homozygous expression of Pit1<sup>dw-J</sup> (Jackson dwarf mouse), a mutation that independently arose at the same (Pit1) locus, produces the same phenotype as Snell dwarfism (Eicher and Beamer, 1980). Compound heterozygotes Pit1<sup>dw</sup>/Pit1<sup>dw-J</sup> are dwarf, do not seem to differ from homozygous Pit1<sup>dw</sup> mice, and have been used in research on aging (Flurkey *et al.*, 2001).

Another autosomal recessive mutation producing dwarfism in the mouse was described in 1961 by Schaible and Gowen. It was shown to be genetically unrelated to Snell dwarfism and located on a different chromosome, and was named Ames dwarf, genetic symbol df (Schaible and Gowen, 1961). After cloning of the affected gene on chromosome 11, Ames dwarf became known also as a mutant of the Prophet of Pit1 (Prop1), Prop1<sup>df</sup> (Sorenson *et al.*, 1996). Mice homozygous for the Ames dwarf mutation that appear identical to Snell dwarfs and similar to Snell dwarf mice are GH, TSH, and PRL deficient (Bartke, 1979a, 1979b). Although the primary hormonal deficits and the resulting phenotype of Snell and Ames dwarf mice appear to be identical, detailed comparisons of the effects of these mutations expressed on the same genetic background have not been made, and subtle differences may exist. For example, the time course of postnatal changes in the number of hypothalamic (tuberoinfundibular) dopaminergic neurons was recently shown to differ between Snell and Ames dwarf mice (Phelps, 2004).

Studies of the genetic control of development and cytodifferentiation of the anterior pituitary in fetal mice lead to the demonstration that the Prop1 and Pit1 genes, which are mutated in the Ames and Snell dwarfs, respectively, are normally sequentially expressed during days 12.5–15.5 of embryonic development. The Prop1 gene controls differentiation of Pit1 producing cells that give rise to cell lineages that eventually develop into somatotrophs, lactotrophs and thyrotrophs, i.e., adeno-hypophyseal cells that produce GH, PRL, and TSH (Li *et al.*, 1990; Sorenson *et al.*, 1996). In the adult, the normal product of the Pit1 gene controls expression of GH, PRL, and  $\beta$  subunit of TSH by binding to promoters of the corresponding genes. Mutations of either of these genes block normal pathways of the differentiation of GH, PRL and TSH producing cells (Sorenson *et al.*, 1996) and thus produce primary deficiency of these hormones.

Recent study of early postnatal development of the pituitary in Ames dwarfs revealed enhanced apoptosis and reduced proliferation (Ward *et al.*, 2005).

Failure to synthesize and secrete GH, PRL and TSH from the pituitary leads to a host of secondary hormonal deficits and phenotypic alterations, including reductions in hepatic expression of IGF-1, circulating IGF-1 levels, growth and adult body size, hypothyroidism, reduced body temperature and spontaneous locomotory activity, reduced circulating insulin and glucose levels, altered regulation of carbohydrate metabolism, delayed puberty, and female sterility due to luteal failure (reviewed in Bartke and Brown-Borg, 2004). Other characteristics of Snell and Ames dwarf mice include alterations in the profiles of gene expression, body composition, immune function, fibroblast responses to cytotoxic stress, and also significantly extended longevity, which is the subject of this chapter. For more detailed review of the characteristics of Snell and Ames dwarf mice and references to the corresponding studies, the reader is referred to recent reviews (Bartke, 2000; Bartke *et al.*, 2001a; Bartke and Brown-Borg, 2004).

## Longevity of Dwarf Mice

Although Ames and Snell dwarf mice are now used in many laboratories to study the mechanisms of extended longevity, the evidence that they have increased lifespan was obtained only recently. Curiously, one of the first studies to address this issue concluded that Snell dwarf mice are extremely short lived because they are immunodeficient and succumb to infectious diseases at a very early age (Fabris *et al.*, 1972). These findings must have been unique to this particular population or to the husbandry conditions, because shortly afterwards other investigators working with Snell dwarf mice reported that they did not encounter early mortality of the dwarfs (Shire, 1973; Schneider, 1976). However, these reports did not provide any information on the average or maximal longevity of the dwarf mice. In contrast to the study of Fabris *et al.* (1972), in a paper published in the same year, Silberberg (1972) referred to Snell dwarf mice as having an “unusually long lifespan” and reported data from dwarfs that were killed at the ages ranging up to 41 months. Although no data on longevity or survival plots were provided or referenced, this was the first mention of extended longevity of these mutants. Moreover, this report included important evidence for delayed aging of joint cartilage in Snell dwarf as compared to normal mice and absence of osteoarthritis in the dwarfs (Silberberg, 1972).

In 1996, Brown-Borg *et al.* reported that Ames dwarf mice live significantly longer than their normal siblings with the increase in average lifespan being over 45% in males and over 60% in females (Brown-Borg *et al.*, 1996). The survival plot included in this report suggests that the maximal lifespan of Ames dwarf mice was similarly

increased and that there was a delayed onset of age-related mortality in the dwarfs with little change in the slope of the survival curve. Delayed longevity of Ames dwarf, compared to normal mice, was replicated in subsequent studies and in animals fed different diets (Bartke *et al.*, 2001b, 2004).

Flurkey *et al.* (2001) reported significantly extended longevity of Snell dwarf mice with an increase of average lifespan of 42%. The same report contained important evidence for delayed aging of the immune system and collagen in Snell dwarf as compared to normal mice (Flurkey *et al.*, 2001). The conclusion that the biological process of aging is delayed and/or slowed down in both Snell and Ames dwarf mice compared to normal animals received further support from the studies of cognitive function (Kinney *et al.*, 2001a) and incidence and severity of neoplastic and nonneoplastic disease (Ikeno *et al.*, 2003; Vergara *et al.*, 2004) in these animals. Extension of both the average and the maximal lifespan in Ames and Snell dwarf mice is also consistent with this conclusion. Thus prolonged longevity of Snell dwarf ( $Pit1^{dw}$ ), Ames dwarf ( $Prop1^{df}$ ), and GHRKO mice is associated with a major extension of “health span” and multiple symptoms of delayed aging.

Studies in Snell and Ames dwarf mice provided clear evidence that, similar to what was discovered earlier in yeast, worms, and flies (reviewed in Guarente and Kenyon, 2000; Tatar *et al.*, 2003), mutations of a single gene can produce a delay of aging and significant increase in life expectancy in a mammal. Similar extension of mean and maximal longevity in two types of dwarfism which are due to mutations of different genes located on different chromosomes but result in essentially identical defects in endocrine function indicates that prolonged longevity is due to these endocrine deficits rather than to some other unknown effects of  $Prop1$  and or  $Pit1$  mutations. Results obtained in mice with mutations or targeted disruption of genes related specifically to somatotrophic (GH/IGF-1) signaling suggest that deficiency of GH is an important and probably the main cause of prolonged longevity of Ames and Snell dwarf mice. These results are discussed below.

### Growth Hormone Receptor Knockout Mice

The first animal model of GH resistance was produced by Zhou *et al.* (1997) by targeted disruption of the GH receptor/GH binding protein gene in the mouse. GHR/GHBP knockout mice (hereafter referred to as GHRKO) lack functional GH receptor and therefore exhibit GH resistance manifested by a dramatic decrease in circulating IGF-1 levels, reduced growth, and approximately 60% reduction in adult body weight. GHRKO mice are of nearly normal size at birth, exhibit profound growth deficits starting before weaning, but thrive under standard

laboratory conditions and most of them are fertile. Plasma GH levels are elevated presumably due to lack of negative GH feedback. In addition to reduced IGF-1 and diminutive size, GHRKO animals exhibit greatly reduced insulin levels, small reduction in circulating levels of thyroxine and 3',3,5-triiodothyronine, hyperprolactinemia, reduced levels of follicle stimulating hormone (FSH), delayed puberty, and various deficits in reproductive function (Zhou *et al.*, 1997; Hauck *et al.*, 2001; Chandrashekar *et al.*, 2004).

In 2000, Coschigano *et al.* reported that the GHRKO ( $-/-$ ) mice live significantly longer than both normal ( $+/+$ ) and heterozygous ( $+/-$ ) animals from the same population. The increase in average lifespan ranged from 38 to 55%, depending on the gender and genotype of the control ( $-/-$  or  $+/-$ ) (Coschigano *et al.*, 2000). The observation of prolonged longevity of the GHRKO as compared to normal mice was replicated in subsequent studies of the same author (Coschigano *et al.*, 2003) as well as in another laboratory in animals with different genetic background (Bartke, 2002). Importantly, Coschigano *et al.* (2003) reported significantly extended lifespan of GHRKO mice backcrossed to the long-living C57BL/6 strain. Studies of cognitive function (Kinney *et al.*, 2001b; Kinney-Forshee *et al.*, 2004) and end of life pathology in GHRKO mice (Ikeno and Bartke, unpublished) suggest that these animals, similar to Snell and Ames dwarf mice, experience delayed aging.

Roughly comparable life extension in GHRKO mice with isolated GH resistance and in dwarf mice deficient in GH, PRL, and TSH suggests that reduced somatotrophic (GH/IGF-1) signaling is an important determinant of delayed aging and prolonged longevity in each of these mutants.

### Other Mutations Affecting the Somatotrophic Axis

Evidence for prolonged longevity of mice with reduced activity of the somatotrophic axis is not limited to results obtained in GHRKO,  $Pit1^{dw}$  and  $Prop1^{df}$  mice. Flurkey and his colleagues reported that “little” mice with a mutation of the GH releasing hormone (GHRH) receptor and the resulting GH deficiency live approximately 25% longer than normal mice if fed a low-fat diet (Flurkey *et al.*, 2001). “Little” ( $GHRHR^{lit}$ ) mice exhibit profound, although not complete, suppression of circulating GH levels and reduced rate of postnatal growth. Body weight of young adults is reduced to about 50% of normal. Afterwards, this difference in body weight gradually diminishes due to a combination of slow growth and progressive development of obesity in little mice. If this mutation is maintained on the C57BL/6 background and the animals are fed a standard diet that contains 7% fat, the obesity of “little” mice is very pronounced, and their lifespan tends to be comparable to that of

normal mice. Reducing fat content of the diet to 4% prevents extreme obesity of these mutants and uncovers their propensity to outlive their normal siblings (Flurkey *et al.*, 2001).

Targeted disruption of IGF-1 or IGF-1 receptor (IGF1R) genes produces animals with profoundly suppressed fetal growth, low birth weight, and high perinatal mortality. However, animals heterozygous for the “knock out” of the IGF1R gene (IGF1R+/-) exhibit a fairly small reduction in postnatal growth, are healthy and fertile, and have increased resistance to the lethal oxidative stress-related effects of paraquat. Female IGF1R +/- mice live 33% longer than normal females from the same stock (Holzenberger *et al.*, 2003). Males tend to live longer, but the 50% difference in lifespan between IGF1R +/- and normal animals were smaller and not statistically significant. A 50% reduction in the levels of IGF-1 receptors in various organs of IGF1R +/- mice suggests that these animals are partially resistant to IGF-1. Important implications of these findings include support for the role of IGF-1 signaling in the control of mammalian longevity and a demonstration that a modest reduction of somatotrophic signaling that does not lead to overt dwarfism or compromised fertility can be sufficient to increase stress resistance, slow down aging, and increase lifespan. Although the role of IGF-1 in the control of aging was strongly suggested by the results obtained in GHRKO “little” and hypopituitary dwarf mice, the potential role of GH actions not mediated by IGF-1 could not be evaluated in these animals. Although the interpretation of the exciting findings of extended longevity of IGF1R+/- mice is somewhat complicated by a short lifespan of normal females of the employed stock, this work stands out as the first report that specifically associates reduced IGF-1 signaling with extended longevity in a mammal.

Studies in other types of genetically altered mice provide further support for the role of IGF-1 in the control of aging. Preliminary evidence suggests that lifespan is increased in mice with reduced IGF-1 levels due to a hypomorphic mutation of the IGF-1 gene (C. Sell; personal communication). Association of prolonged longevity with reduced plasma IGF-1 levels was also described in transgenic mice expressing urokinase-type plasminogen activator in the brain (Miskin and Masos, 1997). In these animals, suppression of IGF-1 may be due to reduced food consumption, thus resembling the situation in genetically normal animals subjected to caloric restriction (Masoro, 2001).

In contrast to numerous examples of extended longevity in animals with reduced levels of GH and/or IGF-1 or with GH or IGF-1 resistance, lifespan was not increased in transgenic mice overexpressing a GH antagonist (Coschigano *et al.*, 2003). In these animals, the action of endogenous GH is compromised as evidenced by reduced postnatal growth and adult body size, but lifespan is not affected. GH antagonist transgenic

mice become extremely obese, resembling the phenotype of GH deficient GHRHR<sup>lit</sup> mice, and it can be speculated that obesity masks or counteracts the effects of reduced GH signaling on longevity. Examining the effects of reduced dietary fat intake on longevity of GH antagonist transgenic mice would be of considerable interest.

Data concerning the relationship of somatotrophic signaling to aging in other mammalian species will be discussed later in this chapter.

### Cognitive Function of Ames Dwarf Mice; Possible Role of Hippocampal IGF-1 Expression

As mentioned earlier in this chapter, hypopituitary mouse mutants live much longer than their normal siblings and also exhibit various symptoms of delayed aging. In Ames dwarf mice this includes maintenance of youthful levels of cognitive function into a very advanced age. Studies conducted by Kinney (Kinney *et al.*, 2001a) using inhibitory avoidance task and other behavioral tests resulted in two striking and largely unexpected observations. First, learning and memory as measured by these tests did not differ between young adult dwarf mice and normal animals from the same stock. Second, the examined measures of cognitive function in old (22–29 months old) dwarf mice did not differ from values measured in young dwarf or normal mice. This was in contrast to results obtained in old normal mice that exhibited the expected age-related significant decline in learning and memory. These results were surprising and indeed opposite to what might have been expected in animals with profound suppression of circulating IGF-1 and thyroid hormone levels (details and references in Sun *et al.*, 2005a,b). The role of thyroid hormones in the development of the central nervous systems (CNS) and in adult brain function is very well documented. Perhaps Ames dwarfs benefit from exposure to maternal thyroid hormones via placental circulation and milk and from the amounts of thyroid hormones that can be produced in the absence of TSH stimulation. Coexistence of normal (and in aging animals, superior) cognitive function with the absence of GH and the resulting suppression of hepatic IGF-1 expression and IGF-1 deficiency is more difficult to explain. IGF-1 has major and very well documented neurostimulatory and neuroprotective effects. Eliminating IGF-1 production by targeted disruption of the IGF-1 gene in the mouse leads to severe defects in brain development (Cheng *et al.*, 2003). Deletion of the IGF-1 gene in the human is associated with mental retardation (Woods *et al.*, 1996). This discrepancy led Liou Sun in our laboratory to examine IGF-1 expression in the hippocampus of Ames dwarf mice, a brain region critically involved in learning and memory. His studies resulted in the demonstration that in both young adult and aging dwarf mice the levels

of IGF-1 mRNA in the hippocampus do not differ from the levels measured in the hippocampus of normal animals of the same age (Sun *et al.*, 2005a). Moreover, IGF-1 protein levels in the same tissues were significantly higher in dwarfs than in normal mice (Sun *et al.*, 2005a). In keeping with the elevation of hippocampal IGF-1 levels, and the role of IGF-1 in the control of neuronal proliferation, the number of proliferating cells in the granular cell layer and the subgranular zone of the dentate gyrus in the hippocampus was greater in young adult Ames dwarfs than in normal animals of the same age (Sun *et al.*, 2005b). Results of labeling with specific neuronal and glial markers suggested that most of the proliferating cells in this region were neurons (Sun *et al.*, 2005b).

Although association of different phenotypic characteristics cannot prove causality, we strongly suspect that normal cognitive function in Ames dwarfs and its preservation during aging are related to enhanced IGF-1 expression in the hippocampus. These findings also indicate that Ames dwarf mice cannot be regarded simply as “IGF-1 deficient” in spite of undetectable levels of IGF-1 in peripheral circulation, because local IGF-1 levels in the various organs may be biologically significant or even elevated. This conclusion is consistent with prior evidence that IGF-1 expression is GH-dependent only in some tissues, and IGF-1 levels in the brain are either unrelated or only weakly related to peripheral levels of GH (Lupu *et al.*, 2001). The etiology of the elevation of IGF-1 protein levels in the dwarf hippocampus is unknown, and we can only suspect that some compensatory mechanisms or local (CNS) expression of GH or other regulatory factors are involved in the presumably altered post-transcriptional control of biosynthesis of IGF-1.

These observations pertain also to some broader issues concerning organ-specific or, more likely, cell type-specific mechanisms that may account for the phenotypic characteristics of animals expressing various “longevity assurance genes.” Overexpression of antioxidant enzymes limited to the CNS was reported to extend the life of fruit flies (Phillips *et al.*, 2000), and longevity of two fruit fly mutants, with altered insulin-like signaling, was recently linked to the action of the corresponding genes in the heart (Wessells *et al.*, 2004). Without additional data, we can only speculate about the relative roles of the absence of GH action in the liver, adipose tissue, pancreatic beta cells and other targets, the reduction of IGF-1 levels in peripheral circulation, and maintenance of IGF-1 biosynthesis in the brain of long-lived mutant mice.

### **Altered Insulin Signaling as a Potential Mechanism of Extended Longevity**

The mechanism or, more likely, mechanisms linking reduced somatotrophic signaling with delayed aging remain to be identified. Our laboratory is interested

in the possibility that alterations in insulin signaling, control of blood glucose levels, and expression of insulin-related genes are among the mechanisms involved. In Ames and Snell dwarf mice, levels of both insulin and glucose in peripheral circulation are significantly reduced (Borg *et al.*, 1995; Hsieh *et al.*, 2002). In GHRKO mice, insulin levels are dramatically suppressed while glucose levels are modestly reduced (Coschigano *et al.*, 2003). Coexistence of reduced insulin and low glucose levels in the long-lived mutant mice implies enhanced insulin sensitivity. In support of this conclusion, administration of insulin was shown to cause significantly greater suppression of plasma glucose levels in GHRKO and Ames dwarf mice than in age- and sex-matched normal animals from the same stock (Dominici *et al.*, 2002; Liu *et al.*, 2004).

There is considerable indirect evidence to support the view that these changes in the insulin control of glucose metabolism may contribute to extended longevity. Reduced levels of insulin and glucose, and enhanced insulin sensitivity, are found in genetically normal mice and rats subjected to caloric restriction, a dietary intervention that reliably delays aging and extends longevity in laboratory stocks of these rodents (Masoro, 2001). A contrasting phenotype of hyperinsulinemia and insulin resistance is associated with reduced lifespan and various symptoms of accelerated aging in transgenic mice overexpressing GH (Bartke, 2003). Insulin resistance represents an important risk factor for major age-related diseases in the human (Facchini *et al.*, 2001).

Chronic elevation of insulin levels and hyperglycemia are believed to promote aging (Parr, 1999). Insulin effects are likely mediated by its action on mitochondrial function (Lambert *et al.*, 2004), while elevated glucose levels can lead to formation of advanced glycation products (AGE) and damage of proteins (particularly those with a low turnover) by nonenzymatic glycation (Baynes and Monnier, 1989). There is recent evidence that this type of damage to hemoglobin, as measured by the levels of HbA1c, is a risk factor for cardiovascular disease and all-cause mortality in nondiabetic individuals (Khaw *et al.*, 2004).

In contrast to increased insulin sensitivity of Ames dwarf and GHRKO mice, the ability of these animals to dispose of an injected glucose load is reduced rather than increased (Dominici *et al.*, 2002; Liu *et al.*, 2004). This is presumably due to reduced ability to release insulin in response to an increase in plasma glucose levels. Diminished insulin responses to exogenous glucose and also to re-feeding after a fast (Bonkowski and Bartke, unpublished) may, in turn, reflect reduced mass of insulin-secreting  $\beta$  cells in the GHRKO mouse (Liu *et al.*, 2004) and reduced number of large islets in the pancreas of Ames dwarfs (Parsons *et al.*, 1995). Reduced responses of the skeletal muscle to insulin represent another factor likely to contribute to the counterintuitive association of improved insulin sensitivity and

reduced glucose tolerance in these mutants. Acute effects of exogenous insulin on the early steps of insulin signaling are enhanced in the liver of Ames dwarf and GHRKO mice, but reduced in the skeletal muscle of these animals (Dominici *et al.*, 2000, 2002, 2003, and unpublished data). We suspect that the increased responses of the liver to insulin in Ames dwarf and GHRKO mice may account for the enhanced ability of insulin to suppress glucose levels while reduced insulin responsiveness of the skeletal muscle may contribute to the limited ability of these animals to dispose of glucose.

Reduced insulin/IGF-1/GH signaling in the liver of Snell dwarf mice is associated with decreased activity of the translational initiation pathway presumably leading to down-regulation of protein synthesis (Hsieh and Papaconstantinou, 2004).

Studies of gene expression in different insulin target organs and measurements of plasma adipokine levels suggest some possible mechanisms of altered insulin signaling in Ames dwarf and GHRKO mice. In the liver of 18-month-old Ames dwarfs, the levels of PPAR $\gamma$  mRNA and proteins, as well as the levels of insulin receptor, IRS-1, and IRS-1 proteins, were higher than the corresponding values measured in normal mice (Masternak *et al.*, 2004). PPAR $\gamma$  is an important regulator of insulin sensitivity and a target of antidiabetic drugs: IRS1 and 2 play a key role in transduction of insulin signals.

In the liver of GHRKO mice of similar age, the levels of phosphorylated (active) Akt were reduced, presumably reflecting reduced strength of the insulin signal in these profoundly hypoinsulinemic mice (Al-Regaiey *et al.*, 2005). The expression of a PPAR coactivator, PGC-1 $\alpha$ , was increased in the liver of GHRKO mice with marked elevations of both PGC-1 $\alpha$  mRNA and PGC-1 $\alpha$  protein (Al-Regaiey *et al.*, 2005). PGC-1 $\alpha$  is a key mediator of the effects of energy intake on metabolism and an activator of the gluconeogenic pathway, and there is increasing evidence for its involvement in the regulation of lifespan and mediating the antiaging actions of caloric restriction (Rodgers *et al.*, 2005). Consistent with reduced insulin signaling and increased expression of the PGC-1 $\alpha$ , expression of genes related to gluconeogenesis (PEPCK, G6Pase) was elevated in GHRKO as compared to normal mice (Al-Regaiey *et al.*, 2005). Microarray analysis of the broad profile of hepatic gene expression in Ames dwarf mice provided evidence that gluconeogenesis and  $\beta$ -oxidation of fatty acids are increased in these animals similar to the situation described in GHRKO mice. Results of this study also suggested that improved insulin sensitivity of Ames dwarfs may be related to reduced Gas6 and PTEN signaling in the liver (Tsuchiya *et al.*, 2004).

Recent studies suggest that secretory products of the adipocytes, collectively referred to as adipokines, have major effects on insulin sensitivity and that visceral fat is particularly important in this regard. In both Ames

dwarf and GHRKO mice, the levels of adiponectin, an adipokine known to sensitize the animal to the actions of insulin, are significantly elevated (Al-Regaiey *et al.*, 2005).

Moreover, expression of IL-6 and TNF- $\alpha$ , adipokines that promote insulin resistance, was reduced in the adipocytes of Ames dwarfs as compared to adipocytes of normal mice, while plasma levels of adiponectin were increased (Wang and Bartke, unpublished data). The increase in adiponectin and decrease in IL-6 and TNF- $\alpha$  presumably contribute to increased insulin sensitivity of long-lived mutant mice and imply that the secretory profile of their adipocytes is different from the values encountered in normal animals. Obesity is normally associated with reduced adiponectin levels, and yet in GHRKO mice, adiponectin levels are elevated in spite of increased adiposity (Berryman *et al.*, 2004). In Ames dwarfs, percent of body fat is somewhat greater in young adults than in the corresponding normal mice and increases with age. In older adult dwarfs it is relatively lower than in normal animals due to greater age-related increases in adiposity of normal mice (Heiman *et al.*, 2003). Increased plasma adiponectin levels in Ames dwarf as compared to normal mice were detected at the age of 18 months when percentage of body fat presumably did not differ between the genotypes (Heiman *et al.*, 2003). We do not know whether the unexpected association of normal or increased percent body fat, with significantly increased circulating levels of adiponectin in Ames dwarf and GHRKO mice, may be related to different distribution of the adipocytes among different (e.g., visceral vs. subcutaneous) fat depots.

## Other Mechanisms of Prolonged Longevity of Dwarf Mice

While reduced insulin release and enhanced responsiveness of the liver (and possibly other organs) to insulin appear to be important in mediating the effects of hypopituitarism and GH resistance on longevity, related and possibly unrelated mechanisms are undoubtedly also involved.

Reduced insulin signaling combined with reduced IGF-1 levels and hypothyroidism (which is modest in GHRKO and profound in Ames and Snell dwarf mice) is expected to lead to reduced oxidative metabolism. Oxygen consumption in Snell dwarf mice was reported to be reduced (Grüneberg, 1952), and body core temperature is slightly reduced in GHRKO (Hauck *et al.*, 2001) and markedly suppressed in Ames dwarf mice (Hunter *et al.*, 1999). Reductions in oxidative metabolism and reduced action of insulin on mitochondria would also be expected to result in reduced generation of hydrogen peroxide and a decrease in the total levels of reactive oxygen species (ROS). In support of this hypothesis, reduced H<sub>2</sub>O<sub>2</sub> generation was observed in the

mitochondria isolated from livers of Ames dwarf mice (Brown-Borg *et al.*, 2001).

There is also evidence that in addition to reduced levels of ROS, Ames dwarf mice have improved ability to eliminate free radicals and thus may be protected from ROS-induced oxidative damage. A series of studies by Brown-Borg and her colleagues provided evidence that the levels of antioxidant enzymes, including catalase, two forms of superoxide dismutase (SOD1 and SOD2), and glutathione peroxidase, are generally increased in various organs of Ames dwarf mice including the liver, kidney, heart and brain (Brown-Borg and Rakoczy, 2000, 2005; Brown-Borg *et al.*, 2001). Consistent with reduced generation of ROS and improved antioxidant defenses, oxidative damage to proteins, lipids, nuclear and mitochondrial DNA is smaller in Ames dwarfs than in normal mice (Brown-Borg *et al.*, 2001; Sanz *et al.*, 2002). There is also evidence for improved antioxidant defenses in GHRKO mice, although alterations in the activity of antioxidant enzymes were less consistent in these animals than in Ames dwarf mice (Hauck *et al.*, 2002).

Since oxidative damage is believed to represent a key mechanism of aging, these findings provide a very plausible explanation for extended longevity of hypopituitary and GH-resistant mice. Reduced generation of ROS and improved antioxidant defenses are likely acting downstream from reduced IGF-1 and insulin signaling and provide a final effector pathway for the life-extending actions of these hormonal alterations.

In further support of the role of improved antioxidant defenses in the longevity of dwarf mice, fibroblasts isolated from these animals are more resistant to oxidative cytotoxic stress than fibroblasts derived from normal mice (Murakami *et al.*, 2003; Salmon *et al.*, 2005). Other mechanisms that could contribute to delayed aging and prolonged longevity of dwarf mice include altered activity and responses of the hypothalamic–pituitary–adrenal axis (Hauck *et al.*, 2001; Al-Regaiey *et al.*, 2005), delayed sexual maturation (Chandrashekar *et al.*, 2004 and unpublished data), reduced activity of the hypothalamic–pituitary–gonadal axis (reviewed in Bartke, 2000; Bartke and Brown-Borg, 2004; Chandrashekar *et al.*, 2004), and/or some presently undefined characteristics that correlate with reduced postnatal growth and diminutive body size. Early sexual development and fecundity are, in general, negatively correlated with lifespan, even though many important exceptions are also known to exist (Partridge *et al.*, 2005). However, the importance of hypogonadism in the etiology of longevity of mutant mice discussed in this chapter is unlikely. Comparable relative extension of lifespan was detected in Snell dwarf mice which are severely hypogonadal and sterile, and in GHRKO mice which exhibit relatively minor deficits in gonadal function and can successfully reproduce (Zhou *et al.*, 1997; Chandrashekar *et al.*, 2004). Recently Vergara *et al.* (2004) reported that longevity

of male Snell dwarf mice was not reduced by a regimen of hormone replacement therapy that promoted testicular development and induced fertility.

Suppressed transcription of genes related to cholesterol biosynthesis (Boylston *et al.*, 2004) and increased expression of PPAR $\alpha$  regulated genes (Stauber *et al.*, 2005) in the liver of Snell dwarf mice may also contribute to extension of longevity in these animals.

Although it appears very unlikely that diminutive body size per se is conferring any important advantages in terms of survival, negative correlation of adult body weight and lifespan in mice was consistently found in studies of various natural and experimentally produced mutants as well as different stocks of genetically normal animals (Rollo, 2002) and individuals within a genetically heterogeneous population (Miller *et al.*, 2002). We suspect that these associations are due to the relationship of growth and adult body size to somatotrophic signaling.

### Somatotropic Signaling and Aging in Other Species

Negative correlation of body size and longevity, which was demonstrated in numerous studies in laboratory stocks of mice and in recent meta-analysis (Rollo, 2002), applies also to rats (Rollo, 2002) and to other species. Probably the most striking data are derived from the study of different breeds of domestic dogs as well as mixed-breed individuals from this species (Patronek *et al.*, 1997). Small dogs live longer than large dogs, and in several studies differences in body size and longevity were related to differences in peripheral IGF-1 levels (Eigenmann *et al.*, 1988). Negative correlation of height and longevity was shown in various cohorts of human subjects (Samaras *et al.*, 2003). There are also anecdotal reports of exceptional longevity of miniature breeds of horses and donkeys. Controversies concerning relationship of GH to human aging will be discussed later in this chapter.

In rats, suppression of GH signaling by hemizygous expression of GH missense transgene produced a modest but statistically significant extension of longevity (Shimokawa *et al.*, 2002). Unexpectedly, animals homozygous for the expression of this transgene had a reduced rather than increased lifespan (Shimokawa *et al.*, 2002). Genetically GH-deficient mutant dwarf rats have normal lifespans. However, when these animals were treated with GH during the period that normally encompasses rapid postnatal growth to create a model of adult GH deficiency, they lived longer than vehicle treated mutant controls or genetically normal rats (Sonntag *et al.*, 2005).

There is considerable evidence that in invertebrates, specifically in a worm, *Caenorhabditis elegans*, and a fly, *Drosophila melanogaster*, cellular signaling pathways homologous to IGF-1 and insulin signaling in mammals

are important in the regulation of aging and longevity (Guarente and Kenyon, 2000; Tatar *et al.*, 2003). Numerous mutations that reduce IGF-1/insulin-like signaling in these species cause an impressive increase of lifespan. Most intriguingly, homology of genes related to these signaling pathways and to aging extends also to unicellular yeast (Jazwinski, 1996). These homologies, extending across organisms that are taxonomically very distant and have enormous differences in physiology, life history, modes of reproduction, and life expectancy, strongly suggest, the existence of a fundamental relationship of IGF-1/insulin (or homologous) signaling to aging that is prevalent and likely universal in the animal kingdom and thus is almost certain to apply also to our own species.

### Controversies Surrounding Relationship of Somatotropic Signaling to Human Aging

Congenital absence of GH signaling in the human, in addition to preventing normal postnatal growth, is believed to constitute an important risk factor for cardiovascular disease (Rosen and Bengtsson, 1990; Besson *et al.*, 2003). Unfavorable serum lipid profiles in these individuals likely represent secondary consequences of obesity that develops in the absence of GH signal. Increased risk of cardiovascular disease would obviously lead to reduced rather than increased life expectancy in sharp contrast to the situation in hypopituitary and GH resistant mice. Comparisons are further complicated by cardiovascular disease being a major cause of mortality in humans but not in mice, and by the relatively greater importance of cancers in mortality of mice.

In humans, absence of anti-insulinemic actions of GH improves insulin signaling, but obesity related to GH deficiency leads to insulin resistance. Potentially opposing effects of stimulation of the biosynthesis of IGF-1 and the IGF-1 binding proteins by GH may have to be completely elucidated before we reach a good understanding of all consequences of GH deficiency.

Individual human subjects with hypopituitarism due to a mutation of the *Prop1* gene (the same gene that is mutated in the Ames dwarf mouse) or Laron dwarfism (homologous to the endocrine deficits in GHRKO mice) can survive to a very advanced age (Krzisnik *et al.*, 1999; Laron, 2005), but available data do not allow meaningful evaluation of their average or maximal lifespan. However, individuals with dwarfism due to congenital GH deficiency were recently reported to live significantly shorter than normal individuals from the same region (Besson *et al.*, 2003). Recent analysis of the relationship between height, survival, and polymorphisms of genes related to GH, IGF-1 and insulin in the human revealed that in, women, reduced activity of the insulin/IGF-1 signaling pathway was associated with improved old-age survival (van Heemst *et al.*, 2005). Carriers of a variant

GH1 allele were shorter and had significantly reduced mortality (van Heemst *et al.*, 2005).

In contrast to these controversies, mitogenic and anti-apoptotic effects of IGF-1 have been linked to promoting cancer in both rodents and humans (Yu and Rohan, 2000). Height and plasma IGF-1 levels represent risk factors for several types of cancer (Tretli, 1989; Rosen and Pollak, 1999; Yu and Rohan, 2000). Pathological hypersecretion of GH from the pituitary tumor of acromegalic patients is associated with reduced life expectancy (Clayton, 2003) similar to the findings in transgenic mice overexpressing GH (reviewed in Bartke, 2003).

In the human, as in other mammalian species, GH secretion by the pituitary and circulating GH levels decline with age. Because many age-related changes in body composition including loss of muscle mass and increase in adiposity resemble symptoms of adult GH deficiency and can be at least partially reversed by GH administration, GH therapy has been and continues to be widely promoted as an “anti-aging treatment.” Potential difficulties in extrapolating the findings in young or middle-aged adults with GH deficiency to endocrinologically normal elderly subjects and the issues related to the risk-benefit ratios of GH therapy are outside the scope of this chapter. However, it should be emphasized that from the available data it is not possible to determine whether GH therapy can influence the rate of aging or life expectancy in the human in either direction.

Pertinent to the studies of Snell and Ames dwarf mice that are TSH-deficient and hypothyroid, experimentally-induced hypothyroidism increased the lifespan of rats (Ooka *et al.*, 1983), and a recent study in humans over 85 years of age suggested an association of subclinical hypothyroidism with reduced rate of mortality (Gussekkloo *et al.*, 2004).

### Breeding and Husbandry of Long-lived Dwarf Mice

As was mentioned earlier in this chapter, Snell dwarfism and Ames dwarfism are caused by autosomal recessive mutations. Targeted disruption of the *GHR/GHBP* gene is also transmitted as an autosomal recessive trait. Consequently, homozygous Snell dwarf (*dw/dw*), Ames dwarf (*df/df*) and GHRKO (*-/-*) mice can be readily produced by mating heterozygous carriers of these mutations. Since homozygosity for these mutations appears to have no effect on prenatal mortality, matings of heterozygous carriers (e.g., *dw/+* × *dw/+*) produce 25% of dwarf (*dw/dw*) progeny, 25% of progeny carrying only wild-type alleles at this locus (*+/+*), and 50% of heterozygotes (*dw/+*). Heterozygous and *+/+* animals can be distinguished by DNA analysis (Dolle *et al.*, 2001; Chandrashekar *et al.*, 1999) or by breeding tests.

Since nearly all GHRKO (*-/-*) males are fertile, they can be bred to *+/-* females to produce equal

numbers of  $-/-$  and  $+/-$  progeny. Fertility of male Snell and Ames dwarfs depends on the genetic background, and most Ames dwarf males in the author's colony are fertile, although they attain puberty later than normal males. In stocks in which dwarf males are not fertile, fertility can be induced by treatment with thyroxine, GH, PRL, or combinations of these hormones (reviewed in Bartke, 1979a, 1979b, 2000; Bartke and Brown-Borg, 2004). The obvious advantages of using homozygous dwarf ( $dw/dw$ ,  $df/df$ ,  $GHRKO -/-$ ) as breeders is that mating them with heterozygous females produces 50% rather than 25% of dwarf progeny. Moreover, in this breeding system all of the phenotypically normal animals are heterozygous carriers of these mutations and thus can be used as breeders without the need for genotyping or genetic testing. The only disadvantage of this breeding system is that it does not produce homozygous normal ( $+/+$ ) animals. Using heterozygotes as normal controls is justified by lack of any obvious phenotypic differences between heterozygous and  $+/+$  mice, except for a small reduction in body weight in young adult  $GHRKO +/-$  as compared to  $+/+$  females. However, one must be cognizant of the possibility that any parameter under study might be influenced by heterozygous expression of the dwarfing genes.

Transplantation of anterior pituitary glands from normal mice under the kidney capsule of Snell or Ames dwarfs provides continued release of PRL and induces fertility in both males and females (Bartke, 1965, 1979b, 2000). Induction of female fertility in these mutants allows production of all-dwarf litters. This eliminates the need for genotyping individual animals in studies of the effects of these mutations during prenatal or early postnatal development. Fertile females can be used to provide placental tissue of purely mutant genotype (Soares *et al.*, 1984).

In contrast to their normal siblings, Snell and Ames dwarf mice often fail to thrive when they are weaned at 21 days of age. At this age, they may have difficulties in chewing pelleted diet and in reaching the food hopper and the water sipper in standard mouse cages. It is recommended to leave them with the dam (or both dam and sire) for a minimum additional 2–3 weeks. This is particularly beneficial if the dam becomes pregnant from postpartum estrus and is nursing her next litter during this period. After weaning, dwarfs should be housed in groups with other dwarfs or with normal females. Some laboratories consistently use normal female companions to house the dwarfs, and some provide them with readily accessible food in the bottom of the cage and use longer sipper tubes and/or thicker layer of bedding. Using a diet with high fat content (e.g., mouse breeder chow with 6.5 or 7.0% fat) is very important and probably essential. In the author's breeding colony of Ames dwarf mice, normal pups are weaned at 21 days of age, while dwarf pups are weaned 3–4 weeks later and housed in groups of 5 dwarfs per cage

(or, occasionally, in groups comprised of dwarfs and normal females) but otherwise receive the same care as normal mice.  $GHRKO -/-$  mice can be weaned at the age of 21 days and require no special housing conditions, care or diet.

## ACKNOWLEDGMENTS

Contributions of numerous colleagues, fellows, and students to the progress of our work on this topic are gratefully acknowledged. Recent and current studies of dwarf mice in our laboratory are supported by NIA (NIH) AG019899 and U19 AG023122 and by the Ellison Medical Foundation. We apologize to those whose work pertinent to this topic is not mentioned due to limitations of space or inadvertent omissions.

# The Canine Model of Human Brain Aging: Cognition, Behavior, and Neuropathology

P. Dwight Tapp and Christina T. Siwak

*Dogs develop age-dependent cognitive deficits that parallel declines observed in normal and pathological aging in humans. Like humans, some dogs show no decline, some show mild decline, and others of the same age develop severe cognitive impairments. Aged dogs show decreases in locomotion and changes in other behaviors but continue to display appropriate responses, just to a lesser extent compared to young dogs. Impaired dogs by contrast, show abnormal responses. These dogs are hyperactive, unresponsive to social stimuli or toys, and often engage in stereotypical behaviors. The aged dog is also well suited for investigation of the initial stages of plaque formation in the aging brain. Beta-amyloid deposition in the form of diffuse plaques is a prominent feature of the aged dog brain. Oxidative damage and neuron loss are also features of the canine brain while neurofibrillary tangles are absent. MRI procedures also reveal commonalities between the aging dog and human brains, including shrinkage, spontaneous lesion formation, and reduced blood flow. These findings suggest that the dog can be used to model the earliest phases of cognitive, behavioral and neuropathological changes associated with brain aging in humans. The existence of dogs that maintain cognitive function with age may provide insight into promoting successful aging in humans.*

Improvements in medical care for animals enable dogs to live longer; subsequently they may be at risk for developing age-related behavioral disorders comparable to the aging human. Clinically diagnosed as canine cognitive dysfunction syndrome, impairments include decreased activity, altered social interactions or responsiveness, disturbances of the sleep-wake cycle, disorientation, and a loss of prior house training (Landsberg, 1995). The aged dog develops more than 400 diseases that are phenotypically the same as the human, including reduced metabolic function, cardiovascular disease, inflammatory arthritis, decreased kidney function, cancer, visual and auditory impairments, and immunodeficiencies (Committee on Animal Models for Research on Aging, 1981).

These similarities make the dog a practical model for investigating the biological bases of human aging and disease.

For over a decade, our laboratory has been investigating brain aging in the dog. We adopted a clinical-neuropathological approach to empirically investigate cognitive processes and concomitant neuropathological changes in aging dogs. This approach involved the development of neuropsychological tests to evaluate cognitive function and correlate these measures with behavioral and neuropathological analyses to assess brain aging in the dog. There are several advantages in using the dog to study brain aging, including (1) the ability to study large populations of aging dogs at reasonable costs, (2) the highly gregarious nature of dogs which makes them easy to work with, (3) the sophisticated repertoire of cognitive functions and behaviors innate to dogs, (4) analogous patterns of cognitive decline, behavioral alterations, and neuropathology in dogs and humans, (5) the ability to control intervals between cognitive testing and neuropathological analyses, (6) the critical 3–5 year period of age-dependent neuropathology, which makes longitudinal investigations practical, and (7) common environments shared between dogs and humans, which exposes dogs to the same environmental stressors present in human aging.

Although our initial work involved dogs of various breeds, most of our research has primarily focused on the beagle dog. We selected a single breed to control for differences in physiological aging between breeds (Patronek *et al.*, 1997). Although studying multiple breeds is useful to examine genetic influences on behavior, differences in the life span of dogs of different sizes result in dogs that age at different physiological rates. Thus, a large dog of the same chronological age as a small dog will differ in physiological age. For example, a 10-year-old Beagle is equivalent to a 66.6-year-old human, while a 10-year-old Great Dane would equal 76.3. Our age-related classifications of Beagle dogs attempted to equate physiological age to humans in the same category: young dogs were

adults equal to the chronological age of humans considered to be young adults.

The utility of the dog as a model of brain aging will be presented in three sections, each summarizing one major research area. The first section will review findings from the neuropsychological tests our laboratory developed to evaluate the effects of age on different cognitive domains (learning, memory, and executive function) in the dog. The second section will describe changes in behaviors other than cognition such as locomotor activity, social responses, and exploratory behaviors in dogs. In the third section, the underlying neuropathology correlated with age-related cognitive and behavioral impairments in the dog will be presented. The objective of each section is to demonstrate that many aspects of aging empirically studied in the dog are consistent with functional and neuropathological markers of human aging, making the dog a practical model to study human brain aging.

### Cognitive Function and Aging in the Dog

Interest in the cognitive abilities of dogs can be traced as far back as the late 1800s, with anecdotal reports of dogs displaying long-distance navigational memory and associative learning (Romanes, 1884). Although subsequent studies under controlled laboratory conditions supported these early observations, the effect of age on cognitive function in dogs did not gain scientific appeal until the 1970s, focusing primarily on the developmental stages (Fox, 1971).

The single most comprehensive research program to examine cognitive aging in the dog, however, is the work conducted in the Beagle dog by N.W. Milgram and colleagues. Using a modified version of the Wisconsin General Test Apparatus (Figure 35.1), dogs are tested on a number of standard tasks (Figure 35.2) designed to

measure changes in learning, memory, and executive processes as a function of age.

Over a decade of research using these testing procedures has revealed that cognitive aging in the dog, like humans, is complex and nonlinear; striking individual differences are more the rule than the exception (Adams *et al.*, 2000a,b; Head *et al.*, 1995, 2001). Like elderly humans, some dogs show very little cognitive decline with age (i.e., successful agers) and perform at levels comparable to young animals (Figure 35.3).

Others exhibit a mild decline frequently observed in normal human aging. In certain cases, some dogs exhibit severe impairment corresponding to features of dementia observed in humans. Our studies have also revealed that learning and memory impairments can occur independently of one another and that executive dysfunction may be the earliest hallmark of cognitive decline in aging dogs.

### IMPAIRED LEARNING IN THE AGED DOG

We developed a number of tests to investigate age-related changes in canine learning. Specific tests were designed to examine procedural learning, associative learning, and more complex types of learning.

#### *Procedural learning*

The procedural learning task, designed to assess skill acquisition in the dog, consists of two learning phases: reward-approach and object-approach learning (Milgram *et al.*, 1994). Procedural learning is well preserved in normal human aging (Vakil and Agmon-Ashkenazi, 1997) and Alzheimer's disease (Almkvist, 1996). In dogs, however, procedural learning depends on previous rearing experience. Aged dogs raised as pets, having diverse and varied life experiences, perform as well as or better than young dogs. Conversely, old kennel-reared dogs with limited experiences in the environment are slower than

**Figure 35.1** Toronto General Test Apparatus (TGTA) used to assess cognitive function in the Beagle dog. See the color plate section.

**Discrimination Learning**

**Object Discrimination**

**Size Discrimination**

**Oddity Discrimination**

**Object Learning and Memory Task**

**Spatial Learning and Memory Task**

**Modified Spatial List Learning Task**

**Figure 35.2** Example of tasks developed to assess cognitive function in dogs. Shown are tests of discrimination learning (object, size, and oddity discrimination), object and spatial learning and memory, and complex working memory (modified spatial list learning task). See the color plate section.

**Figure 35.3** The combined sum of errors required to learn a delayed nonmatching-to-position task and an object discrimination and reversal task are plotted by age group. Aged dogs with scores greater than 2 standard deviations from the mean of the young dogs are considered impaired.

young dogs to acquire the procedural learning tasks (Milgram *et al.*, 1994). Thus, dogs with enriched experiences show a pattern similar to human learning, but having access to animals with restricted environments also revealed a dependency of learning ability on rearing history.

*Discrimination learning*

A common measure of learning used in animals is the discrimination task—an associative learning problem in which subjects must attend to the relevant stimulus feature(s) and acquire an association between the stimulus parameters and a food reward (Sutherland and Mackintosh, 1971). In the object discrimination task, an animal must learn that one object is associated with food reward. The two objects used differ on multiple stimulus dimensions (i.e., size, color, brightness, shape). Studies in nonhuman primates (Voytko, 1999) and dogs (Head *et al.*, 1998; Milgram *et al.*, 1994) indicate that simple discrimination learning tasks, like the object discrimination, are insensitive to age. The discrimination learning task can be made more difficult when the differences between the objects are reduced. In the size discrimination task, the two objects are identical in appearance but differ only in size (Figure 35.2). The task now becomes more complex and age differences appear (Tapp *et al.*, 2003a).

The importance of task complexity in evaluating discrimination learning in dogs is further demonstrated using an oddity discrimination task. In this task, the number of object choices is increased to make the task

more difficult (Milgram *et al.*, 2002b). The animal is presented with three objects, two identical and one different. To obtain reward, the animal is required to respond to the odd object. After reaching criterion, the animal is presented with three new oddity tasks where the odd object progressively becomes more similar in features to the other two identical objects, until four problems are solved. Old dogs are not only impaired at this task, but the number of total errors increases with each successive oddity problem, suggesting a lack of ability to learn the rule of selecting the odd object. Young animals, less than 6 years old, show rapid learning after the initial problem relative to old dogs, 9 to 13 years old, despite the increasing similarities in the appearance of the objects.

*Object recognition learning*

Object recognition learning, the ability to classify and register the identity of objects, is examined using a delayed nonmatching to sample (DNMS) paradigm (Figure 35.2; Callahan *et al.*, 2000). Originally developed by Mishkin and Delacour (1975) for nonhuman primates, the DNMS paradigm begins by presenting the dog with a single stimulus object located over the center food well. A response to the object is followed by a delay interval, after which, two objects are presented over the two lateral wells—the original object and a novel discriminandum. The correct response for the dog is to choose the novel stimulus. The location of the novel stimulus is randomized across trials, and different stimuli selected from a large pool of objects are used for each trial.

### 35. The Canine Model of Human Brain Aging: Cognition, Behavior, and Neuropathology

Initial attempts to test dogs on the DNMS task suggested that dogs were impaired at object recognition learning (Milgram *et al.*, 1994). Using a weak criterion, only 4 of 10 young animals were successfully able to learn the task. Moreover, when tested on increasing delays, young dogs were able to respond with only 63% accuracy. None of the aged dogs could learn how to solve the problem. These results were initially interpreted as evidence that the canine visual system was not well suited for visual object recognition performance. A subsequent study, however, reported substantial improvements in object recognition learning in the dog when two important task-specific factors were modified (Callahan *et al.*, 2000). The first was to control for the dogs' visual near point, the shortest distance from the dog's face for an object to be in focus, which is 25–30 cm. This ensured that objects were distinctly visible to the dog before making a choice on the nonmatch phase of the task. The second was to increase the visual processing time for the dog by introducing a 5-second pause between presenting the objects and allowing dogs to respond. Aged human subjects tested on delayed matching-to-sample tasks perform less accurately than young adults, but the level of performance in both groups improves when the sample stimulus duration is increased (Oscar-Berman and Bonner, 1985). With these two modifications, most young and some old dogs were able to solve the DNMS task at over 80% accuracy, but aged dogs generally performed more poorly than young animals (Callahan *et al.*, 2000). A small proportion of severely impaired dogs, however, continued to fail the task, consistent with the strong DNMS impairments observed in Alzheimer's patients (Swainson *et al.*, 2001).

#### *Spatial learning*

One of the most consistent cognitive deficits in old dogs is the ability to acquire and use spatial information. In humans, spatial learning impairments are a common feature of aging and become more severe in neurodegenerative disorders (Freedman and Oscar-Berman, 1989). Spatial learning, the ability to locate objects in space, can be accomplished in two ways: (1) by reference to the observer's body position (egocentric learning) or (2) by reference to the position of an external referent or landmark (allocentric learning).

In the dog, we have assessed egocentric spatial learning with a delayed nonmatching to position (DNMP) task. Two versions of this task were developed, a 2-choice DNMP (Head *et al.*, 1995) and 3-choice DNMP (Chan *et al.*, 2002). In the 2-choice DNMP (2cDNMP) task (Figure 35.2), dogs are presented with a single object located over one of two lateral food wells, the sample phase. After a brief delay, a second identical object is presented over the remaining lateral food well, the match phase. Only responses to the nonmatch location are rewarded with food. Some old dogs perform as well as

young dogs on this task while others show marked impairments.

The 3-choice DNMP (3cDNMP) task uses three food wells (two lateral and one medial) instead of two to prevent the use of positional strategies in solving the 2cDNMP. Similar age-related deficits were obtained using the 3cDNMP task, but this version of the DNMP procedure is much more difficult for all dogs (Chan *et al.*, 2002). Compared to only 18% of old dogs that failed the 2cDNMP (Adams *et al.*, 2000 a,b; Head *et al.*, 1995), 83% were unable to complete the 3cDNMP task. Young dogs never failed the 2cDNMP, but 12% were unable to solve the 3cDNMP.

Allocentric spatial learning in the dog is assessed with a landmark discrimination test originally developed in nonhuman primates (Pohl, 1973). In this task, subjects are rewarded for selecting one of the two identical objects that is closest to an external landmark. Solving the task relies solely on the use of allocentric spatial cues, because information about the correct response is provided only by the location of the landmark. Tests of allocentric learning in the dog indicate that landmark discrimination is far more difficult for both young and old dogs compared to the DNMP tasks. Initial attempts to train dogs on the landmark task were unsuccessful. The only way dogs could learn this task was to teach them to attend to the landmark. This was achieved by placing the landmark on top of one of the two identical objects and progressively move the landmark away from the object. Once the animals learned to attend to the landmark, allocentric spatial learning was observed in young and old dogs with age-related decrements in performance. Performance on this task declines in the old dogs as the distance between the landmark and the rewarded discriminanda increase (Milgram *et al.*, 1999; 2002a).

More recently, our lab developed an egocentric discrimination learning task to assess spatial learning where dogs were rewarded for responding to an object farthest to the left or right side of the tray (Christie *et al.*, 2005). Acquisition of the initial discrimination did not depend on age but the reversal task produced age-dependent declines in performance and correlated with performance on the landmark task. Thus, although the egocentric discrimination is similar to a visual discrimination, there is a common component with the allocentric spatial task suggesting that egocentric and allocentric based learning share some common neural substrates but are also subserved by unique brain regions.

Together, these results suggest that: (1) dogs in general may be predisposed to spatial learning based on an egocentric frame of reference, and (2) both egocentric and allocentric spatial learning are impaired with age.

#### AGE-RELATED MEMORY IMPAIRMENTS IN THE DOG

A gradual decline in memory occurs with normal aging and is relatively benign, but more extensive and

selective memory loss may signal a transition into dementia. For example, mild cognitive impairment (MCI) is characterized by a selective impairment in memory and is thought to represent early or prodromal Alzheimer's disease. In the dog, we have developed two protocols for assessing age-related changes in memory function. One involves measuring task performance as a function of increasing the amount of information to be used in working memory. The second involves increasing the amount of time that information must be held in working memory. Learning deficits can be dissociated from memory deficits in the dog, revealing that a dog may be learning impaired but its memory is excellent, or that a dog can learn quickly but have a poor memory.

#### *Spatial memory*

Aged humans and patients with neurodegenerative diseases are often impaired on tests of spatial memory (Freedman and Oscar-Berman, 1989). Old dogs that do not exhibit spatial learning deficits may exhibit impairments when the memory demands of the task are increased. We developed two protocols for the DNMP task to study spatial memory in the dog. The first involves a variable delay paradigm in which the delay between the sample and match phases of each trial is varied between 20, 70, or 110 seconds. Both young and old dogs perform less accurately as the delay increases, but there is significant variability within the aged group of animals. Like young dogs, some old dogs continue to perform well as the delay interval increases. For others, accuracy decreases as the interval is increased from 20 seconds to longer delays (Adams *et al.*, 2000b; Head *et al.*, 1995). For these dogs, performance decrements do not represent impaired spatial learning since the animals successfully acquire the learning phase of the task (i.e., at 5-second delays). Rather, the deficit represents a working memory impairment—the inability to retain spatial information in memory during the delay interval.

The second protocol for studying memory uses a maximal memory paradigm in which the delay interval is progressively increased until the dog is unable to satisfy the pre-established task criterion or a preset number of sessions is attained. On the 2cDNMP, young dogs can perform this task at delays of 210–300 seconds. By contrast, old dogs generally reach delays of only 30–50 seconds (Adams *et al.*, 2000b), suggesting they cannot hold information in working memory for as long as young animals. When the maximal memory procedure is used on the 3cDNMP task, spatial memory for both young and old dogs is attenuated reflecting the greater complexity of this task. On the 3cDNMP, only 10% of young dogs achieve delays of 110 seconds or longer. Fewer than 10% of old dogs complete the 3cDNMP memory task at delays of 30 seconds; most (80%) are unable to complete the task at delays longer than 5 seconds. This suggests that while most old dogs can

acquire the more difficult 3cDNMP, few can retain spatial information on this task at delays longer than 5 seconds (Chan *et al.*, 2002).

#### *Nonspatial memory impairments*

In the dog, object recognition memory is examined using a delayed nonmatching to sample (DNMS) paradigm with either the variable delay or progressive delay protocols, comparable to the DNMP task (Callahan *et al.*, 2000). Most young and some old dogs can perform the DNMS task at over 80% accuracy, but performance declines with longer delay intervals. The progressive delay protocol indicates that dogs are capable of responding accurately with delays up to 5 minutes. Spatial and nonspatial memory may be subserved by independent neural pathways that are differentially disrupted in aging (Courtney *et al.*, 1996).

### EXECUTIVE DYSFUNCTION IN THE AGING CANINE

Absent from many early investigations of cognitive aging in the dog were measures of complex cognitive processes. Higher-order cognitive processes, often characterized as executive functions, include categorical abstraction, set maintenance and manipulation, shifting of set, and inhibitory control (West, 1996). Largely controlled by the frontal lobes (Fuster, 1999), tests of executive function are some of the most sensitive measures of aging; they indicate that executive function deficits precede many cognitive impairments in human aging (West, 1996). This final section on canine cognitive aging will describe the effects of age on executive functions in the Beagle dog.

#### *Inhibitory control in aging dogs*

Inhibitory control and performance monitoring are executive functions that show decreased efficiency during normal aging (McDowd *et al.*, 1995). According to the inhibitory deficit hypothesis of aging, the inability to maintain attention to relevant task features and to inhibit interfering information or previously activated cognitive processes is the single greatest factor affecting age-related cognitive decline (Hasher and Zacks, 1988). Deficits on tests of sensory processing, memory, and reading comprehension are often attributed to a lack of inhibitory control with age (McDowd *et al.*, 1995).

Although not exclusively designed to measure executive function, the nature of errors on discrimination reversal tasks provide evidence of inhibitory control deficits. Discrimination reversal tasks require subjects to inhibit prepotent responses to previously correct stimuli and shift responses to a new stimulus–reward contingency within the same perceptual dimension. In humans, reversal deficits correlate with dementia severity. For example, perseverative responding, a measure of impaired inhibitory control, is more severe in Alzheimer's patients than demented Parkinson's patients or normal controls

### 35. The Canine Model of Human Brain Aging: Cognition, Behavior, and Neuropathology

(Freedman and Oscar-Berman, 1989). Similar deficits are observed in aged nonhuman primates (Voytko, 1999) and rodents (Means and Holsten, 1992).

Reversal learning in the dog was previously examined using an object discrimination task (Milgram *et al.*, 1994). Aged dogs were impaired relative to young dogs on the object discrimination reversal task but not the initial object discrimination. Although this study found that aged dogs required more sessions for the initial phase of the reversal task, it did not determine whether this was an inhibitory control deficit or a stimulus–reward association deficit. More recently, the types of errors made during a size discrimination reversal learning task were examined to dissociate inhibitory control deficits from stimulus–reward learning deficits (Tapp *et al.*, 2003a). After learning an initial size discrimination (Figure 35.2) in which dogs were rewarded for responding to one of two identical stimuli that differed only in size (i.e., height), the reward contingencies were reversed. Reversal learning errors were categorized by stages based on previously published criteria (Duel *et al.*, 1971). Stage I errors were defined as seven or more errors per 10-trial test session and represented perseverative responding. Stage II and III errors were defined as four to six or less than 3 errors per 10-trial test session respectively, and represented a stimulus–reward deficit. Overall, old dogs made more errors than young dogs on both the size and size reversal tasks. Qualitative analysis of errors on the reversal task however, suggested that separate cognitive processes were

responsible for the learning deficits in two subgroups of old dogs (Figure 35.4).

Most errors made by old dogs (aged 8–11 years) were Stage II, reflecting a deficit in learning a new stimulus–reward contingency. By contrast, senior dogs (aged 11.5–14 years) made significantly more Stage I, or perseverative errors. The old dogs were separated into old and senior dogs based on neuropathological and neuropsychological information. Senior dogs are over 11.5 years of age, equivalent to approximately 74 human years. Executive function deficits in humans commonly occur in people over the age of 70, and we wanted to isolate this age population in our dogs (Tapp *et al.*, 2003a, 2004b). Dogs over the age of 11.5 also show particular vulnerability to reduced frontal lobe volume and beta-amyloid deposition (Tapp *et al.*, 2004a; Head *et al.*, 1998), which warrants a distinction in the aged group. These data suggest that inhibitory control deficits are a characteristic of aging in very old dogs and, like aging humans and patients with dementia, may underlie patterns of cognitive or executive dysfunction in aging dogs.

#### *Maintenance and manipulation impairments in aging dogs*

Working memory incorporates a system for temporary storage and a mechanism for on-line manipulation of stored information during a wide variety of cognitive activities (Baddeley, 2001). In this context, maintenance is defined as the transferring, maintaining, and matching of

**Figure 35.4** Median number of sessions spent at Stage I, II, and III during reversal learning by young, middle-aged, old, and senior Beagle dogs. Compared to young and old dogs, senior dogs exhibited greater perseveration and stimulus–reward learning deficits. Reprinted with permission from Cold Spring Harbor Laboratory Press. Copyright 2003, *Learning and Memory* 10(1), p. 68.

information actively held in working memory, whereas manipulation is viewed as the additional reorganization or dynamic updating of information in a memory set. Both maintenance and manipulation functions in working memory may be differentially vulnerable to aging.

Tasks that require subjects to reorganize or manipulate information held in working memory before that information is recalled place greater demands on subjects' working memory processes. Alzheimer's and Parkinson's patients are particularly sensitive to tasks that place greater demands on working memory, especially those that elicit active processes (i.e., manipulation) during a working memory task (Belleville *et al.*, 2003).

The standard tests used to assess working memory in the dog are the DNMP and DNMS tasks. Working memory demands on these tasks are manipulated by changing the delay interval between the sample and non-match phases of the task. As mentioned previously, dogs do not perform as well with longer delays. An alternate method for changing working demands is to increase the amount of information that must be monitored or manipulated in memory during a task. In a recent study, the spatial list learning (SLL) paradigm was developed to examine this component of working memory in aging dogs (Tapp *et al.*, 2003b). Comparable to the delayed recognition span task used in primates (Herndon *et al.*, 1993), a key component of the SLL paradigm is that each response cannot be made in isolation, but must be made with reference to earlier responses and information in the trial. Thus, success on this task depends on the ability to maintain and continually up-date an on-line record of which locations were previously selected, and which were not.

In the original design the dog is presented with a single red disc randomly located over one of three food wells during the first phase of a trial (Figure 35.2). After a response is made, a brief delay interval occurs, followed by the second phase of the trial in which two identical red discs are presented, one in the original location and a second in one of the two remaining spatial locations. Only responses to the novel location are rewarded on the second phase. After a second delay period, the third phase of the task occurs in which the dog is presented with three identical red discs, two in the familiar locations and a third in the final novel location. Only responses to the novel location are rewarded. Locations of each object are randomized across trials.

This task proved to be much more difficult than the 3cDNMP task. Half of the young dogs tested on this task reached delays of 50 seconds, but only one-third of the old dogs successfully completed the 10-second delay. This was particularly surprising since the old dogs included in this study represented successful agers—dogs that performed the 3cDNMP task as well as young dogs. Impaired performance among the successful agers suggested that age-related impairments in spatial list learning reflect deficits in executive functions (i.e., manipulation), rather

than maintenance processes. To further explore this finding, a modified version of the SLL task (mSLL) was developed (Figure 35.2).

The original SLL task design was such that positional strategies could be adopted for solving the task. The mSLL task minimizes nonmnemonic strategies and maximizes the cognitive demands on working memory by presenting the first and second discriminandum separately, rather than concurrently. This modification proved to be much more difficult for the old dogs. Only one old dog completed the learning stage of the task (i.e., a 5-second delay) but was unable to complete the task at the 10-second delay. All young dogs however, learned the task at the shortest delay and achieved the highest delay used of 50 seconds.

The results from both SLL tasks suggest that in the Beagle dog, working memory processes of maintenance and on-line monitoring are differentially affected by age. Specifically, executive processes associated with manipulating or updating information appear to be impaired relative to low-level processes required for actively holding information in working memory. These dissociative effects may represent differential rates of aging in distinct neuroanatomical regions specific to maintenance and executive functions.

#### *Rule induction and concept abstraction in aging dogs*

One of the most commonly observed executive deficits in aging is the inability to categorize or sort objects based on a conceptual dimension. In human studies, the most common paradigm to assess this deficit is the Wisconsin Card Sort Test (WCST; Berg, 1948). On the WCST subjects are required to sort stimuli according to an unknown principle, which the subject must deduce from feedback provided by the clinician. Elderly subjects frequently make more perseverative errors and complete fewer sorting categories on this task, which may reflect impaired rule induction, inhibitory control, performance monitoring, or set shifting abilities (Ridderinkhoff *et al.*, 2002).

Animal studies have also examined concept learning in a range of species, but few have explored the effect of age on this ability. We recently developed a size concept task to examine the effects of age on concept learning in the Beagle dog (Tapp *et al.*, 2004b). The protocol consisted of training dogs on several 2-choice and 3-choice size discrimination tasks, using the same sets of blocks, to teach the animals to attend to size. Subsequently, novel stimuli differing only in size were introduced to determine if dogs learned that size could also be used conceptually to solve this new task. Young dogs were the only age group successfully able to acquire the size concept and transfer this knowledge to the concept tests. Old and senior dogs were not able to transfer the information and approached the concept tests as new tasks without using the previously learned information. The results suggest that executive functions such as rule induction and concept abstraction

## 35. The Canine Model of Human Brain Aging: Cognition, Behavior, and Neuropathology

decrease with age and may begin as early as 8–10 years of age in the dog.

### SUMMARY

Dogs develop a variety of age-dependent cognitive deficits that parallel declines observed in normal and pathological aging in humans. Our studies revealed a large amount of variability in cognitive aging in the dog. Like humans, cognitive aging in the Beagle dog is complex and non-linear, and striking individual differences are common. In both humans and dogs, some individuals show little decline (successful agers), some show mild decline, and others of the same age develop severe cognitive impairments. The earliest signs of cognitive decline observed in the dog appear to include executive functions.

### Noncognitive Functions and Aging in the Dog

Although cognitive decline is the most common and frequently studied hallmark of aging and dementia, a number of noncognitive impairments are observed in elderly and demented subjects. The term *noncognitive* will refer to a range of diverse behaviors that do not explicitly involve testing for learning and memory but could be related to cognitive status. Such behaviors include general activity, social interaction, and psychotic and aggressive behaviors. A similar distinction is made in the case of humans (Folstein and Blymsa, 1999). Using the dog as a model system to study aging, we have reported several noncognitive behavioral changes, which correlate with changes in cognitive functioning. The specific noncognitive behaviors examined include locomotor activity, activity rhythms, social interactions, and exploratory behavior.

### LOCOMOTOR ACTIVITY

Physical movement or motor activity significantly declines with advancing age in humans (Bennett, 1998). Changes in physical activity become more severe in neurodegenerative disorders and can take several forms including ceaseless walking, trailing and checking, and wandering (Folstein and Blymsa, 1999). We have observed similar changes in locomotor activity in the dog, which vary with cognitive impairment (Siwak *et al.*, 2001, 2003). Locomotor activity in the dog is assessed with three different tests: the open field test (Siwak *et al.*, 2001, 2002; Head *et al.*, 1997), the home cage test (Siwak *et al.*, 2002); and the Actiwatch<sup>®</sup> activity monitoring system (Siwak *et al.*, 2003). The general finding is that locomotor activity decreases with age in the dog (Figure 35.5), but is dependent upon several factors including test situation, cognitive status, and previous experiences.

First, the environmental testing situation influences motor activity in dogs. In a novel environment, such as the open field arena, young and old dogs are aroused

and responsive to the change in surroundings. Measures of locomotor activity are affected such that age-related decreases in activity are not observed. As the open field becomes familiar, locomotion declines in both young and aged dogs (Siwak *et al.*, 2001, 2002). Familiar home cage environments may reflect more spontaneous activity, and age-related decreases in motor activity are more easily observed (Siwak *et al.*, 2002).

Second, motor activity is related to cognitive impairment. When aged dogs are divided into cognitively impaired and unimpaired subgroups, robust differences in locomotor activity are observed (Siwak *et al.*, 2001; Head *et al.*, 1997). Aged dogs that are severely impaired on tests of cognitive function tend to be hyperactive compared to unimpaired aged dogs. This is consistent with studies in humans showing a relationship between hyperactivity and several disorders including dementia, autism, and attention deficit disorder (Folstein and Blymsa, 1999; Castellanos *et al.*, 2001). These increased levels of activity in impaired dogs may be a manifestation of neurodegenerative changes that contribute to cognitive impairment.

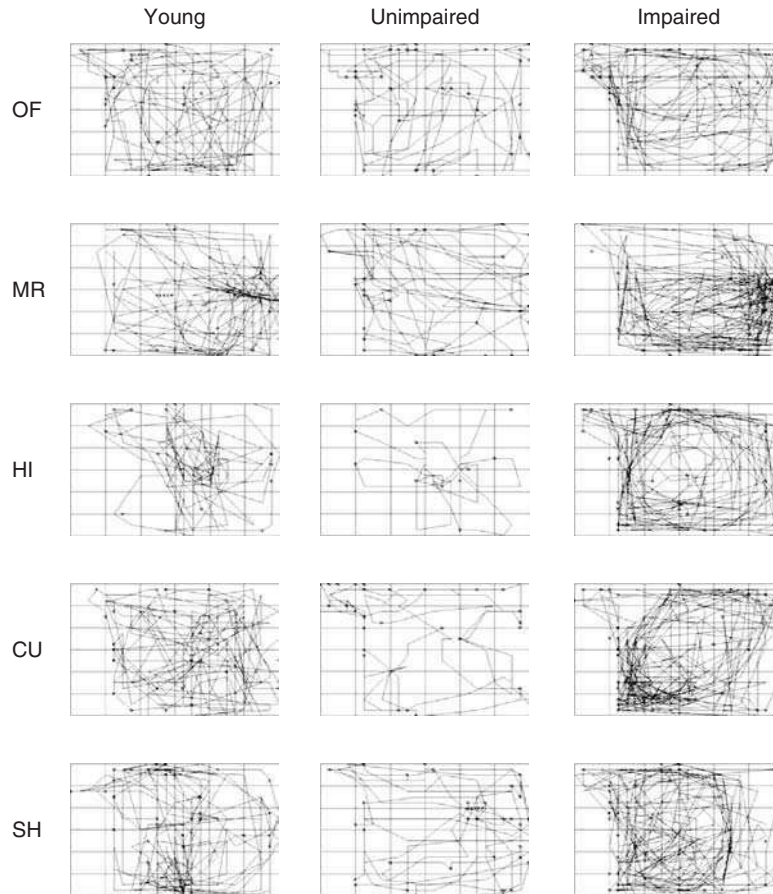

Third, previous rearing history or possible genetic factors may affect locomotion. Dogs born and raised in a laboratory are hyperactive compared to dogs reared outside of the laboratory (Fox, 1971; Siwak *et al.*, 2003). Thus, environmental enrichment during the lifespan of the dog may interact with genetic factors and contribute to the severity of locomotor decline and cognitive dysfunction in aging (Siwak *et al.*, 2001; Head *et al.*, 1997).

### ACTIVITY RHYTHMS

Approximately 40–70% of elderly people suffer from some type of sleep disorder such as increased waking at night or frequent napping during the day (Van Someren, 2000). These effects are exacerbated in subjects with dementia (Satlin *et al.*, 1991). We have assessed the circadian pattern of locomotor activity in dogs with the Actiwatch<sup>®</sup> actigraph monitoring system (Siwak *et al.*, 2003). Dogs exhibit clear activity–rest rhythms in which activity levels are high during the day and low at night. Moreover, circadian patterns of locomotor activity in dogs exhibit age-related alterations, which vary with cognitive status and housing environment.

Cognitively impaired aged dogs display higher levels of activity and fewer periods during the day where they exhibit no activity compared to unimpaired aged dogs. Peak activity for impaired dogs was shifted to later in the day, an observation consistent with findings in demented patients (Satlin *et al.*, 1991). The timing mechanism could be compromised due to neuropathology in both demented patients and impaired dogs.

Housing environment also influenced activity levels. Aged dogs housed indoors had shorter bouts of activity, required more time to become active after the lights came on, and exhibited extended periods of rest during the day compared to young dogs. These age-related differences

**Figure 35.5** Tracings of the movement patterns of a representative dog from each group in the testing room. More lines reflect more movement. The activity patterns of the age-impaired dogs did not change with the different tests. This group showed the same pattern with all the stimuli except the mirror. The young and age-unimpaired showed similar responses and modified their behavior according to the test situation. were not present in dogs housed outdoors exposed to the bright sunlight, suggesting that exposure to bright light is effective in synchronizing and consolidating the activity rhythm.

#### SOCIAL RESPONSIVENESS IN AGING DOGS

Like humans, dogs are highly social creatures. Dogs interact with other dogs and humans and share common environments with both species. In humans, demented individuals undergo several abnormal changes in social behavior. In the early stages of Alzheimer's disease, patients become withdrawn in social settings. As the disease progresses to within 4–7 years of disease onset, social function declines. Disruptive behaviors including agitation, restlessness, and aggression become more common. Gradually, patients neglect personal grooming, demonstrate poor table manners, and engage in socially inappropriate behaviors. In the final advanced stage of the disease, patients are completely withdrawn and

unresponsive to their social surroundings (Folstein and Blysm, 1999).

We adapted a series of behavioral tests to assess social responsiveness in the aging dog (Siwak *et al.*, 2001; Head *et al.*, 1997). These tests include the mirror test, the human interaction test, the silhouette test, and the model dog test. Changes in social behavior varied with age and correlated with the severity of cognitive decline.

#### *Human interaction test*

In the human interaction test, the amount of time during a 10-minute session the dog spends near or physically in contact with a person seated in the center of the observation room is recorded (Siwak *et al.*, 2001). In this test, active social responses such as initiating physical contact, climbing, sniffing, and licking were more common in younger dogs. Age-unimpaired dogs preferred more passive responses like sitting or lying quietly beside the person. Both groups were significantly different

## 35. The Canine Model of Human Brain Aging: Cognition, Behavior, and Neuropathology

from cognitively impaired dogs who exhibited very little interest in the person.

### *Mirror test*

In the mirror test, dogs are placed in an enclosed arena with a mirror secured to one wall of the room. Reactions to the reflection in the mirror depend on the dogs' ability to recognize its own species (Fox, 1971). Consistent with Gallup (1968), the reactions of the dogs toward the mirror reflection were initially *other-directed*. Responses included jumping at, barking at, trying to play with the dog in the mirror as well as attempts to look behind the mirror to find the other dog. Differences between cognitively impaired and unimpaired aged dogs were very prominent in this test (Siwak *et al.*, 2001). Unimpaired old and young dogs habituated to the reflected image rapidly. Old impaired dogs spent significantly more time reacting to the reflection in the mirror, suggesting a deficit in habituation.

### *The silhouette and model dog tests*

To further explore social responses to conspecifics, we used the silhouette and model dog tests (Fox, 1971). In the silhouette test, a black laminated cardboard-dog figure is attached to one wall of the open field test room and dogs are observed for their interactions (i.e., sniffing) with this object for 10 minutes. Dogs treated the cardboard cutout as a real dog by targeting sniffing in the facial and anal regions as is typical when dogs meet. Initially, all dogs sniffed the object with the same frequency, but young and old-unimpaired dogs habituated to the silhouette. When retested on the silhouette task two weeks later, young and old-unimpaired dogs paid little attention to the silhouette. The old-impaired dogs spent much more time sniffing the silhouette, probably reflecting a deficit in habituation or stimulus recognition.

We subsequently modified the procedure to make the conspecific more realistic by using a 3-dimensional model dog that more closely resembles a real living dog. In this test, beagle dogs are observed for their interactions with a life-sized sand-cast model of a Golden Retriever. Young dogs spent more time sniffing and interacting with the model than old-impaired and unimpaired dogs. Old-impaired and unimpaired dogs did not differ in the amount of time spent sniffing the model dog.

Together, the results from the four tests indicate that as in humans, social behaviors change with age in dogs. Old dogs, like elderly people, continue to be social creatures with age but become more passive in their social interactions compared to young dogs. As cognitive functions become increasingly impaired, however, social behaviors change from normal, appropriate responses to disrupted and inappropriate reactions.

### EXPLORATORY BEHAVIOR

Reduced novelty seeking, curiosity, and exploratory behaviors are common hallmarks of normal aging

(Daffner *et al.*, 1994). The decrement in exploratory behavior is more severe in demented patients (Daffner *et al.*, 1999). The curiosity test in the dog was intended to measure changes in exploratory behavior with age. Dogs were placed in an observation room with seven novel commercially available toys distributed throughout the room. Total time spent playing with or sniffing objects was recorded. Results from this task revealed a pattern of behavioral change consistent with other noncognitive measures. Specifically, young dogs spent more time playing with and sniffing objects than either group of old dogs. Old-unimpaired dogs showed similar reactions as young dogs but spent less time exploring objects. Exploratory behavior also varied with cognitive status. Old-impaired dogs generally avoided the toys and expressed no interest in investigating the objects (Siwak *et al.*, 2001).

### SUMMARY

Taking all noncognitive tests into account, young and aged dogs exhibit distinct behavioral profiles. Young dogs exhibit higher levels of activity and more interest in interacting with toys, people, and artificial dogs, which modifies their movement pattern as shown in Figure 35.5. Aged dogs show decreases in locomotion and other behaviors but continue to display appropriate responses, just to a lesser extent than young dogs. Impaired dogs by contrast show abnormal responses. These dogs are hyperactive, unresponsive to social stimuli or toys, and often engage in stereotypical behaviors. These impaired subjects display atypical social responses on tests of human and mirror-image interactions. The profile of the impaired dogs is consistent with behavioral disruptions that occur in demented people.

### Neuropathology

In parallel with our work on characterizing cognitive and behavioral changes in aging dogs, a third strategy in developing the canine as a model system of human brain aging involves identifying pathological brain changes related to age-associated cognitive-behavioral dysfunction in the dog. Specifically, we have examined beta-amyloid deposition, neuron loss, oxidative damage, and structural anatomy in the aging canine brain. These studies reveal that brain aging in dogs begins as early as middle age, varies across brain regions, and correlates with cognitive and behavioral impairments; dogs develop some of the pathological hallmarks found in Alzheimer's disease. This final section will summarize current knowledge on neuropathological and neuroanatomical markers of brain aging in the canine.

### BETA-AMYLOID DEPOSITION

One of the hallmarks of Alzheimer's disease is the development of senile plaques. Dogs do not develop all

**Figure 35.6** Beta-amyloid immunostaining in the hippocampus of a 5-year-old dog (A) and a 12-year-old dog (B) and in the temporal cortex of a 12 year-old-dog (C). Higher magnification in the 12-year-old (D) illustrates the presence of intact neurons (arrow) in the diffuse plaques. Bar in D is 20  $\mu\text{m}$ . See the color plate section.

of the hallmarks of Alzheimer's disease, but the aged dog is particularly well-suited for studying early stages of beta-amyloid deposition in the aging brain. Plaque morphology in the dog is generally diffuse and cloud-like (Figure 35.6) and deposits are thioflavine-S negative, suggesting a lack of  $\beta$ -pleated sheets formation (Satou *et al.*, 1997).

In addition, dogs accumulate the longer, more toxic and less soluble form of  $A\beta_{1-42}$  prior to the shorter more soluble  $A\beta_{1-40}$  type, consistent with human brain aging (Cummings *et al.*, 1996). Beta-amyloid builds up initially in and around neurons and is present within apical and basal dendrites. Furthermore, beta-amyloid is deposited uniformly in select synaptic terminal fields, such as the terminal zone of the perforant pathway, that show a predilection for extensive plaque formation in Alzheimer's disease.

The regional pattern of beta-amyloid deposition in the dog parallels human brain aging. In the dog, the earliest and most consistent distribution of beta-amyloid plaques occurs in the prefrontal cortex beginning around 8 years of age (Head *et al.*, 1998). Early prefrontal beta-amyloid deposition is also common in nondemented (Bussière *et al.*, 2002) and preclinical Alzheimer's disease subjects (Yamaguchi *et al.*, 2001). By 14 years of age, beta-amyloid deposition progresses to the entorhinal and parietal regions of the canine cerebral cortex equally, leaving the cerebellum relatively unaffected. Further, our studies reveal a strong correlation between regional beta-amyloid deposition and cognitive decline in aging dogs (Head *et al.*, 1998; Tapp *et al.*, 2004a).

#### NEUROFIBRILLARY TANGLES

In humans, abnormal hyperphosphorylation of the microtubule protein tau leads to the development of neurofibrillary tangles (NFTs), which are linked to cognitive decline in aging (Duyckaerts *et al.*, 1997). In the dog, the role of neurofibrillary tangle formation is unclear. Although dogs exhibit early stages of tangle formation characterized by tau phosphorylation and an intracellular punctuate distribution, the morphology is distinct from the human brain and does not progress into thioflavine-S or silver positive NFTs (Cummings *et al.*, 1996). Using AT8, a marker for early neurofibrillary tangle formation, Head *et al.* (2001) observed hyperphosphorylated tau in select neuronal populations in middle-aged but not old dogs. This is consistent with earlier studies of cytoskeletal abnormalities (Cumming *et al.*, 1996), distended neurites (Wisniewski *et al.*, 1970), and tau positive neurons (Uchida *et al.*, 1993) in the dog.

One explanation for the absence of NFTs in the dog is that the tau protein in the dog is different from human tau protein and thus dogs are not predisposed to develop full NFTs with age (Head *et al.*, 2001). The implication of this finding is that beta-amyloid and not tau pathology may be sufficient to lead to cognitive and behavioral dysfunction in the aging dog. In the absence of NFTs, cognitive dysfunction increases proportionately with beta-amyloid deposition in the dog. All old dogs develop pathology, but old animals with extensive beta-amyloid deposition are more impaired than those with less beta-amyloid deposition (Head *et al.*, 1998). This suggests that beta-amyloid deposition may influence neuronal function and may lead to impaired cognition.

## NEURONAL LOSS

Neuron loss is another potential morphological correlate of cognitive decline in normal and pathological aging in humans. Stereological studies have revealed regionally specific neuron loss in the hilus and subiculum of the hippocampus (West, 1993), the islands of the entorhinal cortex (Simic *et al.*, 2005), and mild loss in the neocortex including the frontal, temporal, parietal and occipital cortices (Pakkenberg *et al.*, 1997) in humans with age. In Alzheimer's disease the extent of neuron loss is even greater, occurring in the same regions as normal aging, hilus and subiculum, but extending into additional areas including area CA1 (West *et al.*, 1994). Age-related neuron loss in the canine brain occurs in the cingulate gyrus, superior colliculus, and claustrum (Ball *et al.*, 1983; Morys *et al.*, 1994). Calbindin-positive GABAergic neurons in the prefrontal cortex of the canine brain are also lost with age (Pugliese *et al.*, 2004). Our own stereological studies in the canine hippocampus reveal a reduction in the number of hilar neurons in aged dogs (Siwak *et al.*, 2005a).

## OXIDATIVE DAMAGE

Another biological correlate of cognitive and behavioral dysfunction in dogs is the progressive accumulation of oxidative damage with age. Neurons in the brain are highly vulnerable to oxidative damage, which accumulates with age due to the high respiratory demands of the central nervous system. Generation of reactive oxygen species in the brain damages proteins, lipids, and nucleotides, which contribute to neuronal dysfunction and neurodegeneration in aging (Floyd *et al.*, 2001).

The brains of aged dogs accumulate oxidative damage to lipids and proteins (Head *et al.*, 2002). Beginning around 8 years of age, levels of malondialdehyde (MDA), a marker of lipid peroxidation, progressively increase in the prefrontal cortex and serum in the dog. In parallel with increased MDA, glutamine synthetase activity, an endogenous antioxidant, decreases with age in the prefrontal cortex. These age-related changes in oxidative damage coincide with increased beta-amyloid deposition in the prefrontal cortex and together may impair neuronal function.

If oxidative damage is a key contributor to cognitive dysfunction, then antioxidant supplementation may ameliorate these deficits. In Alzheimer's patients, antioxidant supplementation can improve cognitive function (Morris *et al.*, 2005) and delay institutionalization (Sano *et al.*, 1997). We hypothesized that if brain aging and the progressive accumulation of oxidative damage are related to cognitive and behavioral decline in the dog as well, then dogs treated with dietary antioxidants or mitochondrial cofactors should exhibit less cognitive decline with age relative to controls. This hypothesis was examined in a 4-year longitudinal study from 1999 to 2002 involving the collaborative participation of three laboratories in

Canada and the United States. In this study, 48 aged dogs received either a control diet or a diet enriched with antioxidants and mitochondrial cofactors (to promote mitochondrial health). The antioxidant diet was enriched with vitamin E, vitamin C, l-carnitine, dl-alpha lipoic acid, and a 1% inclusion of spinach flakes, tomato pomace, grape pomace, carrot granules, and citrus pulp. Every six months after the start of the study, all dogs were routinely tested on an extensive battery of cognitive tasks (Milgram *et al.*, 2005, 2004) to evaluate the efficacy of antioxidant therapies on cognitive and behavioral function in aging. At the completion of the study, the effect of antioxidant treatment on beta-amyloid deposition was examined in the brains of half of the old dogs.

Cognitive function was significantly improved and maintained with dietary treatment. Old dogs performed more poorly than young dogs on many of the complex discrimination tasks, but old dogs given the enriched antioxidant diet performed significantly better than old dogs fed the control diet (Milgram *et al.*, 2002a,b; Siwak *et al.*, 2005b). The antioxidant diet had little effect in young dogs. In addition, old dogs fed an antioxidant diet improved on a number of noncognitive behavioral measures including recognition, interaction, agility, and compulsive behaviors (Dodd *et al.*, 2003).

Treatment with the antioxidant-enriched diet also reduced beta-amyloid deposition in old dogs, but the effects were brain-region specific. The extent of beta-amyloid, measured by loads, was lower in the parietal, entorhinal, and occipital cortices, but not the prefrontal cortex in aged treated dogs compared to control dogs (Pop *et al.*, 2003). The age at which dogs were provided with the antioxidant diet was previously established to be a time when prefrontal beta-amyloid deposition had begun (Head *et al.*, 1998). The absence of an effect in the prefrontal cortex therefore suggests that treatment with a broad spectrum antioxidant diet may prevent beta-amyloid deposition but does not reverse existing beta-amyloid deposition.

Collectively, the results from this study indicate that combinations of antioxidants and mitochondrial cofactors work together synergistically to improve age-related cognitive and behavioral decline. The mechanisms for this improvement may reflect a decrease in oxidative damage and beta-amyloid deposition, but our data suggest that a critical window exists for reducing beta-amyloid deposition in the brain; the earlier the treatment begins, the greater the benefits.

## BRAIN IMAGING IN THE DOG

Recent advances in brain imaging technology permit noninvasive analyses of metabolic, vascular, and structural changes associated with normal and pathological aging. In addition to improved image acquisition devices, computer technology and software development have also advanced, producing more sophisticated methods for analyzing brain imaging data. Techniques such as

manual-based region of interest (ROI) planimetry and voxel-based morphometry (VBM), widely used in humans, indicate that biological characteristics such as age, sex, and underlying pathology contribute significantly to the variability in brain aging.

In addition to *in vitro* neuropathological measures, we have used several imaging protocols to examine brain aging in the dog model. In the remaining section, the application of MRI to study structural, pathological, and cerebrovascular markers of aging in the dog brain will be discussed.

*Age-related changes in global and focal brain volume*

Our initial work with MRI involved using manual ROI planimetry to evaluate changes in brain and ventricular volume as a function of age. Standard quantitative procedures involved meticulously tracing brain regions of interest on multiple slices to compare differences in brain volume across subject cohorts (Figure 35.7).

This revealed that aged dog brains show increased cortical atrophy, ventricular dilation, decreased total brain volume, and decreased frontal lobe volume (Su *et al.*, 1998; Tapp *et al.*, 2004a). Age-related decreases in frontal lobe volume were associated with increased beta-amyloid deposition and impaired executive function (Tapp *et al.*, 2004a).

An alternate method of assessing volumetric brain changes in aging is VBM. VBM permits rapid voxel-by-voxel comparisons of local gray and white matter brain regions without the need for a priori selection of ROIs and is highly sensitive to volumetric differences in normal and pathological aging (Tisserand *et al.*, 2004). Despite its popularity in human brain imaging, application of VBM for mapping brain aging in animal models is less common. We recently developed a VBM procedure for analyzing regional brain aging in the dog (Tapp *et al.*, 2005b). The initial steps of this procedure are time consuming and require the creation of standardized dog brain templates and a priori probability maps; but once

**Figure 35.7** Coronal MRI slices through the frontal cortex of the dog brain. Images are presented rostrocaudally (front to back) top to bottom, left to right. Hemispheric and regional differences in brain volume were performed using manual planimetry to trace each region of interest.

### 35. The Canine Model of Human Brain Aging: Cognition, Behavior, and Neuropathology

complete, rapid voxel-by-voxel comparisons of gray and white matter volumetric changes in the aging dog brain are possible. Using this technique, we found a number of age and sex dependent changes in gray and white matter volume in the dog (Figure 35.8).

Age-related reductions in gray matter volume were observed bilaterally in the frontal gyrus, orbitalis gyrus, ectosylvian gyrus, olfactory bulb, and superior olivaris nucleus in the brainstem. Unilaterally, gray matter loss occurred in the preoreal gyrus, sylvian gyrus, suprasylvian gyrus, cerebellum, and brainstem nuclei with advancing age. The effects of age on brain volume, however, differed in male and female dogs; decreased frontal lobe volume was more predominant in males, and decreased temporal lobe volume was more common in females. Similar patterns were observed in white matter brain regions as well. Age-related white matter loss was largely bilateral and included the internal capsule (including a small portion of the genu of the corpus callosum), white matter tracts of the anterior cingulate (anterior fascia cinguli), and the alveus of the hippocampus. Decreases in the volume of the internal capsule were more frequent in males, whereas atrophy of the alveus of the hippocampus occurred primarily in female dogs. The VBM results not

only validated earlier findings of frontal lobe atrophy in aging dogs but extended these findings and suggested that brain aging in the dog, like humans, varies regionally and differs between males and females.

#### *Progressive lesion formation in the aging dog brain*

A second useful application of MRI is the ability to monitor longitudinal changes in the brain of aging dogs. Serial MRI (sMRI) techniques allow images collected longitudinally to be quantified at the individual level instead of using cross-sectional images to compare differences between young and old groups. In sMRI, images are co-registered using a goodness-of-fit function to align images collected at different time points into a unified stereotaxic space. In humans, sMRI studies are difficult to conduct due to attrition rates and long intervals required to observe significant changes in brain morphology—problems not encountered with dogs. sMRI procedures used in the dog to monitor lesion formation revealed that aging is associated with an increased frequency of a specific type of lesion resembling small lacunes (Su *et al.*, 2005). The majority of lesions observed in the dog brain were located in the frontal cortex and caudate nucleus (Figure 35.9). This is consistent with other evidence that

**Figure 35.8** 3-dimensional rendering of brain regions showing a significant age-related reduction in gray (A) and white matter (B) brain regions. Regional atrophy for males and females is shown in green and red, respectively. Areas of overlap for old males and females are shown in yellow. Brain renderings are presented in sagittal and axial orientations. (Abbreviations: FL = frontal lobe, PL = parietal lobe, TL = temporal lobe, CB = cerebellum, IC = internal capsule, AVH = alveus of the hippocampus, OpN = optic nerve bundle, IC/Hyp = internal capsule/hypophysis.) See the color plate section.

**Figure 35.9** Coronal T1-weighted MRI slices presented rostrocaudally displaying two types of lesions in the aged dog brain: small (less than 1 cm diameter) lacunes (solid arrow-line) and large (greater than 1 cm diameter) infarcts (broken arrow-line).

## 35. The Canine Model of Human Brain Aging: Cognition, Behavior, and Neuropathology

the frontal lobes are especially vulnerable to aging in the dog (Head *et al.*, 1998; Tapp *et al.*, 2004a).

### *Cerebrovascular changes in the aging dog brain*

MRI is also used to assess hemodynamic changes in the dog by combining high-resolution MRI and paramagnetic intravascular susceptibility contrast agents (e.g., Gd-DTPA) to derive measures of cerebrovascular volume, flow, and blood–brain barrier integrity. In humans, dynamic susceptibility contrast enhanced (DSC)-MRI is sensitive to decreases in blood volume in temporoparietal brain regions in AD and MCI patients relative to healthy age-matched controls (Harris *et al.*, 1998). In a study of 18 dogs aged 4–15 years of age, a significant correlation was found between blood–brain barrier (BBB) permeability, beta-amyloid deposition, and ventricular dilation (Su *et al.*, 1998). Further, this increased BBB leakage occurred in the absence of cortical atrophy, suggesting that changes in BBB integrity precede cortical atrophy and may be an early consequence of aging.

Reduced blood flow and volume are frequently associated with age-related cognitive decline in humans. DSC-MRI studies performed in dogs have illustrated that impaired hemodynamics also contribute to brain aging (Tapp *et al.*, 2005a). First, gray matter regional cerebral blood volume (rCBV) was consistently higher than white matter rCBV in young and old dogs. Second, gray and white matter rCBV declined with age. Third, age-related changes in rCBV were largest in white matter brain regions compared to gray matter brain regions. Moreover, decreased rCBV and increased BBB permeability occurred in tandem with regional gray and white matter cortical atrophy.

### SUMMARY

The aged dog is particularly well-suited to investigate the initial stages of plaque formation in the aging brain. Beta-amyloid deposition in the form of diffuse plaques is a prominent feature of the aged dog brain. The morphology of beta-amyloid exhibited in the dog is almost identical to the early plaque pathology reported in nondemented and demented human subjects and Down's syndrome individuals. Oxidative damage and neuron loss are also features of the canine brain even though NFTs are absent.

MRI procedures commonly used in humans offer a viable, noninvasive, and reproducible method for evaluating brain changes in vivo in the aging dog. Structural and vascular changes as well as spontaneous pathology can easily be monitored and show many similarities to observations in humans. Aged dogs show reduced brain volume, increased ventricles, spontaneous lesions, and reduced blood flow.

### Conclusion

The canine is an innovative model for studying cognitive, behavioral, and brain aging. Aging in dogs leads to the

manifestation and development of many hallmarks characteristic of human aging. Dogs exhibit cognitive decline with the same general patterns as well as individual variability that occurs in humans. Behavioral consequences are also common to both human and canine aging with parallel changes in locomotion, social responsiveness and exploration. Neuropathological investigations reiterate the similarities between canine and human conditions. In aged dogs there is a strong association between beta-amyloid deposition and cognitive dysfunction but other morphological correlates exist including oxidative damage and neuron loss. The canine is clearly a valuable model of aging to examine the relationship between cognitive function, behavior, and neuropathology, given the many demonstrated similarities to observations in human aging and dementia.

# Bats as a Novel Model for Aging Research

Anja K. Brunet-Rossinni and Rocco E. Rossinni

*Despite small body size and high metabolic rate, bats are exceptionally long-lived mammals. This longevity, the ecological, behavioral and morphological diversity, and the unique life history traits of this multispecied order of mammals make bats well-suited as model systems for aging research. Including bats in comparative investigations may provide insight into universal mechanisms of senescence as well as reveal mechanisms that confer resistance to expected senescent processes. In this chapter we provide a general description of this extraordinary order of mammals within the context of their potential use for aging research. We describe general methodologies including captive care, capturing and aging techniques as well as some of the health precautions researchers should observe when working with bats. We conclude with a brief summary of the current state of longevity and senescence research on bats and potential future lines of research. Probably most useful is a list of resources we have included, which can provide initial information and direction for researchers interested in using bats as a model system.*

## Introduction

Over the past several decades, biologists have assembled a long list of lifespan records for several species of bats providing clear evidence of the exceptional longevity of this order of mammals (Chiroptera). In fact, after accounting for body size and metabolic rate, bats are among the longest-lived mammals (Austad and Fischer, 1991). Despite our knowledge of this exceptional longevity, very few studies have examined the questions of why and how bats live so long. This is surprising considering the extensive literature available describing the ecology, behavior, physiology and anatomy of certain bat species, as well as some of the unique traits of Chiroptera, which may provide insight into universal mechanisms of aging.

This paucity in research is likely due to some of the logistical difficulties of working with bats, and a disconnect between the community of researchers on aging and that of bat biologists. With this chapter we hope to bridge that gap and promote interest in pursuing

future research that includes bats. We will first describe the general characteristics of the order Chiroptera, focusing on traits that we feel make bats an excellent model system for aging research. We then discuss some of the advantages and disadvantages of using bats as model systems and summarize the limited research completed to date on bat senescence and longevity. We present methods and resources for the study, captive care, and age determination of bats, and finally, we finish the chapter by presenting some potential future lines of research.

## General Characteristics and Life History Traits of the Order Chiroptera

With over 1100 species of bats worldwide, the order Chiroptera is the second most multispecied among mammals, accounting for almost one-fourth of all mammalian species. The order is divided into two suborders. The Megachiroptera is a group of just under 200 species, which includes the flying foxes and fruit bats of the Old World. The Microchiroptera with over 900 species includes all the bats of the New World and some Old World species. The two suborders differ in sensory and feeding characteristics. Megachiroptera are fruit- and nectar-feeding bats with a binocular visual pathway and rely on olfaction and vision to find food. Species of Microchiroptera consume a broad range of food including insects, fruit, nectar, small vertebrates, and blood. They have a monocular visual pathway but rely on echolocation to forage and navigate (Simmons and Conway, 2003). Despite the differences between the two suborders, the order Chiroptera is believed to be a single evolutionary lineage, and this monophyly is supported by extensive morphological and molecular evidence (Simmons, 2000).

Chiroptera are incredibly diverse in regards to ecology, behavior, and morphology. Bats can be found on every continent except Antarctica. They inhabit deserts, stone beaches, temperate forests, rainforests, and cities. They roost in caves, under tree bark, in tree hollows, among foliage, under rocks, and in buildings. Behaviorally, several bat species are solitary, others form harems, and

still others form colonies that can include several millions of individuals.

Body sizes of bats vary from the hog-nosed or bumble bee bat (*Craseonycteris thonglangyai*), which weighs only 2 g, to the large flying fox (*Pteropus vampyrus*), weighing in at 1200 g. Their size is probably restricted by flight, as are several other anatomical and physiological traits. For example, females of most species have one reduced ovary and uterine horn likely to reduce body mass for flight (Barclay and Harder, 2003; Jones and MacLarnon, 2001), and juveniles have to achieve almost full adult size before fledging because full bone ossification is necessary to withstand twisting stresses and maintain the wing shape during flight (Barclay, 1994, 1995).

These flight-imposed restrictions translate into very unique life history traits. Mammals can be placed along a continuum of life history traits. At one extreme are small mammals with high metabolic rates, high reproductive rate, rapid maturation, and short lifespan. At the other extreme are typically large mammals with lower metabolic rates and long lifespan, which produce few, large offspring that mature slowly (Read and Harvey, 1989). Bats are paradoxical in that despite being relatively small and having high metabolic rate, they lie on the latter end of the continuum. The majority of species have one offspring per litter, and newborns weigh 15–30% of the body mass of the postpartum mother (Barclay and Harder, 2003; Tuttle and Stevenson, 1982). The gestation period in bats is long, and after birth, offspring take relatively long to reach full adult size (3–4 months in many species; Tuttle and Stevenson, 1982) and typically even longer to achieve sexual maturation (Jones and MacLarnon, 2001). Finally, on average, bats live three times longer than expected based on their body size and metabolic rate (Austad and Fischer, 1991). The oldest longevity record to date is 38 years from a 7-g Brandt's bat (*Myotis brandtii*). A small sample of bat longevities is listed in Table 36.1, and a more extensive list can be found in the appendix of Wilkinson and South (2001) and in Gaisler *et al.* (2003). Bat lifespan records come from the fortuitous recapture of wild individuals who were tagged at birth. Therefore, records likely are underestimates of actual maximum longevity (Wilkinson and South, 2002).

Bats have very high metabolic rates and many species are thermolabile. Ultimately, the thermoregulatory strategy of a species is determined by body size, habitat, diet, roosting choice, and social behavior. Because each of these traits varies greatly among species, bats exhibit a broad spectrum of thermoregulatory strategies. Species in the higher latitudes, where temperature varies seasonally, are heterothermic and use hibernation to survive cold winters without food and torpor during the remainder of the year to reduce energy expenditure while roosting. During hibernation, a bat will reduce its body temperature to a few degrees above ambient temperature, and its metabolic rate may drop to one-hundredth of waking rate. The extent of metabolic suppression during torpor

TABLE 36.1  
Maximum lifespan records of selected bat species  
(Geisler, 2004; Wilkinson and South, 2002)

Species	Body mass (g)	Maximum lifespan record (yrs)
<i>Myotis brandtii</i>	7	38
<i>Myotis lucifugus</i>	8	34
<i>Rhinolophus ferrumequinum</i>	23.5	30.5
<i>Pteropus rodricensis</i>	400	30
<i>Myotis daubentonii</i>	9	28
<i>Rosettus aegyptiacus</i>	146	22.9
<i>Desmodus rotundus</i>	30	19.5
<i>Eptesicus fuscus</i>	22	19
<i>Tadarida brasiliensis</i>	11	10
<i>Vespertilio murinus</i>	16	12

depends on ambient temperature. Species living in tropical areas or which migrate to warmer latitudes during the winter do not hibernate and therefore are considered homeothermic. However, the extent of homeothermy varies among species from true homeothermy in Megachiroptera to different degrees and frequency of torpor (Speakman and Thomas, 2003).

### Bats as Models for Aging Research: Advantages and Disadvantages

Uncovering differences and similarities in patterns of aging among various organisms from a broad phylogenetic spectrum is likely to yield insight into universal mechanisms of senescence. The inclusion of out-groups in aging research would allow investigators to assess whether these mechanisms or traits are unique to a given study species or shared by a broader taxonomic group (Austad, 1997). Bats may be an excellent out-group because they share life history traits with primates and other long-lived organisms, such as slow reproductive output and slow maturation.

Another advantage is that bats can be maintained in captivity (see following sections), which allows a researcher to carefully monitor individuals and eliminate several environmental factors that may confound results. Additionally, because some species exhibit high fidelity to roosting areas, it is possible to find a permanent wild colony where results from a captive colony can be tested (Brunet-Rossinni and Austad, 2004).

Heterothermic bats are metabolically malleable. A researcher can increase or decrease the metabolic rate of a bat by exposing it to lower or higher temperatures and, with the appropriate environmental cues, a bat may even enter torpor or hibernation. This plasticity makes bats an ideal system to study the role of metabolism and

### 36. Bats as a Novel Model for Aging Research

metabolic pathways in determining longevity and rates of senescence. Researchers will find extensive information in the literature on the physiology and metabolism of bats, though it should be noted that studies have focused on only a few bat families and not all species within a family can enter torpor. On the other hand, this prompt flexibility may pose a problem for studies where metabolic state should remain constant, especially caloric restriction studies, as bats may enter torpor in response to food scarcity (Brunet-Rossinni and Austad, 2004).

The extreme longevity of bats is both an advantage and a disadvantage. Studying an organism that naturally lives long should give insight to the physiological mechanisms that underlie its extended lifespan. However, long-term studies on bats that live 20–30 years are logistically difficult. This is exacerbated by the fact that unless a bat is tagged upon birth, there is currently no robust method to precisely estimate chronological age of an adult bat (see following sections). Nonetheless, there are a number of studies that have been tagging and monitoring bat colonies for over 10 years, and cellular mechanisms underlying extended longevity should be present in young adults (Brunet-Rossinni and Austad, 2004).

A final disadvantage is that only segments of nuclear and mitochondrial DNA of bats have been sequenced. This is, however, changing quickly as researchers continue to sequence new segments of both genomes.

#### Aging Research on Bats

Few studies have examined bat longevity, and due to continually improving lifespan data, it is not surprising that some of these studies have reached contradictory conclusions. Some of the earliest work that considered the question of *why* bats live so long was a comparative survey of lifespans by Bourliere (1958). Addressing the question from the standpoint of the rate of living theory (Pearl, 1928; Sacher, 1959), Bourliere described the extreme longevity of bats as a simple consequence of reduced metabolism during hibernation. This explanation, of course, neglects the long lifespan of homeothermic bats, which do not hibernate. In fact, Herreid (1964) and Austad and Fischer (1991) found no difference in maximum lifespan between hibernating and tropical bats. Jürgens and Prothero (1987) found that after accounting for torpor and hibernation, lifetime energy consumption and body mass predict maximum lifespan reasonably well in hibernating species, but fail to do so in nonhibernating species. The most recent survey study on bat longevity, which included an extensively updated dataset, found that the average longevity of hibernating species is about 6 years longer than that of nonhibernating species (Wilkinson and South, 2002).

Hibernation does appear to contribute to lifespan extension by concealing bats from predators, protecting them from inclement weather, and retarding physiological

deterioration (Barclay and Harder, 2003). However, it does not account for the fact that *all* known bat longevity records exceed those of similar sized nonflying mammals, including those that hibernate (Austad and Fischer, 1991). In its original formulation, the rate of living theory predicts the existence of a constant mass-specific lifetime energy expenditure for all mammals (Sacher, 1959). Bats exceed the lifetime energy expenditure of nonflying placental mammals by two-fold (Austad and Fischer, 1991), contradicting the rate of living theory. Another formulation of the rate of living theory describes an inverse correlation between maximum lifespan and metabolic rate or body size. Austad and Fischer (1991) calculated that on average bats live over three times longer than expected based on body size, again contradicting the rate of living theory. There is ambiguous evidence regarding a possible correlation between body mass and longevity within the order Chiroptera. Two studies found no correlation (Austad and Fischer, 1991; Jones and MacLarnon, 2001), yet a third found a correlation when using a phylogenetic analysis method which accounts for relationships among the species analyzed (Wilkinson and South, 2002).

From an evolutionary perspective, the exceptional longevity of bats is consistent with the evolutionary theory and the disposable soma theory of aging. The evolutionary theory of aging attributes senescence to the decreasing strength of natural selection with increasing age (Williams, 1957). This predicts that organisms that excel at escaping extrinsic mortality such as starvation, predation, disease, and accidents evolve to be long lived. Bats have terrestrial and aerial predators (e.g., snakes, opossums, owls, hawks) and are vulnerable to climate; however, the exposure is low relative to nonflying mammals. Like birds, which also exhibit exceptionally long lifespan, bats are able to escape predation by flying, and many species will migrate or adjust body temperature and metabolic rate to avoid adverse food and weather conditions (Wilkinson and South, 2002; Barclay and Harder, 2003).

The disposable soma theory of aging describes an inevitable evolutionary tradeoff between using limited resources and energy for somatic maintenance or to increase reproductive output (Kirkwood, 1977). An organism that experiences high extrinsic mortality is likely to die prior to the next reproductive season and would do well to invest in high and quick reproductive output instead of in somatic maintenance. The opposite would be true for an organism that experiences low extrinsic mortality as it can spread out reproductive output over a longer lifespan. Bat species with high reproductive rates and early sexual maturation exhibit shorter longevity (Rachmatulina, 1992; Wilkinson and South, 2002). Even within a species, females who delay breeding to a later age have higher survival rates than females who breed early in life (Ransome, 1995).

Very little is known about the physiological and molecular mechanisms underpinning the exceptional longevity of bats. Röhme (1981) included a bat (*Vespertilio murinus*) in a comparative study, which found a positive correlation between organism maximum lifespan and replicative lifespan of fibroblasts cultured from eight mammalian species. The involvement of cellular replicative lifespan in aging is still disputed (Cristofalo and Pignolo, 1995), and several laboratories are in the process of evaluating this correlation using fibroblast cell cultures from other species of bats (Brunet-Rossinni and Austad, 2004).

Baudry *et al.* (1986) examined a potential correlation between calpain activity and species maximum lifespan. The calpains are a family of calcium-dependent cysteine proteases that have been implicated in age-related pathologies of kidneys, heart, and brain tissue deterioration, as calpain activity increases with age likely due to impaired inhibitory mechanisms. Based on a negative correlation between calpain activity and brain size, and a positive correlation between brain size and maximum longevity, Baudry *et al.* hypothesized that brain calpain activity should be inversely correlated with maximum longevity. By quantifying degraded proteins in the presence of calcium, the study compared calpain activity in brain tissues of two bat species to that of mice and found significantly lower calpain activity in the bat tissues. It should be noted, however, that bat brain size is not consistent with the reputed correlation between lifespan and brain size.

A more recent study tested the free radical theory of aging (Harman, 1956) as an explanation for the extreme longevity of bats. In a comparative study, Brunet-Rossinni (2004) measured mitochondrial hydrogen peroxide production in heart, kidney and brain tissue of the little brown bat, *Myotis lucifugus*, the short-tailed shrew, *Blarina brevicauda*, and the white-footed mouse, *Peromyscus leucopus*. Hydrogen peroxide production per unit of oxygen consumed was significantly lower in the bat tissues than in the two nonflying mammals. Brunet-Rossinni also measured activity of superoxide dismutase, a key enzyme in the antioxidant defense system of mammalian tissues. Activity of this enzyme did not differ between the three species. Though not an all-inclusive assessment of antioxidant defenses, this study suggests that free radical production is a better predictor of bat longevity than metabolic rate and antioxidant activity. Similar results have been found in birds and other mammals (Herrero and Barja, 1998; Ku, *et al.*, 1993).

## Methods for the Study of Bats

### WILD BAT POPULATIONS: MONITORING AND CATCHING

Bat roost selection varies considerably; they will roost in caves, mines, occupied and unoccupied buildings, trees,

under leaves, under bark, under rocks and in cliff crevices (Kunz, 1982). Usually, roosts occupied by colonial species are easier to find because of the number of bats present and because some of these species exhibit high fidelity to their roosts. This is especially the case for species that form nursery colonies, as roosts that provide adequate climatic environment for fetal and neonatal development are at a premium. Most researchers conducting long-term monitoring of wild bat colonies identify a permanent roost like a cave or a building, which they then visit regularly. The composition of the colony varies from year to year as bats are very vagile, likely moving repeatedly among roosts, but the presence of the species is consistent over time. An excellent way of finding areas that are used by bats is to listen for vocalizations or look for evidence of foraging (such as guano or dropped fruit). With microchiroptera, researchers can listen for echolocation calls with an ultrasonic detector. These “bat detectors” slow down the ultrasonic calls emitted by bats as they fly, making them audible to the human ear. High echolocation activity may indicate the area is a good foraging site or a roost is nearby. Furthermore, specific patterns of echolocation frequencies have been used to identify the species of bats found in an area.

There are several techniques for capturing bats, and success with any requires knowledge of the roosting and foraging behavior of bats, as well as their emergence and dispersal patterns (Kunz and Kurta, 1988). Regardless of technique, three critical pieces of equipment for capturing bats are a light source, gloves, and “bat bags.” Because bats are nocturnal, most capture sessions take place at dusk or at night when they emerge for foraging. Headlamps with halogen bulbs and battery packs are ideal for this work as they are reliable and keep a researcher’s hands free for handling bats and manipulating equipment. Leather gloves should be used when handling bats to prevent bites and reduce stress to the animal. Lightweight leather gloves (e.g., baseball batter gloves) can be used for juveniles and smaller species, but heavier leather will be necessary for larger and more aggressive species, especially vampire bats and the large megachiroptera. The gloves should be soft and pliable to allow for improved dexterity and loose-fitting because sometimes it helps to let a bat chew on part of a glove during handling. “Bat bags” are simple drawstring bags made of muslin or nylon mesh that are used to temporarily hold bats after capture. We typically carry 50–100 bags for a trapping session so that each bat captured can be kept individually in a bag. However, this might not be practical if large numbers of bats are captured, and Kunz and Kurta (1988) describe several alternative temporary holding devices.

The most commonly used devices for capturing bats are mist nets and harp traps. It is possible to capture bats within a roost using hand nets, but this can be very disruptive and cause bats to abandon the roost. Mist nets are practical because they are lightweight, compact, easily erected, and commercially available in several lengths.

### 36. Bats as a Novel Model for Aging Research

They can be erected on the ground or raised up into tree canopies, thereby targeting bats that fly at different heights. The preferred mist nets for capturing bats have four shelves formed by mesh made of 50 or 70 denier/2 ply nylon (Kunz and Kurta, 1988) that is tiered with shelving cords. The nets should be erected on 10-ft poles that are sunk into the ground and/or secured with rope. While lightweight aluminum mist net poles are commercially available, bamboo, small trees, electrical conduit and paint poles are also effective. Unable to detect the net, bats fly into the mesh and drop into a pocket formed by the netting and the shelving cords. There they usually become entangled as they try to escape the mesh. Researchers should continually monitor the mist net so that trapped bats can be removed as quickly as possible because the longer they remain in the net the more difficult it becomes to disentangle them. Removing a bat from a mist net takes some practice. It should be done from the side of the net the bat entered, and one should take particular care with wings as they can become damaged if handled roughly.

Harp traps are often used to capture bats that elude mist nets. Harp traps consist of one or two large frames holding banks of fine wires or monofilament fishing line that run vertically along the length of the frame. A large bag attached to the base of the trap serves to collect falling bats that have lost momentum after flying into the bank of filaments. Current harp trap designs are collapsible and portable and have the advantage that they do not require constant attendance as the bats do not become entangled in the filaments but are held in the trap bag. It should be noted, however, that bats in the trap bag are susceptible to predators and aggressive interspecies interactions, so bats should not be left in the trap bag for too long (Kunz and Kurta, 1988).

Placement of a mist net or harp trap will influence the capture success. The most successful locations can be identified by sighting flying bats or listening for vocalizations and are usually near roosts, near sources of water such as streams and lakes, and along clearings used as flyways. Other factors that may influence capture success are amount of moonlight, rain, wind, the visual and acoustic resolution and flight behavior of the bats (Kunz and Kurta, 1988). A few cautionary notes regarding netting or trapping bats at the entrance or in large roosts such as caves, mines or attics: (a) It is not uncommon to catch large numbers of bats at one time as they emerge together from a roost. This can damage the net and distress both bats and handlers as the bats become increasingly tangled in the mesh. (b) Bats may abandon a site where they are caught and handled so it is recommended to capture bats away from roosts and keep handling to a minimum (Barclay and Bell, 1988; Kunz and Kurta, 1988).

If a study requires multiple observations on the same individual, markings will be necessary. Several methods for marking bats have been used, and the choice of method

will depend on the species of bat, how long the marking must last, how visible the marking needs to be, and how often the marking can be checked or renewed. It is also very important to ensure that the object used to mark a bat weighs less than 5% of the bat's body mass as the excess weight will impact flight.

Short-term marking of bats can be achieved by clipping patches of fur down to the skin, which can take up to four months to grow back if the bat is not molting. Obviously, this technique requires close handling of the bat for identification and should not be used during hibernation as the loss of fur can interfere with a bat's thermoregulation. Alternatively, livestock markers can be used to identify individuals. The nontoxic, lead-free paint of these markers adheres well to fur, comes in a variety of colors, and is safer to use than nail polish and dyes. In our experience, a colorful spot drawn between a bat's shoulder blades will last several weeks, depending on how often the individual grooms.

Long-term marking is most commonly done by wing banding. Metallic, aluminum or plastic bands are placed on the forearm of a bat, and identification is based on a unique number and/or a unique combination of colors. Reflective colored tape may be applied to the bands to permit identification of individuals during flight and while roosting. Wing bands should be used with caution as they can cause injury and infection. The band should be loose enough to slide freely along the forearm but tight enough to not slide onto the wrist and elbow joints, which can result in severe injury and immobility (Barclay and Bell, 1988). The opening of plastic split bands should be filed down to widen the gap and to smooth the edges that touch the wing as they will otherwise tear the thin wing membrane (Lollar and Schmidt-French, 1998) causing severe wounds likely to become infected. Some bats may chew at bands to the point of self-mutilation. In such instances, researchers should consider alternative methods. For example, neck collars made of bead-clasp chain or ratchet-style plastic ties have been successfully used to mark some bats (Barclay and Bell, 1988; Issac *et al.*, 2003). It is important that the collar fit properly. Wounds and infection can result from tight collars, and small bats can trap their wrist under a loose collar. We do not recommend the use of either wing bands or neck collars for juveniles that have not yet achieved adult size as the markers can interfere with proper development.

Other banding techniques used for bats include radiotransmitters and chemiluminescent light tags which are glued to a bat's back, skin tattoos, and radioactive tags. We refer the reader to Barclay and Bell (1988) for more details, advantages and disadvantages of these techniques. Toe-clipping, ear-notching, or ear-tagging, which are routinely used to mark other mammals, should not be used with bats because toes are essential for perching and grooming and ears are critical for echolocation in microchiroptera (Barclay and Bell, 1988; Lollar and Schmidt-French, 1998).

## CARE OF CAPTIVE BAT POPULATIONS

Several species of bats have been maintained in captivity, and there is ample information available regarding the proper care of captive bats. The following is a brief summary of some basic considerations for the captive care of bats. We refer readers to books listed in the Resources section of this chapter for more detailed information. Generally, a researcher interested in maintaining a captive colony must consider roosting and flight needs, climate and lighting needs, nutritional needs, and social needs. How these needs are met depends on the species of bat.

### *Flight cages and roosting cages*

Bats need exercise and may lose the ability to fly if deprived of flight space for over a month (Wilson, 1988). Flight cages can be made of a variety of materials to meet the particular needs of the research, but good visibility, easy cleaning, and plenty of perching sites are important considerations. If the cage is made of wire mesh, it is important that the gaps in the mesh are small enough that wings and feet will not get trapped. Also, wire mesh can cause irritation to the wrist and ankle area of the bat as well as tear wing tissue, so it should be coated with a Teflon spray. Alternatively, one could use softer materials such as nylon or rubberized mesh (Lollar and Schmidt-French, 1998). While mesh provides good perching sites, toenails may grow excessively and require clipping. Therefore, it is recommended to provide branches which the bats can use to file their toenails. Other good perching materials include burlap, cork board, bark, plywood with small holes and textured plaster (Wilson, 1988). Lollar and Schmidt-French (1998) provide detailed instructions for well-designed flight cages.

Smaller roosting cages can be placed inside the flight cage to either isolate individuals, provide a location where mothers can keep their young, or accommodate specific roosting needs. There are a variety of different roosting cages ranging from small aquaria with mesh tops to plywood and mesh cages such as those described by Lollar and Schmidt-French (1998). The key is to meet the roosting needs of the species in question. For example, crevice-dwelling bats like to roost in tight, dark spaces. Many bat rehabilitators attach small padded pouches to the walls of roosting cages that bats can crawl into (for patterns see Lollar and Schmidt-French, 1998). Tree-dwelling bats like to roost among foliage typically in relatively high areas. One can tie branches or leaves of the foliage preferred by the species in question to the upper corners of a cage.

### *Climate and lighting conditions*

Temperature, relative humidity, and light cycles play key roles in the digestive and reproductive function of bats (Heideman, 2000; Wilson, 1988). The optimal climate and lighting conditions are likely those experienced by the particular species naturally. For example, heterothermic

bats in temperate areas experience warm roost temperatures with high relative humidity and long days in the summer but then require low temperatures and short days in the winter for torpor or hibernation. Digestion is most efficient at thermoneutral temperatures, and photoperiod and seasonal temperature changes are critical for reproduction in many bat species. In many species mating takes place in the fall, but fertilization of the ovum or implantation of the zygote occurs in spring. Also, spermatogenesis is likely influenced by photoperiod (Heideman, 2000). Many people working with captive bat colonies mimic natural conditions, while others keep their colonies within sites that bats might normally pick for roosting, such as old barns or attics. This way, the colony experiences natural cycles in temperature, relative humidity and light.

Providing climatic and light cycles that imitate natural conditions may not always be possible. Another option is to use a space heater, heating pad, or a lamp with a 25-W red light bulb to create a temperature gradient in the cage so individuals can choose the temperature they prefer (Lollar and Schmidt-French, 1998; Wilson, 1988). Generally, bats should be kept at a temperature between 24 and 35°C and a relative humidity between 50 and 90% (Lollar and Schmidt-French, 1998; Wilson, 1988), but determining a good climate regime may take some trial and error. Researchers establishing a new colony should consult the literature to find data on the thermoneutral temperature range of the species in question. If breeding is desired, researchers should investigate mating behavior and physiology and determine the ideal conditions for mating and proper fetal and neonatal development (Heideman, 2000).

### *Nutritional requirements*

The dietary requirements of bats are easily accommodated in captivity, though at times training may be necessary so bats will accept the offered food. Regardless of the diet, vitamin, mineral, protein and fatty acid supplements should be provided when necessary. Vitamin and mineral supplements may be added by dusting food with vitamin/mineral powder or fortifying water with liquid vitamins. One should supplement vitamins and minerals with caution as overdoses may result in medical problems (Lollar and Schmidt-French, 1998). Linatone, a veterinary product for birds, dogs and cats, is an excellent source of additional fatty acids for bats.

The most common diet for insectivorous bats is mealworms, the larvae of *Tenebrio molitor*. Mealworms should be raised on a mixture of bran and oats enriched with a high protein cereal. Wedges of apple or potato provide the moisture mealworms need. Most insectivorous bats will need to be taught to eat the mealworms, and the speed with which they learn varies among species. To train a bat, one should offer a mealworm with a pair of tweezers. Sometimes it may be necessary to decapitate the mealworm to expose viscera but once bats recognize

## 36. Bats as a Novel Model for Aging Research

mealworms as food, they will feed independently on mealworms in a bowl. In lieu of live mealworms, bat handlers may use “bat glop,” a blended mixture of mealworms and other ingredients such as baby food and veterinary vitamin/mineral supplements. Lollar and Schmidt-French (1998) provide excellent recipes for blended mealworm mixtures which can be frozen in ice cube trays and then thawed for a meal.

Suggested food items for carnivorous bats include chunks of beef, rabbit meat, chicken meat, birds, lizards, white mice, rats, bats, chicks, quail, papaya, mango, melon and banana. Piscivorous bats will readily accept small pieces of fish supplemented with red meat and enriched mealworms.

Frugivorous bats will eat several fruits and vegetables including banana, figs, apples, orange, guava, passion fruit, grapes, pineapple, papaya, mango, pear, tomato, lettuce, cooked sweet potato, cooked carrots. This diet should be supplemented with canned feline diet or New World primate diet. Nectivorous bats can be fed instant nectar combinations, though one should ensure that the used combination is properly supplemented and balanced (Wilson, 1988).

The common vampire bat (*Desmodus rotundus*) does well on a diet of 50 mg of fresh blood per day, which can usually be obtained from a local slaughterhouse. The blood must be defibrinated by stirring or by treatment with sodium citrate or oxalate and is usually served in a shallow dish or ice cube trays. While fresh blood is preferable, frozen citrated blood has been used successfully for extended periods of time (Dickson and Green, 1970).

Different bat species have variable needs for water, depending on the diet provided. However, water should always be provided *ad libitum* in multiple containers placed throughout a cage. Some bats can be trained to lick water from drinking bottles but all bats will readily drink from open containers. Water in open containers is easily fouled by food and feces, so it is critical to change the water at least twice a day. Also, deep water dishes should be filled with marbles to prevent bats from falling in the container and aspirating water (Lollar and Schmidt-French, 1998).

It is important to keep a systematic record of the health condition of every bat in a captive colony. Individuals should be weighed regularly to assess for weight loss, which may be a sign of illness, as well as hyperphagia, though it is important to remember that hibernating bats will gain weight in preparation for hibernation. Other clinical signs to assess include diarrhea, vomiting, loss of pigmentation and/or dryness of the skin, hair loss, and lethargy. Several of the books listed in the Recommended Resources section of this chapter have helpful information on diagnosing common medical conditions.

### *Sociality*

Bats should be housed in accordance to their natural social behavior (Johnston, 1997). Solitary bats should

always be caged separately except for a mother and her pups. Upon weaning, however, the pups should be separated from their mother. Colonial bats should always be housed with roost mates, as they often practice allo-grooming and may thermoregulate by clustering. For most colonial species, the sexes should be kept separate. Species that normally form harems may be housed in groups of multiple females with one male, though regardless of the social system researchers should continually look for signs of aggressive behavior and redistribute individual animals to minimize aggressive interactions.

## HEALTH PRECAUTIONS FOR RESEARCHERS HANDLING BATS

### *Rabies*

Rabies is a significant concern for researchers handling bats, not because bats exhibit a higher incidence of rabies infection than other wild mammals, but because without prompt treatment rabies is nearly always fatal in humans. The virus is most commonly transmitted via contact with infected saliva through a bite, but other means of transmission include contact of infected saliva and nervous tissue with mucous membranes of the mouth, nose and eyes. There have also been two cases of transmission by aerosolized rabies virus in a Texas cave (Constantine, 1988), but no other cases have been reported since. A bat infected with rabies is not aggressive, but rather lethargic and incapacitated as the virus spreads through its nervous system causing paralysis. Thus, the main source of rabies infection from bats is inappropriate handling of the sick animal which bites in self-defense.

Symptoms of rabies usually develop 10–14 days after exposure and include pain, burning and numbness at the site of infection, headaches, insomnia, fever, and difficulty swallowing. However, usually by the time the symptoms are apparent, the progression of the disease can no longer be prevented, ultimately resulting in fatal inflammation of the brain and spinal cord. Therefore, it is imperative that a person seek immediate medical attention after any potential exposure. People handling bats should obtain pre-exposure immunization, which is conferred by 3 doses of vaccine, and check their titers regularly. Additionally, they should simply avoid exposure. Bats captured to establish a captive colony should be quarantined for at least 6 months to assess possible sickness. Always wear gloves when handling bats and avoid rapid and unpredictable movements which increase the chance of bites.

### *Histoplasmosis*

Histoplasmosis is a respiratory infection caused by the fungus *Histoplasma capsulatum*, which develops well in organic materials such as bat and bird feces. Fungal spores become airborne when dry guano is disturbed and can be inhaled resulting in infection. Greatest likelihood of infection is in caves and mines with large guano

accumulations where warmth and humidity enhance growth of the fungus, though cases of infection in buildings with large bat populations have also been reported (Smith, 1955). Symptoms of histoplasmosis usually appear one or two weeks after exposure and range from a dry-cough, chest pain and labored breathing to fever, nightsweats, weight loss and even blood-stained sputum. Histoplasmosis can be fatal. Persons entering a potentially contaminated roost should wear respirators with 2 micron filters and should bathe soon after departing the roost.

#### *Hazardous atmospheric gases*

Caves, mines, and other underground spaces are poorly ventilated, which can result in the accumulation of noxious gases and/or dangerously low concentrations of oxygen. These gases include irritants such as ammonia and sulfur dioxide, asphyxiants such as nitrogen, methane and carbon dioxide, and toxic asphyxiants such as carbon monoxide and hydrogen sulfide (Constantine, 1988). Several of these gases are odorless, and the concentration of others may increase due to the presence of large amounts of guano. One of the authors (ABR) has experienced respiratory distress and nausea from nitrogenous fumes emitting from vampire bat guano. A researcher should always obtain as much information as possible about a cave or mine prior to entering it and may wish to use portable toxic gas detectors during exploration.

### **Methods of Age Determination in Bats**

Bats are difficult to age once they reach adulthood, and the currently available methods of age determination have several limitations. To begin with, bats show no visible markers of aging, and the few traits that have been correlated with age to establish reference standards show significant variation due to genetic structuring of populations and environmental variation which impacts development. Additionally, available reference standards lack data from very old bats, likely because the oldest individuals are few and seldom caught. Finally, several of the more robust methods are invasive, making repeated measures impossible, and their accuracy is questionable (Anthony, 1988).

Undoubtedly, the best method for age determination is capturing and tagging individuals during their birth year. Thereby, at every subsequent recapture exact chronological age can be easily calculated. However, long-term monitoring of marked individuals can be very time consuming, and recapture rates are often low. A researcher must assess the level of estimate precision necessary for his or her investigations. If exact chronological age is necessary, then permanently marking individuals is the appropriate method. Otherwise, one of the following methods may suffice.

After birth, bats grow quickly, achieving almost full adult size prior to fledging (Barclay, 1994; Jones and

MacLarnon, 2001). During this time, long bones grow linearly and many researchers use forearm length measured with calipers to determine age of growing juveniles. In fact, this method provides very accurate estimates of age (Anthony, 1988). Its usefulness, however, is restricted to the first 2 to 6 weeks after birth, depending on species (Brunet-Rossinni and Wilkinson, *in review*). During this growth phase, the cartilaginous epiphyseal growth plates of the phalanges in the wing first expand to generate the phalangeal growth necessary for wing development and then become increasingly calcified. This process results in a linear increase and subsequent linear decrease in total length of the cartilaginous region between the bony diaphysis of a metacarpal and the bony diaphysis of the proximal phalanx (a.k.a. total gap). Epiphyseal growth plates are easily visualized by trans-illuminating the wing with a light source, as cartilaginous tissue allows more light to pass through than bone. Calipers can be used to measure total gap, though many researchers use a dissecting microscope with an ocular micrometer and a sub-stage light source to increase measurement accuracy (Kunz and Anthony, 1982). This linear change in total gap is a robust and accurate method for determining age of juveniles well beyond the valid age estimates provided by forearm length. The ease of obtaining measurements and the minimal equipment requirement are advantages of this aging method. However, once the epiphyseal growth plates are calcified, age estimates are no longer possible.

Nonetheless, the presence of cartilage in and the shape of phalangeal joints can be used to classify bats into general age categories such as infant, juvenile, and adult. If when trans-illuminating a wing cartilage is visible, the bat is a juvenile. Once the epiphyseal plate calcifies, one can still distinguish juveniles from adults as juvenile phalangeal joints are more tapered and less knobby than adult joints (see Figure 1 in Anthony, 1988). External reproductive traits can also be used to distinguish adults and juveniles. The presence of scrotal testes and well-developed teats are characteristic of reproducing adults (Racey, 1988).

The methods of age determination for adult bats involve assessing tooth wear and counting incremental dentin and cementum lines in teeth. Both methods are based on traits that vary tremendously and are difficult to measure, so researchers should exercise caution when using them for age estimations.

Bats have a permanent set of teeth by the time they can fly and feed independently, and mastication over a lifetime results in tooth cusps wearing down and becoming dull. Assessing the extent of tooth wear can be used to place bats into relative age categories, and standards have been developed for a few species (Brunet-Rossinni and Wilkinson, *in review*). However, noticeable differences in tooth wear occur over long time periods, which necessarily results in broad age categories. Additionally, scrutiny of some established reference standards attests to the

limited predictive power of this method due to extensive variation in tooth wear associated with diet and behavior (Hall *et al.*, 1957). Due to this variation, it is critical that estimates be based on reference standards developed for the particular study population and that these estimates be made by investigators with extensive experience and knowledge about tooth wear patterns in the particular species.

Dental incremental lines or “annuli” have been used to determine age of adult bats under the assumption that one new layer of dentine and cementum is laid on pre-existing dental tissue each year (Klevezal’ and Kleinenberg, 1967). Thus, by extracting and sectioning a tooth, the lines can be visualized and counted under a microscope, giving an estimate of a bat’s age in years. However, incremental lines may be difficult to count, especially in small species, the number of incremental lines counted may depend on the tooth extracted, and several factors can result in nonannual cycles of deposition (Batulevicius *et al.*, 2001; Cool *et al.*, 1994; Phillips *et al.*, 1982). The aforementioned problems put in question the accuracy of this method. An additional drawback is the laborious process of preparing the sectioned tooth, which can only be extracted from a dead specimen, making repeated measures impossible.

### Future Lines of Research

Future research using the bat as a model for the study of aging may reveal mechanisms that confer resistance to expected senescent processes observed in other long-lived mammals. Elucidation of the physiological mechanisms that give rise to the exceptional longevity observed in bats may provide insight into the development of novel treatments and therapies of degenerative diseases associated with senescence in humans. Chien and Karsenty (2005) describe the typical manifestation of the aging phenotype in long-lived mammals as development of osteoporosis, reduction in body weight, lean-reduced fat tissue, loss of hair or alopecia, cardiomyopathy, early loss of fertility in females, anemia with extramedullary hematopoiesis, reduction in physical activity, and lack of obvious cause of death. Following is a brief review of potentially heuristic lines of research using the bat as a model for the study of aging.

#### CARDIOVASCULAR RESILIENCE

The capabilities of the cardiovascular system of the typical bat are exceptional. Heart rates vary from as few as 10 beats per minute during hibernation up to 700–1000 beats per minute during flight (Brunet-Rossini and Austad, 2004; Pauziene *et al.*, 2000). Given the exceptional longevity of bats, one would expect that a cardiovascular system exposed to such extremes in hemodynamic demand would exhibit a decline in cardiac function over time. One would also expect to

observe ischemic cardiomyopathy associated with potentially low availability of oxygen during arousal from hibernation. The mammalian heart is composed of distinct cardiomyocyte lineages that give rise to the various anatomical components such as the atrium, ventricles and conduction systems (Chien and Karsenty, 2005). Examination of the mechanisms responsible for the development and maintenance of these cell lineages using techniques such as cell-fate mapping should help to elucidate the mechanisms by which bats mediate the expected cardiovascular senescent processes seen in other long-lived mammals. For example, humans exhibit a stereotypic reduction in cardiac ventricular ejection fraction, pacemaker function and electrophysiological conduction fidelity over time (Schwartz and Zipes, 2005). A potentially heuristic line of research would be to determine if these same senescent processes are exhibited in old bats. Cell lineage fate mapping may reveal protective mechanisms, potentially at the genetic level, that staves off expected decline in cardiovascular function. For example, Wallace (2001) has proposed that gradual accumulation of mutations in mitochondrial DNA over time might explain observed senescent processes in long-lived organisms. No studies have focused on the burden of mitochondrial DNA mutations in aged bats.

#### NEUROPHYSIOLOGICAL RESISTANCE

Bats exhibit an unusual ability to tolerate potentially ischemic conditions in both the cardiovascular and neurophysiological systems during arousal from hibernation and/or daily torpor. Lee *et al.* (2002) reported that oxygen consumption during arousal thermogenesis increased from near zero to 11.9 ml/kg/h. They also reported a rise in body temperature from 7 to 35°Celsius, suggesting potentially ischemic conditions in the heart, brain and other vital organs and tissues. Glucose related proteins (GRPs), which are oxidative stress signaling molecules, were also observed to increase in the brain of the bat. One potentially valuable line of research might be to determine whether expression of the GRPs change over time in the bat and if a similar mechanism prevent cardiac damage due to hypoxia.

The auditory system of Microchiropteran bats is highly refined and potentially represents the single most valuable sensory system inherent to their survival as they rely in echolocation to forage and navigate. Kirkegaard and Jørgensen (2000) report that adult Daubenton’s bats exhibit both innervated hair cells and apoptotic hair cells, suggesting a continuous turnover in their postembryonic life. This is contrary to what is observed in humans and mice where the number of innervated hair cells continuously declines with age. Research into the mechanisms underlying regeneration of innervated hair cells might provide a useful model for potential therapeutic applications in humans.

## SKELETAL CHANGES

Osteoarthritis and osteoporosis are stereotypically observed in aged long-lived mammals (Cooper and Melton, 1996). Strong bones are critical for bats to handle the physical stresses of flight (Barclay, 1994), and bone remodeling and formation is typically observed during the summer months in bats; however, sex differences have been observed. Kwiecinski *et al.* (1987) report that lactating bats exhibit significant bone loss over the summer months. A compensatory bone resorption mechanism via osteocytic osteolysis exists that alleviates observed bone loss over time. It is not known whether this mechanism declines with age. Conversely, males show continual bone accretion over the summer months. Elucidation of the mechanisms underlying bone resorption and remodeling in bats may provide novel insight into a therapy for osteoporosis in humans.

A critical future line of research will be the establishment of a robust and well-tested method for the determination of chronological age in adult bats. Efforts are currently underway to assess the utility of mitochondrial DNA mutation accumulation and advanced glycation end product accumulation (Wilkinson, G.S., pers. comm.) to estimate age in bats. A great part of developing such methods will be uncovering the actual manifestation of senescence in bats. Research to date on bats has focused on determinants of longevity, yet, aside from tooth wear, we know nothing about the physical decay of bats with age. What do old bats die of? Do they get cancer? Do they develop cardiac disease? Given the high sugar-content in the diet of nectar-feeding bats, do they develop hyperglycemia or diabetes with age? This is a small sample of questions that if answered have the potential to contribute significantly to our understanding of universal mechanisms of senescence. We hope that this chapter will serve to promote the utility of bats in furthering aging research and expose the truly unique qualities of Chiropterans.

## Recommended Resources

The following is a list of books and webpages that may be of use to researchers working with bats. Most of the books provide a survey of bat research and can direct a person in their exploration of the literature.

## PHYSIOLOGY, ANATOMY, REPRODUCTION, ECOLOGY, AND EVOLUTION OF BATS

- The Biology of Bats*, Vols. 1–3. 1970. W.A. Wimsatt, ed. Academic Press, New York.
- Ecology of Bats*. 1982. T.H. Kunz, ed. Plenum Press, New York, 425 pp.150.
- Communication in the Chiroptera*. 1985. M.B. Fenton. Indiana University Press, Bloomington, Indiana.
- Recent Advances in the Study of Bats*. 1987. M.B. Fenton, P.A. Racey, and J.M.V. Rayner, eds. Cambridge University Press, Cambridge.

- The Natural History of Hibernating Bats*. 1990. R. Ransome. Christopher Helm, London.
- Walker's Bats of the World*. 1994. R.M. Nowak. Johns Hopkins University Press, Baltimore.
- Bat Biology and Conservation*. 1998. T.H. Kunz and P.A. Racey, eds. Smithsonian Institution Press, Washington, DC.

# Memory in the Aging Hippocampus: What Can Place Cells Tell Us?

Iain A. Wilson

*Spatial memory impairments in normal aged individuals are associated with changes in hippocampal connectivity and plasticity. Electrophysiological recordings of single-cell activity while an animal is freely behaving allow us to see the brain in action and compare how young and aged individuals process information differently. Specifically, as a rat explores an environment, hippocampal neurons referred to as place cells show location-specific activity. Because the same network of cells is activated for repeated visits to one environment whereas a completely different network is used to represent a second environment, place cells provide a promising window into how the hippocampus forms and uses memories. Studies have found that place cells of aged rats, while showing robust spatial selectivity, do not encode or recall environmental landmark information as well as those of young rats. These weakened processing capabilities may be closely related to the spatial memory impairments suffered by aged individuals. The view from the place cell window is particularly revealing towards age-related memory impairments when placed in the context of known neurobiological changes to the normal aging brain. For these reasons, hippocampal place cells have been and will continue to be a useful tool to investigate memory disabilities of the aged and to evaluate potential preventive measures.*

## Introduction

Aged people often seem to maintain strong memories of childhood places, but sometimes have difficulties making new memories of new places. My great-grandmother, for example, would tell stories of her childhood, bringing us all vividly back to explorations of her favorite red-brick house, but after the story, she would wonder how we got to the living room of the nursing home.

Indeed, normal aging is associated with diminished memory capacity in both humans and animals (Gallagher and Rapp, 1997). How can we study why the aging brain has trouble making memories? This chapter will address how we can gain insight into the mechanisms underlying age-associated memory impairment. Memories are believed to be formed by strengthening some connections

between neurons, while weakening others. Accordingly, encoding a memory involves binding a network of neurons together so that later the same neuronal network will be recalled into activity. The chapter will focus on one technique: recording electrophysiological signals from single cells in rats that are freely behaving. By recording action potentials of single neurons, researchers can ask how networks of neurons store information in their patterns of activity. Although this technique is far from explaining all questions of the aging brain, it does provide powerful insight into its information processing capabilities, especially when considered alongside well-documented neurobiological changes to the aging brain.

## Why Study Spatial Memory and the Aging Hippocampus?

Because age-associated memory impairment occurs only in specific systems of learning, it is important to focus on a kind of memory that is impaired similarly in both humans and in animals. The learning and memory of places is particularly appropriate for investigations into the mechanisms of cognitive aging for four reasons. First, diminished spatial memory capacity is associated with aging in humans and in animals (for review, see Gallagher and Rapp, 1997). Second, spatial learning and memory play significant roles in the daily functioning of both humans and other species of mammals, and memories of places are easily tested in many different species. These tests can be arranged to compare the strength of memories for well-learned places with memories for novel places, a distinction relevant to aging (for review, see Hedden, 2004). Third, the mechanisms of spatial memory appear largely conserved between animals and humans, and these have been and continue to be well-studied in young individuals. Much research in young animals has shown that the hippocampus region of the brain is intimately linked with spatial cognition. Fourth, the hippocampus of rats, like that of humans, undergoes specific age-associated degenerations to its circuits.

As discussed in Chapter 32 by Bizon and Nicolle in this book, rats provide a useful model for studying the mechanisms underlying age-associated impairments in spatial memory. The spatial water maze task, which requires the use of spatial landmarks to navigate in an open field (described in detail by Bizon and Nicolle), is abnormally difficult both for aging rats (Gallagher *et al.*, 1993) and for aging humans on dry land and virtual versions (Moffat and Resnick, 2002; Newman and Kaszniak, 2000). Spatial learning and memory are critically dependent upon the hippocampus region of the brain (O'Keefe and Nadel, 1978), and indeed many of cognitive impairments suffered by aged individuals are similar to disabilities caused by lesions to the hippocampus, both in humans and in animals (Gallagher and Rapp, 1997). This has inspired researchers to focus on the hippocampus as a possible source of age-associated memory impairments.

The hippocampus receives highly processed multimodal information from the association cortices (Amaral and Witter, 1995). This information from all the sensory modalities—vision, hearing, touch, and so on—flows in a circuit through the hippocampal formation where relationships can be rapidly bound together, perhaps into a memory of an event, place, or context (Eichenbaum *et al.*, 1999; O'Keefe and Nadel, 1978; Redish, 2001). Information flow within the hippocampus is classically described as a tri-synaptic circuit, signifying a cascade of processing (Amaral, 1993; Amaral and Witter, 1995). Information flow in the tri-synaptic circuit cascades from the entorhinal cortex to the dentate gyrus (1) to the CA3 (2) and to the CA1 (3). The principal cells that provide the output of each subregion are arranged in tightly packed layers (see Figure 37.1). To complete the circuit, the entorhinal cortex receives the output of the CA1 (via the subiculum).

**Figure 37.1** A histological section showing the recording sites of hippocampal place cells. Tetrodes (drawn in the right hemisphere) were advanced through the overlying cortex to the CA1 pyramidal cell layer. The actual recording sites in both hemispheres are marked with lesions and indicated with arrows. The cell layers of the CA1, CA3 and dentate gyrus (DG) subregions of the hippocampus are highlighted by the Nissl staining.

## Why Measure Neuronal Activity?

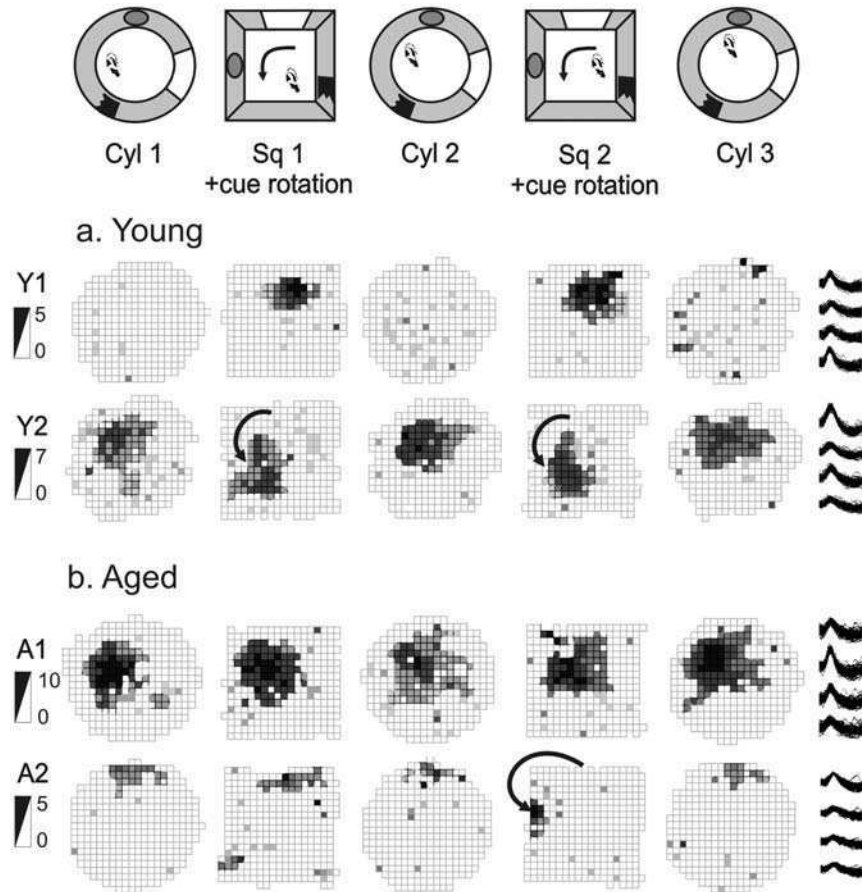

In order to understand how the hippocampus processes the information it receives, and to compare how the aged hippocampus does this differently from the young one, one useful technique has been to study brain in action. The brain represents information by activating networks of neurons, and each piece of information will be represented by a different network of neurons. It is therefore keenly interesting to identify which neurons are active at which times. By placing extracellular electrodes near the soma of cells inside the brain, it is possible to record the action potentials of neurons as they communicate with one another through changes in electric potentials. The great advantage of this technique is that we can monitor cell activity while the animal is awake and even performing a task. By providing a window to *when* neurons are active, single cell recordings have given unique insight into *what* information is processed within particular brain regions. In other words, by knowing when action potentials occur (to the nearest tenths of a millisecond), we can ask how this activity relates to what the animal was doing at that particular time. Much of our understanding of the function of a particular brain region has come from this window into the brain's activity. For example, single-cell recordings have made enormous contributions to our understanding of how each region of the visual cortex contributes to vision—from responses in the primary visual cortex to precisely oriented lines to responses in the inferior temporal cortex to particular classes of objects.

## Neuronal Activity of the Young Hippocampus: What Are Place Cells?

Because single-cell recordings can be done while an animal is exploring an environment, the technique provides researchers with a view of the neurons of the hippocampus in action as it is processing spatial information in the rat (O'Keefe and Dostrovsky, 1971), the monkey (Rolls, 1999), and the human (Ekstrom *et al.*, 2003). The best-researched of these is the freely moving rat. The pyramidal cells of the CA1 and CA3 hippocampus fire action potentials when the rat occupies particular places (for review, see Muller, 1996). "Place cells" have high firing rates in a particular area of an environment, referred to as the place field; outside this place field the cells are nearly silent (see examples of Figure 37.2).

In typical place cell experiments, the rat is placed into an environment, either an open field or a linear track. The rat then explores the arena, often with the encouragement of randomly placed food rewards. In the top row of the example (Figure 37.2) the rat is shown exploring cylindrical and square environments, which contain three distinct landmarks on the walls that the rat

### 37. Memory in the Aging Hippocampus

**Figure 37.2** Place fields of hippocampal cells in young and aged rats. The top row depicts the experimental setup with the rats exploring a familiar cylindrical arena (Cyl) and a novel square arena (Sq). Each subsequent row represents the activity of one cell over the entire experiment. Firing rate scales are provided on the left of the figure, such that darker pixels indicate areas in which more action potentials occurred. Sample tetra-waveforms of each cell are shown on the right side. Data are shown (a) for two place cells of two young rats and (b) for two cells of two aged, memory-impaired rats. Cell Y1 is an example of the generation of new spatial representations by cells of young rats. Cell Y2 shows a place cell whose field rotated, following the landmarks in the square. Cell A1 shows an example of rigid place fields of aged memory-impaired rats despite changes in the environment. Cell A2 is rigid in response to the first exposure to the novel-square, but then rotates with the square's landmarks in the second trial (Figure adapted from Wilson *et al.*, 2003).

can use for orientation. As the rat explores, the action potentials of pyramidal cells from the hippocampus are recorded. Each row in the figure depicts the activity of one neuron throughout the manipulations of the experiment. Each grid represents the floor space where the rat was moving. Dark pixels show high firing rates for a particular cell, whereas white pixels indicate no action potentials but that the rat did visit the area. The dark areas are referred to as the place field for that cell. Each time the rat passes through the place field, the place cell fires action potentials; outside the field the place cell is silent.

With thousands of cells active within an environment and each cell with its own place field, these neurons could compute the rat's spatial location and reflect elements of a rat's "cognitive map" (O'Keefe and Nadel, 1978). Wilson and McNaughton (1993), recording

simultaneously from as many as 141 pyramidal cells, were able to estimate the rat's position to 1-cm accuracy even with only this number of cells. It is clear that these cells participate in a broad system of spatial processing that is important for navigation (Redish and Touretzky, 1997). The cells may also participate in a broader spectrum of memories; alternatives to the cognitive map theory posit that these cells could represent places where significant events occur within episodic memories (Eichenbaum *et al.*, 1999) or participate in associations of contexts within memories (O'Reilly and Rudy, 2001; Redish, 2001).

Regardless of what they imply for hippocampal theory, place cells possess four characteristics that make them a useful window into how the hippocampus stores information, especially spatial information. The first property of place cells that attracts memory researchers is that

they are *not simply sensory neurons*. The hippocampus receives multimodal information, so it is not a surprise that place fields are controlled by contributions from all the sensory modalities. Rats navigate by vision, smell, touch, hearing, and self-motion information; all of these have influence over place cell firing patterns (Muller, 1996). This characteristic means that researchers can study how the sensory modalities interact to control stored patterns of activity.

The second property of place cells that makes them attractive as a model of memory is their remarkable *stability* across time. Place cells are active in the same location with respect to each other and to the environment both within a continuous session in an environment and when the rat reenters the same environment after an absence (Muller and Kubie, 1987; Thompson and Best, 1990). This is clearly illustrated in cell Y1 in Figure 37.2. The cell is silent in the cylinder 1 environment. The rat is then removed from the arena and placed in a holding bucket while the arena is changed to a square out of the rat's sight. The rat is lifted back to the arena, and this process is repeated several times. Each of the three times that the rat explored the cylinder, this cell fired very few action potentials. The two exposures to the square arena, though, had distinct place fields in the same location; hence, the place fields were stable. This appears to be a function of memory recall because different environments are represented by different sets of place cells (discussed later), and reentering the original environment primes the retrieval of the original spatial representation. This characteristic of place cells indicates that a representation of the environment is stored in the hippocampus, and place cells allow researchers easy access to explore the mechanisms of these memories.

The third important feature of place cells is that they are largely controlled by visual landmarks, and therefore the place cells *rotate with rotations of the visual landmarks*. When the rat is removed from an arena and the visual landmarks of an arena are then rotated by 90°, upon reentry the place cells follow the landmark rotation by almost exactly 90° (Muller and Kubie, 1987; O'Keefe and Conway, 1978). This effect is shown in the cell Y2 of Figure 37.2. The place fields in the square environment have simply followed the 90° rotation of the landmarks (in this experiment the landmarks were the same in both environments, but rotated by 90°). Because tests of spatial memory, such as the water maze, rely upon use of the visual landmarks, the fact that place cells rotate with visual cues strengthens the link between hippocampal cells and spatial navigation. The rotations provide a simple way to test how well the cues of a particular environment control the hippocampal spatial representations.

The fourth attraction of place cells for memory researchers is the creation of *new spatial representations* in new environments. When a rat enters a visually new

arena from a familiar one, the place cells drastically alter their place field firing patterns, quickly forming completely new firing patterns in the relation of the cells to each other and to the visual landmarks (Frank *et al.*, 2004; Hill, 1978; Wilson and McNaughton, 1993). For two environments, two different sets of hippocampal neurons are active. Cell Y1 of Figure 37.2 illustrates a cell that is silent in one environment (the cylinder) and active in the other (the square). Alternatively, the cell may use two different place field locations to represent two environments. Each environment recalls into activity the unique network of neurons bound to it, much resembling a stored memory. The learning of a new environment and the creation of new spatial representation are not always rapid. When two environments are similar, place cells may initially use the same representation but with additional exposure may slowly (over as many as twenty days) develop distinct representations for each (Lever *et al.*, 2002). Place cells, therefore, provide researchers the perfect opportunity to study the storage of a memory from its creation in the hippocampus.

In support of these assertions, several experiments have found that successful spatial navigation to a goal requires place fields consistent with that goal (Lenck-Santini *et al.*, 2001; Lenck-Santini *et al.*, 2002; O'Keefe and Speakman, 1987; Rosenzweig *et al.*, 2003). For example, in a study by Lenck-Santini and colleagues (2001) rats performed a continuous spatial alternation task in a 3-armed Y-maze. After a series of landmark rotations, some place fields became out-of-register with the goal arm, and for these rats, performance on the task was poor. Place fields of other rats maintained their correct relationship with the goal arm, and for these rats, performance on the task remained accurate. These studies strongly suggest that a consistent place field-goal relationship is essential for finding goals that require spatial navigation.

## How Can Place Cells Be Useful for the Study of Memory and Aging?

CA1 and CA3 pyramidal cells reflect how spatial information is processed and stored in the hippocampus. Because place cells are not simply sensory neurons, because place cells are stable over time and repetition, because place cells clearly use the visual landmarks, and because place cells form new spatial representations of new environments, they provide an intriguing window into the formation of memories by the brain. Furthermore, consistent spatial representations are necessary for correct performance on spatial tasks and serve as a likely step in the mechanisms of spatial navigation and memory. Because these are precisely the behavioral impairments from which some aged individuals suffer, researchers have turned to place cells in order to tighten the connection between the

behavioral deficits of aged animals and information processing capabilities within the hippocampus region. Hence, comparing the information processing of place cells of young and aged rats can yield unique insight into what goes wrong in the hippocampus of aged memory-impaired individuals.

### Technical Challenges and Advances – What Are Tetrodes and Microdrives?

Action potentials of single cells are recorded by bringing small-diameter wires close to the soma of neurons (see Figure 37.1). Because the pyramidal cells of the hippocampus are so tightly packed, a single 13-micron diameter electrode will detect action potentials from many neurons. This is good, except that with a single electrode, one cannot differentiate action potentials from individual neurons. To solve this problem, hippocampal researchers twist several electrodes together into a tetrode with four electrodes (Gray *et al.*, 1995; McNaughton *et al.*, 1983). Tetrodes bring four electrode tips to the hippocampal pyramidal cell layer, and therefore triangulation can be used to discriminate between active cells. The amplitudes of the waveforms that the wires record are largest for cells that are nearest to a particular electrode tip. More distant electrodes will have waveforms of smaller amplitude for that cell. This is illustrated in the waveforms of Figure 37.2. The action potentials of each neuron produce their own unique signature of tetrode waveforms. This allows researchers to distinguish between different neurons that are recorded simultaneously. With this technological advance, it is now possible to record simultaneously from ten or more well-isolated neurons from one tetrode.

Another important technological development has been the ability to advance many tetrodes individually down to the cell layers. Because the position of the electrodes must be precisely in the pyramidal cell layer during recordings, the electrodes are not advanced to the hippocampal layers when the rat is anesthetized during surgery. Instead, the tetrodes are implanted to the overlying cortex and slowly advanced (50 microns/day) so that the rat is awake and potentially ready for recordings when the cell layer is found (see Figure 37.1). To do this, each tetrode is attached to its own microdrive, enabling precise adjustments in recording location to be made so that each tetrode will find the ideal layer and stay there for stable recordings over at least several days. Using these demanding techniques, today laboratories are able to record from twelve tetrodes simultaneously, which allows recordings to distinguish between as many as 100 cells at a time. Recording from such a network of activity with stable cells over one week allows investigation of the information processing of neurons during the formation and retrieval of memories.

### What Have We Learned So Far from Aging Place Cell Research?

Although aged rats are certainly impaired in hippocampal-dependent spatial memory, the hippocampus of aged rats does possess place cells with firing properties similar to those of young rats. Most importantly, the hippocampal cells of even the most spatially-impaired aged rats have place fields that are equally as crisp as those of young rats (see examples A1 and A2 of Figure 37.2; for a review of these data, see (Barnes, 1998)). The difficulties of cognitive aging, therefore, do not lie in simply a lack of spatial processing by the hippocampus. Instead, research has consistently shown that differences between the spatial representations of young and aged rats are brought out when the hippocampus is challenged to encode changes in the environment. In order to illustrate how place cells can be used as an effective tool in aging research, I will highlight three experiments that demonstrated these differences in hippocampal information processing and tied them to age-related memory impairments.

The experiment shown in Figures 37.2 and 37.3 was designed to draw a closer association between hippocampal encoding of a new environment and the degree of age-related memory impairments in individual rats (Wilson *et al.*, 2003). The spatial learning abilities of young and aged rats were determined by the water maze task; the young rats and some aged rats performed well, whereas other aged rats were significantly impaired (see Figure 37.3, the Y-axis).

**Figure 37.3** The degree of place cell rigidity predicts the magnitude of spatial learning impairment. Similarity in place fields between exposures to the familiar cylinder and novel square are plotted against spatial learning performance in the water maze. Poor spatial memory is indicated by high spatial learning search error scores. Similarity scores (rigidity) correlated strongly with spatial memory performance of all groups combined ( $r(29) = 0.63$ ,  $p < 0.001$ ), and within the group of nine aged rats ( $r(17) = 0.55$ ,  $p < 0.05$ ). (Figure adapted from Wilson *et al.*, 2003.)

Subsequently, hippocampal place cells were recorded as the rats explored a familiar environment (the cylinder) and a geometrically altered version of the environment (the square; see Figure 37.2, top row). Place fields of young and aged memory-intact rats changed upon exposure to the altered environment (Figure 37.2, cells Y1 and Y2). In contrast, many place fields of aged memory-impaired rats were unaffected by the environmental alteration (Figure 37.2, cells A1 and A2).

One possibility that must always be considered with aged rats is that the aged memory-impaired rats fail to use the visual landmarks in the water maze and place cell recordings because their vision is poor. The example in Figure 37.2, cell A2, illustrates why poor vision appears unlikely to account for the rigidity in the place cells in this experiment. The field was rigid during the first exposure to the square arena (Sq 1), but during the second exposure the field rotated with the landmarks (Sq 2). This indicates that the visual information could at least reach the hippocampus, but on some occasions it was not encoded properly.

To quantify this place field rigidity of aged rats, pixel-by-pixel correlation comparisons were done between the firing rate maps of the two environments. Place cells with different place fields in the cylinder and square environments had correlations near 0.0 (Figure 37.1, young cells Y1 and Y2), whereas place fields that are similar between the two environments had higher correlations approaching 1.0 (aged cells A1 and the first three trials of A2). These place cell characteristics of aged rats were then related to the abilities of the same rats on the spatial water maze. As Figure 37.3 shows, the degree of the rigidity in spatial representation predicted the magnitude of the spatial memory impairment. Thus, the heterogeneity of the spatial memory capacity with aging may be due to differential information encoding capacities by the young and aged hippocampus.

In a complement to these encoding difficulties, Barnes *et al.* (1997) have shown that, under other conditions, aged rats do not retrieve place cell representations properly. In an elegantly simple experiment, place cells were recorded in a familiar environment, and then the rats were taken on a tour of several new environments. When the rats were placed back into the familiar environment, the authors performed a correlation analysis between the place fields used initially in the familiar environment and those used after the new exposures. The young rats used the same place fields to represent both sessions in the familiar environment. The aged rats, on the other hand, recalled the former place fields correctly only about 70% of the time. On 30% of the occasions the aged rats used a completely novel arrangement of place fields to represent the familiar environment, suggesting a multistability of spatial representations in aged rats. As a control, the authors compared the place cell activity within uninterrupted sessions; in this case the aged rats, as well as the young, maintained the same spatial

representations throughout the sessions. These results suggest that the aged rats had no difficulties maintaining a consistent representation during uninterrupted exposure to an environment, but that new experiences could interfere with successful recall of even a highly familiar environment.

To test how this place cell retrieval deficit related to spatial navigation abilities, the authors (Barnes *et al.*, 1997) compared water maze data from 98 young and 93 aged rats (these rats were different individuals than those recorded). After four days of training, the young rats quickly found the hidden platform almost every time, whereas the aged rats sometimes found it and sometimes had much longer search paths. The variability of the aged rats was not due to between-rat differences, but rather each aged rat had good performances and bad performances. Together these data suggest that the aged rats sometimes got lost; that is, their place cells failed to recall the correct spatial representation, and this caused them to search incorrectly for the water maze platform.

In addition to difficulties encoding and retrieving place cell memories, aged rats are not as capable as young rats at making appropriate updates to their place cell representations during a continuous experience. Rosenzweig *et al.* (2003) recorded place cells of young and aged rats as they were actually performing a spatial navigation task. This cleverly designed experiment manipulated the relationship between external cues and self-motion cues. The goal location on a linear track remained constant with respect to the external visual cues, but the start box was shifted for each trial causing the walking distance to the goal location to vary. On each trial place fields were initially determined by the self-motion cues, and successful performance entailed a switch in the control of place fields from self-motion cues to external landmark cues well before the goal area was reached (Gothard *et al.*, 1996). Young rats successfully updated their spatial representations, whereas many aged rats failed to update their representation to the relevant spatial information and therewith failed on the task. Furthermore, the learning of a goal location correlated strongly with how readily the place fields of the rats were adjusted into control by spatial cues.

This chapter has been intended to provide only examples of how place cells can be a useful tool for aging research; for more complete reviews of the aging place cell literature, please see Rosenzweig and Barnes (2003) and Wilson (2005). The experiments discussed here do serve to illustrate a rising theme from the literature: the hippocampus of aged rats is impaired in the processing of external environmental information. Under different demands on memory processing, this manifests itself in different forms (Wilson *et al.*, 2004). Aged place cells that fail to change despite new environments allow us to see failures during encoding. The multistability of aged place cells upon return to a familiar environment allows us to

see failures during recall. Aged place cells that do not readily adjust from self-motion to external landmark control allow us to see failures during updating of the representation. Place cells, therefore, provide a powerful window into the workings of memory in the aged hippocampus.

### What Are the Limitations to Place Cell Research?

Single-cell recordings allow the study of information processing by individual neurons of a particular region within the brain with enough temporal precision to correlate activity of individual neurons with particular behaviors. The power of single-cell recordings is limited, however, by the facts that the electrodes sample a very small selection of the neurons from only one subregion of the brain, monitoring numerous brain regions simultaneously is difficult (but see Lee *et al.*, 2004), and the anatomical locations and connections of the recorded neurons can be defined only in general terms. For example, the CA1 hippocampus contains roughly 400,000 pyramidal cells (Rosenzweig and Barnes, 2003); even the published “world record” for number of place cells recorded simultaneously of 141 cells (Wilson and McNaughton, 1993) manages only a small sample of the hippocampus. Furthermore, single-cell recordings are highly invasive and cannot be done in human subjects (although see Ekstrom *et al.*, 2003).

Electrophysiological recording of single-cells is not the only means of studying neuronal activity. For example, the fMRI technique is a noninvasive way to study activation over the entire human brain, while the subject thinks about a computer screen (for applications relevant to aging, see Chapter 12 by Small). However, the spatial precision of fMRI is far from individual neurons, the trials must be averaged, which reduces temporal precision, and the subjects are restricted in behavior. Recently in animal research, gene activation studies have proved capable of studying the activity of single neurons simultaneously across many brain regions. cFos, Arc, and Homer are genes whose expression is induced immediately following neuronal activity. Through immunostaining, these genes provide a marker for which neurons have been activated during a particular time period prior to sacrifice of the rat. A drawback of the immediate-early gene technique to study neuronal activation is that the rat must be sacrificed in order to get the information. This means that one cannot measure changes in activity across different behavioral settings or across learning, as one can do with *in vivo* electrophysiology.

Monitoring of place cells contributes one piece to our understanding of cognitive aging through their insight into spatial memory, but there is convincing evidence that the hippocampus handles more than just spatial

information (reviewed by Eichenbaum *et al.*, 1999). Important studies have, therefore, examined the activity of single cells during a nonspatial task in aged rabbits (for example, McEchron *et al.*, 2001). Moreover, to reap the full benefit of the single-cell recording technique, place cell results must be placed in the context of well-researched age-related behavioral impairments and deteriorations to hippocampal connectivity and plasticity (for reviews of this, see Foster, 1999; Wu *et al.*, 2002; Rosenzweig and Barnes, 2003; Wilson, 2005). Many of these neuroanatomical changes to the aging brain are discussed in Chapter 32 by Bizon and Nicolle. Each technique provides its own insight into the mechanisms underlying age-related memory impairments; by putting many technique pieces together, we can begin to understand why the aging brain is sometimes impaired.

### What Can Future Research with Place Cells Tell Us about Cognitive Aging?

Neurobiological investigations on aging have repeatedly stressed the subtlety and the regional specificity of changes within the hippocampus, affecting synaptic connections, physiology, and plasticity (for review, see Barnes, 1994). These changes may cause subtle shifts in how information is processed by the aging brain. In accordance with this view, age-related changes to hippocampal place cells are also subtle. Spatial information is certainly reaching and being processed by the aged hippocampus since location-specific activity is equally robust in both young and aged rats. Nevertheless, place cell studies have shown that aged rats have behaviorally significant deficits in encoding and recall of spatial information within the hippocampal region.

In the near future hippocampal place cells may, therefore, serve as a useful tool for investigating three specific aspects of age-related memory impairments. First, it will be important to understand how aged rats fail to encode and recall spatial goals. Researchers have found that weakened processing of external landmarks by place cells during a spatial task predicts performance of the aged rats on that task (Rosenzweig *et al.*, 2003), and the next step may be to measure the activity of hippocampal cells as the rat is actually learning spatial goals and recalling them.

Second, recent technological advances, such as recordings from twelve independently-movable tetrodes, have made it possible to record cells from several regions of the brain simultaneously. With a better understanding of the particular contributions each region makes to the formation and recall of memories (such as Lee *et al.*, 2004), the way has recently been paved for information processing studies to match the well-documented subregional specificity of age-related changes to hippocampal neurobiology. These advances may prove important as we aim towards prevention of age-related memory

impairments with specifically-targeted pharmacological interventions. Third, place cells of aged rats provide a window for evaluation of these potential drugs. Place cells are already in common use to evaluate effects on memory of receptor-blocking drugs (for example, Kentros *et al.*, 1998) and mutations of specific genes in mice (Cho *et al.*, 1998). With respect to normal aging, therapies that reinstate normal encoding and recall to place cells of aged animals will be particularly promising.

## Conclusion

What have hippocampal place cells told us about why my great-grandmother maintained strong memories of her childhood but failed to make to new memories in her old age? When people are young, spatial environments are fully encoded by hippocampal cells and probably eventually become cortical memories, no longer requiring the hippocampus (Squire and Alvarez, 1995). As people age, new spatial environments are encoded more weakly by hippocampal cells, and they are less able to prompt later recall. Hippocampal place cells, thus, provide a clear window for investigating age-related impairments in the formation and retrieval of memories and may serve as a powerful tool for evaluating potential preventive measures.

This webpage provides a comprehensive introduction to many aspects of hippocampal neuroplasticity. This is an excellent introduction to place cell technique, complete with descriptive photos, references, and links to scientists who do place cell research.

Hedden, T., and Gabrieli, J.D. (2004). Insights into the ageing mind: A view from cognitive neuroscience. *Nat. Rev. Neurosci.* 5, 87–96.

This review presents an elegant overview of normal human aging and relates it to findings from animal research.

O'Keefe, J., and Nadel, L. (1978). *The Hippocampus as a Cognitive Map*. Clarendon, Oxford.

This influential book drew the connection between spatial navigation and the hippocampus, arguing that hippocampal place cells represent elements of the rat's cognitive map. It has spawned a great deal of research into the spatial nature of the hippocampus. Furthermore, the book distinguished between two systems of navigation learning, one based on routes and guidances and another based on the cognitive map of spatial information.

Rosenzweig, E.S., and Barnes, C.A. (2003). Impact of aging on hippocampal function: Plasticity, network dynamics, and cognition. *Prog. Neurobiol.* 69, 143–179.

This article comprehensively reviews age-related changes to the hippocampus from behavioral, neurobiological, and place cell perspectives. This provides an outstanding review of age-related changes to synaptic plasticity.

Wilson, I.A. (2005). *Hippocampal place cells as a window into cognitive aging*. Ph.D. thesis, University of Kuopio, Finland.

This dissertation ties together spatial memory impairments, neurobiological deteriorations in the hippocampus, and weakened processing by hippocampal place cells associated with normal aging.

## ACKNOWLEDGMENTS

This work was carried out at the University of Kuopio, Finland in the laboratory of Heikki Tanila, who made this research possible and contributed invaluable discussions to this chapter. The author greatly appreciates the collaborative contributions of Howard Eichenbaum, Michela Gallagher, and Sami Ikonen to this aging research project. The author is grateful to Silvia Gratz for critical editing comments on this chapter. This work was supported by the National Institute on Aging, grant AG09973, by the Academy of Finland, grant 46000, by the Northern Savo Cultural Foundation, and by the Research and Science Foundation of Farnos.

# The Rhesus Macaque as a Model of Human Aging and Age-Related Disease

Mary Ann Ottinger, Julie A. Mattison, Mary B. Zelinski, Julie M. Wu, Steven G. Kohama, George S. Roth, Mark A. Lane, and Donald K. Ingram

*The rhesus monkey (Macaca mulatta) offers an advantageous model for biomedical research because of the close relatedness of this species to humans. As in humans, the rhesus monkey experiences deteriorating function of multiple physiological systems during aging, as well as an increasing incidence of pathologies and other health issues. These health issues are generally considered part of "normal" aging. However, there are health problems that arise, which contribute to disease states that become more prevalent in aging populations, such as osteoporosis and metabolic disorders, including diabetes. In addition, the rhesus female provides a valuable experimental model for understanding the biological changes that accompany the process of ovarian aging and the perimenopausal transition, which is an area of high visibility and intense research at this time. Rhesus males also experience age-related increases in health issues despite the fact that they do not have the precipitous hormonal changes seen in females. Moreover, evaluation of cognitive performance and other behavioral changes in rhesus monkeys has proven useful for understanding age-related changes and developing clinically relevant interventions and treatments. Once the elements of the biology and endocrinology of age-related changes are well documented, then there is the opportunity for evaluating other potential interventions that may impact aging processes, including dietary or pharmaceutical regimens. The marked advantage of the rhesus macaque as an experimental model is the similarity and parallel changes to aging in humans. However, this advantage is accompanied by other considerations, including the fact that the rhesus macaque is also long-lived with a lifespan that may be 30–40 years. Therefore, studies utilizing this species for investigating the fundamental biology of aging require the inclusion of aged animals in the study or sufficient time for a study to be completed, especially for research on the consequences of early exposures or long-term treatments. Nonetheless, the rhesus macaque is unparalleled for obtaining insights into the complexities of aging processes, especially for alterations in*

*cognitive, sensory, and physiologic changes relevant for biomedical applications. In addition, there is growing recognition of the long-term consequences of environmental and health factors on later successful aging as well as the variability among individuals in their lifetime responses. We will provide an overview of the utility of the rhesus macaque as a biomedical model for the study of aging, with emphasis on studies of behavior and on the biology of aging in the female. We will also review some recent research conducted in our laboratories on the potential impact of interventions such as calorie restriction on successful aging.*

## Introduction

The search for an ideal system for elucidating biological changes that accompany aging and relate to processes in humans has led to the development of a variety of invertebrate and vertebrate models. More recently, fundamental processes have been examined across a number of vertebrate classes to determine if these mechanisms occur more generally and if there are some species that show resistance to these age-related challenges that contribute to the demise of the animal. Invertebrates (including *Drosophila*, nematodes), avian models, and mammalian (rodent) models provide significant contributions to our understanding of aging processes. These models provide essential data that greatly extend the knowledge base to increase understanding of mechanisms of aging. These studies supply the background to facilitate testing of more sophisticated hypotheses. However, the rodent model and other mammalian models do not replace the requirement for subsequent investigations in the nonhuman primate.

In particular, aging is accompanied by increasing incidence of disease and health issues. In some cases, spontaneous disease arises as the physiological condition of the individual worsens. In addition, metabolic and reproductive endocrine systems decline during aging,

resulting in a suite of age-related changes that have global impacts, including altered cognitive function. In particular, female rhesus monkeys experience a true menopause, characterized by the cessation of endometrial sloughing (menstruation). A true menopause is one of the most distinct differences between the nonhuman primate model and other mammalian models. These differences include not only the obvious difference of a lack of a menstrual cycle in rodents, but also differences in neuroendocrine and endocrine events leading to menopause. For example, rodents experience a transitional period of constant estrus, which is associated with declining ovarian function. Although primates also experience a transitional phase in which ovarian function declines with fewer luteal phases, this unopposed estrogen exposure is not as pronounced as in the rodent. In addition, there are a number of high visibility issues associated with the perimenopausal transition that include metabolic, cognitive, and overall health changes. These aspects of the perimenopausal transition require investigations in nonhuman primates, especially relative to development and testing potential interventions for clinical applications.

Therefore, the close relatedness and similarity of physiological systems of the rhesus macaque with humans is a major advantage of this model. In addition, the rhesus monkey has been studied extensively at all stages of the life cycle. This species is considered a long-lived species, with a lifespan of about 1/3 that of humans. However, their long lifespan does present a challenge for researchers because studies on the biology of aging must be long term or utilize retired breeders or other aged individuals. Nonetheless, the complexity of human physiology requires elucidation of fundamental mechanisms operating in the process of aging as well as studies in nonhuman primates to provide definitive data to verify the relevance of these mechanisms to humans.

#### ADVANTAGES AND DISADVANTAGES OF THE MODEL

The major advantage of the rhesus macaque as a research model is its similarity to humans. With 92.5 to 95% genetic homology to humans, rhesus macaques are a closely related, well-characterized animal. The use of rhesus monkeys in biomedical studies spans questions from molecular and cellular biology to physiology and onto behavior. This interest has created an extensive literature and knowledge of this species and its relation to human health and biology. The long lifespan of this species (approximately 40 years) means that age-related changes more closely reflect that of humans than shorter-lived species, and the rate of aging can be compared at an approximately 1:3 ratio.

However, the longevity of this species also presents a challenge for researchers. There are few opportunities to study an individual over the entire lifespan. Most often, intervention studies are more similar to a human clinical trial looking only at specific variables for a preset length

of time, with lifespan rarely used as an endpoint. In addition, due to the high costs of procuring monkeys, sample sizes are generally small, with significant individual variation. Thus, unlike rodent studies where strains are inbred and similar, monkeys are as different as humans. Additionally, monkeys are costly to maintain and require individualized animal care.

Overall, the many advantages of rhesus monkeys for aging studies are also their disadvantages. Yet, no other animal model comes as close to resembling human systems. Furthermore, because there is a generalized recognition of the value of each individual animal, the nonhuman primate aging research community has developed into a collaborative effort to better understand and further characterize the aging process.

### Characteristics of the Rhesus Macaque Model

#### NONHUMAN PRIMATE MODELS

Several macaque species have been routinely used for studies on aging, including rhesus (*M. mulatta*), cynomolgus (*M. fascicularis*), pigtail (*M. nemestina*), stump-tail (*M. arctoides*), and bonnet (*M. radiata*). Obtaining sufficient numbers of aging animals is difficult, and estimating age in wild-caught individuals is a challenge. Some investigators have estimated age by tooth wear, but this is often inaccurate. Age of young animals may be estimated based on maturity, stature, and pubertal status. However, birth records are really the only reliable data.

In the rhesus macaque, there are Chinese- and Indian-derived monkeys, with the latter being most represented in the literature. These monkeys may be considered subspecies in that they differ somewhat in their physical characteristics. There have been some studies that have attempted to identify characteristics that differ between these subspecies to determine if they can both be used in a single study. An excellent study was conducted to compare the subspecies and to evaluate their growth characteristics (for review, see Clarke and O'Neill, 1999). Chinese-origin adult males were larger than their Indian-origin counterparts, whereas the Chinese-derived females were generally larger as young animals. Interestingly, the Indian-derived females caught up and surpassed the Chinese-origin females as adults. To further complicate this issue, there is evidence that individuals born in the laboratory were larger as adults compared to those monkeys caught in the wild. In addition, there are some data that suggest differences in immune response between these subspecies (Messaoudi and Nicolich-Zugich, personal communication). Clearly, the distribution of individuals of these subspecies must be considered when developing an experimental design in which there are limitations in the number of animals and availability of these subspecies.

### HUSBANDRY OF THE RHESUS MACAQUE

There are extensive data on the maintenance of the rhesus macaque in laboratory conditions as well as in outdoor pens. The type of housing may vary with the experimental paradigm and the objectives of the study. In the case of studies in which diet or other interventions are used to determine effects during aging, animals are likely to be housed individually in standard primate caging that meet the NIH Guide for the Care and Use of Laboratory Animals. Studies in which social behavior and family groups are investigated will often utilize field stations with outdoor enclosures and pens within the area. These field stations may include opportunities for individuals to opt out of threatening situations and find areas removed from more dominant animals.

Although the daily routine will vary with the primate facility, there are animal care guidelines that standardize the level of care and husbandry for the rhesus monkey. The diet should meet the National Research Council Guidelines for nonhuman primates with essential nutrients and vitamins in concentrations that insure the monkeys receive appropriate nutrients and energy. Environmental conditions also will vary with the facility. For example, a controlled laboratory environment might have the monkey rooms maintained on a 12-hour photoperiod (12 hr light/12 hr dark), with room temperature at  $78 \pm 2^\circ\text{F}$  and humidity at  $60 \pm 5\%$ .

### Aging: General Characteristics

Aging in the rhesus monkey has many similarities to human aging. The incidence of cancer, type 2 diabetes, and other diseases increase in the rhesus monkey similar to humans. In addition, diseases and clinical conditions, such as osteoporosis, that occur in aging women also occur in the rhesus female. Changes that occur during aging fall into two categories: those associated with declining physiological function and those contributing to a disease state (Hadley *et al.*, 2005). Obvious signs of aging in nonhuman primates and humans include loss of posture due to muscle loss (sarcopenia). Recent evidence has directed new attention to the important role of immune system function as a central element in a possible range of health-related issues and disease states that emerge as the individual ages (Nikolich-Zugish and Messaoudi, 2005). In addition, visual and auditory systems undergo an age-related decline, similar to humans (Torre and Fowler, 2000; Roth *et al.*, 2004). Similarly, there is declining motor function, activity level, and cognitive performance (Moscript *et al.*, 2000; Zhang *et al.*, 2000). Metabolic function slows, similar to humans, and is accompanied by increasing insulin insensitivity and ultimately diabetes. In males, there is a gradual decline in reproductive endocrine function, whereas females experience the perimenopausal transition leading to menopause. In females, these age-related changes include

evidence of declining performance on learning and memory with aging (Voytko, 2000, 2002). Furthermore, in females, the perimenopausal transition presents some additional health challenges, especially as the individual becomes postmenopausal. Thus, it is important to understand the progression of events and to attempt to characterize these age-related changes in endocrine and physiological states.

### Aging and Spontaneous Development of Diseases

#### METABOLIC CHANGES, CARDIOVASCULAR DISEASE, AND OTHER EVIDENCE OF CHANGING PHYSIOLOGY

Metabolic endocrine systems show age-related changes that are similar to those experienced in humans, with increasing risk of prediabetic symptoms and changing metabolic function. Body composition in rhesus also parallels changes observed in humans. Fat mass, particularly abdominal fat, increases with age while lean body mass declines (Schwartz and Kemnitz, 1992). As in humans, rhesus can develop diet-dependent obesity and diabetes, thereby providing an excellent model for testing antiobesity and antidiabetic treatments. Other studies have shown the potential therapeutic value of antidiabetic and antiobesity drugs in obese or insulin-resistant rhesus monkeys (Roth *et al.*, 1995; Oliver *et al.*, 2001; Bodkin *et al.*, 2003). Metabolic Syndrome includes several characteristics known to be associated with increased cardiovascular risk (Scuteri *et al.*, 2005). Studies of the characteristics associated with Metabolic Syndrome in nonhuman primates will provide crucial information about efficacy of potential interventions and the age at which they are most effective. Furthermore, early preventive measures may be identified and then tested in nonhuman primates to attenuate or prevent cardiovascular disease.

Cardiovascular disease poses a major threat to aging individuals. The rhesus monkey has been used extensively in the development of diagnostic methods for cardiovascular disease (Neemen *et al.*, 2004). In women, there is increased incidence of heart disease after the age of 50, presumably associated with the loss of estradiol in postmenopause (Campos *et al.*, 1988). The other suspected problem contributing to the onset of this condition is altered lipoprotein profiles, with increased (10–15%) low density lipoproteins (LDL) in menopausal women. Research in monkeys has shown that hormone replacement therapy (HRT) decreased the severity of atherosclerosis in controlled experiments in monkeys (Mikkola and Clarkson, 2002). Once the data are gathered in the monkey, then it will be important to establish if HRT administered during the perimenopausal transition decreases the risk of cardiovascular disease in women (Speroff and Fritz, 2005).

The resilience of the skin also declines during aging, partially due to glycation, which occurs in a similar manner in rhesus skin proteins to that in humans (Sell *et al.*, 1996). Another evidence of the loss of resilience of the skin is that there is an age-related decrease in wound healing ability (Roth *et al.*, 1997).

#### OSTEOPOROSIS, OSTEOARTHRITIS, AND FRAILITY

Similar to humans, postural and structural changes occur associated with diminished bone mineral density in aging rhesus monkeys (Black *et al.*, 2001). In addition, there are age-related changes in cartilage as the space between vertebrae becomes reduced, resulting in a condition similar to osteoarthritis in humans (Kramer *et al.*, 2002). Taken together, these changes contribute to an overall frailty in which the individual becomes more vulnerable to bone breakage, exhibits poor appetite, reduced activity level, and possibly behavioral changes. As such, frailty is becoming recognized as a serious condition for the elderly.

Postmenopausal women are also at risk for developing osteoporosis due to increased osteoclast activity (Riggs *et al.*, 2002; Riggs, 2004). While calcium supplements, exercise and weight-lifting help, bone loss with estrogen loss appears inevitable. Selective estrogen receptor modulators may ameliorate bone loss (Cranney *et al.*, 2002; Robertson *et al.*, 2004). Often there is loss of muscle that accompanies increasing bone fragility, and together they contribute to overall frailty (Vanitallie, 2003). Moreover, both estrogen and androgens affect bone, muscle, and metabolic function, which in turn contribute to the risk of fractures (Joseph *et al.*, 2005).

#### ENDOMETRIOSIS

Steroids produced by the ovary stimulate uterine endometrial cells. In endometriosis, cells that have escaped from the uterus grow in the peritoneal cavity, resulting in clinical symptoms that include tumors, obstructions, painful menses, and disrupted GI tract function. In women the incidence of endometriosis increases with age and has been estimated to be 10–20% in young reproductive women and up to 35% in women with menstrual difficulties.

Endometriosis in captive colonies of female rhesus monkeys can occur in relatively high incidence (~26%). The causes of endometriosis appear to be varied and range from surgery to radiation exposure (Fanton and Golden, 1991). One of the major issues of endometriosis, especially in rhesus macaques, is diagnosis at a treatable stage of the disease. As observed by a number of laboratories, endometriosis is difficult to diagnose until relatively advanced (Rippy *et al.*, 1996). Use of indicators, such as plasma levels of CA-125, have been examined as a possible indicator of endometriosis (Rippy *et al.*, 1996). The condition is accompanied by lesions, cyst formation, adhesions to organs, anorexia, and abdominal masses

(Fanton and Golden, 1991). The disease progresses in a manner similar to that observed in women (Osteen *et al.*, 2005). Similarly, the escaped endometrial cells retain their responsiveness to ovarian steroids and proliferate vigorously outside of the uterine environment, especially in response to  $17\beta$ -estradiol ( $E_2$ ). This leads to more advanced disease, categorized according to clinical characteristics and gross and histological evaluation of the lesions and cysts (Fanton *et al.*, 1986). These lesions often occur on the serosal surface of the uterus and proliferate to associated regions of the peritoneal cavity (Rippy *et al.*, 1996). Although women do not generally have this disease progression due to earlier diagnosis, endometriosis does present a clinical issue for many young women. However, little is really understood about the etiology of this disease and interventions that may limit the disease and minimize the trauma associated with surgical treatment.

#### Aging and the Hypothalamic–Pituitary–Gonadal (HPG) Axis

Both males and females experience an age-related decline in the HPG axis. However, aging in the male system is a more gradual process in humans and in other species. Nonetheless, data show an age-related decline in testis function and decreased circulating androgen levels (for review, see Ottinger 1998). A recent study showed that circadian patterns in adrenal steroids were maintained in aging males for cortisol (Urbanski *et al.*, 2004). Similarly, levels of dehydroepiandrosterone sulfate (DHEAS) also had a circadian pattern and did show an age-related decline.

#### AGING OF THE REPRODUCTIVE SYSTEM IN FEMALES

The rhesus monkey (*Macaca mulatta*) has been a biomedical model for reproductive studies in women since the early 1900s (Heape, 1900). Female rhesus monkeys are pubertal by 2.5 to 3.5 years of age and exhibit menstrual cycles approximately 28 days in length, similar to humans. Furthermore, rhesus monkeys experience a reproductive decline much like that of human menopause around 24 years (Gilardi *et al.*, 1997; Bellino and Wise, 2003). Urinary hormone profiles demonstrated that, like women, menopause in rhesus monkeys is associated with amenorrhea, low urinary estrogen conjugates, and irregular patterns of urinary concentrations of progesterone metabolites (Gilardi *et al.*, 1997). Urinary FSH levels also increase in postmenopausal rhesus monkeys (Shideler *et al.*, 2001).

##### *Key components of the reproductive decline*

Human fecundity declines rapidly after age 40, with a decrease in the follicular “ovarian reserve” and increased abnormalities in oocyte quality. However, little is known

about the mechanism that initiates menopause. Age alone is not a reliable predictor of menopause, but endocrine disturbances often precede noticeable irregularities in menstrual cyclicality. Few longitudinal studies have addressed these endocrine aspects of ovarian senescence; morphologic studies, when performed, are derived from ovarian specimens obtained retrospectively from aging women of unknown endocrine status. Thus, the rhesus monkey is an ideal model for investigating the mechanisms underlying menopause because females display similar neuroendocrine mechanisms in the menstrual cycle.

There has been extensive research on the hypothalamic changes that accompany ovarian decline in multiple species. In humans, pituitary gonadotropins show age-related changes with a transient increase in plasma luteinizing hormone (LH) and a dramatic increase in follicle stimulating hormone (FSH). Isolating age-related changes in hypothalamic response from ovarian aging is difficult; however, a number of studies have been conducted using the rodent model. Previous studies have examined the response of the HPG axis at various stages in the life cycle of the female as well as the functional changes of the hypothalamus and pituitary gland with aging. Wise (1991) reported decreased amplitude and frequency in LH secretion in older rats and a decline in the number of activated GnRH neurons, despite normal cycles (Scarborough and Wise, 1990; Lloyd *et al.*, 1994). These papers by Wise and colleagues and many others point to alterations in the systems that modulate GnRH as key elements of the reproductive decline. Overall, these studies indicate that hypothalamic response decreases, potentially in tandem with declining ovarian function (Wise, 1991; Mills *et al.*, 2002; Micevych *et al.*, 2003). In addition, ovarian secretion of inhibin is beginning to be studied and may emerge as an important element of the aging process (Groome *et al.*, 1994; 1996; Welt *et al.*, 1999). Data collected in female nonhuman primates and in humans suggest that there are similar mechanisms operating during the perimenopausal transition (Klein *et al.*, 1996; Bellino and Wise, 2003).

*The perimenopausal transition: A time of changing hormones*

As the perimenopausal transition progresses, there is declining function of the hypothalamic–pituitary–gonadal axis (HPG axis), ultimately resulting in cessation of ovarian function and menopause. The average age of menopause in women is approximately 51 years, resulting in a postreproductive period that extends for nearly 1/3 of their lives (Treolar *et al.*, 1981). If menopause merely affected fertility, the study of ovarian aging would likely not be of such high priority. As mentioned earlier, a number of other physiological systems are also affected by the sudden withdrawal of hormonal support associated with menopause, including bone density, cardiovascular

health, cognition and possibly some cancers (Gosden, 1985; Prior, 1998; Sherwin, 2003).

*Characterization of perimenopausal transition*

Rhesus monkeys that have been observed at the Oregon National Primate Research Center (ONPRC) indicate that the frequency of regular menstrual cyclicality declines with age (Wu *et al.*, 2004; Zelinski-Wooten, unpublished data). Approximately 70% of rhesus females between the ages of 20 and 22 years did not exhibit the onset of irregular cycles, but by 23–25 years of age, 50% of females did have irregular cycles. The data from ONPRC agrees with that published by Gilardi and colleagues (1997) at the California Regional Primate Research Center, where the mean age of old animals displaying regular cycles was 22 years, those displaying irregular cycles (i.e., perimenopausal) was 24 years, and postmenopausal monkeys of 29 years as compared to normal cycles observed in young adult females (Zelinski-Wooten *et al.*, 1999).

## Brain Aging and Cognitive Function

### AGE-RELATED NEUROPATHOLOGY

Among other age-related changes in neural anatomy and function, rhesus monkeys also develop pathological characteristics of Alzheimer's disease (AD), specifically regional deposition of amyloid- $\beta$  ( $A\beta$ ) plaques similar to aged humans (Gearing *et al.*, 1996). These  $A\beta$  plaques are associated with angiopathy. Although  $A\beta$  accumulates in rhesus brains, neurofibrillary tangles, another hallmark AD pathology, are not formed (Nelson *et al.*, 1996). Paralleling success in mice, current interest is emerging for producing transgenic monkeys in which AD can be accurately modeled.

Studies have also examined age-related changes in rhesus brain. While brain mass does not decline with age (Herndon *et al.*, 1998), reductions have been observed in specific regional volumes, for example, the basal ganglia (Matochik *et al.*, 2000). The age-related decline in fine motor behavior has been associated with diminished nigrostriatal system function and was not improved in aging female monkeys given ethinyl estradiol treatment (Lacreuse and Herndon, 2003). Interestingly, males showed greater slowing of fine motor function; both males and females had age-related decreases in normalized caudate and putamen volumes (Lacreuse *et al.*, 2005). Furthermore, the age-related decrease in delay-match-to-sample and nonmatch-to-sample cognitive performance was linked to prefrontal cortex activity on fMRI (Lamar *et al.*, 2005).

Also similar to humans, no significant age-related loss of hippocampal or neocortical neurons is observed in rhesus monkeys (Duan *et al.*, 2003; Keuker *et al.*, 2003). Rather, behavioral deficits associated with hippocampal dysfunction appear to result from neurophysiological deficits in interneuronal signaling rather than cell death

(Small *et al.*, 2004). Cerebral blood volume decreases with age in hippocampal dentate gyrus (Small *et al.*, 2004). Cerebral cortex loses dendrites and arbors with advancing age (Duan *et al.*, 2003). Neurotransmitter receptor and transporter binding in specific regions, including postsynaptic dopamine receptors and presynaptic vesicular acetylcholine transporters (Voytko, 2000, 2002; Tinkler and Voytko, 2005), show age-related loss in basal ganglia. Hippocampal cholinergic fibers are also lost with age (Calhoun *et al.*, 2004) as well as changes in the integrity of white matter (Peters *et al.*, 1996).

## MRI

### CLINICAL STUDIES

Magnetic resonance imaging (MRI) is frequently used to document *in vivo* neuropathology in humans, such as stroke, multiple sclerosis and Alzheimer's disease. However, this imaging technology has also been applied to human aging studies, in both cross-sectional and longitudinal designs. The utility of repeated imaging is that each individual serves as his or her own baseline, avoiding many of the pitfalls of cross-sectional studies (secular trends). In general, these studies have concentrated on the evaluation of dual-echo or 3-dimensional scans generated by MRI sequences (SPGR, MPRAGE), which yield high-resolution images that can be used to measure total brain volume or segmented into various tissue compartments (gray, white, cerebrospinal fluid) or specific anatomical regions.

The results of these clinical studies have, in general, revealed age-related declines in overall brain volume or gray and white matter, with a concomitant increase of the volume of cerebrospinal fluid (CSF). For example, a significant trend for an age-related loss of total brain volume (and increased CSF) was observed in elderly (66–90 years) men and women, which correlated with cognitive deficits (Coffey *et al.*, 2001). Examination of a broader age range (1–80 yrs) confirmed that the volume of gray matter decreased in the oldest adults (Courchesne *et al.*, 2000, Good *et al.*, 2001), while another study of men and women (20–86 years) demonstrated decreases in overall volumes of both gray and white matter with age (Ge *et al.*, 2002). However, in a study with good representation of men and women in their 60s and 70s, white matter loss was more evident (Guttman *et al.*, 1998). Age-related volumetric loss was also observed in subregions of the brain, including the hippocampus, cortical and cerebellar gray and white matter (Jernigan *et al.*, 2001). It is also important to note that these recent studies concentrate on healthy subjects, prescreened for general health and free of neuropathology, and as such represent normative aging.

Longitudinal studies of the effects of aging on brain structure have revealed results similar to reports using a cross-sectional design. An earlier report, looking at the

effect of aging on the size of the hippocampus, used repeated annual scans across almost four years in the oldest-old (>84 years) and found a progressive diminution in volume (Kaye *et al.*, 1997). Another study examined a broad range of subject (14–77 years) and reported a longitudinal decrease in white matter and hippocampal volume in older subjects at a second timepoint of 3.5 years (Liu *et al.*, 2003). Resnick *et al.* (2000) reported a cross-sectional difference in brain volume utilizing subjects (59–85 years) from the Baltimore Longitudinal Study, in which after one year, the subjects experienced a further increase in CSF volume. A follow-up study four years after baseline also revealed a significant loss of both gray and white matter with an increase in the volume of CSF (Resnick *et al.*, 2003).

MRI has also more recently been utilized to examine the underlying chemical nature of modifications in the white matter as a function of age (Bartzokis *et al.*, 2004, Davatzikos *et al.*, 2002). Similarly, documentation of age-related volumetric losses in brain sub-regions has provided a functional-anatomical basis for behavioral changes, including the cortex (Bartzokis *et al.*, 2004; Covit *et al.*, 2001), and striatum (Raz *et al.*, 2003). Clinical data have also shown age by sex differences in brain volume (Raz *et al.*, 2004a), with hormone replacement having a significant protective effect on the maintenance of cortical volume (Raz *et al.*, 2004b). Thus, clinical MR imaging studies of normative brain aging have revealed volumetric and neurochemical changes that are related to behavioral and physiological manifestations of senescence.

### MONKEY STUDIES

In parallel to the MRI aging studies of the human brain, there have been similar monkey-based reports of global volumetric changes with age, with decreases in gray matter, compensatory increases in CSF, but stability in white matter volume (Andersen *et al.*, 1999). Age-related changes in the monkey brain were analyzed in another MRI-based study and linked cognitive deficits to white matter loss (Lai *et al.*, 1995; reviewed in Peters *et al.*, 1996; Wisco *et al.*, 2001). A more recent study on the effects of aging in squirrel monkeys also showed cognitive deficits with age, but with an increase in white matter content in the anterior half of the brain (Lyons *et al.*, 2004). However, it is important to note that the other studies cited above used rhesus monkeys and examined a wider range of older animals. Evaluations of subcortical structures have also been published, such as the report on the decrease in overall volume with age in the male rhesus monkey striatum (Matochik *et al.*, 2000). This age-related striatal change was recently confirmed in both sexes, although it was noted that only the aged male rhesus monkeys performed worse than young controls on fine motor tasks (Lacreuse *et al.*, 2005). In the monkey hippocampus, cerebral blood volume, as assessed with MRI, suffered from an age-related decline that correlated with cognitive deficits (Small *et al.*, 2004). Neurochemical

studies in monkeys using proton magnetic resonance spectroscopy are limited (Herndon *et al.*, 1998), but have disclosed effects of aging on various neurochemical parameters of neuronal function.

Few manipulations on monkeys as they relate to MRI-based brain studies have been performed. A recently published study (Matochik *et al.*, 2004) examined the effects of age and calorie restriction (CR) on the caudate and putamen of monkeys, but revealed differential effects of treatment on these subregions. Indeed, acute CR was found not to globally protect against the age-related volumetric loss in male rhesus brain. Additional research will address whether long-term CR is protective against both the structural changes in the brain with age and if cognitive function is preserved in a parallel manner.

### Tests of Cognitive Function and Brain Regions Important for Cognitive Function

One of the most controversial issues pertaining to management of the perimenopausal transition is that of neuroprotection and maintenance of cognitive function. The rhesus macaque provides a highly useful model for performing tasks that provide specific information on neural systems. This allows for characterization of age-related changes in cognitive function with females during the perimenopausal transition and with surgical removal of ovarian steroids. Moreover, selected interventions may be tested for their efficacy in enhancing cognitive performance in aging individuals. A few of these tests will be briefly described below because these tests provide methods for assessment of age-related changes in motor capabilities and cognitive function.

#### MOVEMENT ANALYSIS PANEL (mMAP)

Several behavioral studies have been conducted in monkeys, including assessments of general locomotor activity, motor performance, and simple cognitive tasks. Regarding general locomotor activity, two studies have been published indicating age-related declines in activity of male and female rhesus monkeys measured by an infrared/ultrasonic apparatus placed on the home cage of the monkeys (Weed *et al.*, 1997; Moscript *et al.*, 2000). Monkeys may be assessed for motor performance in the Movement Analysis Panel (mMAP), which has proven to be age-sensitive in rhesus monkeys. This task evaluates the response time required to retrieve a food reward from different manipulanda located in a box mounted to the home cage of the monkey. The simplest task is a flat platform; the next most difficult is a straight rod, and the most difficult is hook. Figure 38.1 shows an apparatus with an individual performing the task using the mMAP (Ingram *et al.*, unpublished data).

Tasks on visual-motor skill have been demonstrated to be age-sensitive (Bachevalier *et al.*, 1991; Grondin

**Figure 38.1** This photograph shows a rhesus monkey retrieving a food reward in the mMAP apparatus. This test allows for assessment of motor control.

2003) and involve deficits in the nigral-striatal pathways. The prefrontal cortex is involved with working memory/executive function, whereas the temporal lobe-hippocampal region is involved in spatial memory (Bartus, 1978; Rapp, 1989). It is clear that consistent with a recent report (Lacreuse *et al.*, 1995) female rhesus monkeys are faster in this task than males.

#### SPATIAL-DELAYED RECOGNITION SPAN TEST (SPATIAL-DRST)

Spatial-DRST is a memory test that depends on the integrity of the hippocampus (Beason-Held *et al.*, 1999). It requires the subject to identify, trial-by-trial, the new location of a stimulus among an increasing array of serially presented identical stimuli. Different versions of this test have been used in normal aged humans and in a variety of neurologic patient populations. In monkeys, the spatial-DRST has been used to examine age-related impairments of rhesus macaques, to examine sex differences in young and old rhesus monkeys (Lacreuse *et al.*, 1999) and to compare the performance of aged OVX and age-matched intact female rhesus monkeys (Lacreuse *et al.*, 2000). This test appears to be useful in detecting memory loss during aging.

#### OBJECT-DELAYED RECOGNITION SPAN TEST (OBJECT-DRST)

Object-DRST follows the same rules as spatial-DRST, but the stimuli are different objects instead of identical disks. The objects are randomly drawn from a pool of 3000 color clipart objects. On each trial, the position of the stimuli changes in a random fashion so that the monkey is able to identify the new stimulus based only on visual, rather than spatial cues. The mean number of objects that the monkey is able to correctly identify before making an error and the mean response times will be recorded. The object-DRST is a task of visual recognition

memory that is sensitive to hippocampal lesions in monkeys (Beason-Held *et al.*, 2005).

### Calorie Restriction: An Effective Intervention in the Rhesus Model

Calorie restriction (CR) has been long recognized for its benefits to health and aging in a variety of species (Weindruch and Walford, 1988). These benefits have been demonstrated in numerous studies of invertebrate and vertebrate models, which have shown that CR is a robust method for slowing aging as evidenced by reduced incidence and delayed onset of age-related diseases, extension of mean and maximum lifespan, increased stress resistance, and improved function (Bordone and Guarente, 2005). However, longitudinal CR studies are difficult in nonhuman primates due to their long lifespan and availability of sufficient numbers of animals to conduct this type of a study (Roth *et al.*, 2004). Long-term studies have focused on obesity and diabetes (University of Maryland Medical School), and on the impact of a nutritious, low calorie diet (30% CR) on aging processes, survival, and longevity (Wisconsin National Primate Research Center and NIA). The NIA and WNPRC studies represent the first experiments to

evaluate effects of CR on aging processes in a primate species. Moreover, the genetic heterogeneity in these primates provides an excellent view of the range of responses likely to occur in the human population with CR. A number of parameters have been examined over the course of these studies, including those shown on Table 38.1. It is clear that new information pertinent to aging processes will emerge from these studies in rhesus monkeys that document parallels to human aging. A range of variables have been considered in both studies, including reproductive, metabolic, sensory, gene expression, and health parameters (Ramsey *et al.*, 2000; Mattison *et al.*, 2003; Roth *et al.*, 2004). Interestingly, CR did not affect bone density in the younger animals (Black *et al.*, 2001). As many of these animals are currently middle-aged, we may still observe differences associated with diet with advancing age.

Because CR was initiated in some of these animals around the time of puberty, it was possible to assess the effects of the diet during sexual maturation and in young adults. Interestingly, a shift appeared to occur in young animals on CR from growth and reproduction to a life maintenance strategy. This was observed in a delay in maturation in some individuals. However, once balance was achieved, these animals became reproductive, with reproductive endocrine function similar to control

TABLE 38.1  
Measurements conducted in females over the course of the long-term CR Study at the NIA, ages/age range at measurement, intervals between repeated assessments, and investigators

Variable assayed	Assay used	When measured	Measurement intervals	Investigators
Ovarian steroids*	Radioimmunoassay (RIA)	2003–2005	N/A	Zelinski-Wooten, Wu, Mattison & Ottinger

monkeys. Interestingly, males and females on the NIA study appear to exhibit normal reproductive function in both control and CR groups, suggesting that moderate CR likely does not have a detrimental impact on reproductive function. Further, the shift associated with the CR dietary regimen is associated with a drop in body temperature consistent with increased protective mechanisms against various insults and pathologies, slower rate of tissue deterioration, and more reserve capacity (Roth *et al.*, 1995, 2004).

## Conclusions

Use of the primate as a model for aging is increasing, and the *in vivo* MRI-based studies enjoy the advantage of repeated measures, with each subject serving as its own baseline control. A controlled longitudinal study of the nonhuman primate, a moderately long-lived species with close phylogenetic ties with humans, could contribute to the brain-aging field in better defining age-related changes in gray and white matter, which are still somewhat controversial in the clinical literature. For example, with about a third of the maximum lifespan of humans, it would be feasible to compare repeat scans of individual monkeys at the critical middle-age to old and old to oldest-old transitions. In addition, with the increased usage of the monkey model and simultaneous evolution of MRI technology, the ability to explore anatomical loci with increasing sensitivity is rapidly evolving. Moreover, the generation of sophisticated neurochemical analysis and physiological measures by MRI will substantially augment existing behavioral and neurophysiological analyses in describing the neurobiological underpinnings of brain function in the nonhuman primate model.

Compared to the rhesus monkey, there is no other well-characterized animal model with such extensive similarity to humans across a wide range of physiological responses. Rhesus monkeys share a significant portion of the genetic information found in humans and are more closely related to humans than rodents. This species has been extensively used in biomedical research and is among the best characterized of the nonhuman primates, particularly with respect to normal aging. Finally, these *in vivo* assays, coupled with neurochemical and histological approaches, will make a powerful approach to addressing aging of the brain, enable a more comprehensive assay of potential interventions, and translate well to the clinic.

# Nonhuman Primates as Models for Reproductive Aging and Human Infertility

Barry D. Bavister and Carol A. Brenner

*Nonhuman primates are invaluable models for a wide range of basic and applied studies related to human health. In vitro production (IVP) of preimplantation embryos makes them available in significant numbers for embryo manipulations and research aimed at a variety of biomedical applications. Rhesus monkeys (Macaca mulatta) are well established models for many biomedical research studies into diseases affecting humans. Their basic physiology and reproductive endocrinology are very similar to those of humans, and they are relatively easy to breed and manage in captivity. The rhesus monkey exhibits an approximately 28-day menstrual cycle, like that of humans. It is also a long-lived species, living up to 30 years, so that age-related diseases similar to those in humans are likely to appear. In these major respects, rhesus monkeys are a much more appropriate model for humans than rodents or other nonprimates that differ markedly in their susceptibility to human-related diseases and in their reproductive physiology. In particular, macaque monkeys are appropriate for research into primate infertility and for effects of aging on this disease. In this chapter, we review some of the key areas for which the rhesus monkey is an ideal transitional model between laboratory animals and humans, and we discuss some of the basic research questions and technologies underlying studies with this animal. Special attention is given to the roles of mitochondria in infertility and aging because anomalies in these key organelles may underlie many of the defects that have been reported in embryos and in embryonic stem cells.*

## Introduction

### FREQUENCY OF INFERTILITY

Infertility is common in humans. It is estimated that about 15% of couples have difficulty in conceiving or are outright infertile. There are numerous contributing factors, some of which can be helped by resorting to Assisted Reproductive Technology or ART, which

comprises artificial insemination, in vitro maturation (IVM) of oocytes, in vitro fertilization (IVF), embryo culture and embryo transfer. For presumptively infertile women aged up to about 37, the outcome of clinical “IVF” (in this general context meaning IVF together with embryo culture and transfer) is good, with an average of about 32% of treatment cycles in the United States resulting in a live birth (Wright *et al.*, 2003). But for women approaching 40 or over, the efficiency of IVF drops sharply, to only about 5% after the age of 42 (Wright *et al.*, 2003). Similarly, the incidence of natural conceptions falls progressively towards the age of 40, prior to overt menopause. The reasons for this precipitous drop in fertility are not well understood, but a decline in the ability of the uterus to support pregnancy does not seem to be a primary factor, in view of the number of births to women over 40 carrying a surrogate embryo made with oocytes from younger women. The quality of oocytes and/or ovarian factors appear to be much more likely contributors to the low pregnancy success in older women.

### QUALITY OF HUMAN OOCYTES AND IMPACT ON FERTILITY

The quality or health of human oocytes is progressively diminished with age due to (i) inherent or genetic factors as part of the natural aging process; and (ii) epigenetic factors such as nutrition, smoking and environmental effects. While reduced fertility in women derives in large part from diminished oocyte quality or “health,” there is currently no reliable way to measure this attribute, nor any real understanding of why it happens.

We need ways to measure oocyte quality that could improve selection of oocytes/embryos in ART clinics, which would increase pregnancy success rates, especially in low-outcome patients such as women aged 40 or over. Such methods will come from better understanding of the cellular and molecular properties of oocytes. A key component of all cells including oocytes is the mitochondrion, which provides energy and possesses its own DNA for encoding protein

production. Defects in either of these functions could lead to loss of oocyte competence in the short term (failure of fertilization or embryo development) or long term (nonviable fetuses or incompetent placentas, leading to pregnancy loss, or possibly postnatal health defects). Human oocytes would be the optimal subjects for undertaking studies on oocyte quality and the embryos derived from them; however, practical and ethical constraints preclude intensive studies with human oocytes and embryos, so suitable animal models must be used.

For investigating oocyte quality, it is important that some studies are conducted with animals closely related to humans, because of the wide diversity in cellular, molecular and endocrine mechanisms used by different mammals in their reproductive strategies. A strong case can be made for using nonhuman primates as the most appropriate models for human reproduction, especially mtDNA studies (see below). In our laboratory, current studies with rhesus monkeys focus on mitochondria as potential markers for oocyte quality and competence, and these efforts may help explain defects in low-quality oocytes.

In higher primates (humans and, for example, macaque monkeys), high extrinsic gonadotropin stimulation in ART cycles produces inherent variations in oocyte quality and competence, possibly by recruiting defective oocytes from potentially atretic follicles. Even in natural human and rhesus menstrual cycles, it is estimated that only about 25% of potential conceptions support clinical pregnancies; most likely, defects in oocytes and anomalies of fertilization are major contributors to this loss. This inefficiency is in marked contrast to natural cycles in some rodents, where 98% of ovulated oocytes develop into blastocysts and almost all of these become viable fetuses (Gonzales and Bavister, 1995). It can be estimated that in infertile patients, human ART efficiency *on average* is only about 15% or less per embryo transferred, or less than 5% per cleaved embryo or oocyte inseminated (Bavister and Brenner, 2004), although some clinics report much higher success rates.

One component of low fertility with increased reproductive age is “ovarian senescence,” which is marked by a rise in circulating Follicle Stimulating Hormone (FSH) levels due to decreasing negative hormone feedback from the ovary, and by declining numbers of competent ovarian follicles (Wright *et al.*, 2003). Concomitant with this condition is an increase in oocyte anomalies, especially aneuploidies but also including mitochondrial defects. Aneuploidy in oocytes of older women is a well-recognized condition, but defects in mitochondria are not so obvious because they are harder to detect. However, considering that mitochondria not only carry their own genomes but also provide most of the energy for cell functions, defects in mitochondria are likely to have serious consequences for oocyte competence.

## ANIMAL MODELS FOR STUDYING INFERTILITY

It is very difficult to study the etiology of chromosomal or mitochondrial defects in humans, or to relate such deficiencies to developmental outcomes, simply because the principal focus in humans is to help infertile women to become pregnant and have healthy babies. This goal is antithetical to basic research because the latter usually involves destructive analysis of oocytes and embryos. Human oocytes and embryos that are surplus to clinical needs and available for research are scarce, and may not be representative of developmentally competent oocytes and embryos. As a result, it is not surprising that the majority of research on oocyte and embryo function has been done with animal material, usually from rodents although sometimes with suitable domesticated animals, such as cattle and pigs. The problem with this approach, though it is logical, is that gamete physiology and even basic reproductive strategies can vary considerably in different mammals, so that it may be difficult to extrapolate from an experimental animal to humans. This is strikingly so in the case of mice, which have been used in the vast majority of studies into mammalian gamete biology, fertilization, embryo development and implantation. However, in all these respects, mice are not appropriate as models for humans. In contrast, nonhuman primates, especially higher primates such as the macaques, are highly suitable models for human reproduction.

Rhesus monkeys (*Macaca mulatta*) are well established models for many kinds of biomedical research studies into diseases affecting humans. The basic physiology of these monkeys is very similar to that of humans, and they are easy to breed and manage in captivity. The rhesus monkey exhibits an approximately 28-day menstrual cycle, and its reproductive endocrinology is very similar to that of humans. Accordingly, rhesus monkeys have been especially used as models to study human infertility and effects of aging thereon. Because of their long lifespan, we should expect that rhesus monkeys would exhibit age-related declines in fertility and ovarian reserve, which is discussed in the next section. By using ovarian stimulation regimens similar to those used for infertile women, rhesus monkeys can provide adequate, although not large, numbers of eggs for embryology studies. Such studies, together with those performed with human embryos, have shown that the basic biology of preimplantation embryology in primates is significantly different from that of rodents. A striking example is the derivation of the centrosome, which is the microtubule organizing center for fertilization: in most mammals studied, including primates, this structure is provided by the fertilizing spermatozoon, whereas in rodents it is maternally derived (Hewitson *et al.*, 2002). The marked similarities in oocyte maturation, fertilization, embryo metabolism, the timing of embryonic genome activation, the endocrinology of reproduction, and the modes of implantation and

pregnancy underscore the need to study nonhuman primate models to obtain information relevant to human infertility and its treatment.

#### AVAILABILITY OF MONKEYS FOR RESEARCH

In spite of their great value as models for studying mechanisms of infertility in primates, macaque monkeys suffer from one major drawback: they are not readily available in substantial numbers for this purpose. This is ironic, because the United States has the largest nonhuman primate research infrastructure in the world, in the form of the eight National Primate Research Centers supported by the NIH. Each of these centers has several thousand nonhuman primates, and rhesus monkeys comprise a large proportion of the total. However, the great demand for this species for AIDS-related research means that few animals are available for other kinds of research, including infertility studies. It may be time to ask if priorities for allocation of monkeys to research studies should be reassessed.

#### Evidence for Ovarian Senescence in Rhesus Monkeys

The number of potentially viable oocytes available to the reproducing female depends on the size of the primordial follicle population within the ovary. In humans, primarily due to follicular atresia and secondarily because of follicular recruitment, the numbers of primordial follicles decrease dramatically from birth to the onset of menopause. At the end of the reproductive lifespan, the “ovarian reserve” of viable follicles and oocytes is essentially depleted, and the ovary is said to be senescent (Faddy and Gosden, 1996). Concomitantly, ovulatory activity ceases and levels of estrogen decrease markedly. As a result, FSH secretion increases strikingly because of diminished negative feedback from estrogen (Walker, 1995). Bioactive FSH retrieved from postmenopausal women’s urine was in high demand for a number

of years as a means to stimulate ovaries of infertile women to produce large numbers of follicles and oocytes. However, such ovarian stimulation for ART becomes ineffective once the ovarian reserve is seriously depleted and oocyte quality is reduced (Hansen *et al.*, 2003). Female rhesus macaques are excellent models for studying the loss of reproductive capacity with increasing age. They are reproductively active over about 20 years starting at about age 5, and undergo similar pathological and hormonal changes to human females nearing the end of their reproductive lifespan (Shideler *et al.*, 2001). Although there have been several reports on ovarian changes in macaques, including oocyte numbers, most studies examined younger females and did not study older animals (ages 15–25) that would be expected to show ovarian senescence. In view of this, our laboratory conducted a study of the ovarian reserve in rhesus macaque females across a wide age range (ages ~1–25), covering the entire reproductive lifespan of this species. Histological examination of ovarian sections showed clear evidence of follicular depletion with increasing age, especially in the older age groups (Nichols *et al.*, 2005).

Ovaries were collected over a 5-year period at the Tulane National Primate Research Center (Covington, LA) and archived for later examination. These ovaries (64 pairs total) were divided into several groups by age (<5, >5–10, >10–15, >15–20 and >20 years old) to examine age-related changes in ovarian morphology. A representative histological section from each ovary was examined for the number of primordial, primary or antral follicles it contained (Figure 39.1).

We found that, while the percentage of antral follicles remained nearly unchanged across age groups, the percentages of primary and primordial follicles changed significantly with age (Figure 39.2).

This change reflects the degenerative processes occurring within the ovary. Similarly, the *total numbers* of follicles in each of the three classes significantly decreased with increasing age of the female. Because growth of

**Figure 39.1** Follicles representing various stages of development in the rhesus ovary. Primordial follicles (A) are characterized by a flattened granulosa cell border. The representative primary follicle (B) demonstrates several layers of granulosa cells surrounding the oocyte and a developed zona pellucida. Antral follicles (C) contain a well-developed antrum. Reproduced from Nichols *et al.* (2005) *Hum. Reprod.* 20:79–83 ©European Society of Human Reproduction and Embryology. Reproduced by permission of Oxford University Press/Human Reproduction.

**Figure 39.2** Ovarian sections illustrating changing follicle populations with increasing age. Reproduced from Nichols *et al.* (2005) *Hum. Reprod.* 20:79–83 ©European Society of Human Reproduction and Embryology. Reproduced by permission of Oxford University Press/Human Reproduction.

primary follicles is gonadotropin-dependent (Macklon and Fauser, 1999), many of the newly formed primary follicles in older females cease development or become atretic, possibly due to lack of FSH receptors on the surrounding follicular cells. Loss of ovarian reserve was most obvious in females undergoing the perimenopausal and menopausal transition (age group 20–25 y.o.), with scattered and atretic follicles, occasional primordial follicles and reduced amounts of stromal tissue. Interestingly, the number of births within each female was significantly correlated with the proportion of primordial and primary follicles independent of her age, with the mean percentage of primordial follicles decreasing and the percentage of primary follicles increasing. This was likely because females who give birth to a large number of offspring are pregnant or lactating for much of their reproductive lifespan. The menstrual cycle stops during pregnancy/lactation, because of continued production of progesterone, which blocks FSH production and secretion from the pituitary gland (Pohl *et al.*, 1982). As a result, recruitment and growth of primary follicles are halted, while recruitment and loss of the primordial follicles continues unabated throughout life because they are independent of gonadotropins.

This study (Nichols *et al.*, 2005) illustrates that in several important respects, the rhesus monkey is an appropriate model for studying age-related loss of fertility in human females. However, it is not a perfect model because some details of human menopause are not shared by macaque females. For example, in humans there is a subtle and gradual onset of menopause-related changes

before irregular cycling begins (Santoro, 2002), whereas macaques appear to undergo abrupt changes at the onset of irregular cycles (Shideler *et al.*, 2001). Also, in this study we did not observe any age-related differences in sex hormone or gonadotropin levels in the rhesus females. However, this is not surprising because we had only one time point measurement for each female from a single blood sample drawn at the time of necropsy, so no comparative data during the reproductive lifespan of each female were available. Additional studies with the rhesus macaque model could be useful for understanding mechanisms underlying reproductive aging, so that it might be possible to devise ART strategies to address this phenomenon.

### Nonhuman Primates as Models for Developing ART

Because the rhesus monkey is a good model for obtaining information about reproduction in primates, the use of ART procedures in this species might reveal details about preimplantation events, including age-related phenomena, that could be relevant to the problem of “IVF” failure in older human females. Ovarian stimulation, IVF and embryo culture, collectively known as “in vitro production” (IVP) are well-established techniques for a variety of species (Bavister and Boatman, 1993; Bavister, 1995). These ARTs are useful and even commercially viable in domesticated animals, and have long been employed in research with rodents and other species. The success of

ART in addressing infertility problems in humans, though not as efficient as it could be, is well known (Olivennes and Frydman, 1998). In contrast, ART has been employed far less frequently or effectively with nonhuman primates, in spite of the huge potential benefits for biomedical and reproductive research. The techniques for nonhuman primate embryo IVP are well established and have been used for more than 20 years for in vitro studies on embryos (Boatman and Bavister, 1984; Bavister *et al.*, 1983, 1984; Bavister and Boatman, 1993). Protocols for IVP of macaque embryos are quite efficient, with approximately 60% of IVF ova becoming blastocysts (Schramm and Bavister, 1996); however, the total number of offspring born from transfer of IVP embryos for all nonhuman primate species is very small. This is because only a small proportion of the total ART research effort in animals has involved monkeys, and because most of the nonhuman primate studies have focused on developing protocols for producing IVP embryos. Relatively little attention has been paid to embryo transfer strategies for producing offspring, and almost none to studying the effectiveness of other ART techniques such as preimplantation genetic diagnosis. Nevertheless, ART in nonhuman primates is successful (Bavister, 2004), and paying more attention to the use of these animals for providing basic information about primate embryology could be very rewarding.

#### OVARIAN STIMULATION

Initially, we used PMSG and subsequently human menopausal gonadotropins for stimulating rhesus monkey ovaries (Bavister *et al.*, 1983; Boatman *et al.*, 1986), but these biological preparations were very immunogenic, so that females could only be stimulated once (Bavister *et al.*, 1986). This restriction on use of animals seriously limited the numbers of macaque oocytes previously obtainable, and this is a major reason why nonhuman primate embryo research lagged behind work with many other species. However, this difficulty was overcome when recombinant human gonadotropins were used for nonhuman primate research. Using these gonadotropins, female macaques have been stimulated successfully up to five times each, before refractoriness becomes apparent.

Limitations of this approach are that IVP embryos most likely have inherent defects such as anomalies of gene expression. Although this has not been examined in monkey embryos, such anomalies including abnormal expression of imprinted genes have been clearly documented in cattle and mouse embryos (Morgan *et al.*, 2005). We may infer that IVP primate embryos, both human and monkey, are likely to exhibit a high incidence of such defects. In that case, it is difficult to ascertain exactly what constitutes a “normal” embryo, and this detracts from our ability to understand defects in oocytes and embryos that may contribute to age-related loss of fertility. It would clearly be valuable to

examine putatively normal embryos flushed from the reproductive tract. For example, it is not known what the inner cell mass (ICM) and trophectoderm cell numbers are in naturally-occurring primate blastocysts. Reduced ICM cell counts in IVP embryos compared with in vivo blastocysts would indicate a reason for their lower average viability. The cell counts of normal, in vivo-produced blastocysts could serve as a benchmark for evaluating the quality of IVP blastocysts. Although embryo flushing was done in one small study with humans, the flushed embryos were immediately transferred to infertile patients (Buster *et al.*, 1985), and no useful information was produced about the characteristics of viable embryos. This approach is very unlikely to be repeated for ethical reasons. Again, the nonhuman primate could serve as a useful model for obtaining information on in vivo produced embryos, but this approach has rarely been exploited.

#### SUPEROVULATION OF RHESUS MONKEYS AND FLUSHING EMBRYOS FROM THE REPRODUCTIVE TRACT

The term “superovulation” is used liberally in human clinical IVF, but in that context it implies ovarian stimulation with gonadotropins to recruit large numbers of follicles, which are then aspirated prior to ovulation to recover oocytes. In animal studies, superovulation usually means allowing or inducing gonadotropin-stimulated follicles to ovulate into the oviduct, followed by collection from the reproductive tract of oocytes for IVF or of embryos for further study in vitro. The U.S. cattle breeding industry has been transformed by the application of artificial insemination together with “Multiple Ovulation and Embryo Transfer” (MOET: Gearhart *et al.*, 1989), which results in the collection of perhaps 10–20 high-quality embryos for transfer to recipient females. Collection of flushed embryos from non-stimulated rhesus monkey females is feasible, as shown by years of effort at the Wisconsin National Primate Research Center (Wolfgang *et al.*, 2001). While these embryos are enormously valuable because they are almost certainly “normal,” and no comparable human embryos are available, the effort involved in collecting them is huge. The application of the MOET principle to rhesus monkeys would be a considerable advantage for the collection of numerous in vivo produced embryos, but success has never been reported in nonhuman primates. Administration of human recombinant gonadotropins to monkeys should make the MOET approach more feasible. This in vivo approach would eliminate the need to culture embryos, which avoids introduction of IVP-induced gene expression anomalies. The embryos collected from superovulated rhesus monkeys (morulae and early blastocysts) would be expected to have high viability, which would benefit not only studies on age-related infertility but also production of better quality embryonic stem cells. Because of their immense value for

embryological studies, the collection of nonhuman primate embryos produced in vivo should be strongly encouraged.

## Methods for Detecting Chromosomal Abnormalities in Monkey Oocytes and Embryos

### FREQUENCY OF CHROMOSOME ERRORS IN PRIMATES

It is well established that aneuploidy is common in human oocytes and IVF embryos, and that the frequency of these anomalies increases with age, especially after age 25 (Munne and Cohen, 1998; Munne *et al.*, 2002). Several studies have reported frequencies up to 50% for aneuploidy (Gras *et al.*, 1992) and as high as 48% for mosaicism (Munne *et al.*, 2002). In the latter study, as many as 84% of cells in “chaotic mosaic” embryos were abnormal. However, all the data are from oocytes and IVP embryos of infertile women, in which occurrence of chromosome anomalies may be especially marked compared with the general population, and may also be exacerbated by gonadotropin stimulation for IVF. Moreover, humans are not suitable experimental subjects for studying the etiology or frequency of aneuploidy in the general population. In order to study these questions, a suitable experimental model is needed, which clearly needs to be a nonhuman primate. However, no study has adequately examined the frequency of aneuploidies in monkey oocytes, either under natural conditions or following ovarian stimulation with gonadotropins.

Aneuploidy is defined as any deviation from the normal number of chromosomes, usually meaning a cell nucleus possessing too many or too few chromosomes. Aneuploidy generally results from nondisjunction events during meiosis, subsequent to “germinal vesicle” (GV) breakdown. About 85% of aneuploidy errors in mice derive from meiotic nondisjunction (Hunt and Hassold, 2002). Alternatively, aneuploidy can result from errors subsequent to meiosis, i.e., mitotic nondisjunction during embryo development. This represents about 15% of chromosomal anomalies. One study reported a significant relationship between maternal age and embryo mosaicism caused by mitotic nondisjunction (Munne and Cohen, 1998). In addition, embryos with impaired developmental competence had a higher frequency of chromosome abnormalities. Gross forms of aneuploidy such as polyploidy can also result from polyspermic fertilization or failure of second polar body extrusion. However, these gross errors are easily distinguishable from nondisjunction errors that are more prevalent in primate IVP embryos. It is important to understand the etiology of these high error rates so that more normal embryos can be produced, with consequent improvement in the success rates of human IVF, especially for older women for whom

the aneuploidy rate is much higher. There are two main possibilities.

1. High rates of aneuploidy and associated mosaicism in embryos due to aberrant chromosome separation are inherent in humans and other “Old World” primates, and this frequency increases with age. If this is true, then little or nothing can be done to decrease the frequencies of these errors. This possibility seems unlikely, partly because such high error rates are not seen in oocytes or embryos from other species examined, such as laboratory or domestic animals. Another reason for doubting this explanation is the source of the information on aneuploidy/mosaicism rates in human oocytes and embryos, as discussed next.
2. The high aneuploidy/mosaicism rates reported in human IVP embryos may result from several factors. (i) The subjects are patients attending IVF clinics; many of these women are infertile, and thus, they are not representative of the general population; (ii) These patients are mostly in the 30–40 years age bracket, and it is likely that the frequency of aneuploidy (nondisjunction) and mosaicism errors in oocytes increases with age (Pellestor *et al.*, 2003); (iii) The patients are stimulated with gonadotropins which raise estradiol levels much higher than normal (Hughes *et al.*, 1990). This abnormal endocrine environment could adversely affect chromosome separation during meiosis. Recent data in mice indicate that estrogenic compounds that elevate blood estradiol levels greatly increase the nondisjunction frequency (Hunt *et al.*, 2003); (iv) The artificial culture conditions used for embryo production (IVP) may have an impact on genetic quality of embryos by influencing chromosomal segregation during early cleavage (Bean *et al.*, 2002). The mechanism of this effect is not known. Factors (iii) and (iv) may synergize to increase the overall rate of chromosome anomalies. If (iii) is true, then the high rate of aneuploidy/mosaicism seen in many infertile women is potentially treatable by designing new stimulation regimens, or even avoiding gonadotropin stimulation altogether. This may be especially important for older women who are at higher risk for chromosome anomalies. If (iv) is true, then new embryo culture media are needed to reduce mosaicism frequency.

Without reliable information on the cause(s) of high error rates during chromosomal segregation in humans, it is difficult to know how to proceed in order to ameliorate the condition to produce more normal IVF embryos. It is also entirely plausible that the conditions giving rise to chromosomal anomalies cannot be ameliorated, but again, this will not be

elucidated without further studies. It would be useful to know the frequency of aneuploidy/mosaicism in the general human population, but this information is not available, nor is it likely to be. Alternatively, donor oocytes from young women could be examined, but this is not practical because chromosome analysis is destructive and thus precludes use of these oocytes for their primary purpose of embryo production and transfer. Information on oocytes from unstimulated, infertile patients would be helpful, but there are almost no data on this. Because of all these difficulties in obtaining relevant information from humans, the etiology of aneuploidy/mosaicism in primate oocytes and embryos remains a mystery.

The rhesus monkey should prove an ideal model for unraveling this mystery, for several reasons. First, destructive analysis can be done on rhesus oocytes and embryos because this is an experimental model, and complete analysis of all cells is needed to gauge the degree of mosaicism in embryos. Second, we can obtain oocytes from several sources to help determine the etiology of chromosome defects: in vivo matured oocytes from nonstimulated and from gonadotropin-stimulated monkeys, and IVP embryos from IVM or from in vivo matured oocytes. In effect, we can devise a  $2 \times 2$  factorial study with stimulation vs. nonstimulation and in vivo vs. IVP embryos, which is impractical in humans. In these ways, we could compare aneuploidy and mosaicism frequencies, within and across age groups. We would expect to find substantial chromosomal error rates (perhaps 20% or more) in embryos derived from IVM oocytes due to errors in nondisjunction as a result of the artificial conditions during meiosis in vitro. This would help to account for the low developmental competence of primate (monkey and human) IVM oocytes, and help to determine whether the high frequency of aneuploidy observed in oocytes and embryos of older women is inherent or if their oocytes are more susceptible to ART procedures.

#### CYTOGENETIC ANALYSIS OF RHESUS MACAQUE OOCYTES AND EMBRYOS

Aneuploidy analysis can be done in two ways. First, standard karyotyping analysis can be performed on metaphase II oocytes exhibiting a first polar body. Karyotyping was previously used to examine age-related defects in rhesus monkey oocytes (Schramm *et al.*, 2002). In that study, no statistically significant difference was found between young vs. old rhesus monkeys in aneuploidy frequency of oocytes. However, the number of oocytes examined was very small, totaling only 30 oocytes for both groups. We need to reexamine the question of whether aneuploidy increases with age in rhesus oocytes, using much larger numbers of oocytes obtained from ovaries excised at necropsy. The rhesus chromosome number is 42, and the homologies to the human karyotype are simple. There are two homologues

of human chromosome 2 (HSA2), HSA14 and 15 as well as HSA 7 and 21, and HSA 20 and 22 are fused. Rhesus macaque BAC clones have now been generated in the laboratory of Dr. Leslie Lyons at the School of Veterinary Medicine, University of California-Davis. In collaboration with Dr. Lyons, our laboratory is trying to develop a macaque whole chromosome paint set. Meanwhile, we are developing three or four chromosome probes simultaneously, either by chromosome painting with human probes or by FISH with human BAC clones. Dr. Lyons' laboratory is making progress in developing a series of rhesus macaque FISH probes that we plan to compare against simple karyotyping methodologies using rhesus blood cells.

Interestingly, we have found that the AneuVysion<sup>®</sup> Assay (CEP 18, X, Y-alpha satellite, LSI 13 and 21) Multi-color Probe Panel from Vysis does not work on rhesus blood cells. Since these human centromeric probes from Vysis do not hybridize with highly repeated human satellite DNA sequences usually located at the centromeric region of the chromosome, Dr. Lyons' laboratory is now comparing repeat sequences in the monkey genome to the human genome. We found that Vysis LSI probes that consist of DNA probe sequences homologous to specific human genes or unique sequence FISH probes do hybridize quite well with human, chimpanzee and baboon as well as rhesus blood cell chromosomes (Figure 39.3).

In summary, because the FISH probes for detecting rhesus chromosomes are not fully developed yet, we recommend using standard karyotyping to ensure results. In a well-designed experiment, half of the oocytes, selected at random, from each cohort should be examined by karyotyping, while the other half is fertilized to study chromosome error rates in the embryos derived from the oocytes. After adequate FISH probe analysis methods become available for rhesus oocytes, then some oocytes should be examined in this way, to find if this is more suitable for future, larger-scale studies. Alternatively, for karyotype analysis, oocytes or embryo blastomeres can be processed and chromosomes prepared using methods previously described (Schramm and Bavister, 1999). Metaphase spreads are performed on mature (metaphase II) oocytes as described by Kamiguchi *et al.* (1993).

#### Aneuploidy-Causing Mechanisms

Mosaicism is defined as differences in chromosome numbers among blastomeres of the same embryo, that is, nondisjunction errors occurring during mitosis. We might expect to find substantial frequencies of mosaicism within macaque embryos, because this has been the experience with human embryos produced in vitro (Munne *et al.*, 2002). For any single embryo, a chromosomal segregation error during second meiosis will result in all cells being aneuploid. However, an error

**Figure 39.3 Human** (left) and rhesus monkey (right) blood cell nuclei, stained with probes for LS12 and LS 21. From pilot experiments performed to determine if human probes can be used in fluorescent in situ hybridization (FISH) for monkey chromosomes. Unpublished data by Brenner *et al.*

during mitosis will result in mosaicism of varying levels depending upon the embryonic developmental level at which the error occurs. Therefore, if mosaicism is not present, any aneuploidies can be assumed to be due to meiotic nondisjunction. Since reports indicate that there is over 50% aneuploidy and 30% or more mosaicism in human embryos after IVF (Munne *et al.*, 2002), we can expect that both anomalies will also be present in macaques. It is also likely that the frequency of aneuploidy increases with age of the animals. This was not found in the study reported by Schramm *et al.* (2002), but probably insufficient numbers of oocytes were examined in this study. Both higher numbers of oocytes need to be examined as well as using more animals to assess the true frequency of aneuploidy, and especially the effect of age on aneuploidy frequency needs to be examined more rigorously.

Cohorts of oocytes exhibiting high aneuploidy frequencies ought to produce embryos showing poor development, for two reasons: first, because from a logical viewpoint aneuploidy should be detrimental to normal embryo development; and second, because poor development of human embryos was correlated progressively with higher frequencies of chromosomal abnormalities in the embryos (Munne and Cohen, 1998). However, the logical expectation does not seem to always be correct. Some human embryos exhibiting chromosome defects can develop to the blastocyst stage and, it has been suggested, may even go to term after embryo transfer. We should be cautious about accepting the latter statement, because sampled aneuploid blastomeres may not faithfully represent the remaining cells in an embryo, due to mosaicism, while complete ploidy analysis requires destruction of the whole embryo, so how can aneuploidy be tightly correlated with embryo development? An advantage of using rhesus monkeys is that, following gonadotropin stimulation and oocyte collection, half of the oocytes can be randomly assigned to immediate chromosome analysis while the remainder are subjected to IVF and embryo culture, and then

destructively analyzed for chromosome complements, as described above. This strategy, which is impractical in a human IVF clinic due to the primary goal of achieving pregnancy, allows the frequency of nondisjunction defects to be compared in meiosis vs. mitosis. In addition, the consequences of high aneuploidy frequency on embryo development can be evaluated. It is possible, however, that this experiment will show low frequencies of aneuploidy in stimulated oocytes and embryos derived from them, due to the fact that mostly young, fertile females are used, unlike the situation in human clinical patients. This outcome would indicate that monkeys are not a good model for assessing effects of aneuploidy on embryo development in infertile humans. This remains to be seen. However, monkeys could still be good models for investigating the etiology of aneuploidy in primate oocytes and embryos.

Another problem is that we should control for male aneuploidy because this can also contribute to chromosome defects in embryos. A high frequency in anomalies of the sex chromosomes was found in human spermatozoa (Martin *et al.*, 1991). To control for this, we could assess spermatozoa, preferably from a known fertile male, in one of two ways. Using a variation of a technique used for analyzing human sperm aneuploidy rates (Martin *et al.*, 1991), intracytoplasmic sperm injection (ICSI) could be used to inject monkey spermatozoa into zona-free hamster oocytes. The ooplasm will decondense chromatin and support formation of chromosomes for karyotyping. For this approach, ICSI is necessary because, unlike spermatozoa of many other species including humans, macaque spermatozoa do not readily fuse with the hamster oocyte membrane. In another approach, macaque spermatozoa could be chemically decondensed *in vitro* using established protocols (Spriggs *et al.*, 1996). To avoid contributions from sperm chromosome defects when studying aneuploidy in oocytes, males should be rejected for IVF embryo production if their spermatozoa show more than 1 or 2% aneuploidy.

## Mitochondria, Reproduction and Infertility

### THE ROLE OF MITOCHONDRIA IN EMBRYO DEVELOPMENT

Mitochondria play a key role in the physiology of eukaryotic cells. They are important for mammalian oocyte and preimplantation embryo development, as well as for nuclear transplantation and stem cells (Bavister and Squirrell, 2000; Cummins, 2001a, 2002; Hiendleder and Wolf, 2003). This is not only due to the fundamental role of mitochondria in energy metabolism, but also because they are semi-autonomous organelles and each one contains one or several copies of its genome (mtDNA) that must be replicated during embryo development. In humans, the mitochondrial genome is a 16.6kb circular strand of DNA encoding 37 genes. These include 13 components of the oxidative phosphorylation (OXPHOS) pathway, two ribosomal RNAs and 22 transfer RNAs. The coding capacity of mtDNA is quite limited, because over 200 of the genes needed for mitochondrial function actually reside in the cell's nuclear genome (Cummins, 2001a). This indicates that most of the original mitochondrial genome has migrated to the cell nucleus, with only a small subset of genes remaining within the mitochondrion for OXPHOS control. Existence of this arrangement is verified by several mutations found either in the nuclear and/or mitochondrial genes that impair OXPHOS; potentially lethal disorders are often associated with these mutations (Thorburn and Dahl, 2001). As a result, we know that mitochondrial functions depend on cytoplasm-nucleus information exchange. This exchange is exerted through nuclear-encoded transcription factors, such as mitochondrial transcription factor A (TFAM), that regulate mitochondrial biogenesis and energy metabolic functions.

### MIGRATION OF MITOCHONDRIA IN OOCYTES AND EMBRYOS

Data from our laboratory using hamsters and rhesus monkeys show that during fertilization, active mitochondria become unequally distributed in the oocyte cytoplasm. In general, active mitochondria relocate to surround the pronuclei (Barnett *et al.*, 1996, 1997; Squirrell *et al.*, 2003). In hamster oocytes, active mitochondria were homogeneously distributed in the oocyte cytoplasm before activation by spermatozoa, but a few hours later they began to translocate to the peripronuclear region (Squirrell, 2002; Squirrell *et al.*, 2003). This localization occurs naturally and is tightly correlated with embryo development competence *in vitro*, because culture conditions that disturb or block embryo development *in vitro* also disrupted the normal mitochondrial localization profile (Barnett *et al.*, 1997; Squirrell *et al.*, 2001; Ludwig *et al.*, 2001). Although we

do not know whether this is a cause or effect relationship, the observation does suggest that caution is needed in designing culture conditions for IVP of embryos in ART.

We next studied rhesus monkey oocytes using multiphoton laser scanning microscopy (MPSLM; Squirrell *et al.*, 2003). During fertilization, oocytes exhibited a peripronuclear clustering of mitochondria, but this accumulation was not present throughout the entire period prior to syngamy. The duration ranged from <1 hr to 10 hr, with a mean of 3 hr. However, unlike in hamsters, the distribution of mitochondria became more homogeneous after fertilization. The localization profile of active mitochondria differed among oocytes from the same cohort. To understand possible relationships between mitochondrial distribution, especially pronuclear localization, and subsequent embryo development, macaque oocytes were labeled, then imaged, inseminated, imaged again and allowed to develop in separate culture drops. Mitochondrial localization in the oocytes was consistent with their competence to develop into blastocysts. Similar studies revealed a relationship between mitochondrial localization and competence in cattle oocytes (Krisher and Bavister, 1997, 1998). Mitochondria also relocate to the perinuclear region in fertilized human oocytes, but data are insufficient to establish a link with development (Van Blerkom *et al.*, 2000; Sathananthan and Trounson, 2000).

### IMPLICATIONS OF MITOCHONDRIAL ANOMALIES FOR ART

Mitochondrial dysfunction is suggested as a prime cause of low oocyte and embryo quality and hence the low efficiency of human ART on a per-embryo basis. Not surprisingly, attention has been drawn to possible effects of current ARTs on mitochondrial function. The coexistence of different mitochondrial genomes in the same cell is termed mitochondrial heteroplasmy. There is evidence that heteroplasmy in some infants resulted from "ooplasm transfer," a technique involving injection of ooplasm from oocytes from young women into oocytes from older women patients in an effort to improve their developmental competence (Cohen *et al.*, 1998). In this procedure, about 10% of the ooplasm from an oocyte of a presumptively fertile donor was microinjected into a recipient oocyte from an older, infertile patient with presumptively compromised oocyte quality (Cohen *et al.*, 1998). However, this transfer would introduce numerous cytoplasmic components into the recipient oocytes, including proteins and mRNAs as well as mitochondria and other organelles (Van Blerkom *et al.*, 1998). It is still unknown if injection of donor mitochondria can improve the quality of oocytes and embryos derived from them, although several babies were born after this procedure. The children resulting from IVF of these oocytes were found to be carrying mitochondria from

both the donor and recipient, in varying proportions in different tissues.

Heteroplasmy also results from nuclear transfer—the fusion of somatic cells with enucleated oocytes (somatic cell nuclear transfer, SCNT)—in studies on cloned sheep, cattle and monkeys. All efforts to produce identical monkeys by SCNT have failed so far to produce cloned (identical) monkeys for biomedical research, but any success in this approach will have to contend with the problem of heteroplasmy. It may be that techniques such as ooplasm transfer, nuclear transfer and other approaches involving heteroplasmy perturb the normal interchanges between nuclear and mitochondrial genomes required for proper mtDNA replication, as described above. This could account for the low success of these technologies. Nevertheless, if ooplasm transfer or the reverse procedure, “pronuclear fusion” (see below), is ever to gain acceptance for treatment of infertility in the older patient, it seems that their safety as well as their efficacy must first be confirmed in monkeys.

Other approaches that may cause heteroplasmy or other mitochondrial problems include the transfer of oocyte nuclei (germinal vesicles) from oocytes of older women into enucleated oocytes of younger women, in efforts to allow older women to be the genetic mothers of their babies even though “oocyte donation” is used. In a related technique, the nucleus of an IVF oocyte is removed and injected into an enucleated donor oocyte (“pronuclear fusion”; Zhang *et al.*, 1999). Whether or not these techniques are effective for treatment of infertility in older patients, heteroplasmy is a concern, and possible effects of age on this condition cannot be discounted. In addition, because many of the genes required for mitochondrial function reside in the nucleus, mismatches between mitochondrial and nuclear genomes may cause problems in bioenergetics.

While mitochondria are strictly maternally inherited, paternally-derived mitochondria are eliminated selectively during early fertilization and/or subsequent embryonic cell divisions (Sutovsky and Schatten, 2000; St. John, 2002). Nevertheless, there are some reports from human patients as well as in animals that occasionally paternal mitochondria escape the elimination process, which has sometimes resulted in severe pathologies (Cummins, 2001b). Because invasive techniques such as ICSI are becoming more prevalent in human ART, there is some concern that such techniques may increase the frequency of heteroplasmy. Paternal mitochondria can sometimes survive in abnormally fertilized embryos (St. John *et al.*, 1997). If spermatozoa carrying mitochondrial point mutations and deletions were introduced into an oocyte by ICSI, and mitochondria of such spermatozoa are not properly eliminated in the embryo, then there could be a possibility for inadvertent transmission of mitochondrial diseases and/or introduction of fertility problems. Because mechanisms of paternal

mitochondrial elimination may differ across species, it is important that consequences of introducing sperm mtDNA mutations into embryos should be examined in an appropriate, nonhuman primate model such as the rhesus monkey using ICSI (Hewitson *et al.*, 2002).

Recently, transmission of paternal mitochondrial DNA into nonhuman primate offspring produced by embryonic cell nuclear transfer (ECNT) was described (St. John and Schatten, 2004). This process involves not only introduction of the blastomere nucleus but also a substantial volume of blastomere cytoplasm that includes remnants of mitochondria from the fertilizing spermatozoon. Thus, there is considerable risk of aberrant mtDNA transmission in ECNT. Nonhuman primate offspring produced by ECNT actually contained three mtDNA populations, derived from maternal mtDNA from the recipient oocyte, a different maternal mtDNA from the donor blastomere, and paternal mtDNA from the fertilizing spermatozoon. This outcome represents another example of multiparental mtDNA heteroplasmy.

## Mitochondrial Point Mutations in the Control Region and Aging

### RELATIONSHIP BETWEEN mtDNA MUTATIONS AND OOCYTE COMPETENCE

The origin and mechanism of mutant mtDNA accumulation (up to 99% in some tissues) in patients with mitochondrial diseases are still debatable. Several mutations of mitochondrial DNA occur either as sporadic large-scale rearrangements (deletions and duplications) or maternally inherited point mutations, which have been associated with defined clinical syndromes. Point mutations of mtDNA can occur in several different regions of the mitochondrial genome. Also, the severity of the clinical and biochemical phenotype correlates with the degree of mtDNA heteroplasmy in the somatic tissues. Mitochondrial mutations and rearrangements in oocytes and preimplantation embryos and resulting mitochondrial dysfunction may have important implications for embryo development. Numerous laboratories have detected a particular mtDNA mutation called the “common deletion,”  $\Delta$ mtDNA4977, in human oocytes at a frequency of 30 to 50% (Brenner *et al.*, 1998; Barritt *et al.*, 1999; Keefe *et al.*, 1995). In our laboratory, this mutation was found in 30 to 50% of human oocytes. Additionally, 23 novel mtDNA rearrangements have been identified in human oocytes and embryos (Barritt *et al.*, 1999). Using a nested PCR strategy, 51% of human oocytes and 32% of embryos exhibited mtDNA rearrangements, while multiple rearrangements were detected in 31% of oocytes and 14% of embryos. However, the important question is whether the mutational load actually reflects the quality of affected oocytes.

**Figure 39.4** Mitochondrial hypervariable D-loop 600 bp PCR amplicon from 3 female and 1 male rhesus macaques. Samples were run on a 1.0% agarose gel at a constant voltage of 70V for 45 min. Initial primer sets have been designed, and preliminary PCR demonstrated positive amplification of a ~600 bp region of the mitochondrial D-loop of Indian origin rhesus macaques. We have now cloned and DNA sequenced the complete 1600 bp *M. mulatta* mitochondrial DNA, D-loop hypervariable region (see Figure 39.5). Unpublished data by Brenner *et al.*

**Figure 39.5** A. Mitochondrial hypervariable D-loop PCR amplicons from monkey, cat and bovine. Lanes 1, 7, 10: 100 bp ladder. Lanes 2-4: *M. mulatta*. Lanes 5, 6: *M. nemestrina*. Lanes 8, 9: *F. catus*; Lane 11: *B. taurus*. B. DNA chromatogram of *M. mulatta* mitochondrial control region. C. *M. mulatta* mitochondrial DNA, D-loop hypervariable region (1600 bp). Unpublished data by Brenner *et al.*

Since all embryonic stem (ES) cell lines are derived from fertilized oocytes, it is expected that such oocyte defects are also present in these cells, and because virtually all primate (monkey and human) oocytes used in research or

IVF clinics come from females stimulated with gonadotropins, which may increase mtDNA error frequencies, we must be cautious about heavily investing in research using this source of material.

Several mtDNA mutations appear in somatic tissues at a higher frequency in older than in younger subjects. Some of these mutations are associated with overt pathologies while others are not. A key question is, Do mitochondrial DNA mutations affect oocyte quality and developmental capacity? This raises a related question: because mtDNA mutations accumulate in oocytes with increasing age of the patient, do these errors play a significant role in age-related loss of fertility? Our laboratory has investigated whether there is an age-dependent, oocyte-specific point mutation in the mtDNA control region of human oocytes. Preliminary data showed that a prevalent point mutation at bp position 414 in the mitochondrial genome may preferentially accumulate with age in human oocytes (Barritt *et al.*, 2000).

**EVALUATION OF MITOCHONDRIAL COPY NUMBER, DELETIONS AND MUTATIONS AS MARKERS OF OOCYTE COMPETENCE**

Accumulation of mtDNA mutations in the mitochondrial genome may be inherent in oocytes and in embryos derived from them, especially those derived using IVP (see above), and could contribute to impaired metabolic function and thus to developmental incompetence (Keefe *et al.*, 1995; Brenner *et al.*, 1998; Barritt *et al.*, 1999, 2000). Mutations may result in diminished ATP content, leading to defects such as slow or arrested cell division, apoptosis, numerical chromosomal abnormalities such as aneuploidy, and ultimately failure to develop or establish pregnancy (Barnett *et al.*, 1997; Van Blerkom *et al.*, 1995, 2001). But any adverse affect of mtDNA mutations associated with respiratory function would depend upon the magnitude of the mutant population (mutant load). This load could increase with each embryo cell division. Functional defects could also result from asymmetrical mitochondrial distribution following cell division, which could lead to disproportionate mitochondrial inheritance and perhaps thereby produce cells with diminished ATP-generating capacity. This type of error could be related to mitochondrial distribution in the cell (see Migration of Mitochondria in Oocytes and Embryos) (Van Blerkom *et al.*, 1995, 2000). Mitochondria are not only the major site of ATP production in cells but also an important source of reactive oxygen species (ROS) under certain pathological conditions. Because mitochondrial DNA (mtDNA) in the mitochondrial matrix is exposed to ROS that leak from the respiratory chain, this extranuclear genome is prone to mutations. Therefore, the mitochondrial genome is a rich site for both deletions and mutations.

### MITOCHONDRIAL COPY NUMBERS IN PRIMATE OOCYTES

The number of mitochondrial genomes in human oocytes has been estimated by fluorescent rapid cycle DNA amplification, a highly sensitive technique for quantifying mtDNA copy numbers in individual cells (Steuerwald *et al.*, 2000). From the log-linear phase of amplification during real-time PCR, preliminary results showed 90,000–1,000,000 copies of mtDNA in each human oocyte (Steuerwald *et al.*, 1999, 2000). The average mtDNA copy number in over 70 human oocytes during maturation was  $779,000 \pm 240,000$  (range 240,000–1,550,000) (Barritt *et al.*, 2000). Age-related differences were not seen (Steuerwald *et al.*, 2000; Barritt, unpublished results). The relationship between copy number and function (ATP production) remains to be investigated. However, a minimum amount of mitochondrial activity must be necessary for normal cell functions (Barnett and Bavister, 1996; Van Blerkom *et al.*, 1995, 2000). Perhaps the total numbers of mitochondria are not as relevant as the proportion of functional mitochondria in the cell, indicative of ATP production, or their distribution profile. Such detailed analyses have not yet been conducted with monkey oocytes, and it will be informative to obtain this information to establish whether the monkey is a faithful model for the human in this respect. However, as mentioned previously, there are inherent differences between human and monkey IVP, since studies in humans are usually done with discarded oocytes or embryos, unlike in monkeys, while monkey embryo research generally uses fertile individuals vs. infertile humans.

### MITOCHONDRIAL MUTATIONS IN PRIMATE OOCYTES

One of the most promising leads related to mitochondrial mutations in primate oocytes has been found in the control region of the mitochondrial genome. The main control region of mtDNA, or the D-loop, is adjacent to transcription promoters, is the most variable portion of the human mitochondrial genome, may contain heteroplasmic point mutations, and is responsible for DNA replication. Our laboratory showed that an oocyte-specific mtDNA point mutation occurs frequently in oocytes of some women (Barritt *et al.*, 2000; Michikawa *et al.*, 1999) and appeared to be more prevalent in the oocytes of women of advanced reproductive age. This point mutation represents a single base pair transversion of a thymine (T) to guanine (G) at base pair 414 (T414G) in the mitochondrial genome. DNA sequence analysis confirmed this mutation in only one oocyte from 11 patients aged 26 to 36 ( $n = 23$ ), compared to 17 oocytes from 10 patients aged 37 to 42 ( $n = 43$ ). The younger group exhibited this mtDNA point mutation in only 4% of oocytes compared to 40% from the older group ( $p < 0.01$ ). Therefore, single human oocytes may contain the mtDNA T414G transversion point mutation, which

accumulates with age. The potential significance of this point mutation may be its correlation with reproductive senescence or ovarian reserve. Furthermore, other oocyte-specific mutations may also be present in the mitochondrial control region and thus may be responsible for impaired transcription and replication regulation. If these potentially high copy number point mutations can be confirmed by more extensive studies in normal oocytes from aging primates, this could be an important and unrecognized factor in pregnancy outcome because mitochondrial replication is believed not to begin until after implantation. Therefore, replication defects would not be expected to compromise preimplantation development, but depending upon mutant load, could manifest as postimplantation death. These data imply that ES cell lines derived from embryos made with oocytes from older individuals (human or monkey) may exhibit impaired mitochondrial function.

### ES Cells from Primate Blastocysts Produced *in vivo* vs. *in vitro*, and Aging

Thus far, we have discussed aging in the sense of changes occurring in the fertility of an individual female primate as she becomes older. But in another sense, aging is a property of individual cells, and this not only may underlie age-related events in the individual but also account for functional changes in a cell as it reaches the end of its life. In this context, aging is a key aspect of cultured cells, including ES cells. We believe that a major focus on mitochondria is warranted in ES cell studies. A sufficient number of normal mitochondria is required in somatic cells to support normal functions. A high frequency of genetically abnormal mitochondria (mutational load) could reduce the number of functional mitochondria, leading to poor cell performance, manifested as slow cell divisions, karyotypic anomalies, and/or perturbation of mitochondrial distribution profiles. Moreover, the presence of mtDNA anomalies may be increased in cell lines derived from *in vitro* produced embryos compared with embryos produced *in vivo*.

Mitochondria play a key role in early development, though one that is far from being fully understood (Barnett and Bavister, 1996; Van Blerkom *et al.*, 2000; Bavister and Squirrell, 2000; Barnett *et al.*, 1996; Ludwig *et al.*, 2001). By analogy with their fundamental metabolic roles in somatic cells (Yaffe, 1999), we can expect that mitochondria have similar importance in the inner cell mass (ICM) of blastocysts and in the ES cells derived from them, which are primordial somatic cells. Culture conditions that affect mitochondrial activity, such as providing oxidizable substrates, during oocyte maturation or early cleavage stages can profoundly alter embryo development in several species including nonhuman primates (McKiernan *et al.*, 1991; Rose-Hellekant *et al.*, 1998; Krisher and Bavister, 1999; Zheng *et al.*, 2001,

2002). Mitochondria sequester cytoplasmic calcium, and “uncoupling” them caused apoptotic cell death in embryos (Liu *et al.*, 2001). Moreover, mitochondrial structure and activity change strikingly during preimplantation development, suggesting an increasingly important role once differentiation (blastocoele formation) occurs. Some somatic cells such as fibroblasts and neurons also exhibit a pronounced clustering of active mitochondria (Yaffe, 1999; Mattson and Partin, 1999). In some cells, the distribution of mitochondria is under genetic control (Yaffe, 1999). In fibroblasts, mitochondria cluster around the nucleus while peripheral cytoplasm is devoid of mitochondria, the same profile as in fertilizing oocytes and early preimplantation embryos (Yaffe, 1999; Barnett *et al.*, 1996; Squirrell *et al.*, 2003). In neurons, mitochondrial clustering is involved in establishing cell polarity and disrupting their distribution results in loss of polarity (Mattson and Partin, 1999).

In view of these observations on preimplantation embryos and on somatic cells, it seems very likely that clustering (nonrandom distribution) of mitochondria occurs in primate ES cells and thus may be important for their normal functions. If so, the distribution profile(s) could become a simple marker of ES cell competence, as well as an indicator of impending differentiation. We should examine primate (human and monkey) ES cells to determine this. Next, we should ascertain if mitochondrial localization patterns are different in ES cells from IVP vs. in vivo produced blastocysts, because most of the IVP embryos are nonviable, while we expect most blastocysts produced in vivo to be viable. This difference should be reflected in ES cell quality and functional competence. However, because of the complete lack of human embryos produced in vivo, this comparative study can only be done in a suitable nonhuman primate model, such as the rhesus monkey, in which protocols both for IVP and for flushing uteri of mated animals have been established (Schramm and Bavister, 1996; Wolfgang *et al.*, 2001). Once this study has been completed, we can move on to examination of effects of aging, in both senses of the term: (i) effects of age of the individual on mitochondrial localization (and other aspects such as mtDNA errors as described above) in ES cells from IVP and in vivo produced embryos, and (ii) effects of aging of the ES cells in culture (i.e., increasing passage numbers) on these parameters.

## Conclusions

The reproductive physiology and embryology of the rhesus monkey make this species a good model for examining the etiology of reproductive failure in humans. In addition, because this is a long-lived species, we would expect that age-related impairment of infertility will have similar causes to that seen in humans. A great advantage of using rhesus monkeys is that it is possible, albeit with considerable difficulty, to collect normally-developing

embryos from the female reproductive tract. These represent the most normal primate embryos available, and are thus invaluable for providing comparative data against which we can assess cellular and molecular parameters of IVP embryos. This advantage also applies to embryonic stem cells, both human and macaque, for which some kind of benchmark is greatly needed. Much attention has been focused on aneuploidy frequencies in human IVP embryos, both to explain the lack of viability in many human IVP embryos and to understand why the frequency of this anomaly appears to be so high. We propose that IVP macaque embryos are more suitable for addressing the latter question, because they can all be destroyed to obtain the maximum amount of information, whereas in humans, usually only discard oocytes and reject embryos are available for research. We believe that it is important to study mitochondria in oocytes and embryos, as well as in ES cells, because defects in these important organelles are likely to contribute to lack of developmental and functional competence. Both the bioenergetic function and the genomic aspects of mitochondria should be examined, in order to gain better understanding of infertility caused by oocyte incompetence, and we suggest that these two properties may be functionally linked. In conclusion, using rhesus monkeys for well-designed experimental studies is likely to provide insights into reasons for human infertility and age-related loss of fertility, and also to supply valuable information on embryonic stem cell culture and differentiation.

## ACKNOWLEDGMENTS

We are grateful to the National Institutes of Health NCRR and NICHD for supporting parts of our studies mentioned in this chapter, through grants no. RR15395, HD046553 and HD04596.

# Neurobiology of the Aging Brain

Carlo Bertoni-Freddari, Patrizia Fattoretti, Tiziana Casoli, and Giuseppina Di Stefano

*Different anatomical, histological, cellular, and sub-cellular alterations occur in the human brain during aging. Because of this wide variety of changes, often masked by compensating reactions, the identification of clear-cut decays due to age may constitute a difficult task. In the elderly, brain volume and weight decrease because of an insignificant loss of neurons, dendritic atrophy, and glial cells degeneration. Damage of blood vessels, due to atherosclerosis and amyloid angiopathy, by reducing brain blood perfusion, may play a role in neuronal, glial, and dendritic degenerative phenomena. Impaired cellular membrane turnover leads to accumulation of age pigments or lipofuscin. Loss of synapses, paired with an imbalance of neurotransmitter systems, occurs in physiological and, to a higher degree, pathological aging.*

*Brain energy metabolism also declines in aging, which involves a decay in the mitochondrial metabolic competence that can be considered an unfavorable condition affecting several other processes such as calcium homeostasis and the development of SP and NFT. Nonhuman primates and transgenic mice, presently adopted as animal models to investigate human brain aging and AD, may further our understanding of the mechanisms underlying the formation of Alzheimer-like alterations, and may help to set up intervention strategies leading to an increase of the percent of cognitive intact and successfully aged subjects.*

## Introduction

A well-accepted definition of aging is that it is a time-related progressive loss in the cell capacity to maintain homeostasis. With advancing age, somatic changes come into being because the persistent action of stress conditions is not fully counteracted by cellular repair functions, thus resulting in alterations of organ and system functions. A typical inherent feature of aging is heterogeneity; that is, in addition to genetic individual variability vs. physiological values, vitality is markedly influenced by different lifestyles (Rowe and Kahn, 1987). Thus some elderly individuals age successfully since their aging parameters fall within the adult range; others typically show marked declines of some functions. With specific reference to the brain, the heterogeneity existing

among individuals and the different groups of neurons must also be considered when looking for the potential factors and/or the causative events leading to age-related alterations. In this context, it must be stressed that brain aging represents a condition in which pathological changes exist without clinically evident manifestations. At variance with other organs, where the functional and structural units are repeated, the brain is a composite assembly of groups of cells with different metabolic features and functional tasks. Deterioration of function occurs when the number of neurons or their connections decreases below a critical reserve level, and coping with environmental stimulation is seriously hampered. Moreover, the well-documented brain's plastic condition plays a critical role in the balance between deteriorative events and compensating reactions, thus contributing to mask significant changes and to delay decline of function.

In this chapter, we will consider the age-related alterations occurring in the brain on different systems, at cellular and subcellular levels, with the aim to provide a comprehensive view of the many factors and interdependent mechanisms involved in such a multifactorial process.

## Brain Atrophy and Neuron Loss

A significant decrease in brain weight is a widely documented sign of aging. In neurologically normal elderly individuals, it has been estimated that this decrease begins at the age of 60 years and proceeds at a rate of 2 to 3 grams/year. Considering the average brain weights of adult men (1400 g) and women (1250 g), by the age of 80, an overall reduction of about 3 to 5% has occurred. In addition to brain weight another more reliable measurement of the extent of the brain macroscopic decline in elderly subjects is the ratio between brain and skull volume, which is reported to remain constant around the value of 95% up to the age of 60, but decreases to 80% beyond 90 years of age. Widening of sulci and enlargement of ventriculi are also estimations accounting for an age-related brain atrophy and are reported to progress according to the reduction in brain weight. It has been estimated that the average volume of the lateral and third ventricles undergoes a fourfold increase in elderly over 60 when compared with young subjects between 13 and 19.

Studies *in vivo* by imaging methodologies have confirmed this data obtained from autopsy studies, and have shown a great individual variability, suggesting that age-related changes, at least at macroscopic level, may be significantly influenced by genetic determinants and environmental factors, first of all the very specific lifestyle of each individual. During the past two decades, neuron loss has been supported to occur at a significant extent in the aging brain (it commonly was accepted that adults lose as many as 100,000 neurons a day). As reported by an extensive review by Coleman and Flood (1987), some early papers on this research topic documented that most neocortical areas and hippocampal subfields lose 25 to 50% of their neurons, and they were able to influence successive investigations that substantially confirmed a consistent and widespread neuronal death in aging, although these data were reporting different degrees of neuronal loss. The common feature of these studies is that, as a morphometric parameter, they took into account the density of neurons within a given structure and not the total neuron number. Thus, although all these studies agreed in supporting an extensive neuron loss in aging, over the past several years it was increasingly evident that confounding factors might have influenced neuron counting and led to obtaining erroneous results. Namely, tissue processing, method of sampling, strain differences, and the specific anatomy of the area of the central nervous system (CNS) where neuronal counts were performed have been reported to represent sources of potential mistakes in estimating the number of neurons. Contrary to the previously held conviction that with advancing age there is a progressive neuron loss, the development of more accurate counting procedures produced more reliable estimations and led to the conclusion that normal aging does not involve a significant neuronal numeric decrease through neuron death. Unbiased stereological analyses (i.e., the disector; see the section, "Age-related Alterations of Synaptic Structural Dynamics") have shown that, across the overall lifespan, the loss of neurons is around 10%, but this cannot be interpreted as a specific time-related significant impairment since sex has been found to be more important than age in modulating the total neuron number in a given brain region, for example, the neocortex (Pakkenberg and Gundersen, 1997). The marked heterogeneity of the whole brain and even of specific brain regions makes it difficult to interpret any decrease of neuron number from a functional standpoint, thus only those studies conducted in localized CNS zones with clearly demonstrated functions and connections have provided useful information on age-related impairments in which neuron loss may play a role. In this context, because of their documented direct implication in memory, entorhinal cortex and hippocampus have been investigated in different animal models and in human beings. In these CNS areas from old rodents, old nonhuman primates,

as well as old human beings, there is no significant neuron loss that may account for the known decay in memory functions due to age (Gomez-Isla *et al.*, 1997). However, these CNS areas show a significant neuron loss in Alzheimer's disease (AD), and this lends support to the assumption that the severity of neuronal death is different in physiological aging and age-related pathological conditions, and that selected areas of the CNS are preferentially affected by age and pathology-related changes (West *et al.*, 1994). It must be stressed that neuronal loss reflects the cumulative tissue damage accrued with age (and, eventually, an age-related neuropathological status). Thus even if the lack of significant neuron loss cannot be considered as the main causative alteration of a manifest functional decline, the neuronal circuits on which the specific function, for example, memory, relies may undergo a progressive damage leading to a subtle deterioration and resulting in impaired brain performances.

Summarizing the results on neuron number and changes in brain size in aging, at present, the well-documented brain shrinkage due to age does not appear to be due to the numeric loss of neurons that has been demonstrated to be far less significant than previously thought and occurs in localized CNS regions, whereas other zones are not affected at all. Atrophy of neurons and of their connections is reported to be the main causative event responsible for the age-related reduction in brain volume, and this provides a rationale for interventional strategies to repair dysfunctional neuronal networks.

## Glia Alterations

Glial cells are very numerous and in some parts of the brain they outnumber the nerve cells by 10 to 1. The well-known classification of this type of cells into astrocytes, oligodendrocytes, and microglia in addition to referring to their morphological features also categorizes their specific functions that include providing structural support for nerve cells, isolation and grouping of nerve fibers and terminals, participating in metabolic pathways that modulate the ions, transmitters, and metabolites involved in nerve cell functions. The function of oligodendrocytes is to form the myelin around axons in the CNS; microglia are small cells scattered throughout the nervous system that play a central role in injury and degeneration; that is, these cells proliferate, move to the site where damage has occurred, and transform into large macrophages that remove and phagocytize the debris, thus defending the CNS against inflammation and infection. Glial cells and neurons interact intensely; thus many alterations of this type of cells occurring with advancing age may be secondary to neuronal damage and not regarded as primary glial changes. Given the many functions in which glial cells are involved, it appears difficult to rule out the early different changes affecting

these cells in aging. An improved characterization of primary glial changes occurring in the aging CNS has been achieved by the use of recently developed immunohistochemical and silver impregnation methods that enabled the revelation of new aspects on time-related glial degeneration. As an example, paired helical filaments (PHF), long believed to occur only in neurons, were also demonstrated in astrocytes from AD patients (Nakano *et al.*, 1992). In glial cells, the demonstration of variegated abnormal argyrophilic structures immunoreactive with ant-tau antibodies is supporting the concept that glial cytoskeletal abnormalities are related to the specific pathological condition in which they occur. With specific reference to physiological aging, reactive gliosis, probably occurring as a consequence of neuronal damage, is the most common of all glial changes. It has been found that in the eighth decade there is an age-associated increase in the number of cerebral cortical astrocytes immunoreactive for glial fibrillary acid protein (GFAP) (Hansen *et al.*, 1987). This reaction is directly connected with the essential function of astrocytes that play important roles both in nutritional supply, via glucose transfer to neurons, and in the metabolism of glutamic acid, used as neurotransmitter. The early step of gliosis is represented by a consistent swelling of the nucleus followed by proliferation of astrocytes and hypertrophy of a strongly GFAP-positive cytoplasm. In the human cerebral cortex, these activated astrocytes are reported to be immunoreactive for a neurotrophic cytokine (S100 $\beta$ ), which is involved in the development of neuritic senile plaques (SP) in AD. In normal aging, S100 $\beta$ -immunoreactive astrocytes increase in number together with the tissue level of S100 $\beta$  protein and S100 $\beta$  mRNA, thus supporting that with advancing age the appearance of SP may predispose to the development of an AD pathological condition (Sheng *et al.*, 1996). Over 60 years, microglia also show changes due to age in the human brain: in addition to an altered morphology, the increased number of activated microglia express the immunomodulatory cytokine interleukin-1, which is paired by increased tissue levels of interleukin-1 mRNA (Mrak *et al.*, 1995), an alteration implicated in AD pathogenesis. On the basis of these data, in addition to the age-related neuronal damage and loss, glial degenerative phenomena also must seriously be taken into account in studying brain aging. A better understanding of glial alterations and of neuron-glia interactions may help in identifying the precocious signs of degenerative phenomena and dysfunction.

### Vascular Changes

The consistent damage of blood vessels documented with advancing age in the body also affects the cerebral arteries with the outcome of a significant reduction of blood supply to the brain. As a consequence, selective loss of nerve cells and infarcts may occur and these alterations may lead to the aggravating dementing process

of multifactor dementia. Since atherosclerosis and amyloid angiopathy are reported to represent the most important changes responsible for the age-related progressive decay in blood cerebral perfusion, they were thoroughly investigated in the brain of both humans and experimental animal models. The results have provided detailed information on mechanisms, determinants, and the many causative events involved in these alterations of the aging brain.

### ATHEROSCLEROSIS

Atheroma is the term used to define the caseous material, containing high amounts of lipids, found in plaque-like thickenings of the interior portion of the vessel wall. Accordingly, the term *atherosclerosis* reflects the fibrous character of these pathologic alterations affecting large and small peripheral arteries in aging. Atherosclerosis begins as a disease of the innermost layer of the vessel wall (the intima), where the main lesions responsible for its development have been categorized as fatty streaks, fibrous plaques, and complicated lesions.

Fibrous streaks consist mainly of monocyte-derived macrophages that have entered the intima from the blood stream. The abundant presence of lipid droplets, mainly cholesterol ester, within the cytoplasm transforms these macrophages into foam cells. In advanced fatty streaks, lipid infiltration may proceed to fill smooth muscle cells in the tunica media of the blood vessel wall.

The fibrous plaque is a dense fibrous cap at the inner surface of the atherosclerotic lesion that contains a connective tissue matrix rich in collagen that surrounds smooth muscle cells and macrophages on the side of the vessel wall, and is covered by endothelial cells on the side of the lumen. The complicated lesion is supposed to represent a calcification of a fibrous plaque, with the serious possibility of developing cracks, ulcerations, hemorrhages, and thrombosis. In turn, these changes may lead to a cerebral infarction. Specifically in hypercholesterolemic subjects, foam cells are particularly abundant in the area where a complicated lesion occurs in addition to the presence of several muscle cells and macrophages containing lipids that are localized beneath the dense fibrous cap. In advanced lesions, necrotic changes may be found, which results in consistent amounts of extracellular debris and caseous material. The frequent occurrence of cracks and fissures constitutes a further complication of these lesions and results in secondary intramural hemorrhages in large arteries leading to stenosis and thrombosis that obliterate the vessel. As mentioned earlier, these changes affect the intima, but are responsible for secondary damage to the tunica media that may progress to the lamina elastica interna with a final conclusion of a breakdown of the vessel wall.

As it appears from this description, atherogenesis is a very dynamic process involving not only the cells of the

arterial blood vessel, but also circulating blood cells, that is, macrophages, monocytes, platelets, and lymphocytes. With the aim of repairing cell and tissue damage, various growth factors are produced by these cells, and their combined action serves to maintain or remodel the function of the vascular system. In this context, injuries to endothelial cells induce to express mitogens such as platelet-derived growth factor (PDGF) and interleukin-1. Activated macrophages are also capable of forming fibroblast growth factor (FGF), which plays a significant role in capillary formation and in secreting transforming growth factor (TGF-alpha) responsible for epithelial migration and proliferation and transforming growth factor (TGF-beta) that inhibits cell proliferation and induces collagen synthesis. The macrophages themselves may be responsible for further tissue injury and play a role in maintaining the progression of atherogenesis by acting as scavenger cells that oxidize ingested lipids through free radicals formation. Namely, secretion of oxidized material and hydrolytic enzymes may cause damage in the still healthy cells located close to the initial lesion. Activated platelets secrete an epidermal growth factor-like substance (TGF-beta) and play a major role in the coagulation and thrombosis process. In turn, proliferation of smooth muscle cells within the thrombi induces the deposition of connective tissue that is stimulated by many growth factors released by platelet aggregation and degranulation.

The many risk factors able to trigger the atherogenetic process have been revealed by several epidemiological studies. As primary determinants, these include hypercholesterolemia and hypertension, but several other causes and causative changes, such as diabetes and cigarette smoking, are reported to be seriously involved. A defective metabolism of lipoproteins is responsible for a high cholesterolemia that may be specifically due to a deficient cholesterol removal or overproduction, or to a combination of both these processes. Monogenic or polygenic hyperlipidemias also play a significant role in atherogenesis, as demonstrated by epidemiological studies reporting a clear correlation between these diseases and the incidence and severity of atherosclerosis. The mechanisms leading to cellular changes involved in atherogenesis are not known in hypertensive patients; however, an acceleration of the atherogenetic process resulting in an increased incidence of cerebrovascular and coronary heart disease has been documented by epidemiological studies. It is suggested that increased monocyte adherence and the localization of monocyte-derived macrophages at the intima, associated with changes in humoral mediators of blood pressure (e.g., angiotensin and renin), as well as drugs and poisons and hemodynamic parameters may result in an overall unfavorable condition predisposing to the development of atherosclerosis.

Several hypotheses have been proposed to give a tenable interpretation of the different deteriorating phenomena participating in atherogenesis. Considering

the many proposed assumptions, a unifying concept is represented by the fact that the organism responds to the initial injury of an atherogenetic process. Namely, any damage to the endothelium lining triggers a sequence of events leading to a migration, accumulation, and proliferation of intimal muscle cells. The very early step of this process may be represented by a functional change due to different factors such as side-effects of drugs or radiation injury. As a consequence, monocytes and lymphocytes adhere to the endothelium and trigger an accelerated endothelial turnover with the induction of the gene expression of growth factors that accelerate the smooth muscle cell proliferation up to the formation of a typical atherosclerotic plaque.

Cerebral atrophy is responsible for secondary changes of the artery wall that lead to pathological alterations of the aging brain. Narrowing or obliteration of the vessel lumen as well as the formation of thrombi with the consequence of disturbances of the blood circulation in the specifically irrigated cerebral zones are the unfavorable outcomes of atherosclerosis that frequently result in cerebral infarctions. Although the clinical manifestations due to a cerebral infarction are the consequences of the destroyed structures in the brain area where the lesion has occurred, further pathological development of damaged tissue may cause additional symptoms (e.g., multifarct dementia). Multiple microinfarctions, or lacunar infarcts (diameter: 3–20 mm) are lesions most common and most severe in hypertensive patients, although they also have been found in normotensive subjects. The frequency of lacunar infarcts increases in the fifth and sixth decade, but thereafter they become less common. This type of lesion affects the deeper neocortical parts of the brain and brainstem (basal ganglia, thalamus, pons) and is due to the occlusion of penetrating branches of the larger cerebral arteries. In addition to hypertension, vascular hyalinosis, and atheromatous degeneration of the vessels are reported to represent predisposing conditions in the development of a lacunar state. Cortical granular atrophy (CGA) is another development of cerebral infarcts. Namely, reactive gliosis substitutes the lesions of small cortical infarctions, resulting in multiple gliotic micro scars; this, in turn, results in multiple small shrinkages appearing as granuli on the surface of the gyri. In the majority of cases, CGA occurs at the territorial border zones of irrigation between the anterior, medial, and posterior cerebral arteries.

Thickening, hyalinosis, and fibrosis are responsible for the degeneration of arterioles with the consequence of perivascular demyelinating lesions affecting axons and the cerebral white matter, specifically in frontal and occipital areas. Arteriopathy due to hypertension is considered as the causative event of this pathological condition of the white matter (vasculogenic leukoencephalopathy: Binswanger disease), although lacunar changes are found in several patients.

### AMYLOID ANGIOPATHY

The deposition of amyloid in the wall of cerebral blood vessels is a well-documented change found in physiological and pathological (AD) aging of the human brain. Amyloid fibrils are deposited extracellularly and are derived from soluble circulating proteins that have undergone partial proteolysis and polymerization resulting in insoluble aggregates. Different components take part in the final composition of amyloid deposits and include, in addition to the straight, nonbranching protein fibrils (diameter: 7–10 nm), a serum glycoprotein (P-component) showing a structural homology with c-reactive protein (an acute phase reactant) and sulphated proteoglycans. Since amyloid fibrils have an affinity for Congo red stain, show a green birefringence in polarized light and a  $\beta$ -plated sheet pattern at X-ray diffraction analysis, they have been reliably identified and precisely localized in selected areas of the brain tissue. The favorite sites of amyloid deposition are the outer surface of the endothelial basement membrane of the capillaries, the basement membrane of pericytes, and the basement membrane surrounding the smooth muscle cells of veins and arteries (see Figure 40.1).

The basement membranes of astrocytes surrounding the perivascular space are also favorite sites of amyloid deposition. Not all regions are affected by amyloid angiopathy, but capillaries, veins, and arteries may be involved. White matter is reported to be free of amyloid deposits, whereas gray matter regions (cerebral and cerebellar cortex) and leptomeninges may show consistent amyloid angiopathy with advancing age. The progressive accumulation of amyloid around capillaries results in the occlusion of lumen; the same process affecting the smooth muscle cells of arteries and veins leads to degenerative alterations and necrotic lesions of the tunica media of the blood vessel wall, and, as a consequence, the formation of small aneurysms, focal thrombosis, and hemorrhages may occur. Amyloid angiopathy is particularly severe in temporal and occipital regions, and in these CNS areas the clinical manifestation of

a spontaneous intracerebral mass hemorrhage constitutes the first symptom of a pathological condition (Haan *et al.*, 1994). Specifically in generalized amyloidoses, amyloidogenic proteins may come from the blood and their deposition begins at the inner surface of the tunica media, whereas in primary cerebral amyloidoses, the outer side of the same location of the vessel wall is the target of amyloid deposition: a finding supporting that amyloidogenic proteins diffuse from outside into the vessel wall.

More than 30 types of amyloidoses, differentiated according to their location and distribution in the human body, have been classified. With specific reference to brain aging and age-related neurodegenerative diseases, the most common and important is  $\beta$ A4 amyloidosis. The amyloid precursor protein (APP), a protein spanning the cellular membrane, is secreted by nerve and other types of cells. The spontaneous aggregation of short fragments of APP in the extracellular space is one of the early steps in the formation of insoluble fibrillar amyloid deposits. In the brain, nerve cells and their dendrites are the main sources of APP and are responsible for its metabolism; then APP is transported along the perivascular spaces to the subarachnoid space and may deposit in external regions of the blood vessel walls. Although  $\beta$ A4 amyloid angiopathy may occur without evident clinical signs, it is almost frequently combined with the presence of amyloid deposits, in the form of SP in the cerebral parenchyma (hippocampus, frontal cortex, and amygdala) of AD patients.

### Age Pigments

The accumulation of age pigments, or lipofuscin, is a distinctive feature of nerve cells (both neurons and glia) in aging. At the light microscope, lipofuscin can be seen as granules diffused throughout the cytoplasm, aggregated at one pole of the cell or clustered around the nucleus (see Figure 40.2).

**Figure 40.1** Amyloid angiopathy. Transverse section of a human cerebral vessel infiltrated with amyloid. The deposit of amyloid appears white and compact on the vessel wall. Thioflavin S staining.

**Figure 40.2** Lipofuscin granules clustered around the nucleus of a pyramidal cell. Because of the autofluorescence of the lipofuscin granules, no staining is needed to evidence this alteration in the aging neuron.

Since lipofuscin forms during adult life and increases with age, it has been suggested that it represents the morphological outcome of “wear and tear” cellular function. Lipofuscin is a by-product of lipid peroxidation and originates from secondary lysosomes that transform into lipopigment granules. In neurons, the membranes undergo a continuous turnover with the involvement of lysosomal degradation of proteins and lipids. The interaction between the products of the peroxidation of polyunsaturated fatty acids and other biological molecules leads to the formation of these pigments, which are difficult to digest, and accumulate as residual bodies within the cytoplasm. Any type of biological molecule may become a constituent of lipofuscin, and this finds a well-grounded support in the documented ultrastructural heterogeneity of neuronal pigments reported in the aging human brain (Boellaard and Schlote, 1986). Autofluorescence is the most consistent property of lipofuscin. Under stimulation by visible or near-ultraviolet light, lipofuscin granules appear as yellow, yellowish-green, and orange deposits. Most of the lipofuscin lipid constituents (20 to 50%) are phospholipids (75%), and the protein fraction (30 to 50%) shows a high lipid-binding capacity and an amount of enzymes and enzymatic activity similar to intact tissues.

Lipofuscin accumulates in neurons throughout the CNS and is particularly abundant in cranial and spinal motor nuclei, in large neurons of the precentral gyrus, and in cortical pyramidal cells. Within neurons the lipofuscin mass is reported to displace the nucleolus; however, it is not yet proven whether this is due to the excessive accumulation of the pigment or whether the cell first undergoes impairment of function and lipofuscin granules are formed as a consequence of cell deterioration. Although the significance of lipofuscin accumulation in neuronal function is not clear, as a reasonable interpretation, it may be hypothesized that the lipofuscin masses within the neuron may be able to decrease the plastic capacity of the nerve cells to adapt to environmental stimulation. Lipofuscin accumulation has been proposed to be a function of cellular metabolic activity rather than of chronological age and, in this context, repetitive metabolic accidents may lead to the accumulation of a nonfunctional by-product of cellular metabolism. This assumption finds support in the fact that caloric restricted animals (i.e., that have undergone a reduction in metabolic rate) show less lipofuscin accumulation associated with a longer lifespan than age-matched normally fed littermates (Moore *et al.*, 1995).

## Dendritic Changes

An age-related reduction in the number of dendrites and dendritic spines has been reported in normal aging, and this results in an overall decrease of dendritic complexity. The regressive changes occurring at the dendrite tree affect mainly frontal and temporal cortex

and the limbic system in the human brain. The first step in the age-related alterations of dendrites is the loss of spines followed by changes in shape and size of basilar dendrites and then of the branches of the apical shaft (Scheibel *et al.*, 1975). Dendrites are receptor membranes of the neurons, and their spines amplify this function and have been reported to isolate increases of synaptic calcium transport utilized for information storage (Koch *et al.*, 1992). As a consequence, the age-related loss of dendrites and dendritic spines isolates neurons and leads to disturbances in cell-to-cell communication. Because of its dynamic condition, the old CNS is capable of a significant compensating response to the age-related loss of neurons and dendritic retraction by increasing the dendritic growth to fill the neuropil space left by the dendritic trees of dead neurons. In parahippocampal pyramidal cells of cognitively normal individuals the continual growth of dendrites occurs well into the eighth decade of life, whereas in pathological brain aging, for example, AD, this compensating reaction has not been found (Buell and Coleman, 1979).

The dendritic changes due to age have been demonstrated by the Golgi method—an old neurohistological procedure that is still in use. In Golgi-impregnated tissue, staining reveals the complete contours of the cells and of their processes. Nerve cells can be seen against the background because only a small fraction (2 to 5%) of the cells are impregnated, but the reasons of this selective positivity are not known. In the original Golgi method, fresh tissue is hardened in a dichromate solution and impregnated in 1% silver nitrate. In the rapid version of this procedure, the tissue pieces are hardened in 4 parts of potassium dichromate (3.5%) and 1 part of osmic acid (1%) for 2 to 7 days, and then they are transferred to 0.75% silver nitrate for 1 to 2 days. In double and triple impregnations, the tissue samples are returned to osmium-dichromate and then impregnated in the same silver nitrate solution. Although this version of the Golgi method is called rapid, all these steps take long periods of time and several laboratory preparations before obtaining a sample to be analyzed: this increases the possibility to damage the tissue and to see unspecific precipitates.

Several modifications of the original Golgi procedure have been introduced with the aim of reducing the extent and frequency of tissue artifacts. In the Golgi-Cox method, tissue hardening and impregnation take place in a simple bath of potassium dichromate and potassium chromate to which sublimate is added. When the tissue blocks or sections are alkalized, the original yellow compound with divalent mercury is transformed into a black substance. The Golgi-Cox version is more rapid than the original procedure, but the impregnation is rather coarse and never occurs in axons. In the Golgi-Kopsch version the animals are perfused with a freshly prepared mixture of potassium dichromate and formalin (or glutaraldehyde); then the hardened brain is

sectioned and impregnated in silver nitrate (0.75%). Perfusion, as the first step of the Golgi-Kopsch procedure, limits its use to studies to be conducted on laboratory animals. Large sampling of tissue, impregnated with different modifications of the Golgi method, have enabled the collection of several data converging on the common conclusion from different laboratories that in the aging brain basal arborizations are lost in selected areas of the CNS.

### Age-related Alterations of Synaptic Structural Dynamics

It is well demonstrated that the nervous system is capable of consistent structural adaptive changes throughout the individual's lifespan. Specifically, the synaptic terminal regions are in a very dynamic condition responsible for continuous remodeling interventions to optimize the critical role of the synaptic junctional areas in signal transduction and information processing. Synaptic plasticity is the commonly used term defining such a function-driven adaptive response of the synaptic contact zones, and its meaning includes the many different morphological, biochemical, molecular, and genetic changes occurring at synapses as a consequence of environmental stimulation.

During the last decades, the significant advancement in the accuracy and reliability of the investigative procedures has contributed to a better identification and to an improved quantitative analysis of function-related synaptic parameters, thus furthering our understanding of the basic mechanisms contributing to the fine tuning of synaptic transmission. From a morphological point of view, synaptic junctional areas undergo significant rearrangements of their ultrastructural features that mirror the functional status of the neural network where they are located, thus enabling an estimation of the adaptive capacities (i.e., plasticity) of selected CNS zones. In performing any quantitative morphological, or morphometric, study in a given biological tissue, collection of the data is a laborious time-consuming procedure since several histological sections, and perhaps zones within the tissue samples, must be analyzed and measured in order to obtain statistically comparable pools of findings between the experimental groups. Thus, until the late 1980s, analysis and measurement of tissue sections was a significant limiting step in performing these investigations.

The subsequent introduction in laboratory routine procedures of modern computer-assisted image analyzers, though facilitating and objectifying the morphometric procedures, resulted in a marked acceleration of data collection. The application of these procedures to the study of the aging nervous system has provided novel information on the modulation of synaptic architecture to respond to the changing functional needs

(Bertoni-Freddari *et al.*, 1996). It is consistently documented that the staining procedures used in conventional electron microscopy to prepare the tissue samples for qualitative and quantitative analyses enable a better visualization of the whole cellular architecture. This is due to the fact that the traditionally used staining reagents bind ubiquitously to the biological molecules (namely, proteins and lipids), leaving the background completely unstained or faintly stained. The more or less dark and sharp contrast of the cellular structures depends on various factors and, besides the concentration and incubation time of the contrasting reagents (Miquel and Bertoni-Freddari, 2000), also includes the chemical composition of the cellular structure where the staining reaction occurs. In this context, the synaptic contact zones are functionally differentiated areas of the neuronal membrane where polyunsaturated fatty acids are abundant because of the presence of several double bonds between carbon atoms. This very specific feature, although constituting the chemical basis of their plastic condition for adequate functional tasks, is also the reason why pre- and postsynaptic membranes abundantly bind osmium tetroxide and, subsequently other contrasting compounds (namely, uranyl acetate and lead citrate), resulting in being markedly darker than any other zone of the neuronal membrane. These specific properties have favored the conduction of several morphometric studies of synaptic ultrastructure on tissue samples conventionally stained by osmium tetroxide, uranyl acetate, and lead citrate, but they have also prompted the development of various preferential cytochemical techniques with the aim of evidencing selectively fine structural details reporting on specific functional aspects of synaptic morphology. Among the different staining techniques to evidence synaptic junctions, the ethanol phosphotungstic acid (E-PTA) procedure originally was developed to analyze synapse formation and maturation in cultured neurons, and then it was applied to tissue sections. The E-PTA staining enables visualization of the pre- and postsynaptic membranes against a very faint background that is almost completely unstained (see Figure 40.3). This is due to the fact that the fixed tissue pieces are stained in a 1% ethanolic solution of PTA at 60°C for 1 hour, and the nonpositive structures are degraded substantially during this step.

Although the reasons for the specificity of the synapses to this staining technique are still under investigation, it has been clearly demonstrated that PTA binds to the basic amino acid residues of the proteins as also supported by the E-PTA positivity of the chromatin due to the presence of histones. Whatever the mechanisms or reasons of the E-PTA preferential staining of the synapses, the big molecule of the PTA does not penetrate easily into the tissue. Thus in order to obtain good samples for quantitative analysis it is important that very thin sections must be used for incubation in the E-PTA solution. Because of the sharp precipitate due to the

**Figure 40.3** Perforated E-PTA stained synaptic junction from the human cerebral cortex. The postsynaptic density appears as a continuous dark line. The presynaptic apposition can be seen as a dotted line. Arrows indicate the perforations. Bar: 0.5  $\mu\text{m}$ .

E-PTA cytochemical staining, no further contrasting procedure is needed, thus avoiding the risk of staining artifacts. Accordingly, the synapses may be easily identified as two parallel black lines or as a range of dark peaks and a black sharp line representing the pre- and postsynaptic membrane appositions, respectively. At the electron microscope, in the tissue samples stained by the E-PTA procedure, the identification of the synapses is greatly facilitated and the semiautomatic measurement of ultrastructural parameters with a defined functional meaning may be reliably carried out by applying morphometric formulas with the use of computerized image analysis systems.

### SYNAPTIC NUMERIC DENSITY

As points of communication between neurons, the synapses play different roles and are characterized by various degrees of efficacy at different locations; accordingly, their number represents the amount of neural inputs to the neurons of a CNS region. The size of the postsynaptic potential is influenced by the density of the synapses in a given tissue area or volume ( $N_v$ ), and this, in turn, may significantly modulate information processing. Overproduction of synapses occurs in early developmental periods; then the synapses are pruned through competitive interactions and activity-based mechanisms in order to set up the best topographical map of synaptic connections adapted to environmental stimulations. In the fully-differentiated adult CNS, the synaptic pattern can still be modified by the growth of novel connections as a consequence of the experiential framework of each individual. In aging, loss of synaptic contacts has been reported to occur, although the extent and the statistical significance of the age-related reduction of  $N_v$  depends both on the specific vulnerability to aging of the CNS area taken into account and on the method of counting. Namely, despite the fact that the early investigations on synaptic number in aging were carried out about 25 years ago (Cotman and Scheff, 1979; Bertoni-Freddari and Giuli,

1980), there is still no consensus on the criteria for counting them unbiasedly, and this has yielded a consistent amount of sometimes contradictory data (Genisman *et al.*, 1995). Profile counts, assumption-based methods, serial reconstructions, and stereological methods are the procedures that have been used to estimate the number of synapses in tissue sections, and the criteria for these methods are different, thus resulting in a marked variability of data.

In the early 1980s, the introduction of the disector as a stereological procedure for counting objects in tissue sections (Sterio, 1984) resulted in a complete break from the previous methods of counting; now this procedure is becoming the method of choice in the estimation of synaptic number because it is unbiased and easy to use. The disector may be defined as a three-dimensional stereological probe composed of pairs of sections: the reference section and a serial section called the look-up section. The volume of the disector is determined by the area of the sections and the distance between them. Objects are considered to be in the disector and counted if they can be identified in the look-up section, but not in the reference one. In order to detect all the objects to be counted, the distance between reference and look-up sections must be less than the shortest dimension of the objects; with specific reference to synaptic counts, adjacent sections can be used, and they must be located randomly within a given neural region (Bertoni-Freddari *et al.*, 2002). It must be considered that several data on synaptic numeric density have been collected according to methods used prior to the introduction and the frequent use of the unbiased stereological technique of the disector. Thus, these results cannot be compared with those obtained by the disector; however, they may be useful to estimate ratios as, for instance, synapse-to-neuron, and the conclusions drawn must be referred to the portion of the structure from which samples were obtained.

On the basis of these concepts, a decrease of synaptic number in aging has been documented by several authors in different CNS zones from different animal species and human beings, thus supporting the fact that this alteration is a ubiquitous feature of the aging brain. Reliable support to this assumption is given by relating the number of neurons to the number of synapses estimated in the same CNS zone. The synapse-to-neuron ratio is a parameter independent from artifacts of tissue processing (e.g., shrinkage) or the physiological decrease of the overall volume of a given CNS zone, thus providing reliable information on the real situation of the analyzed tissue area from a morphofunctional standpoint.

In a study conducted in CNS samples from adult, old, and demented (AD) patients at autopsy, the synapse-to-neuron ratio estimated in the cerebellum (glomerular areas in the granular layer) and hippocampus (dentate gyrus supragranular layer) showed different findings

**Figure 40.4** Synapse-to-neuron ratio in the cerebellum and hippocampus of adult, old, and demented (AD) patients. No significant difference can be seen in the cerebellar granular layer. This parameter shows a significant (52%) decrease in the hippocampal dentate gyrus of demented vs. normal old patients of the same age. This result suggests that synaptic loss per se is a prominent alteration of the demented brain in selected CNS areas.

according to the CNS zone and the health condition of the patients (see Figure 40.4). Namely, in the cerebellum there was no significant difference between adult, old, and demented subjects although a reduction of this parameter was clearly evident between the adult group and the other two groups of patients.

In the hippocampal dentate gyrus, the synapse-to-neuron ratio decreased insignificantly between adult and old patients, whereas between adult and AD patients a significant decrease of more than 50% was found. Since in both the areas investigated the number of neurons was almost unchanged with aging, these results suggest that the loss of synapses per se is a prominent and early alteration in physiological brain aging and may represent a sustainable pathological marker in AD.

#### SYNAPTIC AVERAGE SIZE

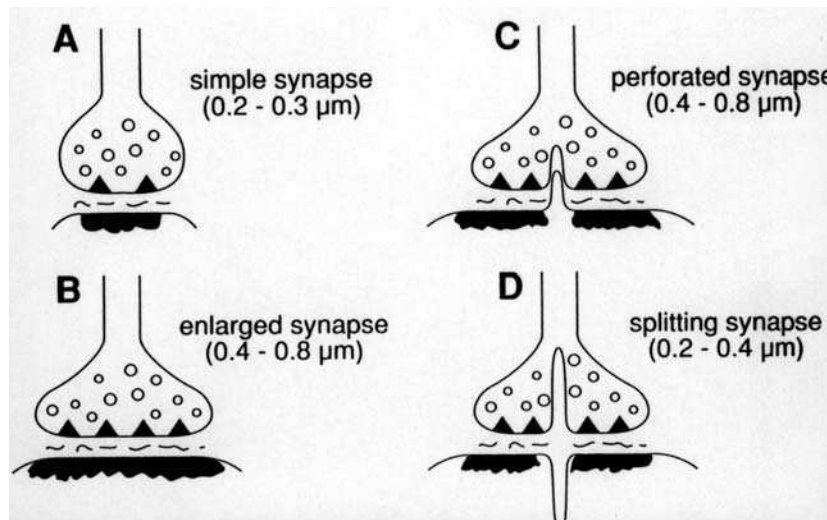

A growing number of reports from the current literature documents that synaptic size is a very sensitive ultrastructural parameter undergoing significant changes as a consequence of different environmental stimulations. Reasonably, it can be assumed that the size of the synaptic contact area may influence the amount of transmitter released and also the extent of trafficking of the many substances involved in information processing, thus strengthening the transmission of the nervous impulse among neurons. As a consequence, enlargement or reduction in synaptic size supposedly may lead to changes in function. On the other hand, the possibility to modulate the extension of the junctional zones may be considered a means to carry out a significant structural intervention on the plastic condition of the synapses. The awareness of the biological significance of changes in synaptic size has prompted the development of several methods to estimate this parameter by

applying conventional morphometric formulas since the early investigations performed around the late 1970s to early 1980s (Dyson and Jones, 1976; Bertoni-Freddari and Giuli, 1980; Hillman and Chen, 1984) up to the present application of the disector (Mayhew, 1996; Bertoni-Freddari *et al.*, 2002). Synaptic size has been frequently estimated by measuring the profile length of the postsynaptic apposition (L) in tissue samples prepared according to both the conventional osmium tetroxide method and to the E-PTA preferential technique. Some authors have considered L as the cord of circular disk (assumed to be the shape of the synaptic contact) and have calculated mathematically the radius and the area (S) of the synaptic disks. In E-PTA processed samples the postsynaptic membrane appears always sharply contrasted, which facilitates the identification and measurement of L by semiautomatic computerized procedures. In the brain of old laboratory animals and human beings it has been found that the size of the synapses is increased. Although not all the data obtained from different laboratories in old subjects are statistically significant vs. the adult values, the synaptic contact zones appear to enlarge with advancing age, and this alteration, in addition to being a feature occurring in different zones of the CNS, has also been documented in the CNS of patients suffering from AD (Bertoni-Freddari *et al.*, 1990; DeKosky and Scheff, 1990). The percent distribution of S showed that the complement of larger synapses increases in physiological aging and AD (see Figure 40.5). This occurs both in zones reported to be very vulnerable to aging and age-related pathologies (e.g., the hippocampus) and in zones documented to be less sensitive to time-related damage (e.g., the cerebellar cortex), thus supporting that this modification in the composition of the synaptic population is a ubiquitous feature of the aging CNS.

In looking for a tenable interpretation of the age- and pathology-related increased complement of enlarged synapses, some current concepts on the mechanism(s) and steps supposed to be involved in synaptic structural remodeling must be taken into account. Along with their dynamic condition, it has been clearly demonstrated that the synaptic junctional areas undergo continuous rearrangements of their ultrastructural features, and, accordingly, some papers report studies proposing mechanisms and suggesting sequential steps occurring during the functional modulation of synapses (Carlin and Siekevitz, 1983; Wolff *et al.*, 1995; Bertoni-Freddari *et al.*, 1996). Although some differences exist in the interpretation of the single steps by different authors, at present, a concept that can be reasonably sustained is that, as a consequence of repeated stimulations, the synaptic size (0.2–0.3  $\mu\text{m}$ ) may increase two- to threefold and up to more than 1  $\mu\text{m}$ . These megasynapses can perforate and split into smaller junctional areas that may again increase in size, perforate, and split (see Figure 40.6).

**Figure 40.5** Percent distribution of the synaptic average size (area: S) in the cerebellum and hippocampus of adult, old, and demented (AD) patients. An increased complement (%) of synapses of larger size is present in the hippocampal dentate gyrus of old and demented patients. The same change can be envisaged also in the cerebellum, although at a lesser degree.

**Figure 40.6** Proposed steps of synaptic remodeling. Each diagram reports the cross-section of a synapse. A: simple synapse reported to measure 0.2–0.3  $\mu\text{m}$ . B: on stimulation, synapse length may increase two- or threefold and even more. C: if synaptic size attains a still undefined limit, perforations may appear. D: the holes in the enlarged synapse cause a break into smaller synaptic clods that, in turn, may give rise to daughter junctions or undergo regression with disconnection of the interested area. (Reproduced with permission from *Gerontology* 42, 170–180, 1996).

The reasons why larger contact zones should divide are not known; however, since they have been found to be associated with a decrease in synaptic number, it has been proposed that synaptic enlargement is carried out as a

compensating reaction to balance the lost contacts. Thus, interpreting the results reported in aging, it can be supposed that the preceding proposed cycle of events occurring in synaptic remodeling is halted at the early step

of synaptic enlargement, thus resulting in only a partial compensation for the reduced number of junctions. Whatever mechanism(s) are activated in synaptic remodeling, the consistent presence of larger contacts in the aging CNS may be considered, at the same time, a sign of impairment and of the CNS plastic reaction to unfavorable conditions as supported by studies conducted on malnourished laboratory animals (Chen and Hillman, 1980).

#### SYNAPTIC VOLUME DENSITY

The overall area of the synaptic contact zones present in a defined tissue volume (usually  $1 \mu\text{m}^3$ ) accounts for the response capacities of the neural circuitries of a given discrete CNS area. The morphometric term to define such a parameter is surface density (Sv), and, as any other morphological feature of the synaptic junctional areas, it may undergo relevant changes as a consequence of several modulating actions including electrical stimulation, behavioral conditioning, and trophic factors. The Sv value may also be influenced by the intensity and the duration of the stimulus as well as the level of plasticity of the specific CNS zone analyzed (Desmond and Levy, 1986). Over the past two decades, the reliability of the results obtained in estimating the Sv value in different experimental models has been continuously challenged by the progressive advancements in the accuracy of the morphometric methods that are presently applied by computer-assisted image analyzers. Namely, sampling and counting of synapses have been refined repeatedly, both by improved staining methods as well as unbiased procedures, which resulted in a better estimation of the Sv value. Several converging data are now supporting that in a given CNS zone, an adequate-to-function value of Sv is maintained according to the experiential framework of each individual. During the maturation of the CNS, an optimal Sv value is attained through a balance between selective pruning of the redundant synaptic contacts and the reinforcement of those junctional areas that have undergone frequent stimulation and physiological response adaptation (Purves and Lichtman, 1980). Although the adult, fully differentiated CNS retains a high level of plasticity, significant modifications of the experience-stabilized neural circuits do not easily occur since the maintenance of Sv constancy constitutes an important prerequisite to preserve the experience-driven fine tuning of select neuronal networks representing the structural basis of acquired skills (Hillman and Chen, 1984). Memory and learning abilities also rely on adequate Sv values, since an extended network of contacts provides a micro-anatomical structural basis of these important functions. Different physiological mechanisms and biological determinants contribute to maintain constant Sv value by modulating number and size of the synaptic contact zones present in selected CNS areas, and this has led to propose the reasonable assumption of the existence of

a close relationship among these three parameters of the synaptic ultrastructure. Namely, although quantitatively measured by independent methodological approaches and analysis procedure, it appears that S and Nv are inversely correlated and that the final outcome of this balance is the Sv value. Thus, while each of these parameters provides specific information on single aspects of synaptic morphology, when taken together per experimental sample, they constitute a reliable index of synaptic plasticity from a morpho-functional point of view. Accordingly, functional decay may result from an imbalance among Nv, S, and Sv leading to altering the maintenance of the synaptic ultrastructural homeostasis. In humans, Sv has been found to be significantly decreased in the old hippocampus, whereas an age-related, not significant reduction of Sv affects the cerebellar cortex. In AD patients a further decrease of Sv occurs only in the hippocampus, probably in connection with the consistent presence in this CNS zone of senile plaques, a typical hallmark of this disease (Bertoni-Freddari *et al.*, 1990, 1996). The Sv decline in physiological aging and AD appears to be due to the numeric loss of contacts (Nv) since the average area (S) of the surviving contacts is significantly enlarged. Although it can reasonably be supported that synaptic enlargement strengthens information processing by the release of more neurotransmitters and the activation of more receptors, this reinforcement of the surviving contacts appears to be less functional than the fine-tuning of the neural networks provided by the higher density of smaller junctional areas typically found in adult individuals.

#### Neurotransmitter Systems

Neurotransmitters play a central role in neuron-to-neuron information processing and in transferring information from neurons to target cells. Classical neurotransmitters include acetylcholine, the catecholamines (norepinephrine, epinephrine, and dopamine), and serotonin. In addition, neurotransmission may be accomplished and/or modulated by amino acids, such as glycine, glutamate, and gamma aminobutyric acid (GABA), as well as peptides (e.g., enkephalin, substance P, and cholecystokinin), gas (nitric oxide and carbon dioxide), and metals, acting as neuromodulators (zinc). Nitric oxide and carbon dioxide originally were viewed as toxic, but it has been demonstrated that they can act as biological messengers in mammals. It is important to consider that different neurotransmitters may coexist within the same neuron, and this implies a vast expansion of the potential for synaptic communication. This coexistence of multiple neurotransmitters results in a reciprocal modulation of the specific action of these substances aimed at providing the adequate response from neurons to environmental stimuli by a fine balance of the inhibitory and excitatory effect of classical

neurotransmitters and their neuromodulators. Turnover, release, and binding of neurotransmitter substances constitute important steps in the mechanisms involved in signal transduction between adjacent nerve cells; therefore changes in any of them may result in functional alterations. It is well known that many synapses are identified by the neurotransmitter released, thus at terminal regions of different synapses very specific mechanisms are operating to work out these processes, and these include, in addition to the synthesis of neurotransmitters, the activity of degrading and synthesizing enzymes. Complete and reliable analysis to detect neurotransmitter changes occurring at synaptic regions should take into account studies aimed at testing proper functioning at different levels. Thus, precursor availability, synthesis of enzymes, degradation of neurotransmitters, their storage, reuptake, and ionic regulation refer to the presynaptic area, and free neurotransmitters as well as the enzymes of their degradation pertain to transynaptic events. Receptor binding, enzyme degradation, ionic regulation, and the induction of second messengers refer to the postsynaptic zone. On the basis of this high complexity of the mechanisms of neurotransmission, the knowledge accumulated on age differences regarding this function is still fragmentary and incomplete, particularly with specific reference to human studies. In humans, the measurement of neurotransmitter substances or their metabolites is carried out in urine, blood, or cerebrospinal fluid or, recently, by using labeled probes and imaging techniques. It is clearly understandable that all these methods enable an indirect and remote analysis of the neurotransmitter substance, and any subtle alteration in the physiological condition may not be identified. Despite these difficulties, a general consensus can be envisaged among the different scientific reports; that is, during physiological aging the levels and activity of neurotransmitters and related enzymes decline in many brain regions, and the corresponding receptors may or may not respond to these changes by increasing their number and/or affinity. In details, with reference to human beings, it has been found that brain acetylcholine transferase levels as well as muscarinic binding decrease in aging (Perry, 1980). The levels of striatal dopamine uptake sites, dopamine and dopamine transporters show an age-associated decline (Kish *et al.*, 1992) as do serotonin binding sites,  $\alpha 2$  and  $\beta 1$  adrenoceptors, and cortical GABAergic innervation (Allen *et al.*, 1983; Kalaria *et al.*, 1989). Alterations due to age in tissue levels of glutamate and aspartate are distributed in different brain areas (Banay-Schwartz *et al.*, 1992). Studies in different discrete zones of the CNS of laboratory animals (rats) have shown that while the concentration of serotonin is constant throughout the lifespan, dopamine and norepinephrine progressively decrease starting from adulthood. Thus, in the aging rat brain the ratio of serotonin to catecholamines progressively increases, but the functional manifestation of this imbalance may be due

to the impairment of only one of these three neurotransmitters. It must be stressed that different neurotransmitter systems show a differential rate of aging that may be responsible for an imbalance as an early event before the appearance of changes affecting a specific neurotransmitter. In summary, although several data have been obtained from animal studies, it may be assumed that alteration of function in aging may result from an imbalance among the many neurotransmitter substances and neuromodulators that could be due to deteriorative event(s) affecting any of them, rather than to specific focal impairments affecting a single neurotransmitter system.

### **Energy Metabolism: The Critical Role of Mitochondrial Function Decay**

The human brain, representing less than 2% of the body weight, receives about 16 to 17% of the cardiac output and accounts for about 20% of the total oxygen consumption in resting conditions. From these data it can easily be inferred that routine brain functions are critically dependent on the synthesis of high energy intermediates by neurons and glia, although these two types of nerve cells have different energy requirements and, of course, there are marked differences between their energy demands.

Cerebral energy metabolism in aging has been investigated in animal models and human beings by measuring different parameters, such as cerebral blood flow (CBF) and cerebral metabolic rate for glucose (CMRGlc) or oxygen (CMRO<sub>2</sub>). Noninvasive techniques have been developed during the past decades beginning in the early 1960s to measure these important parameters. Positron emission tomography (PET) is one of these currently used methods and is based on principles of computerized tomography and radioisotope imaging. Specifically in emission tomography, the image is generated by differences in the distribution in the tissue of injected or inhaled isotopes that are constituents of important biological molecules. The radiation emitted by the isotopes can be detected, analyzed, and used by a computer to visualize the zones where a specific biological molecule is metabolized. In PET, the isotopes of elements that decay after minutes or hours are normally used and emit positrons (positive charged particles similar in mass to electrons). With the exception of severe injury, such as stroke and head trauma, CBF is coupled to cerebral metabolism since neural mechanisms that need energy to be accomplished are also able to modulate the brain's blood perfusion. PET has been used to estimate local rates of CBF and the results obtained documented that in human aging a decrease in this parameter occurs in the limbic system and association areas. This is probably due to the changes that occur with aging in

cognitive functions. Other areas of the old human brain appear to be differently affected by a decrease in CBF, but the most commonly observed age-related impairment has been found in the frontal lobes bilaterally. Moreover it has been found that in aging there is a decrease of CBF in gray, but not in white, matter (Leenders *et al.*, 1990). The quantitative estimations of CBF may easily be affected by physiological, psychological, and environmental factors. However, the regional values estimated in each individual are normalized to the whole brain blood flow with the aim of eliminating variations in the measurements of absolute flow. Multiple factors may be responsible for the age-related changes in CBF, and these include a decline in the mechanisms that regulate CBF, alterations of the cerebral blood vessels due to age (e.g., mild amyloid angiopathy), and a decrease of neuron function leading to brain atrophy. The 18F-deoxyglucose is the most commonly used radiopharmaceutical for PET imaging to investigate CMRGlc or CMRO<sub>2</sub>. In aging, CMRGlc decreases in temporal, parietal, and frontal regions of the brain. CMRO<sub>2</sub> also is reported to decrease with advancing age, particularly in the gray matter in subjects over 51 years of age (Takada *et al.*, 1992). The reliability of the results on cerebral metabolism from PET analysis is challenged by measurements of brain atrophy since PET data are the outcome of an average of signals from the brain tissue and CSF spaces (i.e., the spaces occupied by the cerebrospinal fluid), and a marked atrophy may result in a lower PET value. A reasonable suggestion for a correct interpretation of PET data is that changes in brain volume must be considered. Atrophy correction of cerebral metabolism has been carried out in AD studies, and it has been documented that the AD hypometabolism is related to the loss of tissue, whereas the still existing tissue does not show metabolic differences vs. controls. Age-related brain damage and the appearance of potential neuropathological signs may depend on causative events leading to an impaired metabolism affecting different groups of neurons in which reduction of energy may result from the decay of the cell's metabolic machinery, that is, from subtle, though significant, mitochondrial dysfunctions.

#### IMPAIRMENT OF MITOCHONDRIAL STRUCTURAL DYNAMICS IN AGING

In order to accomplish their peculiar task, consisting of the coupling of respiration to ATP synthesis, mitochondria have a unique and peculiar morphology: namely, an outer membrane surrounding an inner membrane (the cristae) that surrounds an internal matrix. The ordered architecture of this topologically closed bilayered system represents a critical topographic arrangement for the mitochondrial mechanisms involved in the synthesis of adenosinetriphosphate (ATP) from adenosine diphosphate and inorganic phosphate via oxidative phosphorylation. During this process protons

are pumped into the intermembrane space by the respiratory chain located at the inner mitochondrial membrane; therefore all the reactions of the oxidative phosphorylation process (OXPHOS) significantly rely on the structural features of the organelles. Mitochondrial morphology is known to be heterogeneous and may be quite different from cell to cell of the same organ or from one cellular compartment to another within the same cell. In addition, select mitochondrial pools are in a very dynamic condition and may undergo significant ultrastructural remodeling to tailor the cellular energy providing machinery to the functional energy requirements of the actual environmental conditions (Bertoni-Freddari *et al.*, 1993; Bereiter-Hahn and Voth, 1994; Bertoni-Freddari *et al.*, 2001). Quantitative estimations of these mitochondrial structural dynamics may be carried out, in semiautomatic mode, applying morphometric procedures by computer-assisted image analyzers. Namely, volume and numeric densities (i.e., the mitochondrial volume fraction and number/ $\mu\text{m}^3$  of tissue) as well as the average size and/or shape of the mitochondria are the ultrastructural parameters currently investigated and reported to be significantly modulated by actual energy demands. It has been documented that these parameters provide information on discrete aspects of mitochondrial ultrastructure; however, they are dependent on each other. Thus the overall quantitative estimation of their reciprocal changes may represent an index of the mitochondrial functional plasticity. The clear awareness that this function-driven dynamic condition of discrete pools of mitochondria is continuously challenged by any cellular activity requiring an adequate ATP supply has led to several investigations on the many factors potentially able to modulate the mitochondrial morphological features and, in turn, the bioenergetic competence in specific cellular compartments where the organelles are located.

In agreement with this knowledge on the plastic condition of the mitochondrial morphology, the aging process has been considered as a very critical, though physiological, condition able to exert a subtle and significant modulating action on the mitochondrial structural dynamics. Several studies conducted in different organs and types of cells from various animal species and human beings document the notion that a general trend can be clearly envisaged: in old organisms mitochondria decrease in number, but increase in size; the final outcome of these balanced changes is that the overall mitochondrial volume density (i.e., the mitochondrial fraction/ $\mu\text{m}^3$  of tissue) is constant during the individual's lifespan (Bertoni-Freddari *et al.*, 1993; Solmi, 1994; Walter *et al.*, 1999) (see Figure 40.7).

An impaired duplicative capacity, due to age, may account for mitochondrial numeric loss, whereas the enlargement in the average mitochondrial volume has been considered as a compensating reaction aimed at

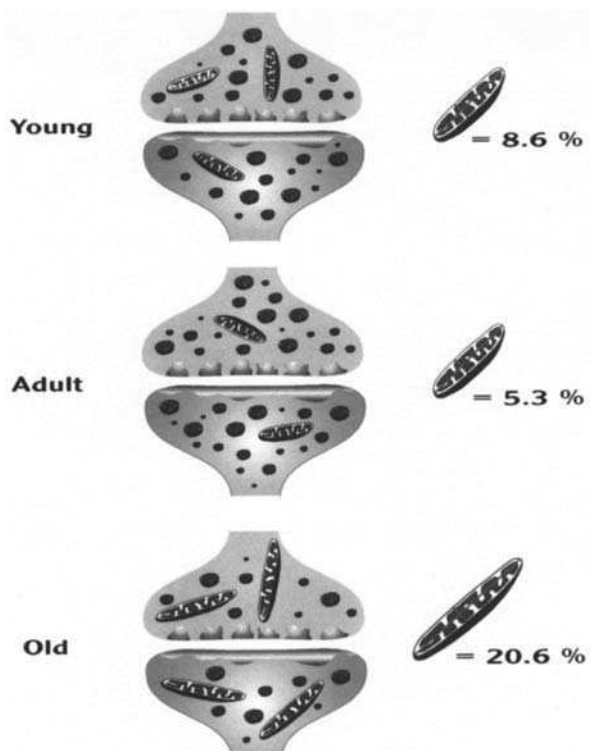

**Figure 40.7** Age-related ultrastructural alterations of rat synaptic mitochondria. The cytoplasmic volume fraction occupied by mitochondria (volume density: Vv) appears to be constant throughout the whole lifespan. With regard to the numeric density (Nv), the average mitochondrial volume (V), and the skeleton (Sk: an estimation of mitochondrial elongation), if the values of these parameters are considered 100%, in the adult rats the increase of Nv (+27%) is paired by a decrease of V (-37%) and Sk (-40%). In old rats opposite changes can be observed; that is, a 31% decrease of Nv is paired by an increase of V (+30%) and Sk (+34%).

increasing the mitochondrial area involved in cellular respiration (see Figure 40.8).

Specifically, at the synaptic terminals of old animals the percent of oversized organelles is reported to be markedly increased. Oversized organelles, also referred to as megamitochondria (MM), have been found in some adverse conditions, sometimes representing a serious threat for cell survival; therefore a positive interpretation of the consistent presence within the cell of MM is questioned. The conventional staining procedures adopted to carry out electron microscopic investigations, though enabling a better visualization of all the cellular constituents by increasing ubiquitously their contrast against the background, do not provide detailed information from a functional point of view. Thus, in order to obtain a better insight into the biological significance of any estimated ultrastructural change, specific cytochemical techniques have been developed to visualize arrays of molecules with well-defined and reliable functional meaning.

#### CYTOCHEMISTRY OF SUCCINIC DEHYDROGENASE ACTIVITY IN THE AGING BRAIN

It is currently supported that the generation of reactive oxygen species (ROS) during the physiological process of cellular respiration is not properly controlled in old cells, and this may be responsible for significant damage to mitochondrial DNA (mtDNA) and membranes resulting, with increasing mtDNA mutation and membrane deterioration load, in alterations of mitochondrial morphology and in a progressive impairment of mitochondrial

**Figure 40.8** Reactive plasticity of mitochondrial size at synaptic terminals in aging. The complement of oversized mitochondria was estimated by considering a Feretratio value threshold of  $\leq 0.2$ . (Feretratio is obtained by dividing the shorter by the longer diameter of each mitochondrion). At the synaptic terminals of old rats, the percent of megamitochondria accounts for 20.6% vs. 8.6% and 5.3% found at the synaptic regions of young and adult animals, respectively.

**Figure 40.9** SDH-positive mitochondria in the perykaryon of a CA1 pyramidal cell. The dark precipitate due to the reaction of copper ferrocyanide with the enzyme molecules is localized at the inner mitochondrial membrane. Bar: 0.5  $\mu\text{m}$ .

functions. This concept has been concisely expressed and convincingly stressed in an important paper by Linnane *et al.* (1989) reporting that in aging the mitochondrial population present in a given cell (or cellular compartment) is composed of a mosaic of units with different metabolic competence because of the different mutation load accumulated with advancing age. This concept particularly applies to the old nerve cells that accumulate mtDNA mutations both as a consequence of ROS attacks during cellular respiration and because of the number of replications of their mtDNA. Namely, in the postmitotic nerve cells, considering that the half-life of neuronal mitochondria is about four weeks (Menziés and Gold 1971), mtDNA replicates at the rate of once a month, thus in 80 to 85 year-old human beings, mtDNA has undergone replication about 1000 times, at variance with the nuclear genome that does not replicate (Toescu *et al.*, 2000). Considering the Linnane mitochondrial mosaic concept, it appears reasonable to hypothesize that the fraction of impaired or less functional mitochondria should increase with advancing age in postmitotic nerve cells, which can play an early significant role in the progressive decay in specific neuronal functional tasks (e.g., memory and learning capacities). In this context, the activity of succinic dehydrogenase (SDH) may represent a reliable parameter to verify the functional state of a given mitochondrial population. SDH, complex II of the oxidative phosphorylation (OXPHOS) process, constitutes a secondary entrance of the electron transport chain and has been reported to play a critical role when mitochondrial oxidative capacity is high. SDH is the only mitochondrial enzyme common both for electron and carbon fluxes, thus representing the unique molecule for cross control between cellular respiration and the Krebs cycle. Frequent burst of activity requiring adequate ATP amounts is an almost physiological condition of nerve

cells; thus the activity of SDH reasonably may be considered as a reliable marker of the efficiency of ATP provision in neurons when energy demand is high. SDH activity can clearly be evidenced within single organelles by the preferential cytochemical reaction of copper ferrocyanide. As originally documented in the mid-1960s by Ogawa *et al.* (1968), the ferricyanide readily accepts electrons from the respiratory chain and is reduced to ferrocyanide that is captured by copper at the site of the enzyme activity. In turn, this molecule is trapped at mitochondrial cristae in the form of insoluble, electron opaque precipitate (see Figure 40.9).

SDH-positive mitochondria are easily identified at the electron microscope, and their ultrastructural features can be estimated reliably by conventional morphometric methods. In performing the preferential staining of SDH by the copper ferrocyanide method, only fresh samples can be used since the tissue must not be fixed to preserve SDH activity. Although this limits these studies to laboratory animals or human bioptic material, the data obtained may be considered as a reliable estimation of the actual oxidative capacity of the mitochondrial population analyzed. Studies conducted in old rats have shown that the volume density of SDH-positive mitochondria (i.e., the fraction of organelles/ $\mu\text{m}^3$  of cytoplasm or neuropil) is significantly decreased in the perykaria of large-sized neurons, such as cerebellar Purkinje cells and hippocampal CA1 pyramidal cells. In both these types of cells, this decrease is due to a significant numeric loss of the SDH-positive organelles, even though their average volume does not change significantly. Because of their large size, Purkinje and CA1 cells are reliable neuronal models to investigate cellular bioenergetics in aging since their extended dendritic trees and lengthy projections need high amounts of energy for normal maintenance and function, thus being

particularly sensitive to any change in ATP supply. Considering the previously mentioned SDH functional features, these data support the idea that, in aging, neuronal mitochondria may not be able to match the energy needs for proper function when ATP demand is high.

#### CYTOCHEMISTRY OF CYTOCHROME OXIDASE ACTIVITY IN THE AGING BRAIN

On the basis of the age-related constancy of the mitochondrial volume density ( $V_v$ ), reported by many investigations using conventional electron microscopic methods, ATP supply is supposed to be adequate to the physiological housekeeping processes of the neuron in resting conditions. Namely, because of the known dynamic condition of mitochondrial morphology, the ultrastructural features of a given population of organelles (i.e., size, number, and volume density) appear to be modulated according to actual physiological stimulations reasonably to facilitate the provision of adequate ATP amounts needed for the cell's proper response to environmental challenges. An obvious question is whether the age-related rearrangements in mitochondrial morphology have any functional significance. According to Linnane *et al.*'s mosaic concept, the heteroplasmic status of a given mitochondrial population implies that each organelle is characterized by its own functional efficiency. This very specific and functional mitochondrial metabolic feature, defined as mitochondrial metabolic competence (MMC) (Bertoni-Freddari *et al.*, 2003, 2005), has been tested in aging by preferential cytochemistry of cytochrome oxidase (COX) activity measured in single organelles by computer-assisted image analyzers and morphometric programs. COX, an integral transmembrane protein of the inner mitochondrial membrane, is the terminal enzyme of the electron transport chain (complex IV) and represents a reliable endogenous marker of neuronal metabolism (Wong-Riley, 1989). By using diaminobenzidine (DAB) as electron donor, COX activity can be preferentially evidenced at the inner mitochondrial membranes as dark reaction deposits (see Figure 40.10).

The overall area of the DAB-COX cytochemical precipitate, measured within each mitochondrion by computer-assisted quantitative methods, represents the surface fraction of the inner membrane of the mitochondria directly involved in cellular respiration, and it also accounts for COX activity. Namely, to observe an accumulation of the cytochemical precipitate, the continuous oxidation of cytochrome *c* by COX is needed. Therefore the overall area of the dark deposits at the inner membranes of the mitochondria is proportional to the functional and actual activity of the enzyme and the ratio ( $R$ ) between the area of the precipitate, and the overall area of the mitochondrion may be considered as a reliable MMC estimation (Bertoni-Freddari *et al.*, 2003, 2005). A recent investigation carried out on synaptic mitochondria in the cerebellum of adult and old rats has

**Figure 40.10** COX-positive mitochondrion at synaptic terminals in the rat cerebellar cortex (glomerular areas in the granular layer). The cristae and the inner mitochondrial membrane appear preferentially stained by the reaction of diaminobenzidine with the enzyme molecules and subsequent osmium staining. The overall area of the reaction deposits (that can be easily measured by an image analyzer) accounts for the fraction (%) of the surface of the inner mitochondrial membrane involved in cellular respiration. Bar: 0.5  $\mu\text{m}$ .

compared the age-related MMC vs. size of each mitochondrion. In old animals the MMC of small and medium-sized organelles was significantly decreased by 31.6 and 26.4%, respectively (see Figure 40.11), but in both adult and old rats the fraction of enlarged mitochondria appeared to show the same capacity for ATP provision (the value of  $R$  was 0.30 in adult rats and 0.29 in old rats).

Most of the mitochondria of a given population (80 to 95%) is represented by small and medium-sized organelles. The provision of ATP required for cellular metabolic needs is in charge of this fraction of organelles, and the enlarged ones are suggested to represent an intermediate ultrastructural feature in the genesis of new mitochondria or in the functional remodeling of the existing mitochondria following fusion. Conceivably, the complement of smaller mitochondria appear to be of critical importance from a functional standpoint since the decreased numeric density of mitochondria found at the aging synaptic terminals is due to a significant loss of the organelles of this size. On the other hand, the age-related increase in the fraction of the enlarged mitochondria, according to their lower value of  $R$ , appears to represent a weak compensating reaction.

By taking together the age-related alterations in mitochondrial ultrastructure as well as SDH and COX activities, it appears that the decay of MMC may play an early and critical role in the development and progression of synaptic pathology associated with physiological and pathological brain aging.

#### Calcium Homeostasis

Several physiological processes ranging from cell division to muscle contraction to secretion and neurotransmission

#### 40. Neurobiology of the Aging Brain

**Figure 40.11** Age-based comparison of the quartile values of R (area of the COX cytochemical precipitate/overall area of each mitochondrion). The quartile values are the respective means of the I, II, III, and IV groups of data ordered by increasing values of the area of synaptic mitochondria (from the rat cerebellar cortex). In adult animals there is a progressive decrease in R (quartiles I–II:  $-4.7\%$ , quartiles II–III:  $-9.3\%$ , quartiles III–IV:  $-11.5\%$ ); in old rats an increasing trend can be envisaged (quartiles I–II:  $+2.6\%$ , quartiles II–III:  $+3.0\%$ , quartiles III–IV:  $+2.7\%$ ). The paired-quartile decreases in R due to aging were: I ( $-31.6\%$ ), II ( $-26.4\%$ ), III ( $-16.4\%$ ), IV ( $-3.0\%$ ). As clearly shown by the intersection point of the two lines, the very large mitochondria showed almost the same values of R (adult animals 0.30, old animals 0.29). (Reproduced with permission from *Naturwissenschaften* 92, 82–85, 2005.)

are accomplished through proper movements of calcium ions. In aging most of these processes decline, and this has suggested the hypothesis that a defective calcium homeostasis may represent an early change responsible for functional decay. The nervous system appears to be very vulnerable to an altered calcium homeostasis since many brain functions depend on many calcium-regulated processes. Within the cell, calcium can be found as bound and free (ionized) and its concentration is maintained at around  $10^{-7}$  M by complex processes. Intracellular organelles, such as endoplasmic reticulum and mitochondria, sequester calcium that can be extruded across the plasma membrane by energy-dependent transport systems. The equilibrium between uptake and efflux mechanisms across the plasma and organelle membranes balances the set point for calcium concentration within the cell or a given cellular compartment. Specific calcium binding proteins (calmodulin, calbindin, troponin, and vitamin D-dependent protein) as well as negatively charged residues within or at the surface of the cell membranes (sialic acid) can bind calcium and modulate the free cytosolic calcium concentration  $[Ca^{2+}]_i$ . Changes in any of these aspects of calcium homeostasis may alter calcium-dependent processes. In looking for age-dependent changes in calcium regulation leading to cellular dysfunction, very subtle alterations in the cell's ability to respond to normal stimuli must be investigated since the changes may be so subtle that they are clearly manifest only when cells are severely stressed, for example, by adverse conditions or excessive stimulation.

By taking into account the multiple roles that calcium plays in neurotransmission and intracellular signaling, it appears reasonable to suppose that minor changes in calcium-regulating processes in neurons may result in the alterations affecting cognition and behavior reported in aging. Because of the complexity of the overall cellular calcium regulation, the identification of alterations due to age in calcium-handling systems is a rather difficult task. Direct measurement of intracellular calcium is possible only in isolated cells or tissue slices that do not mirror exactly the actual situation present in the living tissue; therefore, this enables data to be obtained on very discrete aspects of intracellular calcium regulation. Moreover,  $Ca^{2+}$  relays the signals elicited by the first messengers to their omnidirectional destinations: this  $Ca^{2+}$  dynamic signaling involves  $[Ca^{2+}]_i$  fluctuations within very short time frames (fraction of millisecond) that add further complications in measuring basal levels of calcium even in isolated cells (Chen and Fernandez, 1999). Despite these difficulties, several reports document that in the aging nerve terminals calcium handling is slower and less effective than in terminals from younger laboratory animals. Namely, in aged rats presynaptic  $Ca^{2+}$  signals are prolonged or  $Ca^{2+}$  clearance is slowed; that is, following stimulation the kinetics of the buffering or the clearing of  $Ca^{2+}$  are altered in aging, thus  $Ca^{2+}$  remains elevated for a longer period of time. Considering that calcium regulates metabolic pathways and serves important functions as second messenger, reasonably  $[Ca^{2+}]_i$  must be tightly regulated.

In agreement with this assumption, the age-related changes in  $\text{Ca}^{2+}$  homeostasis just described are supposed to underlie a decline in brain function; however, the complexity of the dynamics of  $\text{Ca}^{2+}$  regulation does not allow the interpretation of a prolonged elevation of  $[\text{Ca}^{2+}]_i$  at the old nerve terminals as necessarily deleterious for neuronal function.

### Alzheimer-like Alterations

The brain of AD patients is characterized by the consistent presence of SP and NFT, two hallmarks of structural protein precipitation occurring in neuronal aging. SP and NFT are also found, but to a lesser degree, in the brain of elderly, cognitive intact individuals. SP are focal and irregular alterations of the neuropil ranging in size from 30 to 30,000  $\mu\text{m}^2$  or more according to the age of the subject, brain size, and neuronal size distribution in the brain cortex. SP appear as a lattice of altered neurites containing at the center of the lesion, amyloid deposits (see Figure 40.12).

Shape size and composition of SP vary according to the age of the patients: younger individuals are characterized by large SP with diffuse neurites and poorly defined shape; in middle-aged subjects SP have a more regular circular shape, and in elderly patients SP show increasing amounts of amyloid and cellular debris. Beta amyloid protein ( $\beta\text{A}$ ), derived from the large precursor (APP), is the major constituent of SP amyloid.  $\beta\text{A}$  is composed of 4–8 fibrils with a  $\beta$ -pleated sheet molecular conformation, a feature that provides amyloid with birefringence after Congo red staining and fluorescence

**Figure 40.12** Classical type of SP stained by a silver impregnation technique. The central dark spot representing the focal deposition of  $\beta\text{A}$  is surrounded by dystrophic neurites. Bar: 10  $\mu\text{m}$ .

after thioflavine treatment. In classical SP, amyloid fibrils are intermingled with a large number of degenerating neuronal processes that may also surround the whole SP. In addition to  $\beta\text{A}$ , other proteins, lipids, and carbohydrates participate in SP formation. NFT are bundles of fibrillary material observed in the perikarya where they can partially accumulate or completely fill the nerve cell soma and the axon hillock (see Figure 40.13).

At the electron microscope, NFT appear morphologically heterogeneous since they contain mainly straight and paired helical filaments (PHF) in addition to other elements. PHF are composed by the microtubule associated protein tau derived from alternative splicing of a single tau gene. PHF width alternates between 8 and 20 nm with an apparent period of 80 nm. There is a wide range of NFT size and aspect that is particularly apparent in NFT located outside the cytoplasm where they look enlarged and less compact. If they look diffuse, it is difficult to differentiate them from SP. Studies conducted in post-mortem human samples have shown that an increasing tendency to develop SP and NFT is typical of some groups of neurons of larger size—that is, the pyramidal neurons found in layers III and V of the neocortex and subiculum and layer II of the entorhinal cortex. By means of a recently introduced silver impregnation procedure (Reusche, 1991), extensive quantitative analyses have shown that SP and NFT incidences increase exponentially with age and increasing neuronal size. It has been hypothesized that SP and NFT may represent different phases of the same neurodegenerative process: the formation of SP is suggested to be a primary neuronal damage affecting neurites that progresses to the onset of NFT in the perikarion (Dani and Weiss, 1994).

### Models of Brain Aging and Age-related Pathologies

The studies on aging of the human brain are hampered by the obvious difficulties of carrying out investigations on fresh samples. On the other hand, post-mortem material may provide erroneous information because of the different circumstances and factors that can affect the reliability of the data obtained. These include, first of all, the agonal state of the patient and the post-mortem delay in performing autopsy. Neurobiological, genetic, and molecular studies conducted in laboratory rodents or *in vitro* systems, have documented the vulnerability of selected pools of neurons and the changes occurring in several neural systems and molecular processing with advancing age. However, in order to get results matching as much as possible those that potentially can be found in the old human brain, some animal models have been developed. These models, though constituting abundant sources of fresh brain samples to be investigated, may be helpful in better delineating the mechanisms of

**Figure 40.13** NFT in a pyramidal neuron from an AD patient. The neuronal body and the axon hillock are completely filled in with NFT. Bar: 10  $\mu\text{m}$ .

physiological brain aging as well as the early pathogenic determinants of age-related diseases. In turn, testing of new therapeutic approaches to treat neurodegenerative diseases, such as AD, can be carried out on these models.

#### AGED NONHUMAN PRIMATES

Nonhuman primates, for example, different monkey strains, develop age-related behavioral and brain alterations similar to those found in humans. Monkeys (e.g., *Macaca mulatta*) have an estimated lifespan of more than 35 years and are the best available model to study AD pathology. Behavioral testing has shown that memory and cognition decline in the second decade of the monkey life and are particularly evident in the mid- to late twenties. In old monkeys, dystrophic neurites, amyloid deposition, and alterations of specific neurotransmitter systems are similar, although less severe, than those reported in the old human brain and AD patients. Namely, slightly enlarged neurites and pre-amyloid deposits constitute the earliest lesions found in the parenchyma of the cortex of the animals around 20 years of age. In addition to the classical alterations found in the human brain (i.e., neurites containing membranous elements, degenerating mitochondria, lysosomes, APP, phosphorylated neurofilaments) in the neuronal perikarya, axons, and neurites within SP containing  $\beta\text{A}$  of old monkeys, an APP-like immunoreactivity has been found. This implies that neurons may serve as a source

of some  $\beta\text{A}$  deposits. As in humans, in the old monkey brain nonneuronal cells may participate in the formation of  $\beta\text{A}$  as shown by the proximity of this peptide to reactive astrocytes, microglia, and vascular cells. On the basis of these features, nonhuman primates appear to represent a reliable animal model of aging to investigate the many alterations occurring in the old human brain.

#### TRANSGENIC MICE

Transgenic mouse models have been developed through the expression of mutated APP (or the overexpression of its wild type) to study the involvement of  $\beta\text{A}$ -containing fragments in AD-type abnormalities. Among the many transgenic mice, the PDAPP mouse is one of the best characterized since it develops  $\beta\text{A}$  accumulation in neocortex and hippocampus after 12 months of age. These mice show consistent pathological symptoms before  $\beta\text{A}$  accumulates, thus suggesting that neuronal pathology may come from developmental abnormalities or that soluble  $\beta\text{A}$  is responsible for these alterations. Namely, loss of dendritic arborizations leading to a reduction in the volume of the dentate gyrus is apparent as early as three months of age.

As in AD, the initial accumulation of  $\beta\text{A}$  occurs in the entorhinal cortex and dentate gyrus, but in PDAPP mice a minimal neuronal death occurs, at variance with AD. In a mouse model with mutations of APP and presenilin 1, neuronal death is significant, and the selective

vulnerability of neurons (e.g., the hippocampal CA1 pyramidal cells) is similar to the results found in AD patients. In this model, at variance with the PDAPP one, loss of neurons close to and in zones devoid of  $\beta$ A deposits is the same, which suggests that aggregation of  $\beta$ A into plaques does not necessarily imply neuron loss. Conceivably, it is clearly apparent that comparison of the results obtained from different transgenic mice may help to envisage the sequential events involved in age- and pathology-related alterations of the brain.

## Conclusion

The process of aging is characterized by a marked heterogeneity among individuals, a hallmark that is reflected also by the different groups of brain cells accomplishing different tasks. Although composed by fully differentiated postmitotic cells, the brain retains a consistent potential for adaptive response even in old individuals. Compensating reactions are actively counteracting age-related alterations, thus masking the decay of specific functions until a critical threshold of impairment is attained. Several determinants are reported to play a role in brain aging, and these may affect interdependent processes that, in turn, compromise the proper efficiency of selected neural network. As a final outcome, coping with environmental stimuli becomes increasingly difficult, particularly under excessive stimulation or stress, and impairment of function becomes clearly apparent. Current literature data support the idea that early disturbances occur on synaptic and mitochondrial functions both in physiological aging and in the progressive pathogenesis of age-related neurodegenerative diseases. This suggests that both synapses and mitochondria may constitute reliable targets for early therapeutic interventions at least to decrease the severity of the alterations occurring in human brain aging.

# Mitochondrial DNA and Aging

Mikhail F. Alexeyev, Susan P. LeDoux, and Glenn L. Wilson

*The goal of this chapter is to introduce the reader to the current state of the mitochondrial theory of aging as it pertains to mitochondrial DNA (mtDNA). Several aspects will be covered, including a basic biology of mitochondrial DNA, the experimental evidence supporting the mitochondrial theory of aging, and the experimental data that appear to contradict this theory. Finally, an overview of experimental approaches used to study mtDNA in aging will be presented, and weaknesses of each approach will be discussed.*

## Introduction

Aging can be defined as a multifactorial phenomenon characterized by a time-dependent decline in physiological function (Mandavilli *et al.*, 2002). This physiological decline is believed to be associated with an accumulation of defects in metabolic pathways. It has been almost 50 years since Harman first put forward his free radical theory of aging (Harman, 1956). Over the years it has been refined to include not only free radicals, but also other reactive species, such as hydrogen peroxide. Another important development was the identification by Harman, in 1972, of mitochondria as a biological clock. Despite its intellectual simplicity, this theory was as universally rejected initially as it is universally accepted today. RNA, proteins, and other cellular macromolecules that are turned over rapidly are poor candidates for progressive accumulation of damage over a lifetime. Therefore, even early studies on the mechanisms of aging focused on DNA (e.g. Price *et al.*, 1971). In mammalian cells, mitochondria and the nucleus are the only organelles that possess DNA. However, until recently the mitochondrial genome has received less attention than its nuclear counterpart in the context of aging.

Today we have at our disposal an overwhelming body of evidence in support of the mitochondrial theory of aging, yet the amount of discordant data continues to grow as well. The controversial nature of the experimental results appears to be rooted in both the intrinsic complexity of the aging process and the imperfection of experimental tools available today. Here, we will review both the role played by mitochondrial DNA (mtDNA)

in the aging process and experimental approaches used to study mtDNA.

## Basic mtDNA Biology

Human mtDNA is a circular double-stranded molecule that is 16,569 bp long (other sequenced mammalian mitochondrial genomes have similar lengths; see Figure 41.1).

It carries 37 genes, of which two encode rRNAs, 22 encode tRNAs, and 13 encode polypeptides. All 13 mitochondrially encoded polypeptides represent components of the electron transfer chain (ETC). Of these, seven are subunits of complex I (NADH dehydrogenase), three are subunits of complex IV (cytochrome c oxidase), two are subunits of complex V (ATP synthase), and cytochrome b (a subunit of complex III). The inheritance of mtDNA is almost exclusively maternal, although instances of paternal inheritance have been reported in humans, mice, and birds. mtDNA is present in one to several thousand copies per cell and is *encapsulated* into mitochondria between 1 and 11 copies per mitochondrion, with the mean being two genomes per organelle. Mitochondria are dynamic structures that, in different cell types and under different physiological conditions, can assume a variety of conformations, the two extremes being *reticular* (all mitochondria in a cell are fused to form a network) and *particular* (each mitochondrion exists as a separate entity). In both conformations, mitochondria perpetually undergo the processes of fission and fusion. Therefore, the earlier definitions of reticulate and particulate mitochondrial conformations are relative terms referring to a snapshot of the mitochondrial network in a cell. Nevertheless, these terms are useful as they describe the prevalence of either mitochondrial fission (particulate conformation) or fusion (reticulate conformation) in a given cell under given physiological conditions. In this light, the average number of mtDNA copies per mitochondrion may simply reflect the extent of mitochondrial fragmentation under the assay conditions, which is defined by two factors: a) the mitochondrial conformation inside the cell, and b) the extent of mitochondrial fragmentation during isolation for the analysis of mtDNA content.

The two mtDNA strands can be separated by denaturing CsCl gradient centrifugation. Most of the information is encoded in the heavy (purine-rich) strand

**Figure 41.1** The map of human mitochondrial DNA. OH and OL, origins of heavy and light strand replication, respectively; ND1-ND6 NADH dehydrogenase (ETC complex I) subunits 1 through 6; Cox1-Cox3, cytochrome oxidase subunits 1 through 3 (ETC complex IV), ATP6 and ATP8, subunits 6 and 8 of mitochondrial ATPase (complex V), Cyt b, cytochrome b (complex III).

(2 rRNA, 14 tRNA, and 12 polypeptides). The light (pyrimidine-rich) strand contains genetic information for only one polypeptide and eight tRNAs. Mitochondrial genes have no introns, and intergenic sequences are absent or limited to a few bases. Some genes overlap, and, in some instances, termination codons are not encoded but are generated post-transcriptionally by polyadenylation (Ojala *et al.*, 1981). mtDNA is totally dependent upon proteins encoded in the nuclear genome for its maintenance and transcription. In fact, although the mitochondrial proteome consists of an estimated 1500 polypeptides, only 13 of those are encoded by mtDNA. The mitochondrial proteome is dynamic; that is, both the precise polypeptide composition and the relative abundance of a given polypeptide may vary in mitochondrial proteomes of different tissues as well as in the same tissue over time. mtDNA replication is conducted by the heterodimeric DNA polymerase gamma. The current paradigm states that replication of mammalian mtDNA continues throughout the lifespan of an organism in both proliferating and post-mitotic cells. It occurs bidirectionally, initiated at two spatially and temporally distinct origins of replication,  $O_H$  and  $O_L$ , for the heavy and light strand origins of replication, respectively (for review, see Taanman, 1999). However, this paradigm recently has been challenged, and evidence has been presented for bidirectional  $\theta$ -like replication initiated over a fairly wide zone (Yang *et al.*, 2002). With the discovery of mitochondrial diseases caused by mutations of mtDNA,

it has been found that wild-type (WT, normal) and mutated mtDNA may coexist in the same cell, a condition called *heteroplasmy*.

## mtDNA Damage and the Mitochondrial Theory of Aging

Despite the fact that in animal cells mtDNA comprises only 1 to 3% of the genetic material, it has been argued that its contribution to cellular physiology could be much greater than would be expected from its size alone. For instance:

1. It mutates at higher rates than nuclear DNA, which may be a consequence of its close proximity to the electron transfer chain (ETC).
2. It encodes either polypeptides of ETC or components required for their synthesis. Therefore, any coding mutations in mtDNA will affect the ETC as a whole. This could affect both the assembly and/or function of the products of numerous nuclear genes in ETC complexes.
3. Defects in the ETC can have pleiotropic effects because they affect cellular energetics as a whole.

Several lines of evidence indirectly implicate mtDNA in longevity. The Framingham Longevity Study of Coronary Heart Disease has indicated that longevity is more strongly associated with age of maternal death than that of paternal death, suggesting that mtDNA inheritance might be involved. On the other hand, longevity was shown to be associated with certain mtDNA polymorphisms. For instance, Italian male centenarians have an increased incidence of mtDNA haplogroup J, whereas French and Japanese centenarians have increased incidences of G to A transition at mt9055 and C to A transversion at mt5178, respectively. However, a study of an Irish population failed to link longevity to any particular mitochondrial haplotype, suggesting that factors other than mtDNA polymorphism also may play a role in aging (Ross *et al.*, 2001).

Mitochondria have been shown to accumulate high levels of lipophilic carcinogens such as polycyclic aromatic hydrocarbons. When cells are exposed to some of these compounds, mtDNA is damaged preferentially. Other mutagenic chemicals, such as chromium (VI), N-methyl-N'-nitro-N-nitrosoguanidine (MNNG), 4-nitroquinoline 1-oxide (4NQO), and aflatoxin B1 also have been shown to preferentially target mtDNA. Therefore, it is conceivable that life-long exposure to certain environmental toxins could result in a preferential accumulation of mtDNA damage and accelerate aging. However, perhaps the most relevant kind of insult to which mtDNA is exposed is oxidative damage. The lack of protective histones and close proximity to the ETC, whose complexes I and III are believed to be the predominant sites for the reactive

**Figure 41.2** “Vicious cycle” during which ROS produced in ETC lead to the inhibition of mtDNA transcription and ETC activity, resulting in even higher levels of ROS production.

oxygen species (ROS) production inside the cell, make mtDNA extremely vulnerable to oxidative stress. Indeed, the free radical theory of aging states that it is the mitochondrial production of ROS and the resulting accumulation of damage to macromolecules that causes aging. Cumulative damage to biological macromolecules was proposed to overwhelm the capacity of biological systems to self-repair, resulting in an inevitable functional decline. The mitochondrial theory of aging can be considered as an extension and refinement of the free radical theory. Its major premise is that mtDNA mutations accumulate progressively during life, and are directly responsible for a measurable deficiency in cellular oxidative phosphorylation (OXPHOS) activity, leading to enhanced ROS production. In turn, increased ROS production results in an increased rate of mtDNA damage and mutagenesis, thus causing a “vicious cycle” of exponentially increasing oxidative damage and dysfunction that ultimately culminates in death (see Figure 41.2).

Since Miquel *et al.* first suggested that mtDNA might be damaged in aging (Miquel *et al.*, 1980), numerous studies over the past two decades have provided a wealth of information consistent with the predictions of the free radical/mitochondrial theory of aging.

#### OXIDATIVE DAMAGE IN CELLS, AND IN PARTICULAR, IN mtDNA, IS UBIQUITOUS, SUBSTANTIAL, AND, LIKE MORTALITY RATES, INCREASES EXPONENTIALLY WITH AGE (SOHAL AND WEINDRUCH, 1996)

Exhalation of ethane and n-pentane, indicators of ROS-mediated lipid peroxidation, increase with age. mtDNA was shown to accumulate oxidative damage in an age-dependent manner in skeletal muscle, the diaphragm, cardiac muscle, and the brain. Additionally, an age-related increase in oxidative damage to mtDNA appears to be more substantial than oxidative damage to nuclear DNA in houseflies. In rodents, an age-related increase in 7,8-dihydro-8-oxoguanine (8-oxodG), a mutagenic DNA

base lesion caused by oxidative stress, was observed in mtDNA isolated from the livers of both rats and mice (Hamilton *et al.*, 2001). Dietary restriction, which is known to retard aging and increase the lifespan in rodents, has been found to significantly reduce the age-related accumulation of 8-oxodG levels in nDNA in all tissues of male B6D23F1 mice and in most tissues of male F344 rats. This study also showed that dietary restriction prevented the age-related increase in 8-oxodG levels in mtDNA isolated from the livers of both rats and mice (Hamilton *et al.*, 2001). Another study found that the activities of the DNA repair enzymes for 8-oxoguanine, hypoxanthine, and uracil increase in liver extracts of Wistar and OXYS rats with age. In both strains, 8-oxoguanine DNA glycosylase (OGG1) activities were about 10 times greater in nuclear extracts than in mitochondrial extracts (Ishchenko *et al.*, 2003). However, although OGG1 activity in nuclear extracts remained relatively constant throughout the study, this activity increased with age in mitochondrial extracts. Importantly, in OXYS rats, which are characterized by the overproduction of ROS, high levels of lipid peroxidation, protein oxidation, and decreased life span, the levels of mitochondrial OGG1 activity were greater than in normal Wistar rats, and an increase in this activity began earlier (Ishchenko *et al.*, 2003). The increase in 8-oxodG levels in mtDNA with aging appears to be a general phenomenon and has been reported by several groups (Hudson *et al.*, 1998; de Souza-Pinto *et al.*, 2001). The steady-state concentration of 8-oxodG in mitochondrial DNA was shown to be inversely correlated with maximum lifespan (MLSP) in the heart and brain of mammals, such that slowly aging mammals show lower 8-oxodG levels in mtDNA than rapidly aging ones (Barja and Herrero, 2000). Furthermore, these authors show that this inverse relationship is restricted to mtDNA, due to the fact that 8-oxodG levels in nuclear DNA were not significantly correlated with MLSP. The correlation between 8-oxodG and MLSP was better in the heart and in the brain, possibly in part because these organs are composed predominantly of postmitotic cells (Barja and Herrero, 2000).

#### LONGER LIFE EXPECTANCY IN ORGANISMS BELONGING TO THE SAME COHORT GROUP IS ASSOCIATED WITH RELATIVELY HIGHER LEVELS OF ANTIOXIDANTS AND LOWER CONCENTRATIONS OF THE PRODUCTS OF OXYGEN FREE RADICAL REACTIONS

All houseflies lose the ability to fly prior to death. Therefore, in an aging population, shorter-lived flies can be identified as flightless “crawlers” in contrast to their longer-lived cohorts, the “fliers.” The average lifespan of crawlers is about one-third shorter than the fliers. Levels of antioxidant defenses (superoxide dismutase (SOD), catalase (CAT), and glutathione) and products of

oxygen free radical reactions (inorganic peroxides and thiobarbituric acid [TBA]-reactants) were compared between crawlers and fliers. The fliers showed greater SOD and CAT activities and glutathione concentrations than crawlers, whereas the amount of inorganic peroxides ( $\text{H}_2\text{O}_2$ ) and TBA-reactants was higher in the crawlers than in fliers (Sohal *et al.*, 1986).

#### AN EXPERIMENTALLY INDUCED DECREASE IN OXIDATIVE STRESS RETARDS AGE-ASSOCIATED DETERIORATION AT THE ORGANELLE AND ORGANISMIC LEVELS AND EXTENDS CHRONOLOGICAL AND METABOLIC LIFE SPAN

Simultaneous overexpression of Cu, Zn SOD, and CAT in *Drosophila* was shown to increase the maximum and average lifespan by one-third, to retard the age-related accumulation of oxidative damage to DNA and protein, to increase resistance to the oxidative effects of X-ray exposure, to attenuate the age-related increase in the rate of mitochondrial  $\text{H}_2\text{O}_2$  generation, to increase the speed of walking, and to increase the metabolic potential defined as the total amount of oxygen consumed during the adult life per unit body weight (Orr and Sohal, 1994). Moreover, others have been able to extend the *Drosophila* lifespan by overexpressing either Mn-SOD or Cu,Zn-SOD in motor neurons. Very recently, it became possible to modestly increase longevity in mice by overexpressing mitochondrially targeted catalase (Schriner *et al.*, 2005). However, Schriner's report is somewhat vulnerable to technical criticisms on the grounds of the experimentally observed mosaic expression of the transgene and nonphysiological targeting of the enzyme (mitochondria in transgenic vs. peroxisomes in WT animals). In *Drosophila*, overexpression of Cu,Zn-SOD or CAT alone failed to extend lifespan (Orr *et al.*, 2003). Additionally, overexpression of Cu,Zn-SOD failed to increase longevity in mice (Gallagher *et al.*, 2000).

#### VARIATIONS IN LONGEVITY AMONG DIFFERENT SPECIES CORRELATE INVERSELY WITH THE RATES OF MITOCHONDRIAL GENERATION OF SUPEROXIDE ANION RADICAL ( $\text{O}_2^{\cdot-}$ ) AND $\text{H}_2\text{O}_2$

As has been mentioned earlier, a longer lived subpopulation of *Drosophila* was found to have a lower rate of mitochondrial  $\text{O}_2^{\cdot-}$  and  $\text{H}_2\text{O}_2$  generation (Sohal *et al.*, 1986). Similar results were observed in a recent cross-species study of bats, shrews, and mice, where mitochondria from long-lived bats were found to produce half to one-third the amount of hydrogen peroxide per unit of oxygen consumed compared to mitochondria from shrews and mice, respectively (Brunet-Rossini, 2004).

#### RESTRICTION OF CALORIC INTAKE LOWERS STEADY-STATE LEVELS OF OXIDATIVE STRESS AND DAMAGE, RETARDS AGE-ASSOCIATED CHANGES, AND EXTENDS THE MAXIMUM LIFE-SPAN IN MAMMALS

Reducing dietary intake has been shown to be the most effective means for modulating the aging processes in laboratory rodents (Weindruch *et al.*, 1986). Dietary restriction also has been shown to be a modulator of membrane lipid peroxidation and cytosolic antioxidant status. Lee *et al.* studied the anti-ROS action of dietary restriction by quantifying the formation of the  $\text{O}_2^{\cdot-}$ ,  $\text{OH}^{\cdot}$ , and  $\text{H}_2\text{O}_2$  by liver microsomes from rats of various ages. The results show that the *ad libitum*-fed group maintained a higher production of  $\text{O}_2^{\cdot-}$  and  $\text{OH}^{\cdot}$  radicals when compared to the food-restricted group of the same age.  $\text{H}_2\text{O}_2$  formation followed the same trend but was statistically greater only at three and six months of age. The food-restricted group displayed higher SOD activity in both cytosolic and mitochondrial fractions compared to *ad libitum*-fed controls (Lee and Yu, 1990). These data indicate that the ROS activity observed in liver microsomes of *ad libitum*-fed rats can be attenuated by dietary restriction, thereby providing a possible mechanism for its life-extending action.

#### MTDNA MUTATIONS ARE PATHOGENIC AND CAN INCREASE ROS PRODUCTION BY MITOCHONDRIA

The discovery, in 1988, that mtDNA mutations can be pathogenic has provided a major support for the mitochondrial theory of aging. That year, several groups reported that both mtDNA point mutations and deletions could be the underlying cause of defined human pathologies. Moreover, being heteroplasmic, these diseases have revealed that not all the mtDNA copies in a cell need to be mutated in order to achieve a disease state. The last decade produced an explosive growth of the number of mtDNA mutations implicated in human disease. The recent release of the Mitomap database lists almost 200 pathogenic point mutations, single nucleotide deletions and insertions (Brandon *et al.*, 2005). Not only have mitochondrial diseases revealed a causative link between mtDNA mutations and pathology, but they also have displayed, in agreement with the predictions of the mitochondrial theory of aging, an increased oxidative burden in patients suffering from these diseases (Kunishige *et al.*, 2003; Lu *et al.*, 2003).

#### mtDNA Repair and Aging

It appears obvious that the physiological integrity of the cell must critically depend upon the integrity of its genome, which is maintained by DNA repair machinery. However, although the organization, synthesis, and repair

of nuclear DNA have been the focus of intense studies, mitochondrial DNA has received much less attention until recently.

In the nucleus, the steady state or induced levels of mutagenesis are determined by a balance between mutagenic insult and DNA repair. In contrast, early studies revealed that mammalian cells could not repair UV-induced mtDNA damage (Clayton *et al.*, 1974). Also, Miyaki *et al.* (1977) suggested that repair of mtDNA after exposure to N-methyl-N'-nitro-N-nitrosoguanidine or 4-nitroquinoline-1 oxide was absent or very slow. These findings led to the belief that damaged mtDNA was destroyed and replaced with replicated undamaged DNA. However, through the use of technical advances in the analysis of DNA repair in specific sequences (Bohr *et al.*, 1985) and the treatment of the whole mitochondrial genome as simply a unique 16.5 kb DNA sequence, it was possible to show that some types of mtDNA damage can be efficiently repaired (Pettepher *et al.*, 1991; LeDoux *et al.*, 1992; LeDoux *et al.*, 1999; LeDoux and Wilson, 2001). Currently, it is believed that mitochondria possess DNA Base Excision Repair (BER) machinery, while lacking the Nucleotide Excision Repair (NER) capacity.

Mitochondrial DNA accumulates high levels of the mutagenic 8-oxodG, arguably the most important base damage caused by ROS, and it is widely believed to play a major role in the aging process (Hamilton *et al.*, 2001). The important role played by DNA repair enzymes in the accumulation of this lesion is underscored by the fact that the liver mtDNA from knockout mice for 8-oxoguanine DNA glycosylase (OGG1, the glycosylase that recognizes this lesion) accumulates 20 times as much 8-oxodG as the mtDNA from WT control mice (de Souza-Pinto *et al.*, 2001). Interestingly, several studies have indicated that OGG1 activity in mitochondrial extracts from old rats is higher compared to extracts from young animals, which is apparently at odds with the observed accumulation of 8-oxodG in mtDNA from older animals (Hudson *et al.*, 1998; de Souza-Pinto *et al.*, 2001). The theory that explains this apparent discrepancy was put forward by Szczesny *et al.*, who have shown that in both hepatocytes from old mice and in senescent human fibroblasts, mitochondrial import of OGG1 $\beta$ , the predominantly mitochondrial isoform of OGG1, is impaired and that a significant fraction of this enzyme remains localized in the outer membrane and intermembrane space in the precursor form (Szczesny *et al.*, 2003). Because UNG, another BER enzyme, has shown a similar age-dependent impairment in mitochondrial import, these authors conclude that there appears to be a general deficiency in the import of BER enzymes into mitochondria from senescent animals and cells. Therefore, although age-related impairment in mitochondrial protein import does not necessarily extend beyond some DNA repair enzymes, it can explain the simultaneous accumulation of 8-oxodG and increased *in vitro* OGG1 activity in mitochondria

from senescent animals in some settings. However, a recent report from Bohr and colleagues has demonstrated that purified OGG1 $\beta$  is not enzymatically active and that mitochondrial OGG1 activity can be accounted for by traces of OGG1 $\alpha$ , a predominantly nuclear isoform (Hashiguchi *et al.*, 2004). These findings may present a challenge to the theory of Szczesny *et al.* or may simply indicate the existence of a yet unknown cofactor required for OGG1 $\beta$  activity in mitochondria. It should also be noted that other studies point out that the ability of mitochondria to import proteins is a dynamic function that can be modulated by various stimuli, such as thyroid hormone (Craig *et al.*, 1998), which may provide an alternative explanation for the observed phenomena. Consistent with this notion is the observation that the rate of mitochondrial import of matrix chaperonins GRP75 and HSP60, which are essential for the import of precursor proteins, increases with age (Craig and Hood, 1997). Also, there is an apparent lack of consensus in the literature regarding the increase in mitochondrial OGG1 activity with aging in both senescent cells and animals. Some groups have reported a decline in both activity and expression of several key mitochondrial repair enzymes, including OGG1 (e.g., S Shen *et al.*, 2003). One of the possible explanations for this lack of consensus is in the intrinsic variability between cell types and tissues with respect to their reliance on antioxidant defenses vs. DNA repair for the maintenance of structural integrity of mtDNA. Results from our laboratory suggest that the differential susceptibility of glial cell types to oxidative damage and apoptosis does not appear related to cellular antioxidant capacity but rather to differences in their ability to repair oxidative mtDNA damage (Hollensworth *et al.*, 2000), and that different glial cell types differ in their capacity to repair oxidative damage (Druzhyzna *et al.*, 2003)

### Experimental Evidence that Is not Readily Explained by the Mitochondrial Theory of Aging

Despite the wealth of experimental evidence in support of the mitochondrial theory of aging, there is a very significant and growing body of data that appear to be at odds with it. Thus, the rate of ROS generation by mitochondria under physiological conditions, which is a cornerstone of the mitochondrial theory of aging, has been recently critically reexamined by several groups. Hansford *et al.* have found that active H<sub>2</sub>O<sub>2</sub> production (an indirect measure of O<sub>2</sub><sup>•-</sup> generation) requires both a high fractional reduction of complex I (indexed by NADH/NAD<sup>+</sup> + NADH ratio) and a high membrane potential,  $\Delta\Psi$ . These conditions are achieved only with supraphysiological concentrations of succinate. With physiological concentrations of NAD-linked substrates, rates of

H<sub>2</sub>O<sub>2</sub> formation are much lower (less than 0.1% of respiratory chain electron flux). This H<sub>2</sub>O<sub>2</sub> production may be stimulated by the complex III inhibitor antimycin A, but not by myxothiazol (Hansford *et al.*, 1997). Staniek and Nohl further reported that mitochondria respiring on complex I and complex II substrates generate detectable H<sub>2</sub>O<sub>2</sub> only in the presence of the antimycin A. They also suggested that the rates of mitochondrial H<sub>2</sub>O<sub>2</sub> production reported by others are artificially high due to flaws in experimental design (Staniek and Nohl, 2000). Martin Brand's group capitalized on these findings and used an improved experimental design to show that mitochondria do not release measurable amounts of superoxide or hydrogen peroxide when respiring on complex I or complex II substrates, but release significant amounts of superoxide from complex I when respiring on palmitoyl carnitine (St-Pierre *et al.*, 2002). However, even at saturating concentrations of palmitoyl carnitine, in their estimation only 0.15% of the electron flow gives rise to H<sub>2</sub>O<sub>2</sub> under resting conditions with a respiration rate of 200 nmol of electrons/min/mg mitochondrial protein. Under physiological conditions, this rate should be even lower due to a) lower partial oxygen pressure, b) lower concentration of palmitoyl carnitine, and c) lower mitochondrial membrane potential. Therefore, under physiological conditions in cells with uncompromised antioxidant defenses, ROS are produced by ETC in quantities that should be efficiently scavenged by mitochondrial antioxidant systems. As a consequence, no significant oxidative damage can be expected in mtDNA due to an electron leak from ETC, provided that cells have normal levels of antioxidants. This conclusion is in agreement with the observations of Orr *et al.* (2003), who recently have reexamined their earlier findings and those of others on the effect of overexpression of antioxidant enzymes on extension of *Drosophila* lifespan. They have found that significant increases in the activities of both CuZn-SOD and CAT had no beneficial effect on survivorship in relatively long-lived yw mutant flies, and were associated with slightly decreased life spans in WT flies of the Oregon-R strain. The introduction of additional transgenes encoding Mn-SOD or thioredoxin reductase in the same genetic background also failed to cause life span extension. These authors conclude that increasing the activities of major antioxidative enzymes above WT levels does not decrease the rate of aging in long-lived strains of *Drosophila*, although there may be some effect in relatively short-lived strains (Orr *et al.*, 2003). In line with this conclusion, Van Remmen *et al.*, in their study of mice heterozygous for the MnSOD gene knockout, have found that although life-long reduction of MnSOD activity leads to increased levels of oxidative damage to mitochondrial and nuclear DNA and increased cancer incidence, it does not appear to affect aging (Van Remmen *et al.*, 2003).

As mentioned earlier, accumulation of 8-oxodG in mtDNA correlates with mitochondrial dysfunction in

aging. In addition, mtDNA 8-oxodG levels inversely correlate with mammalian life span. 8-OxodG-induced mutagenesis is prevented by removal of the lesion from mtDNA via base excision repair (BER), which involves recognition and incision of the modified base by OGG1. MtDNA from mice deficient for OGG1 accumulates 8-oxodG to 20-fold higher levels than WT controls by six months of age (de Souza-Pinto *et al.*, 2001). This elevation of 8-oxodG levels in the mtDNA of Ogg1<sup>-/-</sup> mice is almost an order of magnitude greater than is observed in old mice. One can predict, in line with mitochondrial theory of aging, that these mice would accumulate mutations in their mtDNA, which would result in the production of defective subunits for and decline in activity of mitochondrial respiratory complexes (especially complexes I and IV, to which most of mitochondrially encoded polypeptides cater), which in turn would result in accelerated aging. However, these mice are not reported to age prematurely, nor do they show any decline in mitochondrial respiratory function in the heart and liver, or signs of oxidative stress as judged by protein carbonyl content (Stuart *et al.*, 2005).

Rasmussen *et al.* assayed 13 different enzyme activities using optimized preparation techniques and found that the central bioenergetic systems, including pyruvate dehydrogenase, tricarboxylic acid cycle, respiratory chain, and ATP synthesis, appeared unaltered with age (Rasmussen *et al.*, 2003). Maklashina and Ackrell have recently critically examined the literature regarding the role of ETC dysfunction in aging (Maklashina and Ackrell, 2004). They conclude that the evidence for age-related inactivation of the respiratory chain can be challenged on the grounds of preparation purity and the use of inadequate assay procedures, and that recent experimental evidence does not support the mitochondrial theory of aging (Maklashina and Ackrell, 2004).

In contrast, Jacobs does not challenge experimental evidence supporting the mitochondrial theory of aging but rather points out that all the evidence available to date is indirect in its nature (Jacobs, 2003). He argues that studies performed so far do not address the critical issue of cause and effect; that is, does the somatic mutation of mtDNA result in OXPHOS dysfunction and increased oxidative stress? Does increased oxidative stress promote mtDNA mutagenesis? Finally, he points out that the results from his own lab suggest that, at least in a tissue culture model, progressive accumulation of mtDNA mutations due to expression of mutant DNA polymerase gamma (Pol $\gamma$ ) does not lead to significant phenotypic changes despite the accumulation of mtDNA mutations at a level three times greater than that found in aged tissues.

Very recently, however, Nils-Göran Larsson and colleagues reported the generation of a homozygous knock-in mice that express a proofreading-deficient catalytic subunit of Pol $\gamma$ , the only DNA polymerase found in mammalian mitochondria (Trifunovic *et al.*, 2004).

These mice develop a mtDNA mutator phenotype with a three- to five-fold increase in the levels of mtDNA point mutations, as well as increased amounts of deleted mtDNA. This increase in somatic mtDNA mutations is associated with reduced lifespan and the premature onset of age-related phenotypes such as weight loss, reduced subcutaneous fat, alopecia (hair loss), kyphosis (curvature of the spine), osteoporosis, anemia, reduced fertility, and heart enlargement. Thus results of this study provide the best evidence so far for a causative link between mtDNA mutations and aging phenotypes in mammals.

However, as these authors concede, the detailed kinetics of the accumulation of somatic mtDNA mutations remains to be elucidated. The mutation load in the brain of mutator mice at two months of age is already two- to three-fold greater than in six-month old WT littermates. This, and the rather uniform mutation loads between tissues, suggests that much of the accumulation of mutations may occur during embryonic and/or fetal development. Also, the onset of premature aging in this model is not accompanied, temporally, by a large *de novo* accumulation of mtDNA mutations around six months. Therefore, it appears plausible that the premature onset of aging in this model may be the result of the cumulative physiological damage caused by the high mutation load present during adult life and/or to segregation or clonal expansion of specific mutations. This is supported by the observed mosaicism for the respiratory chain deficiency found in the heart. However, since the effects of high mutational burden in mtDNA during embryonic and fetal development are poorly understood, and since very substantial mutation loads were observed in the mtDNA at the earliest time point tested in this study, we have to consider the possibility that premature aging in this model could be predetermined at the prenatal, rather than postnatal, stage (developmental programming; Cameron and Demerath 2002).

As Aubrey de Grey (2004) has pointed out recently, the only tissues directly affected by the elevated mtDNA mutation rate in these mice are those that are mitotically active. This suggests that embryonic development can be compromised by high mtDNA mutational loads, as embryonic tissues undergo active mitosis. If this holds true, then the issue of a causative relationship between mtDNA mutations and normal aging is likely to remain open, since, in normal aging, accumulation of mtDNA mutations is not observed during embryonic development. Thus, a substantial mutational load in mtDNA during embryonic development might be an important limitation of this model, and a model with an inducible mtDNA mutator phenotype should help to resolve this and other outstanding issues. Finally, mtDNA mutations in this study are generated by a mutator *Poly* rather than by oxidative DNA damage. Therefore, this study does not address one of the central premises of the mitochondrial theory of aging, namely, that oxidative mtDNA damage

is the driving force behind the accumulation of mtDNA mutations.

Earlier we discussed the support provided for the mitochondrial theory of aging by the discovery of mitochondrial disease. We might then reasonably expect, based on the mitochondrial theory of aging, that mitochondrial ROS would be causative in a significant fraction of pathogenic mtDNA mutations. We have analyzed 188 pathogenic mtDNA point mutations (Brandon *et al.*, 2005) and found that the mutagenic effect of 8-oxodG, widely regarded as a prime lesion resulting from an oxidative insult to DNA, can be implicated in the etiology of only a few mutations. Indeed, unrepaired 8-oxodG in mtDNA can pair with both C and A with almost equal efficiency resulting in G to T (and C to A on complementary strand) transversions, which account for only 5.9% of pathogenic mtDNA mutations. Even when the potentially mutagenic pool of 8-oxo deoxyguanosine triphosphate (8-oxo-dGTP, the product of cytoplasmic/matrix dGTP pool oxidation) is taken in consideration (T to G and A to C transversions), the cumulative impact of both types of mutation is still only 8.5%. For comparison, 82% (almost 10 times as many) of the pathogenic point mutations in mtDNA can be attributed to deamination of adenine and cytosine. Similarly, it was found that 8-oxodG-mediated transversions can account for only about 25% of mutations detected in both frontal cortex and substantia nigra of old subjects (Simon *et al.*, 2004). The efficient repair of 8-oxodG by BER pathways in mitochondria (Thorslund *et al.*, 2002) explains these phenomena and argues against it being the prime mutagenic lesion. Transversions, the type of mutations caused by 8-oxodG, are rare events in both nuclear and mitochondrial DNA, which also argues against 8-oxodG being the prime mutagenic lesion. Thus, the exact factors required for the accumulation of point mutations in mtDNA are yet to be fully defined. Oxidative DNA damage can produce a variety of base lesions whose mutagenic potential has not been fully elucidated (Evans *et al.*, 2004). Therefore, it is possible that other, at present unidentified, lesions are responsible for the bulk of ROS-mediated mutagenesis. Alternatively, it can be postulated that ROS do not play a major role in mtDNA mutagenesis.

## Experimental Approaches to Studying mtDNA in Aging

### DETECTION OF AGING-ASSOCIATED LARGE DELETIONS IN mtDNA

The first evidence that implicated mtDNA in aging came from the studies of mtDNA deletions (Corral-Debrinski *et al.*, 1992). Specific mtDNA deletions (e.g., “common” 5kb deletion) can be relatively easily detected by using PCR with primers that flank deletion breakpoints. The selectivity and sensitivity of the assay can be enhanced

by employing a second round of PCR with nested primers. When detecting large deletions, using short extension times in PCR reaction helps avoid amplification of large WT fragments and increases sensitivity. The tradeoff of this approach is that it does not allow for the determination of the cellular content of deleted mtDNA. However, it was possible to perform semiquantitative evaluations by conducting PCR on multiple serial dilutions of samples to normalize DNA content (Cortopassi *et al.*, 1992).

#### DETECTION OF OXIDATIVE DNA BASE DAMAGE

Electron leak from the ETC results in the formation of ROS, which may cause oxidative damage to mtDNA. To date, 24 major products of oxidative damage to DNA bases have been identified (Evans *et al.*, 2004), of which 8-oxodG has received the most attention as marker of oxidative DNA damage because it can readily be detected by various techniques. However, wide discrepancies in the reported basal levels (over two orders of magnitude) of 8-oxodG in DNA recently have prompted the establishment of the European Standards Committee on Oxidative DNA Damage (ESCODD), which consists of 27 member laboratories who will examine critically the different approaches to measuring base oxidation in DNA, in particular 8-oxodG. It is now widely recognized that the guanine in DNA is readily oxidized during sample preparation. Techniques that utilize gas chromatography followed by mass spectrometry (GC-MS) are particularly susceptible to this artifact if the derivatization step is carried out at high temperature in the presence of oxygen. Therefore, protocols currently in use address this problem by the inclusion of anti-oxidants and metal chelators during sample preparation. Several techniques were evaluated by ESCODD: HPLC with electrochemical detection (HPLC-ECD), GC-MS, and HPLC followed by tandem mass spectrometry-mass spectrometry (HPLC-MS/MS). Laboratories that employ HPLC-ECD were able to detect induced 8-oxodG with similar efficiencies with very similar dose response profiles whereas GC-MS and HPLC-MS/MS, employed in three laboratories, failed to detect a dose response. Median values for 8-oxodG in untreated cells were determined to be 4.01 per  $10^6$  guanines. However, approximately a 10-fold difference was observed between the highest and the lowest values of background mtDNA damage (ESCODD 2003). Overall, it can be concluded that because of this high variability in the background damage determined by different labs using the same techniques and starting material, any published quantitative data on the 8-oxodG content in mtDNA should be interpreted with caution.

#### DETECTION OF mtDNA DAMAGE

Quantitative Southern blot analysis can be used for the quantitation of oxidative damage to mtDNA. This method is based on the detection of strand breaks

within linearized mtDNA. These strand breaks can be generated by oxidative stress or by treatment of DNA containing oxidative base lesions with either FPG (recognizes oxidized purines) or *E. coli* endonuclease III (EndoIII, recognizes oxidized pyrimidines) followed by alkaline agarose gel electrophoresis. Under the alkaline conditions, the two mtDNA strands separate and single strand breaks occur at abasic sites created by the activity of FPG or EndoIII, which results in a decreased hybridization signal from the damaged DNA (LeDoux *et al.*, 1999).

An alternative approach for the detection of mtDNA damage was developed by Bennett van Houten. This method, QPCR, is based on the ability of the lesions present in mtDNA to block the progression of thermostable DNA polymerase on a template, resulting in a decrease of DNA amplification in the damaged template when compared to undamaged DNA (Yakes and Van Houten, 1997). The QPCR actually measures the fraction of undamaged template, which decreases with increased number of lesions.

The successful outcome of experiments with both quantitative Southern blot and QPCR is heavily dependent upon the ability to accurately measure the amount of DNA used. Spectrophotometric methods ( $A_{260}$ ) appear to be inappropriate for this purpose because of the intrinsic difficulties associated with controlling the quantity and spectrum of contaminants in DNA preparations. Fluorescence-based methods (PicoGreen and Hoechst33258 dyes), unlike spectrophotometric techniques, show little sensitivity to such contaminants as proteins, single-stranded DNA, RNA, and so on, which are common to genomic DNA preparations and therefore are deemed methods of choice. Also, when using QPCR, one has control for changes in the mtDNA copy number. Indeed, reduction in mtDNA copy number will manifest itself as DNA damage because of the reduction in the number of amplifiable mtDNA genomes in the template. To control for this problem, amplification of a short (about 300bp) fragment of the gene under the study is performed. The rationale is that encountering DNA damage in such a short fragment is an event with a very low probability, and therefore profiles of amplification of such a fragment should be essentially identical between damaged and undamaged DNA. Therefore, variations in the degree of amplification are assumed to be the result of fluctuations in mtDNA copy number, and the results of small fragment amplification are used for the normalization of the data obtained for the large (15 kb) mtDNA fragments.

#### mtDNA SEQUENCING

The total burden of mtDNA point mutations in tissues can be quantified using mtDNA sequencing. This approach measures consequences of oxidative stress and other mutagenic insults on the integrity of mtDNA. The protocol includes PCR amplification of specific DNA

## 41. Mitochondrial DNA and Aging

regions, cloning of the PCR fragments, and sequencing either resulting plasmid DNA or PCR template amplified from it (Simon *et al.*, 2004). The high sensitivity of this technique raises several technical concerns. The first is that PCR errors might be misinterpreted as somatic mtDNA mutations. The use of a high-fidelity PCR system limits this possibility. However, the fidelity of DNA polymerase can be affected by experimental conditions, and therefore the spectrum and the level of contaminants in DNA preparations can affect the level of PCR-induced mutations. The fidelity of this approach was experimentally tested by amplifying a single clone followed by a repeat cloning step. The lack of identification of any mutations out of 107 clones and nearly 98,000 base pairs of sequencing demonstrates the high fidelity of this method. A second concern is that oxidative damage to the original template DNA might lead to the induction of mutations due to replication errors in the early precloning PCR cycles. This possibility is not ruled out by the preceding control study, since cloned DNA would not necessarily have the same oxidative damage as the original DNA. However, a control study failed to detect a significant difference in mutation frequencies when the template DNA was exposed *ex vivo* to high levels of oxidative stress (Lin *et al.*, 2002). The third concern is that it remains possible that some other form of template damage that differs between DNA derived from different brain regions or from subjects of different ages may lead to PCR errors. The fourth concern is inadvertent amplification of nuclear *pseudogenes*. There are 612 independent integrations of mtDNA sequences evenly distributed over the nuclear genome. Our observations indicate that nuclear insertions of mitochondrial sequences occurred independently in human and mouse lineages after their separation from a common ancestor (see Figure 41.3).

Interestingly, no integration of the D-loop region into the nuclear DNA has occurred in either human or mouse genomes, which makes studies focused on mutations in this region free of potential artifacts introduced by amplification of pseudogenes. The interference from nuclear pseudogenes is generally pertinent only to large-scale studies because mtDNA present in the cell in a great molar excess over the nuclear DNA. Additionally, most regions of homology are relatively small and will not interfere if the experimental design involves amplification and sequencing of large mitochondrial fragments. Finally, because of the accumulation of mutations in nuclear pseudogenes, it is often possible to design primers that would specifically amplify mtDNA.

### MEASURING THE CHANGES IN THE LEVELS OF DNA REPAIR ENZYMES

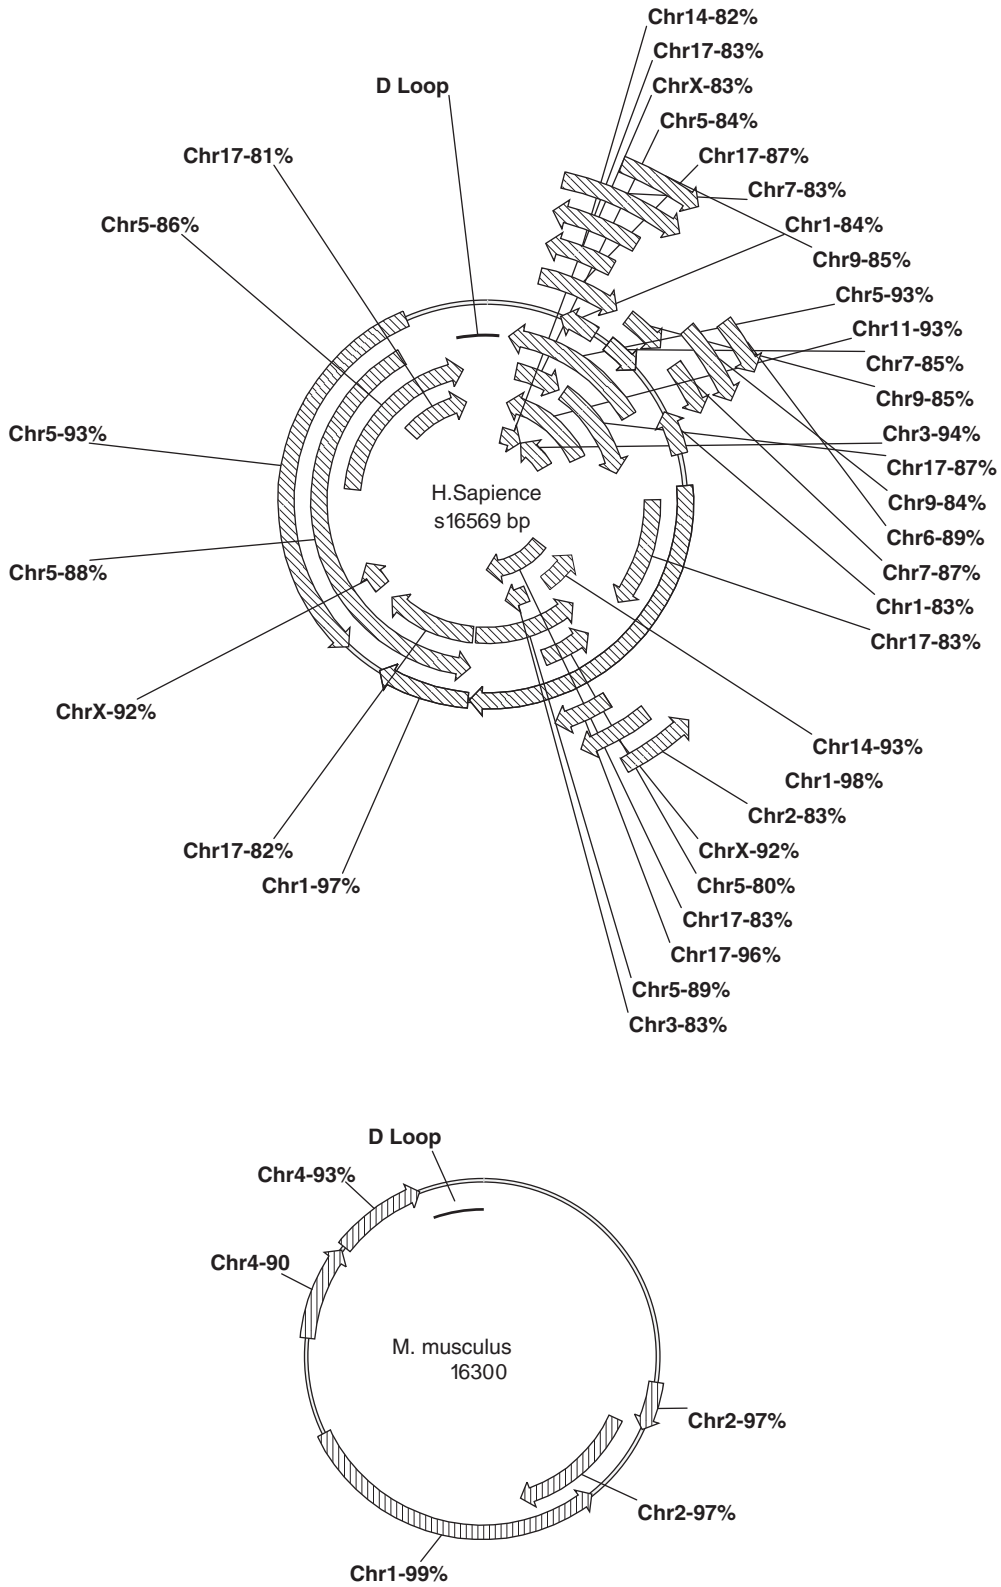

We already have mentioned that mutagenic lesions can only become a mutation if DNA repair systems fail to repair the damage. Mitochondria appear to possess a limited repertoire of DNA repair pathways, and therefore

are incapable of repairing certain types of DNA damage. However, they are proficient in BER, which operates on oxidatively damaged mtDNA. Measurements of the age-related changes in the activity of BER enzymes were used to infer mechanisms of accumulation of mtDNA mutations in aging. The methods used to evaluate activity of these enzymes are described in great detail by Nyaga and Bohr (2002) and will not be discussed here.

Earlier we mentioned the lack of consensus regarding the age-related trend in mitochondrial content of DNA-repair enzymes, with some groups reporting an increase and others reporting a decrease. Both increase and decrease in the activity of DNA-repair enzymes in mitochondria appear to be consistent with increased oxidative stress and an increased number of oxidative mtDNA lesions with aging, phenomena on which a consensus does exist. Therefore, decreased expression of DNA repair enzymes is believed to result in a decreased ability of mitochondria to repair oxidative lesions, which leads to their accumulation. On the other hand, increased expression of DNA repair enzymes was interpreted to represent an adaptive response to increased oxidative stress. The magnitude of this response is believed to be insufficient to completely protect mtDNA when oxidative stress overwhelms antioxidant and DNA-repair systems, resulting in the net accumulation of oxidative DNA lesions. This ambiguity in interpretation somewhat reduces the value of measuring changes in mtDNA repair pathways as end-point assay in studies of aging. Despite this drawback, measurements of DNA repair enzyme activities remain an invaluable component of global evaluation of mtDNA-related parameters in aging.

### Conclusion

Aging is a complex multifactorial process that we are only beginning to understand. Although the current evidence strongly suggests that mitochondria play a role in this process, there appears to be a wide range of opinions as to the exact nature of the involvement of mtDNA in aging. Contradictory data make it difficult to reach a consensus on the rates and precise mechanisms of ROS generation with aging. Unavailability of experimental tools that allow for the discrimination of the effects resulting from oxidative damage to mtDNA from the consequences of oxidative damage to other mitochondrial components adds another layer of difficulty. The lack of validated animal models of mitochondrial aging further complicates progress in this area of aging research. However, a recent report on the generation of mice with a mitochondrial mutator phenotype (Trifunovic *et al.*, 2004) may represent an important advance. Clearly, more research must be done to fully elucidate how oxidative damage to mtDNA contributes to the aging process. It is possible that the seemingly contradictory results of different studies will be reconciled or explained through the use of integrative approaches and unified model systems.

# Models for Apoptosis: From Newborn to Adult

Christiane Charriaut-Marlangue and Sylvain Renolleau

*Neurodegenerative diseases are characterized by progressive impairment of brain function as a consequence of ongoing neuronal cell death. Apoptotic mechanisms have been implicated in this process, but the immature brain differs from the adult brain in its sensitivity. To better understand the pathogenesis and developmental variations of hypoxic-ischemic neuronal death, several models have been developed and investigated to characterize cell death features in the developing brain. Involvement of apoptosis-related proteins such as Bax/Bcl-2 and caspases is overviewed during development and hypoxic-ischemic injury in various models.*

## Introduction

Ischemic stroke results from a transient or permanent reduction in cerebral blood flow that is restricted to the territory of a major brain artery. The reduction in blood flow in a specific region is, in most cases, caused by the occlusion of a cerebral artery either by an embolus or by local thrombosis. With an incidence of approximately 250 to 400 in 100,000 head of population aged 45 to 89 (Warlow, 1998) and a mortality rate around 30%, stroke remains the third leading cause of death in major industrialized countries. Hypoxic-ischemic and stroke injury to the perinatal brain is also a major clinical problem causing death in a large number of affected infants, recognized in about 1 per 4000 live term birth (Vannucci, 2000; Nelson and Lynch, 2004). More than 95 percent of infants who have a stroke survive to adulthood, and many have residual motor or cognitive disabilities (permanent neuropsychological handicaps including mental retardation, cerebral palsy, epilepsy, or learning disability) (Nelson and Lynch, 2004).

The immature brain has long been considered to be resistant to the damaging effects of hypoxia and hypoxia-ischemia (HI). However, it is now recognized that there are specific periods of increased vulnerability related to the developmental stage at the time of the insult. Much of our knowledge of the pathophysiology of cerebral HI is based on extensive experimental studies using *in vitro* and *in vivo* models relevant to mechanisms seen in humans. The major pathogenic mechanisms of brain

injury following cerebral HI include excitotoxicity, inflammation, and apoptosis. This chapter will summarize most of the commonly used models in rodents (rat, mouse) and some of the recent data on developmental differences in the immature brain that create periods of selective vulnerability to hypoxia-ischemia, and are quite distinct from the responses in adult hypoxia-ischemia.

## Models in Immature Animals

It is generally accepted that neurons in the immature brain tolerate a longer period of oxygen deprivation and/or ischemia than those in the adult (Towfighi *et al.*, 1997). However, there are conflicting reports, showing that the immature brain is less resistant to hypoxic-ischemic brain damage than its adult counterpart (Yager *et al.*, 1996). This is supported by other studies after HI or excitotoxic injury (McDonald *et al.*, 1988; Ikonomidou *et al.*, 1989; Marret *et al.*, 1995). Furthermore, clinical data suggest that outcome and mortality after acute brain injury are age-dependent, with more severe injuries in infants than in adults (Adelson and Kochanek, 1998).

Precise correlations with human brain development are difficult, in particular because of the fact that rodents present an arrhinencephalic brain. However, brains of 7-day-old rats and 10-day-old mice are similar to third-trimester (34 to 35 weeks of gestation) human fetuses (and thus premature human newborns), in terms of cellular proliferation, cortical organization, synapse number, neurochemical indices such as neurotransmitter synthetic enzymes, and electrophysiology (Hagberg *et al.*, 1994; Marret *et al.*, 1995). Cortex of the 10- to 12-day-old rats (18–35 g) could correspond to term newborn with myelination of the fiber tract beginning on approximately day 11 in the rat (Rice *et al.*, 1981). Based on these considerations, postnatal day 1 (P1) could be equivalent to 18 to 20 weeks gestation and P3 of 24 to 28 weeks gestation in humans.

## NEONATAL MODELS OF HYPOXIA

In these models, 10 to 24 hours after birth, rat pups were placed in a thermostated Plexiglas chamber flushed with

100% nitrogen for 20 min (see Table 42.1). The temperature inside the chamber was adjusted to 36°C, to maintain body temperature within the physiologic range. Under these conditions, the final rates of mortality were less than 10%. After exposure to gas, rats were allowed to recover for 20 min in normoxic conditions, and then returned to their mothers (Grojean *et al.*, 2003). Similar procedure could be performed with 7-day-old rats, but the N<sub>2</sub> duration was only of 8 min (Grojean *et al.*, 2003). A very small number of laboratories used the piglet as an animal model for hypoxia. Newborn piglets aged 2 to 5 days were ventilated with an FiO<sub>2</sub> of 5 to 7% for one hour (Ravishankar *et al.*, 2001). In these models, apoptotic and/or necrotic features were shown depending on the age of the animal (Daval and Vert, 2004; Delivoria-Papadopoulos and Mishra, 2004).

### NEONATAL MODELS OF HYPOXIA-ISCHEMIA

Until now, the most commonly used model to study hypoxic-ischemic injury in the newborn has been the Rice-Vannucci model in 7-day-old (P7, 12–20 g) rats (Rice *et al.*, 1981), adapted on the Levine procedure (Levine, 1960). The left or right common carotid artery (CCA) was cut between double ligatures of prolene sutures (see Figure 42.1A).

After the surgical procedure the wounds were infiltrated with a local anesthetic, and the pups were allowed to recover for one to two hours. The litters were placed in

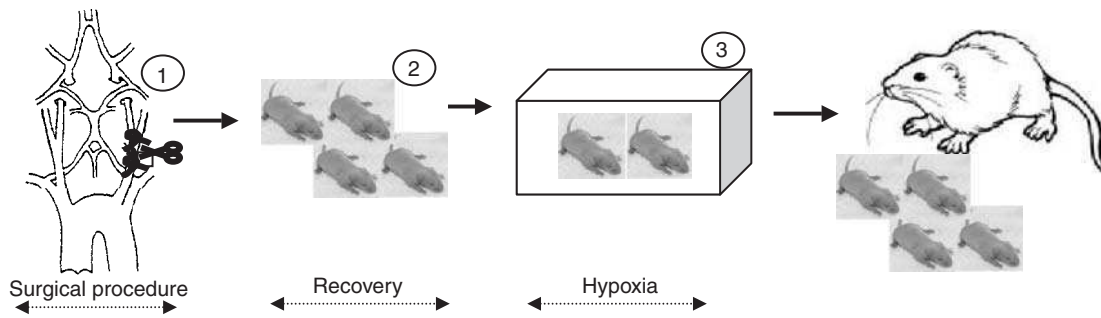

a chamber perfused with a humidified gas mixture (8% oxygen in nitrogen) for 1.5 hour. The temperature in the incubator, and the temperature of the water used to humidify the gas mixture, were kept at 36°C. After hypoxic exposure the pups were returned to their biological dam to recover for several hours or days (see Figure 42.1). The damage usually is restricted to the hemisphere ipsilateral to the ligation and is observed primarily in the cerebral cortex, subcortical and periventricular white matter, striatum/thalamus, and hippocampus. Such neuropathological damage is rarely seen in the contralateral hemisphere and never in pups rendered hypoxic without ligation (Towfighi *et al.*, 1995; Vannucci and Vannucci, 1997). However, it suffers from a certain degree of variability (animals with an infarct score ranging from 0, no infarct, to 3, very large infarct). Therefore, authors have modified two variables (FiO<sub>2</sub> and hypoxia duration) to decrease this variability and obtain a more or less reproducible lesion in most of all animals (see Table 42.1). For example, such a model performed in Hagberg's laboratory with a standardized 7.7% O<sub>2</sub> for 55 min gives a total infarct volume of 42.3 ± 15.4 mm<sup>3</sup> (Zhu *et al.*, 2003). Many investigators have used this technique to study neonatal asphyxia in several newborn species (rat pups, piglets, dogs, kittens) (Rooney *et al.*, 1997). This model was also recently extended to the immature mouse (Sheldon *et al.*, 1998), with 10% oxygen (see Table 42.1). However, it was found that some strains (CD1) are

TABLE 42.1  
Differential hypoxic and hypoxic-ischemic insults in rat, mouse, and piglet depending on the age, strain, percentage, and duration of O<sub>2</sub>, and left or right CCA occlusion or ligation

Rodent	Age Strain	Hypoxic insult	Reference
Rat	P0 (8–24 h) Sprague-Dawley	100% N <sub>2</sub> for 20 min	Daval <i>et al.</i> , 2004

## 42. Models for Apoptosis: From Newborn to Adult

### A-Rice-Vannucci model (1981)

### B-Renolleau model (1998)

**Figure 42.1** Schematic representation of Rice-Vannucci (hypoxia-ischemia, A) and Renolleau (stroke, B) models. **A:** Left, blood supply to the chest and the base of the brain. Position of the two ligatures on the common carotid artery followed by its cutting (1). Rat pups were then allowed for recovery (2). The litters were placed in a thermostated and humidified chamber perfused with a low oxygen percentage for several hours (3). At the end of hypoxic exposure, the pups returned to their biological dam. **B:** Left, MCA branching pattern with electrocoagulation site (arrow in (1)). Right, position of the vascular clip to occlude the left common carotid artery (2). Removal of the clip occurred between 50 and 60 min. After overnight recovery in a thermostated incubator (3), the pups returned to their biological dam.

particularly susceptible to brain damage in this model, whereas others (129Sv) are resistant (Sheldon *et al.*, 1998). In addition, to obtain similar extent of injury in C57/Bl6 mice whatever their postnatal age, Zhu and coauthors adjusted the duration of the hypoxia (10% O<sub>2</sub>) time from 65 min (P5) to 60 min (P9), 50 min (P21) or 40 min (P60) (Zhu *et al.*, 2005).

The Rice-Vannucci model has recently been adapted to the P1 (Sheldon *et al.*, 1996) and P3 (Sizonenko *et al.*, 2003; Stadlin *et al.*, 2003) rat. However, the model performed in P1 was not so easily performed in other laboratories because survival was not possible. In the P3 rat pups, the mortality rate decreased from 33 to 0% with decreasing hypoxia duration (45 to 10 min, respectively).

### NEONATAL MODELS OF STROKE

These models generally require a permanent occlusion of one of the two major cerebral arteries in association with a transient occlusion of the other one to produce low cerebral blood flow, because of the presence of the Circle of Willis. In the Renolleau model (Renolleau *et al.*, 1998) (see Figure 42.1B), anaesthetized rats were

positioned on their backs, and a median incision was made in the neck to expose the left common carotid artery. Rats were then placed on the right side, and an oblique skin incision was made between the ear and the eye. After excision of the temporal muscle, the cranial bone was removed from the frontal suture to a level below the zygomatic arch. Then, the left middle cerebral artery (MCA), exposed just after its appearance over the rhinal fissure, was coagulated at the inferior level of the cerebral vein (see Figure 42.1B). After this procedure, a clip was placed to occlude the left common carotid artery. Rats were then placed in an incubator to avoid hypothermia. After 50 minutes, the clip was removed. Carotid blood flow restoration was verified with the aid of a microscope. Both neck and cranial skin incisions were then closed. During the surgical procedure, body temperature was maintained at 37 to 38°C. After recovery, pups were transferred to their mothers. Such an ischemic procedure leads to damage in the frontoparietal cortex, and in 20% of animals the head of the caudate putamen was also injured. The mean infarct volume is  $58 \pm 6 \text{ mm}^3$  ( $24.3 \pm 2.2\%$  of ipsilateral hemisphere) at 48 hours of

**Figure 42.2** Presence of a cortical infarct in a model of neonatal stroke in 7-day-old rat (P7), 24 hours after reperfusion. **A:** Reperfusion was detected in the MCA territory (MCA, open black arrow, with its different branches and anastomoses), after methylene blue injected in the jugular vein, except at the low level of the MCA (little black arrow). **B:** representative Cresyl violet-stained coronal section. Note the cortical ill-defined pale area. **C–D:** T2 and ADC IRM images (7 Tesla) on 1 mm slice thickness, respectively, demonstrated the presence of a cortical infarct.

reperfusion, with only 5 to 10% animals dying in the first few hours after the clip removal (Ducrocq *et al.*, 2000; Joly *et al.*, 2004). This model evolves in a cystic infarct three weeks post-ischemia (see Figure 42.2).

More recently several groups have adapted to the newborn the filament technique of transient middle cerebral artery occlusion (MCAo) that is preferentially used in adult animal models of stroke. This includes the P7 (Derugin *et al.*, 1998) and the SHR P14 to P18 (35 g) Wistar rat (Ashwal *et al.*, 1995). Duration of endovascular nylon filament (6-0, 0.07 mm) occlusion varied from approximately 90 to 180 min MCAo. The volume of infarct involving cortical and caudoputamenal regions observed in these rat pup models is similar to that in adult models (infarct volume was of  $180 \pm 29 \text{ mm}^3$  corresponding to  $49 \pm 7\%$  of the left hemisphere). However, reliably using such a model of reversible newborn MCAo without craniectomy is technically challenging, and the survival rate was very poor during the occlusion period or within the first hours of reperfusion.

In conclusion, the different models of cerebrovascular neonatal injury at one specific age (P7, for example) can be considered complementary since they analyze different types of cerebral insults (hypoxia-ischemia versus stroke), but no single model can ever replicate the human condition. All these models exhibited apoptotic features as demonstrated by electron microscopy (Pulera *et al.*, 1998;

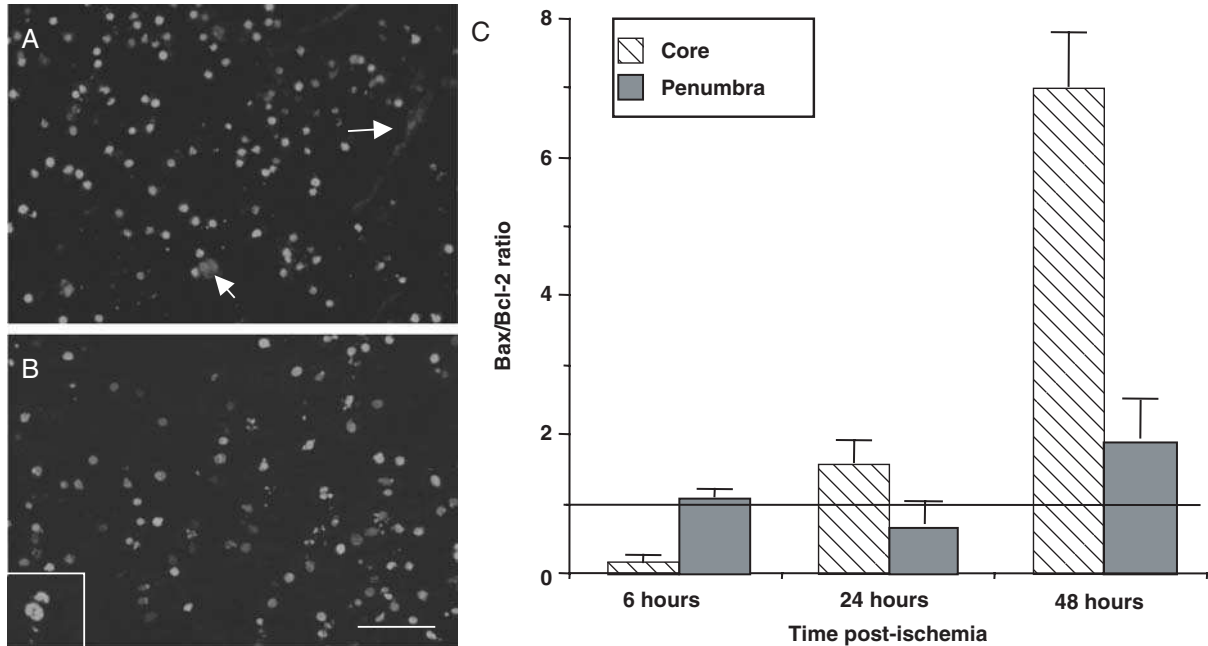

Renolleau *et al.*, 1998; Puka-Sundvall *et al.*, 2000), DNA cleavage in high molecular weight fragments and laddering (Ferrer *et al.*, 1994b; Hill *et al.*, 1995; Cheng *et al.*, 1998; Charriaut-Marlangue *et al.*, 1999) and TUNEL-positive nuclei (see Figure 42.3A, B).

## Models in Adult Rodents

Various animal models have been developed to study cerebral ischemia, and they can be broadly classified as either focal or global. Focal ischemia models try to mimic a human stroke situation, whereas global models try to replicate the consequences of global ischemia following situations such as cardiac arrest or drowning. There is no doubt that such animal studies represent only certain aspects of the complex human cerebral ischemia.

### FOCAL MODEL OF ISCHEMIA

The most stringent model of stroke or focal ischemia is permanent occlusion of the MCA via coagulation or using a suture threaded into the MCA via the internal carotid artery. Permanent MCA occlusion using the coagulation method is used mostly in rats, whereas permanent or transient MCA occlusion (pMCAo or tMCAo) can be used in mice (Benchoua *et al.*, 2001) and rats (Margaill *et al.*, 1996). Focal ischemia results in a necrotic core that is surrounded by a salvageable penumbra in which

**Figure 42.3** Apoptosis in the ipsilateral cortex after neonatal stroke in 7-day-old rat. **A-B:** Typical illustration of DNA fragmentation by the TUNEL assay in the core (A) and penumbra (B), 24 hours post-ischemia. Note the presence of a few necrotic neurons (white arrows in A) near apoptotic nuclei in the core and numerous apoptotic bodies in both the core and penumbra (insert in B). Bar represents 50 (A, B) and 25  $\mu$ m (insert in B). **C:** Evolution of the Bax/Bcl-2 positive cell ratio in the cerebral cortex. Immunohistochemical studies were performed at 6, 24, and 48 h post-ischemia. No Bcl-2 positive cells and a few (2 to 4) Bax positive cells were detected in controls. The data represent mean values  $\pm$  S.D. obtained from three separate experiments. Note a rapid Bax/Bcl-2 ratio increase in the core during time of reperfusion. In contrast, the Bax/Bcl-2 ratio evolution was delayed in the penumbra.

DNA fragmentation and apoptotic bodies could be detected by the TUNEL assay (Charriaut-Marlangue *et al.*, 1995; Charriaut-Marlangue *et al.*, 1996a; Charriaut-Marlangue *et al.*, 1996b; Du *et al.*, 1996; MacManus *et al.*, 1997; Fujimura *et al.*, 1999; Benchoua *et al.*, 2001).

#### GLOBAL MODEL OF ISCHEMIA

The global models of cerebral ischemia consist of a brief period of ischemia (5–15 min), during which complete arrest of cerebral blood flow to the brain is achieved, followed by reperfusion. The common models used are bilateral occlusion of the carotid arteries in gerbils (Cho *et al.*, 2003), occlusion of vertebral arteries and carotid arteries (four-vessel occlusion, 4VO) for 10 to 20 min (Pulsinelli and Brierley, 1979) and occlusion of the carotid arteries (two-vessel occlusion, 2VO) with concomitant hypotension to 50 mm Hg for 5 to 15 min in rats (Gill *et al.*, 2002). Global ischemia tends to result in delayed neuronal death in the hippocampus, cortex, and striatum. In general, this delayed degeneration is also believed to be necrotic (Petito *et al.*, 1997), although DNA laddering and TUNEL-positive nuclei have been reported (Heron *et al.*, 1993; MacManus *et al.*, 1993; Ferrer *et al.*, 1994b; MacManus *et al.*, 1994). Prominent apoptotic cell death occurs following global ischemia in neuronal groups that are interconnected with selectively vulnerable

populations of neurons and also in nonneuronal cells (Martin *et al.*, 1998).

#### Differential Expression of Apoptotic Proteins during Development and Aging

Many of the key elements of apoptosis have been demonstrated to be strongly up-regulated in the immature brain, such as caspase-3 (Hu *et al.*, 2000; Blomgren *et al.*, 2001), apoptotic protease-activating factor-1 (Apaf-1) (Ota *et al.*, 2002), Bcl-2 (Merry *et al.*, 1994), and Bax (Vekrellis *et al.*, 1997), and could be expected to have a prominent role in pathological situations such as HI.

#### BAX/BCL-2 PROTEINS

A differential and unique expression of apoptosis-regulating Bcl-2 family proteins has been demonstrated in the rat brain during the course of development and aging. Bcl-2 is expressed highly during embryonic development but is downregulated after birth (as early as one week) (Min *et al.*, 2003). During naturally occurring cell death (NOCD) in the rat cerebral cortex, neurons expressing Bcl-2 may determine whether a neuron dies or survives, as over-expression of Bcl-2 in transgenic mice protects neurons from NOCD (Martinou *et al.*, 1994). Low levels of Bcl-2 protein are still present in the adult

and aged brain. The sustained expression of this protein may protect neurons from various injuries or neurodegeneration. In contrast, Bcl-x<sub>L</sub> expression is maintained at a high level postnatally in the brain, suggesting that it may play an important role in the regulation of neuronal survival in the adult and aged brain (Gonzalez-Garcia *et al.*, 1995). Bax, Bak, and Bad promote apoptosis, probably by forming heterodimers with Bcl-2 or Bcl-x, and abolishing their protective function (Davies, 1995; Yang *et al.*, 1995). Bax and Bad expression decrease from embryonic to two to four weeks postnatal age (Vekrellis *et al.*, 1997; Shimohama *et al.*, 1998; Polster *et al.*, 2003), but little is known during the development and aging of the brain. In the brain of mice, Bax is highly expressed between embryonic day 19 and one-week postnatal age of early development, but thereafter the expression dramatically declines (Min *et al.*, 2003). In an immunohistochemical study, Obonai *et al.* showed that Bak expression in the cerebrum and cerebellum is high in the human fetuses and elderly subjects, but low in those of young adults, and suggested that Bak regulates neuronal death associated with the development and aging (Obonai *et al.*, 1998).

#### CASPASE PROTEINS

The expression of each caspase is differentially regulated during the development and aging of the brain. One of the most studied was caspase-3, a typical pro-apoptotic executioner protease. A profound downregulation of caspase-3 transcription has been reported between postnatal day 1 (P1) and 12 (P12) (de Bilbao *et al.*, 1999). Developmental regulation of pro-caspase-3 translation has also been reported with high and low or even undetectable levels in the newborn and adult brain, respectively (Krajewska *et al.*, 1997; Ni *et al.*, 1997; Hu *et al.*, 2000). Caspase-3 expression displays an inverse correlation with cytochrome c, as demonstrated in the rat brain (Blomgren *et al.*, 2001; Zhu *et al.*, 2003). It has also recently been demonstrated that procaspase-3 in the neonatal P7 rat cortex exists as a complex of molecular weight of 170 kDa (Kurosu *et al.*, 2004). Caspase-7, -8, and -10 are also highly expressed during embryonic and early postnatal development, but are downregulated after birth (Hu *et al.*, 2000; Shimohama *et al.*, 2001; Yakovlev *et al.*, 2001; Kurosu *et al.*, 2004). Naturally occurring cell death in the development rat cerebral cortex, which increases during the first postnatal week and decreases thereafter, disappearing by the end of the first month, displays the characteristic of apoptosis and is associated with endonuclease activation (Ferrer *et al.*, 1994a). During this process, neurons expressing caspase-3, -7, -8, and -10 may determine whether a neuron dies or survives. In contrast, cytosolic caspase-2, -6, -9, and Apaf-1 are maintained at a high level postnatally in the brain, and both caspase-9 and Apaf-1 are constitutively expressed in the rat brain from E19 to 96 weeks of age (Shimohama *et al.*, 2001). Although the

mechanism remains unknown, continued expression of caspase-2, -6, -9, and Apaf-1 after the downregulation of caspase-3, -7, -8, and -10 may require the maintenance of cell homeostasis during development and aging.

#### Apoptotic Protein Activation Following Cerebral Ischemia: Newborn versus Adult

It is now well accepted that immature neurons may be more prone to apoptotic death, whereas terminally differentiated neurons exhibit pyknosis or die by necrosis. Both neuronal apoptosis and necrosis have repeatedly been observed in neonatal HI (Pulera *et al.*, 1998; Renolleau *et al.*, 1998; Nakajima *et al.*, 2000), whereas neuronal degeneration in the adult cerebral nervous system exists as a continuum between apoptosis and necrosis (Charriaut-Marlangue *et al.*, 1996a; Liu *et al.*, 2004). This morphological continuum is defined as the occurrence of classic apoptosis and necrosis at opposite ends of the spectrum of cell death, with many possible variant forms of cell death residing between these classic endpoints (Martin *et al.*, 1998). These different forms of cell death may explain the presence or absence of apoptosis-associated proteins upregulation in newborn and adult, respectively.

#### BAX/Bcl-2 REGULATION

In models of hypoxia, a significant elevation of the Bax/Bcl-2 protein ratio was determined between 6 and 13 days following injury in the P0-1 rat brain (Daval and Vert, 2004). In contrast, the lack of significant variations of the expression of Bax and Bcl-2 proteins appeared to be in good agreement with the absence of detectable levels of apoptosis as a consequence of the hypoxic insult in P7 rats (Grojean *et al.*, 2003). In the newborn piglet (P2–P5), the ratio of Bax to Bcl-2 proteins increased more than twofold during hypoxia as compared to normoxia (Ravishankar *et al.*, 2001). Similarly, we observed a six-fold significant elevation of Bax/Bcl-2 protein ratio in our neonatal model of stroke in the P7 rat in the core at 48 hours postreperfusion but not in the penumbra (see Figure 42.3C). High levels of Bax immunoreactivity in many neurons undergoing apoptosis were found in one study on global ischemia (Krajewski *et al.*, 1995).

#### CASPASE REGULATION

Caspase-3 is markedly activated after HI in the immature rat brain (Zhu *et al.*, 2000; Wang *et al.*, 2001; Benjelloun *et al.*, 2003) compared to ischemia in the adult brain (Namura *et al.*, 1998). In P7 rat brain, caspase-3 activation contributes substantially to cell death after ischemia with reperfusion not only in the penumbra but also in the core (Benjelloun *et al.*, 2003; Manabat *et al.*, 2003), and cells with the cleaved active form of caspase-3 colocalize with markers of DNA fragmentation in injured brain regions (Zhu *et al.*, 2000). There is also a good correlation

between the downregulation of procaspase-3 expression and a decline of procaspase-3 activation in the maturing rat brain (Hu *et al.*, 2000; Blomgren *et al.*, 2001) as well as for Apaf-1 and caspase-3 genes (Yakovlev *et al.*, 2001). Considering these results together, it has been proposed that, in the brain, the cytochrome c-dependent mitochondrial pathway is abrogated within two to four weeks after birth, whereas this pathway is still observed in other adult tissues such as the liver (Ota *et al.*, 2002). Caspase-3 activity was the most repeatedly detected enzyme activation after synthetic acetyl-Asp-Glu-Val-Asp-7-amino-4-trifluoromethyl-coumarin (ac-DEVD-AMC) substrate cleavage. As shown in Table 42.2, caspase-3 activity was reported in several but not all studies following ischemia in the adult rats or mice, but sometimes authors were unable to detect it. In contrast, DEVDase activity was found in all the studies in neonatal HI, peaking at 24 hours. This DEVDase activity appeared to be 10- to 20-fold higher in the P7 compared to adult rat and 31- and 25-fold in P5 and P9 mice, respectively, whereas it increases by only about 40% in P21 and P60 mice (Zhu *et al.*, 2005). In the mitochondrial apoptotic pathway, caspase-9 activity precedes caspase-3 activity as reported in the P7 rat brain, after stroke (Benjelloun *et al.*, 2003). Caspase-9 activity was reported only in two studies in adult rodents, but the peak of its activity was shown to follow, and not to precede, that of caspase-3 activity. In addition, caspase-9 activity was demonstrated in the penumbra and not in the core of the infarct (Benchoua *et al.*, 2001).

#### POLY (ADP-RIBOSE) POLYMERASE (PARP) CLEAVAGE

PARP is a nuclear protein used for DNA repair. It is one of the prototype substrates for caspase-3-mediated cleavage and has been used in many systems to indicate the presence of activated caspase-3. Disappearance of the full-length (116 kDa) PARP and appearance of the cleavage product 89 kDa allow identification of caspase-3-mediated apoptosis (Duriez and Shah, 1997; Casiano *et al.*, 1998). PARP cleavage into the 89 kDa protein was identified in adult and neonatal models of cerebral hypoxia-ischemia, in studies that demonstrated caspase-3 activation (see Table 42.2).

#### CASPASE INHIBITION

The pharmacology of caspase inhibition is a rapidly expanding field, and effectiveness of blocking caspase activity is still largely debated (Loetscher *et al.*, 2001). Small peptides that irreversibly inactivate the active enzyme site by alkylating the cysteine residue in the consensus sequence QACXG have recently been synthesized, and block caspases and apoptosis *in vitro* as well as *in vivo*. Initially, the involvement of caspases in ischemia-induced cell death was inferred from studies demonstrating that administration of zVAD-fmk, Boc-aspartyl-(Ome)fluoromethyl-ketone (BAF) or

z-DEVD-fmk, which are broad-spectrum caspase-inhibitors, before ischemia were neuroprotective in animal models of focal and global ischemia (Loddick *et al.*, 1996; Adachi *et al.*, 2001; Gill *et al.*, 2002). However, the efficacy of these inhibitors in focal ischemia was less clear in later studies. z-DEVD-fmk also has been tested in a transient ischemic model, and, although some reduction in neuronal death was observed, impairment of motor function and long-term potentiation was not prevented (Gillardon *et al.*, 1999), suggesting that caspase inhibition alone does not preserve neuronal function. Intracerebroventricular injections of the same caspase-3 inhibitor promoted cell survival when administered 30 minutes before or two hours after transient ischemia in adult mice (Fink *et al.*, 1998). Another pan-caspase inhibitor, benzyloxycarbonyl-Asp-CH2-dichlorobenzene (zD), also was shown to have neuroprotective effects in a transient ischemia model in gerbils (Himi *et al.*, 1998). The discrepancy between these results may, in part, be due to the different models of ischemia used (global or focal) and the severity of the insult (mild or severe). Administration of a *broad-spectrum* inhibitor BAF was significantly neuroprotective in P7 rat pups subjected to HI (Rice-Vannucci model) when given by intracerebroventricular injection three hours after cerebral hypoxia-ischemia. In addition, systemic injection of BAF significantly protected brain tissue (Cheng *et al.*, 1998). A combination of systemic hypothermia and BAF produced a strong protective effect against neuronal damage in the same model used (Adachi *et al.*, 2001). These results were not confirmed in the previous model used (Zhu *et al.*, 2003) and in a model of unilateral focal ischemia with reperfusion in 7-day-old-rats, in which systemic BAF administration did not induce a significant reduction in infarct volume (see Figure 42.4A).

However, two populations of animals were found, one of which had no apparent infarct (Joly *et al.*, 2004). A general trend to reduce size lesion was observed after a delayed second dose of BAF administration (Joly *et al.*, 2004). Very recently, a potent nontoxic (due to its carboxy-terminal O-phenoxy group) pan-caspase inhibitor with enhanced cell-permeant properties (due to its amino-terminal quinoline), quinoline-Val-Asp(Ome)-CH2-O-Phenoxy (Q-VD-OPh), was shown to significantly reduce neuronal damage and conferred long-lasting neuroprotection (see Figure 42.4B) and appears as a wider caspase inhibitor than BAF, especially against caspases 2 and 6 (Charriaut-Marlangue *et al.*, 2004). These data were in agreement with a role of mitochondrially derived cytochrome c and pro-caspase-3 activation in ischemia-induced cell death in neonatal but not in adult brain (Gill *et al.*, 2002; Blomgren *et al.*, 2003).

It is now well known that distinct mechanisms of cell protection (i.e., anti-excitotoxic and anti-apoptotic) may be effective in animal models of stroke, suggesting that, when combined, these treatments could act in synergy.

TABLE 42.2

Caspase-9 and -3 activation and PARP cleavage in the different models of hypoxia-ischemia or stroke in adult and neonatal rodent brains. Caspase-9 and caspase-3 activities were determined by fluorogenic LEDH and DEVD substrate cleavage, respectively. The presence of the 89 kDa of the PARP, poly (ADP-ribose) polymerase, a caspase-3 substrate, was described to be an apoptotic feature.

**Figure 42.4** Effect of pan-caspase inhibitors on infarct volume measured 48 hours after neonatal ischemia in P7 rat brain (neonatal stroke model). The drug was given five minutes before clip removal and consisted of a single intraperitoneal injection of either BAF in 10% DMSO ( $n = 16$ ) or vehicle (10% DMSO,  $n = 15$ ) (A) or Q-VD-OPH (B, see text). Control ischemic rats ( $n = 14$  and  $16$ , respectively) also were studied. Data are mean  $\pm$  SEM (bar). BAF did not induce a significant reduction of infarct volume (N.S., not significant) as compared to Q-VD-OPH ( $p = 0.04$ , Mann-Whitney test).

Pretreatment with subthreshold doses of the NMDA receptor antagonist MK-801 and delayed treatment with subthreshold doses of zVAD-fmk provided synergistic protection compared with each treatment alone (Schulz *et al.*, 1998). Moreover, both treatments extended the therapeutic window for caspase inhibition for an additional two to three hours. Further, pretreatment with subthreshold doses of zVAD-fmk extended the therapeutic window for MK-801 by two hours (Ma *et al.*, 1998; Schulz *et al.*, 1998). These data suggest the potential value of combining treatment strategies to reduce side effects and extend the treatment window in cerebral ischemia.

## THE ROLE OF GENDER

Importantly, data from sex-stratified preclinical studies indicate that stroke sensitivity, which means the damage resulting when an ischemic insult occurs, is sexually dimorphic in adults, with less damage tissue in females versus males. It is less clear if ischemic injury in the developing brain is different in males and females. However, provocative new evidence from cells cultured directly from fetal or newborn brain suggests that mechanisms of cell death are not identical in cells that are genetically male (XY) or female (XX). After cytotoxic challenge, programmed cell death proceeded predominantly via an apoptosis-inducing factor-dependent pathway in XY neurons versus a cytochrome *c*-dependent pathway in XX neurons (Du *et al.*, 2004). Recently, deletion of Bax was shown to eliminate sex differences in the mouse forebrain (Forger *et al.*, 2004).

## Conclusion

The importance of apoptosis was found to be dependent on brain immaturity and/or delayed development of tissue injury after mild cerebral ischemia in experimental models. Brain injury is a diffuse process with a range of developmental outcomes. Understanding the characteristics, strengths, and limitations of each of the relevant animal models will enable future studies to address mechanistic issues in smaller species such as rodents, and apply the information obtained to larger animals. In addition, these mechanistic issues will allow the development of new therapeutic strategies to provide long-term efficiency of this protection in terms of functional recovery in both the immature and mature brain.

# Age-related Changes in Hormones and Their Receptors in Animal Models of Female Reproductive Senescence

Jacqueline A. Maffucci and Andrea C. Gore

*Traditionally, the onset and progression of menopause in humans has been attributed to ovarian follicular decline. Because the follicles are the primary source of circulating estrogens, these age-related changes lead to a number of symptoms such as hot flashes, mood swings, irritability, and depression, as well as increased risk of osteoporosis, cardiovascular disease, and age-associated diseases. Recent research indicates that along with the ovarian changes at menopause, the hypothalamic and pituitary levels of the reproductive axis also undergo significant changes during reproductive aging. Indeed, current research suggests a neural, as well as hormonal, mechanism involved in the menopausal process. A number of animal models are available to study these processes, most commonly the nonhuman primates and rodents, and to a lesser extent, avian systems. Here, we will discuss Old and New World monkey models, rats, mice (wild type, transgenic, and genetically modified), and birds as models for reproductive aging. An overview of the reproductive aging process will be discussed for each model, along with their advantages, disadvantages, and biomedical relevance. In addition, we will present recent findings pertaining to the mechanisms for the onset of reproductive aging in all of these models, focusing on the hypothalamic-pituitary-gonadal axis, and emphasizing molecular changes and hormonal output.*

## Introduction

Reproductive senescence is a natural and inevitable part of the aging process in the female life cycle. In humans, this process is referred to as *menopause*. Menopause is defined as the permanent cessation of menstruation and is an immediate consequence of the loss of ovarian follicular activity (World Health Organization, 1996). This depletion results in a decrease in estrogen levels, leading to a number of symptoms including sleep disturbances, vasomotor symptoms, mood swings, irritability, depression, memory loss, urogenital symptoms, osteoporosis, and cardiovascular morbidity. Menopause is

divided into two stages, *perimenopause* and *postmenopause*, as defined by the STRAW panel (Soules *et al.*, 2001). Perimenopause begins when the first symptoms of menopause appear (including increases in menstrual cycle variability, decreases in fecundity, and changes in hormonal status) and continues until one year following the final menstrual period. Once menstruation is absent for a year or more, the female is considered to be postmenopausal. The average age at which perimenopause begins is at 47.5 years, and it lasts for an average of four to six years. However, peak follicular degeneration may occur as early as 38 years old, with declines in fertility occurring between 30 and 35 years (Zapantis *et al.*, 2003).

Despite the universality of menopause among women, its mechanism remains largely unclear, and treatment to ease its symptoms is uncertain. Currently, the most commonly used treatment is estrogen replacement therapy, which has been met with considerable controversy. It is critical that we understand the mechanism by which menopause occurs and the effects of estrogen depletion during menopause in order to evaluate the advantages of estrogen replacement therapy in women and to determine other possible treatments for menopausal symptoms. Animal models are an essential part of uncovering these mechanisms, as studies in humans are often constrained.

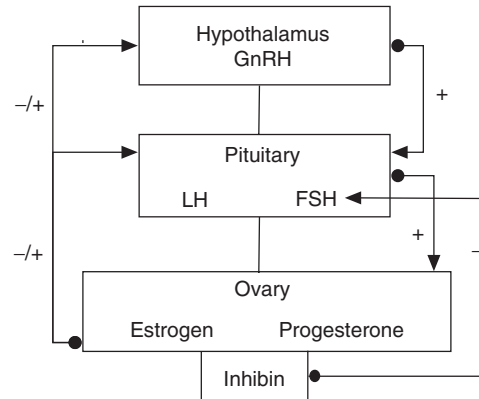

Traditionally, menopause and its resulting symptoms have been attributed to the decline of the ovarian follicle. Although this is clearly the proximal event leading to ovarian failure, recent research using animal models has revealed an interaction of both neuroendocrine and ovarian events that lead to the transition to acyclicity (Wise *et al.*, 1999). Studies on humans are often difficult due to the limitations on invasive procedures and difficulties encountered when trying to normalize the subject population. Animal models are much more useful in these endeavors, each with its strengths and weaknesses. For studies in reproductive aging, primates are commonly used, as they mimic the human menstrual cycle and therefore provide an excellent model for studying the

role of ovarian hormones in this process. However, aged primates are limited in number, extremely expensive, and undergo the menopausal transition far later in the life cycle than women. By contrast, rodents do not undergo extensive follicular decline, but do show changes in gonadotropin-releasing hormone (GnRH) neurons and the central regulatory factors influencing these neurons, making them a relevant model for studying the neural component of this process. Additionally, the use of transgenic or knockout mice has made it possible to understand the role of specific genes in the aging process. Finally, nonmammalian animal models, particularly birds, have been used to shed light on other mechanisms by which senescence occurs. This chapter will examine these animal models in detail.

### The Hypothalamic-Pituitary-Gonadal (HPG) Axis and Age-related Changes

Understanding the mechanisms influencing the onset of reproductive senescence first requires familiarity with the HPG axis that controls reproduction in all vertebrates. The hypothalamus is located at the base of the brain and contains approximately 1000 neurons that release the neuropeptide, GnRH. GnRH is transported to the anterior pituitary gland via a capillary portal system. At the pituitary, it stimulates the synthesis and release of the gonadotropin luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are released into the systemic blood system. At the ovary, LH and FSH are responsible for the growth, maturation, and release of ovarian follicles, and steroidogenesis. The release of GnRH, and subsequently LH, are pulsatile in all mammals, in which pulse amplitude and frequency are important determinants of reproductive function. Additionally, the HPG axis of females is regulated both by negative and positive feedback from circulating estrogens and progestins onto the pituitary and hypothalamus (see Figure 43.1). Although feedback regulation by steroid hormones is negative throughout most of the cycle, increasing preovulatory estrogen concentrations trigger transient positive feedback. This process is referred to here as the preovulatory GnRH/LH surge, and is crucial for ovulation in all animals with spontaneous ovulatory cycles (see Figure 43.2).

Research investigating the mechanisms of estrogen's positive feedback upon GnRH and LH release has localized few estrogen or progestin receptors within GnRH neurons, which express low levels of the estrogen receptor (ER)  $\beta$  but not  $\alpha$  (Herbison and Pape, 2001). This surprising finding suggests that estrogen exerts many of its feedback actions via *inputs* to GnRH neurons. Studies have shown that, indeed, many neurotransmitters and neuropeptides regulate GnRH neurons, and that their receptors are localized to GnRH cells. For example, glutamate,  $\gamma$ -aminobutyric acid (GABA), catecholamines,

**Figure 43.1** A summary of the hypothalamic-pituitary-gonadal axis of females. GnRH stimulates gonadotropin release (LH and FSH), which then stimulates ovarian steroid hormone release (estrogen and progesterone). Estrogen either has positive (just prior to ovulation) or negative feedback actions on the hypothalamus and pituitary. Inhibin is also released by the ovary and inhibits FSH release. In rats, the “estropause” is characterized by continued high estrogen levels and a persistent estrus vaginal cytology until much later in life. On the arrows, the circle refers to the initiator of the signal, and arrows indicate the termination of the signal.

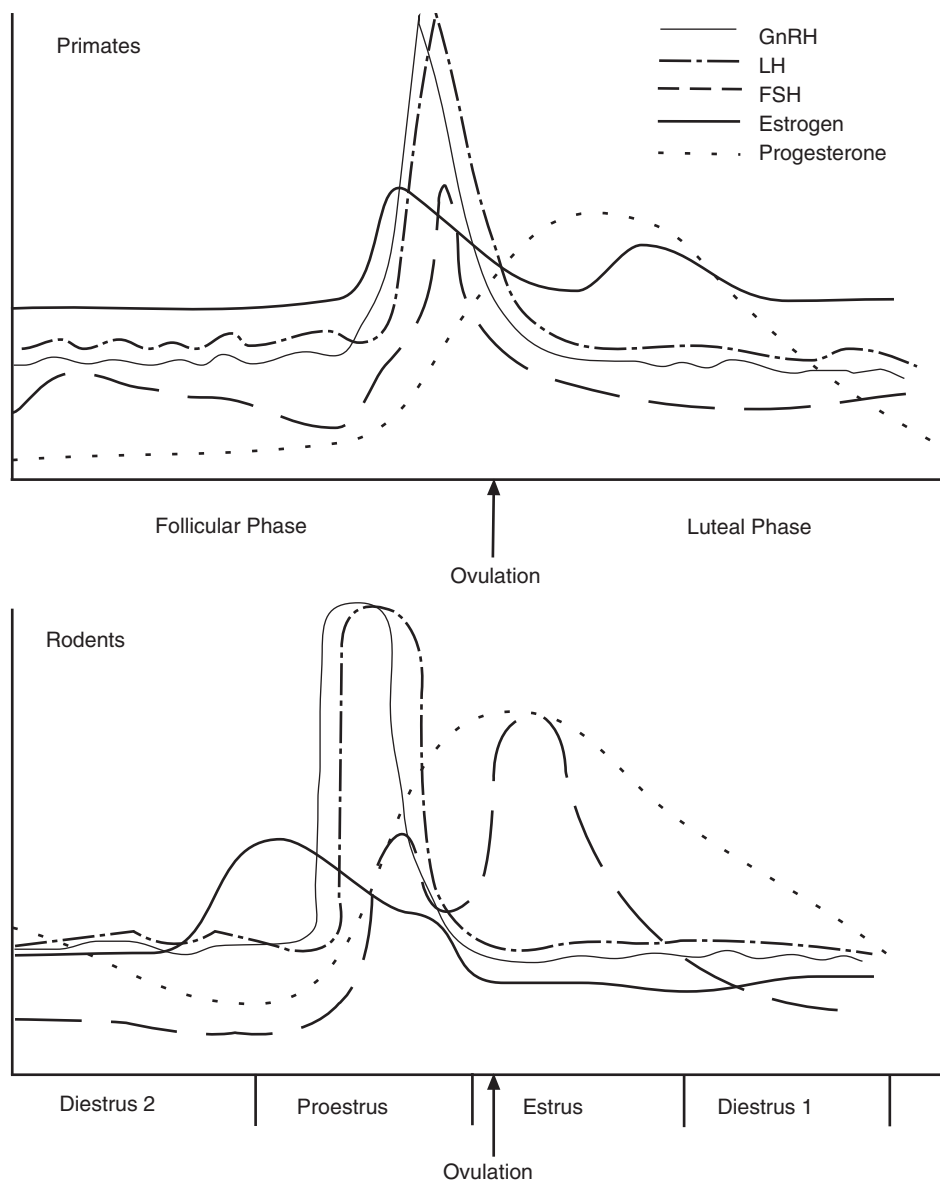

neuropeptide Y (NPY), neurotensin, and vasoactive intestinal polypeptide (VIP) contact GnRH neurons and also express estrogen receptors, making them targets at which estrogen can indirectly regulate the GnRH neuron (reviewed in Gore, (2002)). Additionally, some of these neurotransmitters and their receptors, such as GABA and glutamate, change expression in the brains of aging rats (reviewed in Gore, (2002)), suggesting that these neurotransmitters play a role in mediating age-related changes observed in GnRH output during the onset of reproductive senescence. Therefore, it is important to consider age-associated changes in these neuromodulators as well as direct changes to the HPG axis to understand neural changes affecting the onset of reproductive senescence.

### Nonhuman Primate Models

#### OLD WORLD MONKEYS

Nonhuman primates (NHP) are classified as Old World monkeys, New World monkeys, and Great Apes. The Old World monkeys (OWM) are most commonly used in biomedical research, and, of these, the Asian macaques and the baboons of Africa are most frequently used. OWMs have a genetic makeup approximately 92.5 to 95% similar to humans and undergo similar reproductive processes as humans. The NHP reproductive cycle is approximately 28 to 30 days, with a follicular, proliferative, and luteal phase that results in a hormonal milieu similar to that in humans (Hendrickx *et al.*, 1995) (see Figure 43.2). Additionally, in aging OWMs, as in humans, a decrease in fertility and changes in HPG hormone levels are accompanied by the onset of irregular menstrual cycles and finally, cessation of menses. However, OWMs spend a much shorter period (15–23%) of their

### 43. Age-related Changes in Hormones and Their Receptors

**Figure 43.2** Hormonal changes accompanying the primate (human and nonhuman primates) and rodent normal reproductive cycles. In both primates and rodents, an increase in estrogen occurs immediately prior to the GnRH/LH surge, followed by a slight surge in FSH. A gradual increase in progesterone occurs just prior to ovulation. Levels of progesterone are elevated during the luteal phase of primates, and during diestrus in rodents.

lifespan in an anovulatory state, as compared to humans (50%) (Tardif *et al.*, 1992; Bellino and Wise, 2003), making it difficult to study postmenopausal changes. Additionally, researchers face high costs to obtain and care for these animals (expensive due to the cost involved in maintaining them for 20+ years), the supply is limited, and there is a higher risk of loss of data due to age-related illness or death. Thus, two models have been developed to alleviate these challenges: the intact, aged, and the ovariectomized, young monkey.

The intact, aged model, though costly, provides a natural model of studying hormonal and neural changes

associated with aging. Researchers can use this model to look toward modifications in brain structures as well as ovarian hormones when considering reproductive aging. Thus, differences in neuronal morphology, neuronal populations, and receptor density in the aging brain can be observed. Additionally, studies examining age-associated genetic alterations and relations to neural changes, and age-associated diseases, such as osteoporosis, cardiovascular diseases, and vasomotor symptoms (e.g., hot flash) can be undertaken in this model. These factors make the aged OWM a favored model for studies of reproductive senescence.

Studies in intact, aged macaques and baboons focus primarily on the perimenopausal period, when menstrual cycle variability increases, fecundity decreases, and hormonal status first changes. Humans and OWMs show very similar changes in urinary estrogen and progesterone profiles once they begin perimenopause. However, there are a few differences in the timing of the hormonal transition to perimenopause: middle-aged women show a period of increase in FSH and decrease in inhibin A along with a cyclically high level of estrogen prior to onset, whereas rhesus monkeys do not (Bellino and Wise, 2003). Hence rhesus monkeys show a more immediate transition to perimenopause, whereas the human transition is more gradual. In both humans and OWMs, the onset of perimenopause is accompanied by declines in estrogen and progesterone levels, and a shorter follicular phase is observed during the menstrual cycle. In accordance with this, LH/FSH levels increase, partly due to the release from negative feedback associated with estrogen release (Bellino and Wise, 2003). Although this transition in macaques may occur as early as 18 to 20 years of age, it has been noted that rhesus monkeys may not show this transition until 25 years of age or later, an age equivalent to 65 to 90 years in humans (Gore *et al.*, 2004). It is for this reason that the intact, aged monkey model has yet to meet its research potential, as these animals undergo reproductive senescence so late in their life cycle that they are difficult both to attain and maintain.

Activity of the HPG axis of intact, aged monkeys has been assessed in two studies. First, Woller *et al.* (2002) demonstrated changes in LH pulsatile activity in late perimenopausal and postmenopausal rhesus monkeys, showing not only increases in mean LH amplitude, but also increases in pulse amplitude and higher baseline LH levels when compared to young animals. Estrogen levels of the aged monkeys were also lower; no differences were observed in progesterone. Gore *et al.* (2004) used push-pull perfusion to measure changes in GnRH levels in peri- and postmenopausal monkeys and recorded increases in mean GnRH concentrations and higher pulse amplitudes compared to young monkeys. These latter data are consistent with the observed changes in LH pulses (Woller *et al.*, 2002) and suggest a novel mechanism by which hormonal changes may affect the onset of reproductive aging. Taken together, the age-associated increases in pulsatile GnRH and gonadotropin, even prior to complete ovarian senescence, indicate a role of the hypothalamus and the pituitary, respectively, in reproductive senescence in a NHP model. Moreover, the observations of age-related changes in pulsatility and accompanying neural changes promise to enhance our understanding of the finer mechanism of reproductive decline.

Even though intact, aging animals provide some advantages for studying age-associated neural changes, researchers often turn to the young, ovariectomized (OVX) animal as a substitute. Ovariectomized animals have a negligible level of circulating estrogen and

cessation of menses. Thus, these monkeys model changes that occur during reproductive aging. It is important to remember that these are not aged animals, and that the loss of estrogen in a young monkey by OVX does not necessarily mimic natural, age-related changes in estrogen in the aged brain. However, they have proven to be effective for studying at least some of the neural changes associated with estrogen loss and replacement, including changes to hormone receptor densities and neuronal morphology and populations of neuropeptides and neuromodulators associated with the HPG axis. Concurrently, researchers can uncover the benefits of estrogen replacement therapy (ERT) and the acute and chronic treatment effects of ERT on diseases and symptoms associated with menopause.

As discussed earlier, aged animals show an increase in GnRH and LH levels, and estrogen loss may contribute to these observed increases (Woller *et al.*, 2002; Bellino and Wise, 2003; Gore *et al.*, 2004). The OVX, young monkey model has extended these results to show inhibitory effects of estrogen on GnRH release (Chongthammakun and Terasawa, 1993), GnRH mRNA expression (El Majdoubi *et al.*, 1998; Krajewski *et al.*, 2003), and circulating LH concentrations (El Majdoubi *et al.*, 1998). Parallel results have been reported in humans, in which estrogen replacement for postmenopausal women diminishes LH and FSH levels as compared to nontreated women (Gill *et al.*, 2002), and decreases in GnRH mRNA occur following estradiol replacement (Rance and Usandi, 1996). Additionally, effects of estrogen on hypothalamic neuropeptides associated with GnRH pulsatility have been suggested for norepinephrine and neuropeptide Y. Both of these neuromodulators demonstrate pulsatile release, and increase just prior to the GnRH surge associated with ovulation. Estrogen replacement in OVX females upregulates norepinephrine release and increases the sensitivity of GnRH release to neuropeptide Y, suggesting that neuromodulators playing a role in reproductive aging undergo changes with the age-associated decline in estrogen levels (Terasawa, 1998).

Estrogen receptor expression in neuroendocrine and other brain regions is important to consider in the aging model. In recent years, estrogen has been found to be responsible not only for feedback actions upon the hypothalamus, but also other neurophysiological functions such as cognition and neuroprotection. Two nuclear estrogen receptors, ER $\alpha$  and ER $\beta$ , have been localized in mammalian brain tissue, each showing unique expression patterns in subregions of the hypothalamus (Chakraborty and Gore, 2004). The roles of ER $\alpha$  and ER $\beta$ , as well as the interplay between these two receptors in reproductive aging (i.e., whether they are modulatory, inhibitory, or reciprocal) remain undetermined. It is important to understand the changing dynamics of these receptors in the aging hypothalamus, so as to uncover the potential roles that these play in endocrine function as well as endocrine aging. One study by Gundlach *et al.* (2000)

### 43. Age-related Changes in Hormones and Their Receptors

reported that administration of estrogen followed by progesterone in OVX macaque monkeys decreases ER $\alpha$  mRNA and protein expression in the ventromedial hypothalamus, an area associated with sexual behavior, but has minimal effects on ER $\beta$ . Age-associated decreases in ER populations in various nuclei of the hypothalamus very likely contribute to declines in sexual behavior, ovulation, and fecundity as well as observed changes in HPG hormone levels. Additionally, cognitive decline, onset of stroke, osteoporosis, and other age-related diseases may be in close correlation with such decreases. Studies to this effect have not been extensively pursued in NHPs to determine the presence or absence of these changes, but the finding of Gundlah *et al.* (2000) and those in other animal models (discussed elsewhere) suggest that this warrants further examination. Understanding the distribution and activation of estrogen receptors and their collective role in reproduction and other physiological processes will prove important in future studies of disease and reproductive aging.

#### NEW WORLD MONKEYS

The New World monkeys share some similarities in reproductive aging with their Old World counterparts, such as decreased follicular numbers, reduced numbers of steroid receptors, and lower levels of estrogen and progesterone with higher LH levels in anovulatory females (Tardif *et al.*, 1992). However, these animals do not undergo menstruation; rather, they have an estrous cycle (Hendrickx *et al.*, 1995). Additionally, these animals appear to have moderate levels of estrogen and progesterone in the anovulatory phase of life (see Figure 43.3), as compared to the low levels seen in Old World monkeys, and exhibit a shorter life span.

Evidence of active luteal cell masses on the ovaries of these anovulatory females has been reported, distinguishing them from their Old World counterparts (Tardif *et al.*, 1992) and suggests this as a possible source of these hormones. This difference in hormone levels probably relates to the ability of NWMs to maintain bone mass into the later stages of life, and may provide a unique mechanism for studying the role of estrogen in age-related diseases and disease resistance. Furthermore, their small size and tractability, combined with the absence of susceptibility to pathogens such as Herpes B, which are infectious to humans, make these an attractive model for biomedical studies (Abbott *et al.*, 2003).

#### Rodents

The rodent model is used in a majority of research laboratories due to their high availability, relatively lower cost of care, and less demanding housing needs. Additionally, though not as genetically similar as the primate model, they retain 90% homology with humans, and their shortened reproductive cycle and gestation period affords

them a larger number of offspring each year. The rat and mouse models are most common to the laboratory setting, and each species offers unique benefits to research in reproductive aging.

Rats and mice undergo estrous cycles, as opposed to menstrual cycles in humans. Thus the process by which reproductive aging occurs in rodents is sometimes called estropause, and it shares some similarities, as well as some differences, with human menopause. The rodent estrous cycle is four to five days long, consisting of four phases: proestrus, estrus, diestrus I (sometimes referred to as metestrus), and diestrus II (see Figure 43.2). In rodents, estrous cyclicity can be tracked by observing daily vaginal cytology. Through this methodology, researchers have determined that rodents begin to show irregular cycles at middle age (9–12 months), as defined by prolonged cycles, most commonly with additional days of cornified vaginal cells, interspersed with the normal four- to five-day rhythm. As aging occurs, these animals transition into an acyclic, anestrus status, in which persistent estrus is observed and ovulation has ceased (Rubin, 2000). In accordance with humans, rodents begin to show reproductive decline in middle-age. Prior to the loss of regular estrous cycles, rats show increased FSH and estrogen levels accompanied by an attenuation and delay of the LH surge (Rubin, 2000), similar to humans (Wise *et al.*, 2002). As irregular cycles set in and progress to anestrus, progesterone levels decline, with estrogen levels remaining moderately elevated in rats (see Figure 43.3). This latter phenomenon is dissimilar to that in humans and mice, in which estrogen levels decline (Rubin, 2000).

Age-related changes to the pituitary have also been noted in rodents, with decreased sensitivity to GnRH stimulation, decreased GnRH receptor mRNA during the

**Figure 43.3** A summary of estrogen release across the life cycle in humans, nonhuman primates, rats, and mice. Please note that avians are excluded due to the variability within their group. In these species, estrogen concentrations increase during the pubertal period and are at high levels in adulthood. Declines in estrogen are precipitous in humans, monkeys, and mice, although they occur at different relative times in the life cycle. In rats, the *estropause* is characterized by continued high estrogen levels and a persistent estrus vaginal cytology until much later in life.

preovulatory surge, and decreases in LH $\beta$  subunit mRNA expression during the GnRH/LH surge and following OVX (Rubin, 2000; Wise *et al.*, 2002). However, evidence for hypothalamic involvement in rodents is by far the most compelling reason for using this model of reproductive aging. Transplantation of ovarian tissue from acyclic, aged rats into young females showed that these ovaries can support regular estrous cycling, whereas transference of young ovarian tissue into aged animals showed no resumption of cyclicity. A similar experiment confirmed this for mice as well (Rubin, 2000). Taken together, these studies provide evidence for an age-dependent change in the hypothalamic-pituitary axis that causes a disruption in the normal estrous cyclicity, and suggests that this mechanism may supersede the observed changes in ovarian morphology. Additionally, electrophysiological stimulation of the acyclic, female rat hypothalamus is able to restore function to the reproductive axis (Rubin, 2000), providing strong evidence that a neural aspect contributes to the onset of estropause. Thus, the rodent model has become an important contributor to studies of neuroendocrine influences on reproductive function.

## RATS

Rats have a maximal lifespan of approximately 2.5 to 3.5 years, and they experience reproductive decline beginning at 9 to 12 months of age. Follicular degeneration is complete by two years, and the animal enters persistent diestrus. However, unlike humans, monkeys, and mice, the aged rat retains a much larger number of primary oocytes, resulting in higher estrogen levels at the onset of persistent diestrus (Holmes *et al.*, 2003b; Chakraborty and Gore, 2004). Thus, the OVX rat model is often used to mimic the natural, low estrogen levels found in humans, whereas the intact, aged model is utilized for studying natural changes to the HPG axis. In rodents, the OVX model is also used for research into the role of estrogen manipulation on reproductive aging, effects of estrogen therapy, or to study changes at the level of the hypothalamus or pituitary during the GnRH/LH surge or ovulation (achieved via controlled steroid priming). This differs from the monkey, where ovariectomy and steroid treatment are used as a cost-effective way to mimic a menopausal animal.

When using the OVX animal model, the following parameters must be taken into consideration for data interpretation: (1) Age at OVX: young animals have a more robust response to OVX than older animals. Ovarian hormones clear and gonadotropin levels increase within one week post-OVX in young rats, whereas middle-aged and aged rats take up to four weeks for total clearance of ovarian hormones and for the gonadotropin rise to occur. (2) Duration of steroid replacement: young animals need a shorter duration of estradiol replacement (approximately two days) to reach physiological estrogen levels, whereas older animals may take a

minimum of four days. (3) Steroid hormone responsiveness: in younger animals, effects of steroid negative feedback onset are faster and greater than those of older animals, and positive feedback is also achieved sooner. Additionally, the GnRH/LH surge can occur earlier in the day in younger rather than in older animals, and the amplitude of the surge itself is greater (Chakraborty and Gore, 2004).

### *Hypothalamic changes: GnRH*

To uncover the mechanisms of hypothalamic regulation of reproductive senescence, it is important to observe changes to GnRH neuronal function, as well as changes in neuronal morphology. The former can be done using a number of methods, most commonly through GnRH gene expression, protein expression, and neuropeptide release. The resultant data are controversial due to differences in methodology, hormonal treatments, and animal model (intact versus OVX and rat strain). Overall, there are data supporting age-related increases, decreases, and no change to GnRH expression. Unfortunately, due to the complexity of this field, as well as the variables just mentioned, such contradictions are common. The following will attempt to present these data from a critical viewpoint (summarized in Table 43.1).

Studies in the rat examining changes to GnRH focus on the GnRH/LH surge, since there is a known attenuation and delay of this surge in middle-aged animals in the estropause transition period (Scarborough and Wise, 1990; Wise *et al.*, 2002). Expression of GnRH mRNA in OVX, steroid-primed as well as in intact females shows age-related differences, with young animals undergoing a decline in gene expression just prior to the GnRH/LH surge followed by an increase thereafter. By contrast, middle-aged rats fail to show any significant fluctuation (Rubin *et al.*, 1997; Gore *et al.*, 2000a). Measurements of GnRH gene expression are interpreted as an index of biosynthesis. A parallel study examining GnRH protein expression preceding and following the proestrus GnRH/LH surge in intact rats demonstrates similar results (Rubin, 2000). These findings suggest specific changes to the hypothalamus in animals transitioning to senescence, with a loss of drive on the GnRH/LH surge by middle age.

The aforementioned studies on the preovulatory GnRH/LH surge also examined overall mRNA expression in the hypothalamus of young, middle-aged, and aged rats. Gore *et al.* (2000a) found an overall increase in hypothalamic GnRH mRNA expression associated with aging in intact females, and Rubin *et al.* (1997), using the OVX, steroid-treated model, reported a decline. These differences are possibly due to the different animal models used (intact vs. OVX), or differing techniques used to quantify mRNA. The latter group used *in situ* hybridization, excellent for determining specific populations of gene expression, whereas the former group used RNase protection assays, useful in quantifying overall

TABLE 43.1

RNase protection assay	Intact	None	↑ GnRH mRNA from Y to MA to A; fluctuation in GnRH during proestrus surge in Y, but not MA	Gore <i>et al.</i> , 2002
<b>Protein levels</b>				
IHC: GnRH	4 wks	None	Aged rats show decreases compared to Y rats in GnRH cell numbers in Septum-DBB, OVLT, POA, SON, Rch with more extreme declines in rostral regions	Funabashi <i>et al.</i> , 1995
IHC: co-expression of GnRH and c-fos	Intact	None	Decline in c-fos and c-jun co-expression with GnRH in hypothalamus of regularly cycling MA vs. Y during proestrus surge	Lloyd <i>et al.</i> , 1994
IHC: co-expression of GnRH and c-fos	3–4 wks	EB 4 ug/100 g s.c. ⇒ P 0.8 mg/100 g 2d later	Higher proportion of GnRH co-expression of c-fos in Y vs. MA	Rubin <i>et al.</i> , 1994
IHC: co-expression of GnRH and c-fos	Intact	None	Age-related, region-specific differences of co-expression during varying time intervals on proestrus	Rubin <i>et al.</i> , 1994
<b>Peptide release</b>				
Push-pull perfusion	3 wks	EB 4ug/100g s.c. ⇒ P 0.8mg/100g 2d later	Mean GnRH levels and pulse amplitudes are lower in MA than Y animals	Rubin <i>et al.</i> , 1989

Abbreviations: Y, young; MA, middle-aged; A, aged; d, days; DBB, diagonal band of broca; EB: estradiol benzoate; 17β-E2, 17-beta estradiol; s.c., subcutaneously; OVLT, organum vasculosum of the lamina terminalis; P, progesterone; POA, preoptic area; SON, supraoptic nucleus; Rch, retrochiasmatic nucleus; IHC, immunohistochemistry.

hypothalamic mRNA. It is noteworthy that a study of mRNA expression in human subjects, both pre- and postmenopausal, also supported an overall increase in GnRH mRNA with age (Rance and Uswandi, 1996), in agreement with the findings of Gore *et al.* (2000a). However, it should be noted that the nuclei examined by Rubin *et al.* (1997) are thought to correspond to GnRH neurons involved in maintenance of the GnRH/LH surge (Blake and Sawyer, 1974). Thus, localized decreases may occur in these nuclei, whereas an overall increase in GnRH gene expression occurs more generally in the aging hypothalamus, suggesting a mechanism of decline specific to the GnRH/LH surge generator.

Changes to GnRH mRNA expression are often, although not always, reflected by changes to protein expression. Immunohistochemistry can be used to detect the specific protein of interest, such as GnRH, or changes in the coexpression of GnRH protein with the immediate early genes *c-jun* and *c-fos*, thought to be markers of gene activation (discussed in the next paragraph). Several studies have compared GnRH cell numbers in young, middle-aged, and/or aged animals, the majority of which report no or very slight decreases in the aged hypothalamus (reviewed in Gore, (2001)). There have, however, been reports of age-associated changes in the distribution of GnRH neurons throughout the hypothalamus. In middle-aged animals undergoing the transition to irregularity, a decline of GnRH neurons in the medial septum was seen in irregularly cycling, middle-aged, proestrus females. No differences were seen in other nuclei such as OVLT, POA, or diagonal band of Broca (Gore, 2001). Taken together with data suggesting specific roles of different subpopulations of GnRH neurons, with more caudal regions associated with LH pulsatility and more rostral with the GnRH/LH surge (Blake and Sawyer, 1974; Soper and Weick, 1980), researchers are beginning to examine these areas for specific age-related changes. This will enhance our understanding of the age-associated neuronal changes driving alterations of pituitary and gonadal output. Localized adjustments to GnRH neuronal populations would support a mechanism by which age-related changes to gonadotropin release and maintenance of pulsatility occur, and may explain the inconsistencies seen in studies reporting changes to hypothalamic GnRH neuronal expression.

Immediate early genes are transcription factors that are commonly used to measure the activity of a particular cell. Previously, *c-fos* activity has been correlated with GnRH neuronal activity during the preovulatory GnRH/LH surge in young animals. Studies extending these findings to either intact, or OVX, steroid-treated middle-aged animals reported a decline in the coexpression of *c-fos* within GnRH neurons compared to young rats (see Table 43.1). Similar results were observed using the immediate early gene *c-jun* (Rubin, 2000). These findings support a decline in GnRH neuronal activity during the transition to anestrus.

In support of these observed molecular declines in GnRH activity, push-pull perfusion was used to sample the level of neuropeptide released. GnRH levels were lower in OVX, steroid-treated middle-aged versus young animal, and there was an overall decline in pulse frequency as well as amplitude (Rubin, 2000; Table 43.1). This result is in contrast to the report in the monkey showing an age-related *increase* in pulsatile GnRH release, measured by push-pull perfusion (Gore *et al.*, 2004) as well as studies in humans showing age-related *increases* in gonadotropins (Gharib *et al.*, 1990). This species difference highlights a shortcoming of the rat model, in which push-pull perfusion measurements may simply lack the sensitivity of that in monkeys. Nevertheless, taken together, these results show age-associated differences in GnRH gene expression, protein levels, activity, and release. Now we must focus on the mechanisms driving these changes.

GnRH neurons are regulated by a number of neurotransmitters, including (but not limited to) GABA, glutamate (GLU), catecholamines, and neuropeptide Y (NPY). Both protein and mRNA expression of receptors for these and other neurotransmitters have been colocalized to GnRH neurons (Smith and Jennes, 2001; Wise *et al.*, 2002). Moreover, many of the neuromodulators synapsing onto GnRH neurons are colocalized with a large population of ERs (Smith and Jennes, 2001; Chakraborty *et al.*, 2004). We propose that the modification of these inputs may be responsible for some of the age-associated differences in the HPG axis. Although there has been no indication of changes to synaptic input onto GnRH neurons in intact female aged rats, Romero *et al.* (1994) noted a decrease in the number of rough endoplasmic reticulum and Golgi apparatus, suggestive of a decrease in GnRH biosynthesis. Additionally, long-term OVX (performed at 10 months of age and observed eight months following) resulted in a greater density of synaptic inputs. These data are suggestive of a role for aging, estrogen, and their possible interactions in GnRH synaptic input. These findings suggest that changes in activation of these estrogen sensitive cells may result in the observed changes to synaptic input onto GnRH neurons.

Following is a brief overview of some age-related changes in a few select neurotransmitters known to regulate GnRH neurons (GLU, GABA, catecholamines, and NPY, summarized in Table 43.2). Greater coverage of this subject can be found in (Gore, 2001; Smith and Jennes, 2001; Gore, 2002; Wise *et al.*, 2002).

1. Glutamate: The most abundant excitatory neurotransmitter in the brain and probably the best-studied neurotransmitter with respect to age-related changes in the regulation of GnRH neurons. Glutamate agonists potentiate, and antagonists attenuate, GnRH/LH release, and this is modulated by estrogen (Gore, 2001; Smith and Jennes, 2001;

### 43. Age-related Changes in Hormones and Their Receptors

TABLE 43.2  
Summary of the actions of select neuromodulators on the GnRH system

	Glutamate (+)	GABA (-)	NE/E (+)	NPY (+)
Agonist action	Potentiates GnRH/LH release; enhances mRNA and protein expression.	Attenuates GnRH/LH release; may inhibit preovulatory LH surge.	Stimulates pulsatile and preovulatory GnRH/LH release.	Potentiates GnRH/LH release.
Antagonist action	Attenuates GnRH/LH release; decreases mRNA and protein expression.	Potentiates GnRH/LH release; may cause early preovulatory LH surge.	Alpha-adrenergic receptor antagonists prevent preovulatory LH surge.	Inhibition of gene expression with antisense oligonucleotides or protein with immunoneutralization inhibits the LH surge.
Input onto HPG axis	Direct synapse at GnRH cell bodies and presence of receptor on GnRH perikarya and terminals.	Direct action on GnRH neurons via synapses and presence of receptors.	Neurons project in the vicinity of GnRH neurons (indirect input). Presence of $\alpha$ 1B- and $\alpha$ 2A-adrenergic receptors on GnRH neurons.	Synaptic contacts with GnRH cell bodies and processes in POA and median eminence.
Estrogen regulation	Glutamate receptors and ER $\alpha$ and $\beta$ are coexpressed in hypothalamus and POA.	GABA cells in hypothalamus are colocalized with ER $\alpha$ .	A2 NE neurons express ERs; all E cell types express ERs.	ER $\alpha$ coexpression with NPY cells in arcuate nucleus.
Age-related changes	Decline of NMDAR sensitivity and effects in the aging hypothalamus.	Declines in GABA synthesis in POA with aging.	Decreased NE turnover with aging.	Decreased NPY hypothalamic gene expression with age.

Table modified from Smith *et al.* 2001. Specific aging-related citations: Glutamate (Gore 2002); GABA (Cashion *et al.*, 2004); NE (Wise *et al.*, 1997); NPY (Wise *et al.*, 1997). Abbreviations: NE, norepinephrine; E, epinephrine; NPY, neuropeptide Y; ER, estrogen receptor; GABA, gamma-aminobutyric acid; NMDAR, N-methyl-D-aspartate receptor; POA, preoptic area.

Gore, 2002). Although all classes of glutamate receptors may be involved, the NMDA receptor (NMDAR) is most strongly implicated in this role. NMDARs, made up of heteromeric subunits, undergo age-related changes in subunit expression, both on GnRH neurons as well as in the surrounding hypothalamus-POA. A possible decline in NMDAR sensitivity to GLU has been reported with aging (Gore *et al.*, 2000b). Finally, both ER $\alpha$  and ER $\beta$  are colocalized with NMDAR subunits (Chakraborty *et al.*, 2003b), indicating that estrogen and GLU can act upon the same target cells to exert their effects.

2. **GABA:** The main inhibitory neurotransmitter in the central nervous system, which interacts with GnRH neurons to suppress the preovulatory GnRH/LH surge. Like glutamate, the GABA influence on GnRH function is estrogen-sensitive and GABA receptors are colocalized with ERs in the hypothalamus (Smith and Jennes, 2001). Changes in GABA synthesis in the POA accompany changes in age and estrous cycle stage (Cashion *et al.*, 2004).

3. **Catecholamines:** Epinephrine and norepinephrine release strongly correlate with or are even causal to GnRH/LH pulse frequency and amplitude, and both are found in axons juxtaposed to GnRH neurons in the septum and diagonal band of Broca. Additionally, the A2 cell group of noradrenergic neurons and all cell groups of the adrenergic neurons express ERs, suggestive of direct action of estrogen on these neurons (Smith and Jennes, 2001). Wise *et al.* (1997) noted decreased norepinephrine (NE) turnover rates in middle-aged females in a number of hypothalamic nuclei. Middle-aged animals also lose diurnal rhythms of NE activity, suggesting a mechanism by which declines in NE activity are related to declines in the pulsatile regulation of GnRH release.

4. **NPY:** NPY gene expression and secretion are decreased in middle-aged compared to young animals, and pulsatile release of NPY is also associated with GnRH/LH release (Rubin, 2000). Again, these effects are modulated by estrogen (Smith and Jennes, 2001).

5. Together, these alterations are suggestive of changes to the pulsatile regulation of GnRH by its neurotransmitter inputs. We believe that age-related changes to these and other neuromodulatory systems are key factors contributing to the age-related dysregulation of GnRH function.

#### *Steroid hormones*

**ER $\alpha$ :** The effects of gonadal steroid hormones in the brain are mediated by the hormone receptors, which are expressed at high levels in a number of rat hypothalamic regions associated with reproduction. With regard to the two nuclear ERs, some regions express only one receptor, and others have overlapping expression. In general, these regions of overlap are most strongly implicated in the control of reproductive behavior and physiology (Chakraborty and Gore, 2004). Studies on the role of changing ovarian steroid feedback in aging rats have quantified hypothalamic ER $\alpha$  using a number of techniques, including estradiol binding assays, *in situ* hybridization, and protein expression by immunohistochemistry. Rubin *et al.* (1986) reported age-related, region-specific (preoptic area and medial basal hypothalamus) decreases in estradiol binding in the OVX, middle-aged rat. Wise and Parsons (1984) reported a similar finding in OVX, steroid-treated animals and Brown *et al.* (1990) extended this, finding similar results in aged animals as compared to young and middle-aged. More recent studies using *in situ* hybridization of ER $\alpha$  gene expression are summarized in Table 43.3, and in general, they demonstrate little to no changes in mRNA expression in the observed regions in aging rats. However, this technique does not take into account possible post-transcriptional or translational changes to ER $\alpha$  expression. Experiments

using immunohistochemistry to examine protein expression in the hypothalamus show no age-related changes to ER $\alpha$  cell number in the medial preoptic nucleus (MPN) of intact (Madeira *et al.*, 2000) or OVX, steroid-treated (Chakraborty *et al.*, 2003a) females at young, middle-aged, and aged stages. Chakraborty *et al.* (2003a) also extended their studies to include the anteroventral periventricular nucleus and ventromedial nucleus, and showed an increase in ER $\alpha$  cell number from middle-age to aged animals in these regions. Thus, there are nuclei-specific changes in ER $\alpha$  expression in the aging rat hypothalamus, and uncovering the roles of these nuclei in reproductive aging will be vital to understanding the mechanism behind senescence. Effects of estrogen on expression of its ER have been studied in an age-related context. In the previous study by Chakraborty *et al.* (2003a), estrogen had little effect on overall ER expression in OVX rats of any age in the anteroventral periventricular nucleus, medial preoptic nucleus, arcuate nucleus, and ventromedial nucleus. Wise and Parsons (1984), when examining ER $\alpha$  nuclear DNA expression, found that estrogen treatment did have effects on ER $\alpha$  expression, with a two-day treatment causing decreases in OVX, middle-aged females in the preoptic area and medial basal hypothalamus. This effect was no longer apparent after four days of estrogen treatment. The techniques used in these studies differed in that the former study examined protein expression and the latter studied gene expression. This suggests a mechanism for posttranscriptional or translational changes to ER $\alpha$  mRNA that may compensate for the observed down-regulation of gene expression with estrogen treatment. Additionally, the ER may undergo age-related changes to protein expression, but only in very specific subpopulations. For example, a study

TABLE 43.3  
Representative *in situ* hybridization studies of ER $\alpha$  expression in aging rat hypothalamus

Rat strain	OVX duration before steroid treatment	Steroid hormone treatment	Effect on ER $\alpha$
Fischer 344	Immediate	17 $\beta$ -E2 (50% capsule) for 2 weeks.	↓ ER $\alpha$ in POA with E2 treatment. No age effects (Y, MA, A).
Fischer 344	10 days	17 $\beta$ -E2 (5% capsule) for 4 days.	↓ ER $\alpha$ in VMN and ARC in E2-treated Y; in POA of MA compared to Y.
Sprague-Dawley	1 week	17 $\beta$ -E2 capsules [180 mg/ml; 20 (Y) or 30 (MA) mm], for 2 days.	↑ ER $\alpha$ in PePOA in A compared to Y and MA rats. No differences in MPN, ARC, VMN.

Modified from Chakraborty and Gore (2004).

Abbreviations: ER: estrogen receptor; 17 $\beta$ -E2: 17-beta estradiol; Y: young; MA: middle-aged; A: aged; POA: preoptic area; VMN: ventromedial nucleus; ARC: arcuate nucleus; PePOA: periventricular preoptic area.

### 43. Age-related Changes in Hormones and Their Receptors

examining ER $\alpha$  protein coexpression with the NRI subunit of the NMDAR showed hypothalamic changes as a result of estrogen treatment (Chakraborty *et al.*, 2003b). Since ERs are coexpressed with a number of known neuromodulators to GnRH neurons, this may be an alternate mechanism by which age-related changes of feedback occur in the hypothalamus.

**ER $\beta$ :** Studies examining age-related changes to ER $\beta$  are not as numerous as those on ER $\alpha$ , as this receptor was more recently discovered and thus has not been studied as extensively. However, it is important to note that ER $\beta$  has repeatedly been colocalized to GnRH neurons (Herbison and Pape, 2001) albeit at low levels, whereas ER $\alpha$  has not, suggesting a mechanism by which ER $\beta$  may directly regulate GnRH neurons. An *in situ* hybridization study in young, middle-aged, and aged OVX, steroid-treated rats showed a decline in mRNA expression in the supraoptic nucleus of the hypothalamus of middle-aged as compared to young females, with no declines in other hypothalamic nuclei observed (Wilson *et al.*, 2002; Chakraborty and Gore, 2004). A study that extended this to examine protein expression found a decrease in middle-aged and aged as compared to young OVX, estrogen-treated females in the anteroventral periventricular nucleus (Chakraborty *et al.*, 2003a), an area in which earlier studies reported increases in ER $\alpha$  (Chakraborty and Gore, 2004). These findings suggest a possible interplay of the two ERs, in which differential expression of these receptors in various hypothalamic nuclei at different ages could alter the outcome of estrogen activation and effect on the HPG axis. To our knowledge, no studies on effects of estrogen replacement on specific populations of ER $\beta$  within GnRH neurons or upon GnRH neuromodulators have been reported in aging animals, but this is an important area that warrants future study.

**Progesterone receptor (PR):** Progesterone levels fluctuate throughout the reproductive cycle, with highest levels reported during proestrus and lowest during diestrus (see Figure 43.2). Age-related changes in circulating progesterone concentrations are first observed well before the onset of irregular cyclicity, with delayed release occurring in middle-aged, regularly cycling animals when compared to young. Once the transition to irregular cycles begins, progesterone levels in rats decrease as compared to young animals. However, persistent diestrus animals show relatively high levels of progesterone, demonstrating the persistence of this hormone in aged animals (reviewed in Chakraborty and Gore, 2004).

Progesterone effects are influenced by the presence or absence of estrogen. Progesterone cannot induce a GnRH/LH surge on its own, but when administered at the proper timing following estrogen priming, the hormonal treatment will facilitate a maximal GnRH/LH

surge (Attardi *et al.*, 1997). Therefore, the progesterone response is mediated by the presence of estrogen, in large part due to induction of the PR by estradiol (Chakraborty and Gore, 2004). Interestingly, middle-aged animals treated with chronic estrogen are eventually unable to generate a GnRH/LH surge. However, administration of progesterone within a certain time period will reverse these effects and generate a surge. As the transition to persistent estrus occurs, the hypothalamus is thought to lose its responsiveness to estrogen, followed by a decline in progesterone responsiveness, but these findings show a small time window in which administration of estrogen and progesterone may reinstate the preovulatory surge. Once that window has passed, without hormone treatment, sensitivity is lost and cannot be recovered (Tsai *et al.*, 2004). This suggests that a temporal change occurs within the hypothalamic axis, supporting the supposition that hormone replacement therapy, if it is to work in humans, must be given in the perimenopausal stages, as once the transition to acyclicity occurs (postmenopause), it may not be effective in treating symptomatology.

Few studies have observed the effect of aging on PR expression in the hypothalamus, and those few show differing results, most probably due to different assay methodologies and animal treatments. A summary of these can be found in Table 43.4. In brief, the results range from no age-related change observed in PR mRNA in specific hypothalamic nuclei (Funabashi *et al.*, 2000) to decreases of PR gene expression localized to specific nuclei (Wise and Parsons, 1984). A study of intact females showed decreases in PR expression in specific nuclei in middle-aged (12–15 mos.) animals (Mills *et al.*, 2002), in agreement with Wise and Parsons (1984). Interestingly, the effects were seen in long-term persistent estrus (PE) females, but not in short-term PE, reinforcing the fact that the intact and gonadectomized models both contribute important information when studying age-related declines in reproductive function. It is likely that PR as well as ER expression declines with aging in the mammalian brain, yet more studies must be done to verify this. In these studies researchers must be sure to meticulously monitor and record animal reproductive status and experimental treatments, as these methodologies can play a large role in the reported outcomes of these experiments. Additionally, as is indicated for ERs, any age-associated changes in PRs are more likely to be region-specific.

Overall, the rat is an excellent model for studying neuroendocrine mechanisms of reproductive senescence, as they experience predominantly neural changes in relation to reproductive function, and are relatively inexpensive, easy to attain and care for. The literature on changes in hormone receptors that mediate feedback effects of estradiol and progesterone onto GnRH neurons is also expanding. The number of manipulations

TABLE 43.4  
Effects of aging and hormone treatment on progesterone receptor (PR) expression in the hypothalamus of aging rats

Rat strain	OVX duration before steroid treatment	Steroid hormone treatment	Technique	Effect on progesterone receptor (PR)
Sprague-Dawley	7 d	17 $\beta$ -E2 capsule 2 d ⇒ P 0.2 mg/kg s.c. 17 $\beta$ -E2 4 d ⇒ P 0.2 mg/kg s.c.	Nuclear exchange assay to determine DNA content of POA, MBH, and AMYG of Y and MA.	E2 (2d): ↑ PR binding sites in POA and MBH in Y vs. MA. E2 (4d): No age-related change.
Sprague-Dawley	17 d	17 $\beta$ -E2, 3 d	Binding assay in POA, PVP, BNST, VMN, ARC, AMYG of Y, MA, or A.	No age-related differences in induction of PR binding by E2 in any of the observed structures.
Fischer 344	10 d	17 $\beta$ -E2, 4 d	<i>in situ</i> hybridization in POA and MBH of Y, MA, A.	No differences among any age groups.
Long-Evans	Intact	None	<i>in situ</i> hybridization in AVPV, POA, ARC, VMN of Y and MA (early and late PE).	POA: no age difference. VMN/ARC: PR mRNA lower in long-term PE versus early PE and young, proestrus. AVPV: lower PR mRNA in early and long-term PE compared to young.

Modified from Chakraborty and Gore 2004.

Abbreviations: P, Progesterone; POA, Preoptic area; MBH, medial basal hypothalamus; AMYG, amygdala; PVP, periventricular preoptic area; BNST, bed nucleus of the stria terminalis; ARC, arcuate nucleus; VMN, ventromedial nucleus; AVPV, anteroventral periventricular nucleus; d, days; Y, young; MA, middle-aged; A, aged; PE, persistent estrus; 17 $\beta$ -E2 17-beta estradiol.

and treatments that can be used with these animals warrant careful consideration when constructing a study focusing on effects of age-related changes on reproductive function.

## MICE

### *Normal wild-type mice*

Studies examining age-related changes to the mouse HPG axis have demonstrated similar findings to those of the rat, and thus only the highlights and differences will be presented in this section. The mouse lifespan is similar to that of the rat. In mice, the mean maximal life-span is 30 months, during which persistent estrus appears at approximately 12 months, followed by exhaustion of oocytes at 24 months (Finch *et al.*, 1984). Unlike rats, estrogen levels in mice transitioning from persistent estrus to anestrus are low, as is seen in humans and OWMs (Finch *et al.*, 1984). As in rats, mice show a transition from a four- to five-day cycle to longer cycles and delayed onset and attenuation of the GnRH/LH surge in later stages of life (Finch *et al.*, 1984; Nelson *et al.*, 1995).

Changes in ER expression and binding have been studied in depth in mouse models. Overall, age-related decreases in hypothalamic ER expression and receptor binding, and a decrease in the duration of binding have all been reported (Nelson *et al.*, 1995). Bergman *et al.*

(1991) suggested that there is an age-associated delay in cytosolic ER replenishment in the hypothalamus, which causes the observed decrease in nuclear ER in middle-aged animals. This, accompanied by a decreased amount of time estrogen is spent bound to the receptor, possibly interferes with the positive feedback mechanism associated with ovulation, thus causing eventual delays in estrous cyclicity.

Because the mouse is more similar to humans in ovarian steroid levels and follicular function later in life, this model has been used predominantly for studies into ovarian changes. The few reports examining numbers of GnRH neurons in the hypothalamus showed little or no loss with aging (reviewed in Gore, 2001). Age-related losses in pituitary GnRH receptors were not detected in mice, but increases in GnRH and gonadotropins were, suggesting age-related changes in reproductive status may result from a mechanism independent of GnRH receptor activation (reviewed in Gore, 2001). The latter hormonal increases are similar to those in human and nonhuman primates, and suggestive of a loss of estrogen-negative feedback. Finally, attenuation of the estrogen-induced GnRH/LH surge begins to occur prior to the onset of irregular cyclicity in rodents (Nelson *et al.*, 1995).

Ovarian grafting experiments have been used to examine ovarian versus extra-ovarian influences on

### 43. Age-related Changes in Hormones and Their Receptors

reproductive changes occurring in aging animals. Mice have most commonly been used for such studies. Young ovaries implanted into middle-aged animals prior to cessation of cycling extended the period of cyclicity beyond that of intact controls. This is suggestive of ovarian influences. However, this did not restore cycle frequency to the expected four-day cycle of young animals, suggestive of hypothalamic-pituitary influences. Additionally, the preovulatory estrogen and progesterone levels were restored, but the overall amplitude of these surges was not (Nelson *et al.*, 1995). Further transplantation studies showed these results to be age sensitive, as 17-month old, short-term OVX females showed a shorter period of recovered cyclicity (3 mos. of cyclicity was restored in 25% of the young controls) and 25-month-old females showed a very small recovery (30% of 17-month-old) (Felicio *et al.*, 1983). Together, these studies demonstrate the complexity of the reproductive system, as it suggests different but complementary roles of the ovary and the hypothalamus in the regulation of cycle duration and frequency.

As aging occurs, ovarian morphology changes, and the mouse model has been used to examine these changes in detail. Studies in mice have revealed that there is a similar number of oocytes in middle-aged as in aged animals, clutches of ova continue to be released, follicles do mature (albeit in lower number), and administration of hormones can stimulate normal ovulation (Finch *et al.*, 1984). Recent studies also have led to a challenge of one of the main doctrines of female reproduction. It has remained a firm belief that a female is supplied with a certain number of follicles at birth, and as this supply dwindles, the female enters perimenopause. However, Johnson *et al.* (2004) recently provided evidence for replenishment of ovarian follicles in adult female mice. This group discovered active germ cells in the ovary that seem to replenish the follicular pool. They theorize that there is a fine balance in young adults in which the number of follicles undergoing atresia is matched or surpassed by the number of germ cells undergoing meiosis and forming replacement follicles. As animals age, the number of atretic follicles increases and eventually surpasses the number being replaced, causing an overall decline in the population of ovarian follicles (Johnson *et al.*, 2004). This theory is very new but makes sense. Underlying the old doctrine, in which females were believed to be endowed with a set number of follicles for life, was the question of reproductive survival. It is a basic tenet of biology that the main purpose of all living beings is to reproduce. Hence, where the body is very efficient in most areas, the supposition of a set number of ovarian follicles seems very inefficient. These findings, though extremely recent, pose a new method for looking at follicular decline and may lead to a new arena of research into reproductive aging. Molecular examination of follicular pools may lead to new technologies by which menopause can be treated.

#### *Transgenics*

With the publication of the mouse genome, the mouse model has become first and foremost a means by which genetic manipulation can be used to study the role that each gene plays in the system as a whole. There are a number of transgenic and other mice that are used in studying the reproductive system and its component parts, and these animals can also prove useful in the study of mechanisms of reproductive senescence. This section will cover those mutations or knockouts directly affecting the HPG axis. We will not include those that target neuromodulatory systems of this axis, such as the NMDA receptor, GABA receptor, and dopamine-beta-hydroxylase (a biosynthetic enzyme important in catecholamine synthesis) knockouts, but these, too, may play an important role in examining mechanisms influencing the onset of reproductive aging.

The follitropin receptor knockout mouse (FORKO) is deficient of the FSH receptor (FSH-R). Recall that one of the main indices of the onset of menopause in women and estropause in rodents is an increase in FSH prior to the onset of irregular menstrual cycles. FSH is thought to mediate the apoptosis of follicles, but requires the proper interaction with its receptor to do so (Simoni *et al.*, 1997). Thus, it is possible that changes to the number of FSH-Rs trigger the onset of age-associated ovarian disruption. The FORKO knockout provides one model in which to study this hypothesis.

The FORKO homozygous null ( $-/-$ ) mouse shows estrogen deficiency, sterility, and acyclicity. Histology of the ovary demonstrates that the follicles cannot proceed past the preantral stage and thus cannot completely mature (Danilovich *et al.*, 2004). The heterozygous null mutant shows a reduction in fertility in adulthood, but can still produce offspring. By seven to nine months, these animals no longer breed, thus demonstrating an earlier onset of senescence (see Table 43.5; Danilovich *et al.*, 2004). In aging heterozygotes ( $+/-$ ) testosterone levels and gonadotropins are higher than those of the wild types. Estrogen, progesterone, and inhibin are lower. Measured ovulation rate, number of ova released, and presence of corpora lutea are all lower (with no corpora lutea by 12 months in heterozygotes). Finally, there is a greater change in binding to FSH-R in heterozygotes than wild types (Danilovich *et al.*, 2002) (for a summary, see Table 43.5). These characteristics are similar to that of aging women, and are accompanied by acyclicity, skeletal abnormalities, and obesity, all common to menopausal women (Danilovich *et al.*, 2004).

Danilovich *et al.* (2004) have used these mice to begin investigating changes to the central nervous system accompanied by reproductive senescence, as well as the use of hormone replacement therapy to treat symptoms associated with this condition. They assert that the use of a genetically altered, intact model that does not need surgical manipulation will add to the evaluation of drugs useful for treating menopausal symptoms. Thus far, they

TABLE 43.5  
Follitropin receptor (FORKO) heterozygous mouse (+/−) and wild type (+/+) reproductive aging characteristics at 3, 7, and 12 months

	Age	Wild Type (+/+)	Heterozygous FORKO (+/−)
% reproductive success	3 mos.	96%	85%
	7 mos.	83%	49%
	12 mos.	73%	12%

Abbreviations: WT, wild type; mos, months; NA, not applicable.

have used these animals to examine the status of the ER signaling system and have found that the decrease in estrogen had no impact on ER gene transcription or translation, nor on functional activation of ERs in the uterus, vagina, or adipose tissue of mice (Danilovich *et al.*, 2004). Hypothalamic tissue has yet to be studied. Their initial findings suggest that treatment of these estrogen-deficient animals with estrogen is successful in producing target-specific results, supporting the use of hormone replacement therapy.

Inactivation of luteinizing hormone (LH) receptors results in a mouse that shows acyclicity (and hence infertility), smaller ovaries, and a smaller reproductive tract overall. Ovulation does not occur, and follicular maturation cannot be recovered even with estrogen/progesterone treatment. Hormonally, these animals have increased gonadotropin levels with detectable, but low levels of ovarian steroid hormones. This appears to be accompanied by decreased ER $\alpha$  and increased ER $\beta$  ovarian mRNA, suggestive of effects of LH on ER gene expression (Rao and Lei, 2002). Interestingly, the heterozygotes are virtually indistinguishable from their wild-type littermates, with the exception of a modest increase in FSH and decrease in estrogen levels. As in the FORKO heterozygotes, these animals appear to undergo reproductive senescence earlier than wild types, becoming obese

and showing bone loss by one year (Rao and Lei, 2002). As of yet, mechanisms of aging have not been examined in detail in the female heterozygotes, but they offer an alternative model for studying the role of LH in reproduction and on the onset of reproductive aging. Additionally, changes in hypothalamic morphology would be interesting to observe in these knockouts.

The estrogen receptor knockouts (ERKOs) have played a large role in expanding our understanding of the role of estrogen in reproduction. These include the alpha-ERKO ( $\alpha$ ERKO), beta-ERKO ( $\beta$ ERKO), and the double  $\alpha\beta$ ERKO. There is also an aromatase knockout (ArKO) mouse that lacks the enzyme converting testosterone to estradiol. Table 43.6 summarizes the reproductive phenotypes associated with these mutants. The ArKO is an interesting model, in that the animals have complete expression of both ERs, but are lacking aromatase activity, and thus endogenous ovarian estrogens are not synthesized. Because this has not been examined in the context of aging, it will not be discussed in detail here, but a recent study by Britt *et al.* (2005) observed uterine and ovarian weight and morphology as well as gonadotropin levels resulting from treatment of wild type and ArKO mice fed soy-free, soy, or the isoflavone genistein (a phytoestrogen) diets from two weeks prenatally to 16 weeks of age. Overall, they found estrogenic effects of

### 43. Age-related Changes in Hormones and Their Receptors

TABLE 43.6

Reproductive characteristics of the female estrogen receptor knockout alpha ( $\alpha$ ERKO), estrogen receptor knockout beta ( $\beta$ ERKO), estrogen receptor alpha and beta double knockout ( $\alpha\beta$ ERKO), and aromatase knockout (ArKO) mouse

	Cyclicity	Fertility	Ovarian histology	Folliculogenesis	Gonadotropin levels	Ovarian hormones
$\alpha$ ERKO	Acyclic	Infertile	Hemorrhagic cyst with no corpora lutea	Occurs, but fewer oocytes released	Elevated LH	Elevated estradiol
$\beta$ ERKO	Cycles	Decreased fertility	Small ovaries w/ few corpora lutea	Arrested	Normal	Normal
$\alpha\beta$ ERKO	Acyclic	Infertile	Degenerating oocytes, loss of granulosa cells; no corpora lutea	NA	Elevated LH	Elevated estrogen
ArKO	Acyclic	Infertile	No corpora lutea	Arrested at antral stage	Elevated	Undetectable estrogen

Adapted from Hewitt *et al.* 2005 and Britt *et al.* 2005.

phytoestrogens in the ArKO mice. It would be worthwhile to extend these studies to an aging context.

The progesterone receptor knockout (PRKO) has been useful in determining progesterone's importance in the regulation of ovulation. Even with administration of superovulatory LH levels, these animals do not ovulate. Histological analysis of the follicles showed development through the luteal formation, but progesterone was needed to actually rupture the follicle. These animals also show impaired sexual behavior and gonadotropin regulation, anovulation, and uterine dysfunction (Conneely *et al.*, 2002). The development of the PRAKO and PRBKO now allows researchers to determine the function of the two PR isoforms, A and B, respectively. In PRAKO mice, there are severe abnormalities in ovarian and uterine function that lead to female infertility, whereas the PRBKO shows changes to mammary gland morphogenesis. These differential changes suggest that the two isoforms have differential activities, with studies suggesting PR-A is responsible for the progesterone-dependent responses necessary for female fertility and PR-B for generating the progesterone-induced proliferative response of the mammary gland. It has also been suggested that PR-A may be the dominant of the two isoforms, and exerts a dominant effect over PR-B (Conneely *et al.*, 2002).

To date, we are unaware of any studies characterizing aging in the aforementioned knockout models (excluding the FORKO and the LH receptor knockout mouse). Future research looking at these phenotypes in an age-related context may help to further uncover the roles of these various receptors in the aging mouse model.

Nonconditional knockouts, such as those described above, have an "incomplete" or altered genome from development, and observations generated for these animals must be considered carefully, as developmental effects may influence the interpretations generated for these animals. Conditional knockouts, when available, may be

preferable to nonconditional, as the animals mature with their genome intact, and the researcher may then temporarily inactivate the gene of interest to conduct experiments, and then reactivate it when appropriate. This technology also allows selective areas to be knocked out. Currently, we do not know of any conditional knockouts for the hypothalamic or pituitary levels of the HPG axis, nor have existing lines been used for studies of reproductive aging. However, it is important to note that there are a number of lines that currently exist, which may help to uncover the roles of the neuromodulators of the HPG system, including the NPY receptor, the NMDAR, and the GABAR conditional knockouts. These have not yet been used for studies of reproductive aging, but hold potential for future examination into this system. Finally, this section did not go into detail about the transgenic strains available that *overexpress* genes. These, too, can offer valuable information as to the function of the many components feeding into the reproductive system, and eventually may prove useful in examining the mechanisms of reproductive aging.

#### *Altered mouse strains*

Although rodents are a popular animal model to use for reproductive aging, and are far less expensive than the non-human primate, it is still costly for a researcher to house these animals for the necessary one to three years in order to establish an aging colony. Additionally, mice often need to be kept in a barrier facility to maintain a pathogen-free environment, and the onset of old age also makes these animals more susceptible to age-related decline and death. An additional consideration is the strain of mouse used in these studies, as often they exhibit strain-specific traits. These strains are inbred for homozygosity, a trait useful for controlling genetic variations in animals, but also disadvantageous because of its artificiality. One way to avoid this is to use F1 crosses between inbred strains (Spratt and Ramirez, 1997).

The development of a senescence-accelerated mouse (SAM) is an alternative available for researchers interested in reproductive aging. To date, there exist 12 lines of mice, nine senescence-prone (SAMP) and three senescence-resistant (SAMR). These mice arose while inbreeding pairs of mice from the strain AKR/J (Takeda *et al.*, 1997). The SAMP animals have a lifespan of approximately 9.7 months; the SAMR have approximately 13.3 months (Takeda *et al.*, 1997). These animals have been used to examine deficits in learning and memory, joint disease, cataracts, and other age-related diseases. They show signs of osteoporosis, but to the authors' knowledge, no reproductive studies have yet been conducted. It would be interesting to extend research with these animals to the reproductive level, and with new technologies to compare their genotypes with those of wild-type AKR/J mice, to begin examination of genetic differences that might have resulted in their age-accelerated phenotype.

### Birds

Until this point, we have focused on mammalian models of female reproductive senescence, but there are also a few nonmammalian models worth noting, among them, birds. Some birds, including chickens, are continuous breeders, breeding throughout the year, whereas others, such as parrots or songbirds, are opportunistic or seasonal breeders, having a distinct breeding season dictated most often by environmental conditions and other external cues. All of these animals, however, follow a similar reproductive cycle, with activation of GnRH neurons causing release of gonadotropins, followed by ovarian hormone release, resulting in ovulation. It is important to note that, in contrast to mammals, the

majority of avian species have only one functional ovary and oviduct, with the right ovary regressing during embryonic development. The developing follicles are visible on the external surface of the ovary, in contrast to the mammalian ovary, in which they are hidden within connective-tissue capsules. These avian follicles show a graded size hierarchy, allowing researchers to directly determine reproductive status without having to histologically prepare the ovary, and of course, these cells are different in appearance, with a yolky membrane developing as they mature (Holmes *et al.*, 2003b).

Birds serve as an interesting model of aging, and the study of reproductive aging is slowly becoming more prevalent. Compared to mammals, birds have a much longer overall life span when body size is taken into account. The adaptation of flight causes these animals to have a much higher overall energy expenditure and an extremely fast metabolism, which is thought to keep oxidative and glycoxidative cellular damage to a minimum, causing slower cellular aging (Holmes and Ottinger, 2003a). Additionally, the avian brain has proven to be highly plastic through adulthood, including the reproductive axis (although this is best studied in males) (Holmes *et al.*, 2003b).

Overall, class *Aves* is composed of females with a slower onset of reproductive aging, with a division of this class into three general reproductive groups (see Table 43.7). Theme 1 includes most *Galliformes*, including quail, chicken, and, pheasant so on, and is composed of the rapid breeders. These show rapid declines in reproductive success and shorter life spans (6 years or under). Theme 2, consisting mostly of the *Passerine* songbirds, raptors, and parrots, show moderately slow declines in reproductive aging and moderately long life spans. The final theme, consisting mostly of seabirds, shows

TABLE 43.7  
The three themes of avian reproduction

	Theme 1: Galliformes	Theme 2: Passerine songbirds, parrots, raptors	Theme 3: Sea birds
Commonly studied species	Japanese quail	Zebra finch, canary, white-crowned sparrow, budgerigar	Common Tern
Onset of reproductive decline (measured by reproductive success)	Rapid	Moderately slow: characterized by increased reproductive success followed by gradual decline	Very slow or nonexistent
Life span	Short (under 6 years)	Moderately long (on average 20–30 years, but up to 100 years)	Very long (more than 50 years); maturation delayed and clutch sizes small
Postreproductive life span	Reproductive decline begins by 2–3 years, noted by captive studies	Varies, but documented in some captive species	No captive data available and not documented in wild populations

Modified from Holmes *et al.* 2003b.

### 43. Age-related Changes in Hormones and Their Receptors

very slow to negligible reproductive aging, with very long lifespans (greater than 50 years) (Holmes *et al.*, 2003b). The information on the latter two groups has been collected predominantly in the wild, and as such, observations of reproductive success in later stages of life remain incomplete.

In bird species, declines in reproductive success are noted by decreases in egg production and clutch size, slowed or absent responses to outside cues inducing ovulation, and reduction in the viability and survival rate of the egg, as well as survival of the fledgling (Holmes *et al.*, 2003b). Often this is the only means by which reproductive declines can be measured in wild populations. Studies in wild populations are often difficult, due to a number of factors. Most wild species live 20 years or more and unless the researcher tags them early into development, the exact age of these animals is not known, making senescence studies difficult. Often there is migration in and out of colonies, identification bands may be lost, and most commonly, wild populations of animals often have skewed distributions of younger animals versus older, making longitudinal studies very challenging. Very little to date is known about these populations. The common tern, a long-lived seabird (Theme 3 in Table 43.7), appears to be the only seabird with any data available concerning reproductive status and aging.

The common tern does not seem to show age-related declines in reproductive performance except in the very oldest birds, which make up a negligible percentage of the wild population (Nisbet *et al.*, 1999). Nisbet *et al.* (1999) noted that there may be a very slight decline in reproductive performance by 12 years, but senescence is not evident until 16 years of age. Hormonal studies on these animals indicate an increase in LH levels with age, but the authors note that this might be due either to age, or to the onset of early breeding in older animals, as age and breeding schedule were found to be inversely related. These studies are often useful for environmental research concerning specific populations, but limited results can be obtained purely for the understanding of neuroendocrine correlates of reproductive aging. For this, researchers turn to the captive model.

Birds are extremely hardy animals, are not very costly, are easy to maintain, and many breed well in a laboratory setting. Birds from the order *Galliformes*, specifically the Japanese quail, are often used for captive studies on reproductive aging. Sex differences during the aging process have been reported, the most prevalent being that of the timing of the onset of reproductive senescence. Females age much faster than males, with a decline in fertility noted by 1.5 to 2 years, accompanied by irregular egg production and shorter clutch length due to decreased ovarian function and response of hypothalamus to progesterone. The females generally reach senescence by three years of age (Ottinger, 2001). Aged females show a decrease in plasma progesterone and FSH along

with decreased follicular growth and decline in primary oocyte numbers. A decline in the preovulatory response has also been noted (Holmes *et al.*, 2003b).

Neural changes to the female avian hypothalamus have not been examined in many studies, but Ottinger *et al.* (2004) have reported a significant decline of GnRH-I protein in median eminence of aged laying hens. No difference in expression was observed in the preoptic area of young and aged laying hens, but the authors noted a trend toward increases in GnRH pulse amplitude recorded in hypothalamic slices *in vitro* (Ottinger *et al.*, 2004). This trend is consistent with mammalian studies discussed earlier.

The unique ability of many avians to age at a slower rate compared to mammals, as well as their unique bone structure specific for flight, make these animals an intriguing model to pursue in reproductive aging research. Osteoporosis is a prevalent concern in the aging human population, especially in women. In female birds, their bones act as a repository for the minerals and calcium important for egg production, and as they age, the skeletons become more fragile, providing an avian model for osteoporosis (Holmes and Ottinger, 2003a). The three classes of avian reproductive aging (see Table 43.7) provide a way to compare brain regions and gene expression in these regions among different avian models, which may shed light on specific anatomical and molecular changes in the brain that may delay or even hinder the onset and development of reproductive aging, and specifically, osteoporosis. Research to this point has been limited in that many of the longer lived species can be studied only in the wild, and even this provides limitations, as long-term funding and researcher consistency is difficult. However, establishment of captive populations for some of these longer lived species may prove useful in the long term for further studies into mechanisms of reproductive aging.

### Conclusion

In this chapter, we have discussed several important models of female reproductive aging: the nonhuman primate (Old and New World monkeys), rodents (rat and mouse, including genetically altered mice), and birds, with a presentation of some of the strengths and weaknesses of these models for reproductive aging research. A summary of the reproductive lifespans of the mammalian species is shown in Figure 43.3. Although reproductive aging has been studied in other animals not mentioned here, these models represent the bulk of the literature available on this topic, with other studies providing anecdotal data showing similar changes in fecundity, fertility, and hormonal levels during aging.

Recent findings by the Women's Health Initiative (Anderson *et al.*, 2004) have raised concerns about the use of estrogen replacement therapy as a treatment for menopausal symptoms. Therefore, it is important now more

than ever that researchers focus on the mechanisms contributing to the onset of menopause, and the accompanying symptoms that are typical to this condition. With the increase in average human lifespan, thereby ensuring that the majority of women will spend approximately half of their life in the menopausal state, the development of alternative therapies and the clarification of the use of current therapies are vital for the improvement of female quality of life. Additionally, information as to the mechanisms of reproductive aging may contribute critical information to therapy for infertile females.

# Model of Chaperones in Aging

J. Kröll and J.O. Nehlin

*The molecular chaperones or heat shock proteins (Hsp) are constitutive and stress-induced proteins participating in "housekeeping" functions such as proofreading and folding of other polymers (proteins, RNA, DNA), preventing the aggregation of polymers, disgregation of misfolded molecules, facilitation of the transport of polymers across biological membranes, and participation in the degradation of ubiquitinated molecules. The decrease in the constitutive expression and inductivity of the chaperones with age—possibly caused by progressive silencing of the chaperone genes—probably contributes decisively to the phenotype of aging, as illustrated also from the progeric syndromes caused by mutational defects of the RecQ protein/DNA chaperones. Conversely, high levels of chaperone expression is a common denominator in conditions or procedures leading to an increase in cellular and species longevity as well as in the process of cellular immortalization, the inherent immortality of the embryonic stem cells, and the inhibition of cellular apoptosis.*

*The inherent immortality of the embryonic stem cells implies that replicative senescence as possibly the aging of species are epigenetic phenomena. The involvement of RNA chaperones in the process of cellular immortalization and mutational DNA chaperones in the progeric syndromes suggests that RNA/DNA-chaperones are of major importance for the definition of cellular and species longevity. Accordingly, evidence has been presented to suggest that the evolution of longevity depends on alterations in the expression of relatively few regulatory genes. Possibly the molecular chaperones are evolution facilitators, contributing to the definition of the life span of differentiated cells as well as the longevity of species.*

## Introduction

The term *replicative senescence* describes the observation that normal eukaryotic cells cultured *in vitro* can attain a maximal number of population doublings proportional to the life span of the species and inversely proportional to the age of the individual (Handbook chapter 4). Cells can transgress this *Hayflick limit* to immortalization by viral transformation, for example, by transfection with the SV40 T protein. Analysis of the T protein showed that the immortalizing effect specifically could be ascribed

to the C-terminal ATPase module. Hypothetically it was suggested that this ATPase module somehow could replace—or by transactivation of the ATP-synthase gene—compensate for a functional defect of the beta-subunit of the mitochondrial F1-ATPase: the master of ATPases serving the reverse function of producing ATP, the universal currency of free energy (Kröll, 1994). Support for this suggestion was gained from observations of exposure of the catalytic beta-subunit of the ATP synthase on the surface of different tumor cell lines, indicating an overexpression of this ATPase module in some immortalized cell lines (Kröll, 1996).

The ATPase module is an important subunit also in other essential cellular machines such as the membrane pumps and the heat shock proteins/molecular chaperones. That the SV40 T-protein was recognized as a molecular chaperone gave rise to the suggestion that this property might contribute to the general increased *in vitro* life span and occasional immortalization observed in cells transfected with the SV40 T-protein. This suggestion gained support from the observation that a similar increase in cellular life span *in vitro* could be obtained by transfection with other chaperones or by heat shock or hormetic procedures raising the cellular level of expression of the heat shock proteins. The probable importance of the molecular chaperones for the process of cellular immortalization also appears from the observation that an increase in the level of expression of molecular chaperones is a common feature of the various procedures used to attain immortalization of primary cells *in vitro*, as well as from the frequent hyper-expression of various chaperones in immortal cancer cell lines, as in the inherently immortal primary cell lines from catfish (Kröll, 2002). The recognition that the SV40 T-protein as the human homologue p68 are DEAD box RNA-chaperones and the Werner Protein WRN probably is a RecQ DNA-chaperone places some emphasis on the importance of the RNA/DNA-chaperones in the definition of cellular longevity (Kröll, 2004). Accordingly evidence has been presented to suggest that the evolution of longevity depends on alterations in the expression of relatively few regulatory genes (Kröll, 2005). This chapter presents evidence on the probable importance of the molecular chaperones as antagonists of the aging process and for the evolution of cellular and species longevity.

## Functions and Classes of the Molecular Chaperones

### HOUSEKEEPING FUNCTIONS

The molecular chaperones are a highly conserved class of proteins expressed constitutively or synthesized in response to stressful physiological conditions such as heat shock (cf. the term Heat Shock Proteins, or Hsp). The chaperones are essential for viability even under normal temperatures by assisting in housekeeping functions such as proofreading and correct folding of other proteins, RNA and DNA, preventing the aggregation of polymers and disgregation of misfolded molecules, facilitation of the transport of polymers across biological membranes, and participation in the degradation of ubiquitinated molecules.

### PROTEIN CHAPERONES

During evolution, the number, size, and complexity of chaperones increase from the small Hsp/crystallins, prefoldins, and chaperonins forming the minimal protein-folding system of the hyperthermophilic archaea (Laksanalamai *et al.*, 2004) to the families of larger chaperones Hsp40/DnaJ, Hsp60, Hsp70, Hsp90, and Hsp110 cooperating in the complex chaperone machines of the eucarya (Young *et al.*, 2004).

### RNA/DNA CHAPERONES

The DEAD box proteins (e.g., the viral SV40 T-protein and the mammalian homolog p68) are RNA chaperones, as probably the RecQ proteins are DNA chaperones (Kröll, 2004). Hsp90 is unique among the protein chaperones due to its unconventional highly conserved Bergerat ATP-binding fold shared by the DNA gyrases and DNA-mismatch-repair enzymes. Probably the Hsp90 machinery includes DNA in its chaperoning activity; possibly serving as a chaperone for the reverse transcription of telomeric DNA, in analogy to its requirement for the hepatitis B virus reverse transcriptase function (Hu *et al.*, 2004).

### CHAPERONES OF THE CELLULAR COMPARTMENTS

Molecular chaperones have been described across tissues and subcellular compartments (see Table 44.1 and Figure 44.1).

#### *Cytoplasmic chaperones*

The HSP70 and HSP90 families are found mainly in the cytoplasmic compartment. Hsp90 and Hsp70 refold proteins in an ATP-dependent way, where Hsp90 is dedicated to specific substrates and Hsp70 refolds more general substrates (Young *et al.*, 2004).

The super-family of mammalian small heat shock or stress proteins (sHsp) in humans consists of the known members HSP27,  $\alpha$ B-crystallin,  $\alpha$ A-crystallin, Hsp20,

HspB2, HspB3, and cvHsp. sHsp's have the ability to form supra-molecular structures, either homo-oligomeric or hetero-oligomeric complexes, ranging in molecular weight from 50 to 1000 kDa depending on the degree of stress. The basic structural units of sHsp complexes are dimers that are formed by interaction of segments of the  $\alpha$ -crystallin domain. The sHsp's can bind and prevent aggregation of denatured proteins, but usually they cannot refold them. They may help target their substrate for proteolysis, or they may store it for subsequent refolding by the Hsp70 chaperone system (Laksanalamai *et al.*, 2004).

Whereas unfolded cytoplasmic proteins evoke the heat shock response, other cellular organelles also can evoke appropriate protective mechanisms.

#### *Chaperones of the endoplasmic reticulum*

During protein synthesis, nascent proteins are processed within the endoplasmic reticulum (ER), where a subset of chaperones and folding enzymes form multiprotein complexes. The lectins calnexin and calreticulin and the oxidoreductase Erp57 are involved in ER-quality control, which prevents aggregation and export along the secretory pathway of misfolded and incompletely assembled proteins. Appropriate folding of polypeptides requires chaperone proteins such as Bip/Grp78 and calreticulin. Overexpression of proteins or abnormally folded nascent proteins can lead to protein accumulation and aggregation in cells, causing ER stress, which in severe cases could trigger cell death. A cellular protective mechanism known as the unfolded protein response (UPR) evolved to induce the expression of various genes including molecular chaperones and to activate ER-associated protein degradation (ERAD). The ER-chaperones relay a signal that temporarily induces a general slow-down in cellular division to prioritize the expression of proteins required for the appropriate synthesis of the nascent protein. Cells with high secretory capacity such as the ones found in endocrine glands or immunoglobulin-producing cells often require high ER-chaperone usage. The 47-kDa heat shock protein 47 (HSP47) is an ER-resident, collagen-specific molecular chaperone that has been shown to play a major role during the processing and/or secretion of procollagen in, for example, fibroblasts (Miyaiishi *et al.*, 1995; Castro-Fernandez *et al.*, 2005).

#### *Mitochondrial chaperones*

Mitochondria contain several members of the major chaperone families that have important functions in maintaining this organelle's function. Changes in the energy status of the cells require adaptations in the protein import machinery such as the induction of cytosolic molecular chaperones that transport precursors to the matrix, the up-regulation of outer membrane import receptors, and the increase in matrix chaperonins (e.g., Hsp60) that facilitate the import and proper folding of the protein for subsequent compartmentation in

TABLE 44.1  
Classes of molecular chaperones

Chaperone	Function and subcellular localization
$\alpha$ A-crystallin	Small hsp—Stabilization against aggregation during heat shock. Localization: Post-Golgi membranes
$\alpha$ B-crystallin	Small hsp—Stabilization against aggregation during heat shock. Localization: Post-Golgi membranes
BBS6/MKKS	McKusick-Kaufman syndrome—Homology to chaperonin
Calnexin	Interacts and assists with the folding of new proteins that carry monoglucosylated N-linked glycans; retains incompletely folded proteins in the ER. Localization: ER membrane
Calreticulin/Grp95	Folding of glycosylated proteins in the ER in cooperation with glucosyltransferase; similar to calnexin. Localization: ER lumen
Clusterin/XIP8/apo-J	ERP29 endoplasmic reticulum protein 29. Localization: ER
Erdj4/MDG1	DnaJ family member. Localization: ER
GRP78 (BIP)	Ca <sup>2+</sup> -binding—Hsp70 family member. Localization: ER
Grp94/gp96	Hsp90 ER luminal homolog—Possible role in the antigen presentation pathway. Localization: ER
GRP170	Localization: ER
Hsp20/25/27 HspB2, HSPB3, cvHsp	Small hsp's—Stabilization against aggregation during heat shock. Localization: Multiple
Hsp40/Erdj1-5/DnaJ	Stimulates BIP ATPase activity; binds nascent polypeptides. Localization: ER
Bind unfolded proteins, interact with matching hsp70's	
Hdj1: human dnaJ homologue abundant in neurons	
Hsp47	Processing and secretion of collagen. Localization: ER
Hsp56/FKBP59	FK506 binding protein 59 induced by cardiotrophin; cardiac hypertrophy. Localization: ER
Hsp60/Hsp10	Folding of imported proteins (known as chaperonins in bacteria). Localization: Mitochondria
Hsp70 family	ATP-dependent stabilization of hydrophobic regions in extended polypeptide segments; role in the ubiquitin-proteasome system; binding of nascent polypeptides; maintains translocation-competent ER and mitochondrial precursor proteins in the cytosol Hsp72: stress inducible, Hsc73, binds to nascent chains, constitutive Mortalins mot-1, mot-2/mthsp70/GRP75

(Continued)

TABLE 44.1  
Continued

Chaperone	Function and subcellular localization
Hsp90	Mitochondrial Hsp70 (hsc70) alias Survivin—Conformational maturation of steroid hormone receptors and signalling kinases. Localization: Cytoplasm/Nucleus
Hsp100	ATP-dependent disaggregation and unfolding for degradation. Localization: Cytoplasm
Hsp104	
Hsp105 $\alpha$	
Peptidyl-prolyl	Cyclophilins (A,B) and FK506-binding proteins. Localization: ER Isomerases (PPlases)
Pre-senilins	Localization: ER
Protein disulphide	Protein processing Isomerase A3-PDI/CaBP1. Localization: ER
Thiol-disulphide	Protein processing Oxidoreductases. Localization: ER
PDI, Erp72, Erp57, p5	t-complex-polypeptide-1. Localization: Cytoplasm
SDF2-L1	
TCP-1	
UDP-glucosyltransferase (UDP-GT)	RNA-Chaperones. Localization: Nucleom
DEAD box proteins	
RecQ proteins	DNA-Chaperones. Localization: Nucleom

#### 44. Models of Chaperones in Aging

**Figure 44.1** Roles of subcellular chaperones during aging. Various environmental stressors lead to protein damage and misfolded proteins that bind to chaperones within the various cellular compartments. Irreversibly damaged proteins are targeted for degradation. If degradation is impaired and if there is an increase in protein damage, the chaperone systems might be overwhelmed, compromising the cell's ability to function properly. Also, chaperones might be damaged, leading to their removal and subsequent up-regulation. These events might trigger the senescent phenotype, and consequently, gradual tissue dysfunction.

the matrix or inner membrane. The physiological importance of these changes is an increased capacity for import into the organelle at any given precursor concentration. Defects in the protein import machinery components have been associated with mitochondrial disorders (Hood and Joseph, 2004) During synthesis of ATP in mitochondria, reactive oxygen species (ROS) are generated that are detrimental to mitochondrial and cellular function that with time contributes to the aging process. Chaperone species within the mitochondria could slow down the damage caused by ROS and participate in mitochondrial protein biogenesis (Voos and Röttgers, 2002).

##### *Lysosomal chaperones*

Physiological stresses such as prolonged starvation lead to chaperone-mediated autophagy (CMA) whereby a lysosomal pathway of proteolysis is activated (Majeski and Dice, 2004).

### Chaperones Aging and Longevity

The decrease in the constitutive expression and inducibility of the chaperones with age probably contributes

to the phenotype of aging, as an involvement in the definition of longevity can be assumed from high levels of chaperone expression as a common denominator in conditions or procedures leading to an increase in cellular and species longevity as well as in the process of cellular immortalization. The inherent immortality of the embryonic stem cells implies that replicative senescence as possibly aging are epigenetic phenomena, possibly influenced by the progressive age-related epigenetic changes in promoter methylation that have the potential to permanently silence gene expression (Kröll, 2005).

### AGING AND LONGEVITY OF CELLS

#### *Aging and longevity of differentiated cells in vitro*

That replicative senescence—the model of aging *in vitro*—probably is related to a chaperone deficit can be assumed from the increase in life span obtained by transfection with protein-chaperones, as well as from the attainment of cellular immortalization by heat shock procedures or transfection with RNA-chaperones (Kröll, 2004).

#### *Aging and longevity of differentiated cells in vivo*

The great variability in the life span of differentiated cells in the organism shows a direct correlation to the

constitutive expression of the molecular chaperones. Thus, compared with the short-lived epithelial cells, the basal expression of chaperones is relatively high in the long-lived post-mitotic cells as, for example, the neurons of the brain and the stromal cells of the eye lens. Thus, in the brain, the constitutive unstressed level of expression of Hsp70, Hsp90, and Hsp100 resembles that of heat-stressed somatic cells. In the stromal cells of the eye lens, the dominant chaperone is alpha-crystallin, which constitutes 40% of total cellular protein and assures the preservation of lifelong transparency of the lens in the absence of structural protein turnover. Chaperone dysfunction leads to protein aggregation, lens opacity and cataracts (Krøll, 2005).

The inducibility of Hsp70 by heat shock is reduced to approximately 50% in old rat hepatocytes, suggesting that a reduced ability to express hsp70 in response to stress may be a common phenomenon underlying the aging process. This age-related decline in the Hsp70 stress response was reversed by caloric restriction (Heydari *et al.*, 1996). There is a functional link between age-related decrements in Hsp70 expression and pathophysiological responses to heat stress leading to tissue injury and dysfunction (Kregel, 2002). Efficient removal of oxidized proteins depends on chaperone-mediated autophagy (see the section on lysosomal chaperones). This mechanism is severely impaired during aging demonstrated by the accumulation of oxidized proteins in old age (Kiffin *et al.*, 2004).

Cells derived from older people show a very low heat response in terms of Hsp47 expression, and there is a gradual down-regulation of Hsp47 expression with age, regulated by transcriptional mechanisms. Hsp47 induction is markedly attenuated in high PDL cells, showing an age-related decrease in response to pro-collagen retention in the ER (Miyaiishi *et al.*, 1995). Polyphenol-rich *Salix alba* extracts can obviate this decrease in HSP47 expression (Nizard *et al.*, 2004).

Damage to the ER organelle and its subsequent impaired functionality may be involved in the process of aging, judging by increased ER-chaperone expression, preferential oxidation of ER-resident proteins, and altered calcium homeostasis (van der Vlies *et al.*, 2003).

Old cells show a greater sensitivity to ER stress than young cells, suggesting a link between stress resistance and longevity (Li and Holbrook, 2004).

#### *Experimental procedures increasing the life span of differentiated cells*

Experimental procedures increasing the level of expression of various chaperones have been shown to increase cellular life span and resistance against apoptosis. Thus, intermittent mild heat stress (hormesis) increases the level of various chaperones and improves cellular resistance against noxious agents. Further, an *in vitro* model of caloric restriction (CR) demonstrates an increase

in Hsp70 expression and cellular resistance obtained by cell culture in CR-sera, possibly contributing to the effect of CR on cellular longevity. Also, the anti-apoptotic effect of nitric oxide is associated with an increase in the expression of Hsp70 as well as of the RNA-chaperone p68. The anti-apoptotic effect of nicotine could possibly relate to activation of the heat shock factor (Krøll, 2005).

## AGING AND LONGEVITY OF SPECIES

### *Reference conditions*

An involvement of the molecular chaperones in the definition of species longevity can be assumed from the observed influences of genotypes, levels of Hsp expression, and mutational defects. Thus, a modifier of life span linked to chromosome 4 has been identified as a haplotype marker within the microsomal transfer protein complex comprising the chaperone protein disulfide isomerase (PDI). An influence of genotype can be supposed also from the observation that for Hsp70 the TT polymorphic variant was observed to be significantly increased within a healthy aged Irish population, while conversely the TC genotype was significantly decreased. Also correlations have been observed between a polymorphism in the Hsp70-A1 gene promoter and low self-rated health in aged Danish twins (Singh *et al.*, 2004) as well as impaired longevity in women (Altomare *et al.*, 2003).

A relationship between the level of chaperone expression and the longevity of species can be assumed from the observation that the constitutional expression of Hsp70 in human pancreatic islets is about five times higher than in the islets of mice or rats. Also, the basal level of expression of Hsp70 in the human brain has been observed to be about 50 fold higher than in rat brain. Modifications of chaperone expression caused by hormonal factors may also influence life span. Thus, in humans, the estrogen-induced higher levels of expression of Hsp72 and Hsp90 alpha might contribute to the difference in longevity between genders. Concerning the circulating levels of chaperones, regression analysis has revealed a progressive decline with age in the serum levels of Hsp60 and Hsp70, probably a consequence of the age-related reduced ability to respond to stress (Krøll, 2005).

Possibly, the level of expression or the stress response of selected chaperones could be used for the estimation of a biological age index (Krøll and Saxtrup, 2000).

That not only the protein chaperones but also the DNA chaperones are probably important modifiers of longevity can be assumed from the consequences of inborn errors of the RecQ protein/DNA-chaperones. Thus, various mutations in these proteins shorten life span as observed in the mosaic progeric syndromes of Werner, Blooms, and Rothmund-Thomson (Krøll, 2004).

#### 44. Models of Chaperones in Aging

The increasing awareness of the possible significance of the functional decline of the molecular chaperones for age-related disorders has initiated the development of a mathematical model to explore the chaperone system and its possible implications in aging (Proctor *et al.*, 2005).

##### *Experimental procedures influencing the life span of species*

An increase in the level of expression of the molecular chaperones is a common denominator for the experimental procedures so far known to cause an increase of life span in species.

##### *Transgenic modulation of chaperone expression.*

Transgenic overexpression of chaperones has been shown to extend the life span of a number of experimental organisms as e.g., for Hsp104 in yeast (Shama *et al.*, 1998), Hsp16 in *C. elegans*, Hsp70 in *Drosophila* (Tatar *et al.*, 1997), hsp26 and hsp27 in *Drosophila* (Kröll, 2005). Heat shock proteins normally decrease in expression as a function of age, as judged from individual cases to whole-genome transcriptional profiles in *C. elegans* (Lund *et al.*, 2002).

Overexpression of the transcription factor HSF-1 that controls stress-inducible gene expression and protein folding homeostasis, extends life span in *C. elegans* daf-2-insulin/IGF-1 receptor mutants (Hsu *et al.*, 2003), as down-regulation of HSF-1 shortens life span of the mutants. Down-regulation of the individual molecular chaperones decreased longevity of the mutants to a lesser extent and did not affect life span in wild-type animals, probably due to the redundancy of chaperone function (Morley and Marimoto, 2004).

The Ames mouse model of longevity also showed an up-regulation of a heat shock protein, suggesting a contribution of a chaperone to extended life in a hormone model (low levels of human growth hormone releasing hormone) (Dozmorov *et al.*, 2001).

**Hormesis.** Intermittent mild heat stress (hormesis) increases the level of expression of the molecular chaperones and has been observed to give rise to life span extension in *Drosophila* (Hercus, 2003) and in yeast (Shama *et al.*, 1998). For the possible benefits of exposure to stress in humans, we need to consider that chaperone expression and function might not be the same in all individuals. This reflects the levels of genetic variation in the human population that are expressed as heritable phenotypic variation during periods of environmental change. This phenotypic variation results in differential modulation of chaperone and target function in response to stress. The availability of free chaperones correlated with the type and degree of stress confers the organism a level of protection that ultimately regulates survival fitness (Rutherford, 2003). Thus, exposure to stress in itself might not be beneficial if the response of the organism towards stress is deficient or inappropriate. A competitive edge might be found in organisms whereby stress can induce a good protective response of properly

working molecular chaperones that can help achieve improved life conditions at an advanced age without risk for chaperone overload (Söti *et al.*, 2005).

The extraordinary capacity of centenarians to achieve exceptional old age is due to some extent to their ability to counter the increased cellular stress normally associated with aging. Hsp70 protein induction by heat is reduced in the cells of most aged humans but not in centenarians. This effect is likely due to potent HSF-1 activity. As a matter of fact, HSF-1 has auxiliary factors that contribute to its activation, and could be involved in the age-associated attenuation in the response to stress (Shamovsky and Gershon, 2004). Another study reported that low circulating serum levels of Hsp70 in centenarians could well correlate with the absence of a disease state, since damage to tissues or organs as observed in cardiovascular disease or autoimmune diseases would result in high serum levels of Hsp70 (Kröll, 2005).

**Caloric restriction.** The best experimental intervention so far, which can extend life span in rodents and in multiple invertebrate species and reliably retard aging and age-related degenerative diseases, is dietary caloric restriction (CR). Gene and protein expression profiles are profoundly altered as a consequence of dietary CR. In particular, several molecular chaperones are induced to protect cells from stress, by preserving not only protein structures but also general cellular structure, increasing the levels of GSH, inhibiting apoptotic death, and maintaining a pool of vital proteins (Li *et al.*, 2004). Life-span studies due to CR in nonhuman primates have not yet been completed, but recent data indicate the beneficial effects of CR on a number of physiological markers. The effects of CR on human metabolism are various, but the specific mechanism(s) that lead to its positive effect on life span are not completely understood, but they might coincide with other well-described mechanisms known to regulate life span. Possibly the observed increase in the expression of Hsp70 caused by CR contributes to the positive effect on life span (Ingram *et al.*, 2004).

**Interference with histone acetylation.** The recently discovered histone deacetylase (HDAC) inhibitors (i.e., tricostatin A and phenylbutyrate) can induce the expression of heat shock proteins hsp22 and hsp70, resulting in extended life span in *Drosophila*. In particular, hsp22, a mitochondrial chaperone, has been linked to decreased survival when absent. Life extension has also been shown in cells exposed to polyphenolic compounds capable of activating the sirtuins (family of NAD<sup>+</sup> dependent deacetylases) in a manner comparable to CR (Lamming *et al.*, 2004). Evidence that sirtuin activators might slow down aging by inducing chaperone function has not yet been presented. However, it is likely that organisms in nature responding to signals such as the ones elicited by sirtuin activators might prepare in advance to a deteriorating environment. Such stress-signaling molecules might enhance chaperone function

prior to forthcoming insults (Lamming *et al.*, 2004). Sirt1, the mammalian analog of yeast Sir2, recently has been shown directly to modify chromatin and silence transcription (Vaquero *et al.*, 2004). The question is open whether Sirt1, in addition to silencing transcription, also influences the aging of mammals by suppression of recombination and genomic instability (Lombard *et al.*, 2005) in possible association with histone chaperones (Prado *et al.*, 2004). Thus, the positive effect of the sirtuins on life span might depend less on gene-silencing than on genomic stabilization—a scenario obviating the apparent contradiction that deacetylases as well as deacetylase inhibitors contribute to longevity (Kröll, 2005).

**Chemical chaperones.** Future intervention studies are aimed at inducing the heat shock response with chemical mimicry, that is, with synthetic compounds—chemical chaperones or nonspecific agents—that could imitate the effect of environmental stressors without the damaging effects they might carry (Castro-Fernandez *et al.*, 2005), and in clinical studies follow up the up-regulation of the heat shock response (e.g., by epigenetic derepression or specific reactivation of Hsf-1). Also, the functional promiscuity of the molecular chaperones opens for the possibility of an increase in chaperone capacity by transfection with individual chaperones (Kröll, 2005).

## Conclusion

The housekeeping functions of the chaperones tend to antagonize the phenotype of aging. Thus, aging is characterized by a progressive decrease in the expression and stress-inductivity of the chaperones, whereas an increase in chaperone expression is a common denominator in conditions or procedures leading to an increase of cellular and species longevity, for example, by providing chaperonic protection of the disposable soma.

The inherent immortality of the embryonic stem cells implies that replicative senescence, as possibly the aging of species, are epigenetic phenomena.

The involvement of RNA chaperones in the process of cellular immortalization and defective DNA-chaperones in the progeric syndromes place emphasis on the RNA/DNA-chaperones as contributors to the definition of cellular and species longevity. Accordingly, evidence is given that the evolution of longevity is governed by changes in the expression of relatively few regulatory genes.

Possibly, the molecular chaperones are evolution facilitators participating in the definition of life span of differentiated cells as well as for the evolution of longevity in species.

## Future Developments

The correlation between chaperones and aging/longevity should be further examined with focus on the

chaperone matrix of the inherently immortal embryonic stem cells.

With emphasis on DAN/RNA-chaperones it is proposed:

- To consider a more comprehensive characterization of the differences in the constitutive level of chaperone expression in relation to the life span of different species.
- To further investigate the effect on species life span of a constitutive increase in the expression of the various chaperones with emphasis on p68 (the putative mammalian analogue to the SV40 T-protein).
- To investigate means for a specific reactivation of chaperone genes silenced during aging as well as to stop the progressive silencing of chaperone genes during normal aging.
- To investigate the redundancy of function of the molecular chaperones to approach a definition of a minimal polymer folding system.
- To identify the chaperone of the large heat shock proteins (autonomous small Hsp's).

# Therapeutic Potential of Stem Cells in Aging-Related Diseases

Shannon Whirledge, Kirk C. Lo, and Dolores J. Lamb

*Stem cells are derived from embryonic as well as adult sources and vary in their potential for differentiation. Although obtaining stem cells from their natural source (an embryo or fetus) is controversial, they can also be generated in the research laboratory through somatic cell nuclear transfer. Embryonic stem cells can differentiate into a wide variety of cell types (hematopoietic, neural, muscle, germ, islet, and bone marrow), and provide the promise of new therapies for degenerative diseases of aging, tissue replacement, and organ transplantation. In addition, the more differentiated adult stem cells found in tissues, such as the testis, muscle, liver, hematopoietic system, and neural tissues, have considerable regenerative potential and may also have potential applications to rejuvenate failing organ function associated with aging.*

## Introduction

Embryonic and adult stem cells hold great promise for the treatment of disease and the rejuvenation of aging tissues—a concept that captures the imagination and hopes of the scientific and medical communities. No area of research focus since gene therapy evokes such enthusiasm among scientists and physicians but, nevertheless, raises ethical controversies as well. Proposed to be the ultimate cure for degenerative diseases of aging and a solution for the shortage of donated organs for transplantation, stem cells may even unlock the mysteries of early human development while providing the fountain of youth for an aging society. This chapter reviews the current state of knowledge, the controversies generated by stem cell research, and their application to diseases of aging.

Two basic types of stem cells exist: embryonic and adult. They are characterized by their ability to renew themselves for an indefinite period of time, as well as the ability to divide to create a differentiated cell type while remaining undifferentiated. In the adult, these self-renewing cell types are found in many tissues within a niche that provides a microenvironment that signals to renew the stem cell population or signals to induce unidirectional differentiation.

Depending upon the source of the stem cell, the differentiative potential of embryonic and adult stem cells varies. Fertilized oocytes and blastomeres (up to the eight-cell stage embryo) are described as being *totipotent* with the potential to differentiate and generate a complete organism. In contrast, embryonic stem cells (derived from the inner cell mass (ICM) of a blastocyte (see Figure 45.1) share the property of self-renewal and can differentiate into cells and tissues from any of the three germ layers. These cells are *pluripotent*, but not *totipotent* (these cells cannot form a placenta). As cells progress along the various steps of differentiation, they become less able to exhibit plasticity or to differentiate into cells of different lineages.

Thus, although the pluripotent embryonic stem cell has the capacity to become any cell type, adult stem cells are *multipotent* and persist into adulthood forming cells of the tissue in which they reside. These adult stem cells are responsible for the regenerative potential of the gastrointestinal, integumentary, spermatogenic, and hematopoietic systems. For example, spermatogonial stem cells (located near the basement membrane of the seminiferous tubules surrounded by Sertoli cells) can rejuvenate spermatogenesis following a gonadotoxic insult. Likewise, adult stem cells isolated from the liver, pancreas, kidney, and nervous system exhibit varying regenerative potential.

## Embryonic Stem and Primordial Germ Cells Are Pluripotent

Methods to isolate stem cells were first developed using animal models more than 20 years ago (Evans *et al.*, 1981; Martin, 1981). Pluripotent stem cells are derived from either excess embryos (embryonic stem (ES) cells) or an aborted fetus (embryonic germ (EG) cells). To initiate an ES cell line, they must first be extracted from the inner cell mass (ICM) of a blastocyte (which contains about 30 cells with regenerative potential), cultured, passaged, and eventually maintained *in vitro* (see Figure 45.1). Similarly, primordial germ cells

**Figure 45.1** The Inner Cell Mass (ICM) of a human blastocyst is a source of embryonic stem cells. A blastocyst is derived from an embryo created by *in vitro* fertilization. The arrows denote the inner cell mass of the blastocyst found internal adjacent to the blastocoels (the hollow core). These 30 or so cells have the potential to become embryonic stem cells under proper culture conditions. If implanted into a receptive uterus, they have the potential to also become a fetus.

(obtained from a fetus) exhibit a similar developmental potential (Matsui *et al.*, 1992). Stem cell lines provide the tools for unique investigations into the intrinsic and extrinsic controls of cell growth and differentiation (Guan *et al.*, 2001; Wobus *et al.*, 1997), signaling molecules and transduction pathways and transcription factors (Burdon *et al.*, 2002) in stem cell biology. Stem cells have also been used to evaluate the cytotoxicity of drugs, and this may provide a unique approach to assessing the safety of pharmaceuticals (Rohwedel *et al.*, 2001).

New therapies are expected to be realized with the advent of ES cell culture that provides an unlimited source for stem cell therapy. The technology still has limitations in that transplantation of undifferentiated ES cells results in the formation of teratomas. Indeed, about 20% of the Parkinson rats developed teratoma-like tumors after transplantation of ES cells into the brain striatum of rats resulted in differentiation of dopaminergic cells improving motor asymmetry (Bjorklund *et al.*, 2002). ES cell culture may circumvent the tumorigenic problem; nevertheless, a few contaminating undifferentiated ES cells could be problematic. Not surprisingly, with the technology available today, the tumorigenic potential of undifferentiated ES cells limits its rapid translation to human cell therapy.

The molecular controls of ES cell differentiation are poorly understood, but are thought to require growth factors to control differentiation during development (Schuldiner *et al.*, 2000). The production of human ES and EG cells was reported in 1998 (Shamblott *et al.*, 1998; Thomson *et al.*, 1998). Culture of ES cells under conditions leading to the development of embryoid bodies

(EB) induces the differentiation of neural, dopaminergic, and glial elements (Brustle *et al.*, 1999; Kim *et al.*, 2002; Schuldiner *et al.*, 2000), and insulin-secreting cells (Assady *et al.*, 2001; Lumelsky *et al.*, 2001), among others. Although the results in the mouse were not perfect (transplantation of the insulin-secreting cells did not produce a sustained correction of hyperglycemia in the engrafted animals), the islet-like clusters survive and secrete insulin *in vivo*. Other tissues generated from ES cell lines include mouse and human cardiomyocytes (Kehat *et al.*, 2001; Maltsev *et al.*, 1993; Wobus *et al.*, 1997), hematopoietic cells (Kaufman *et al.*, 2002; Nakano *et al.*, 1996; Wiles *et al.*, 1991), endothelial cells (Risau *et al.*, 1988; Yamashita *et al.*, 2000), skeletal muscles (Miller-Hance *et al.*, 1993; Rohwedel *et al.*, 1994), chondrocytes (Kramer *et al.*, 2000), liver (Hamazaki *et al.*, 2001), neural cells (Carpenter *et al.*, 2001; Reubinoff *et al.*, 2001; Zhang *et al.*, 2001), and adipocytes (Dani *et al.*, 1997). This will be discussed in detail later. Obviously, the potential for the development of new stem cell therapies is immense. Nevertheless, progress has been stymied by the availability of an insufficient number of fully functional cell lines.

Technical challenges remain concerning research using human ES cell lines. Although human ES cells and monkey ES cells are similar, there are significant differences between these primate models and their mouse counterparts. Some differences are as simple as their growth patterns (i.e., human ES cells grow in compact flat colonies, whereas murine ES cells form spherical colonies). Others include differences in protein expression. For example, human ES cells temporally express the embryonic antigens SSEA-3, SSEA-4, and SSEA-1 in a stage-specific manner upon differentiation; the order of expression is reversed in murine ES cells (Andrews *et al.*, 1996; McLaren, 2001; Thomson *et al.*, 1998). Due to these morphological and developmental differences, some investigators have called into question the applicability of murine models to human ES cell research.

Furthermore, after ES stem cell differentiation, transplantation of allogenic cells/tissues may be hindered by immunological incompatibility between the donor ES cells and the recipient. Admittedly, administration of immunosuppressive drugs prior to the transplantation is an option, but not without significant side effects. In the future, genetic alteration of histocompatibility gene expression may be an option, but presently research on this topic is sparse.

## EMBRYONIC STEM CELLS AND CLONING

*Therapeutic cloning* or *somatic cell nuclear transfer* provides one alternative to the ethical dilemmas raised by ES cell research (see Figure 45.2).

With this technology, a somatic cell nucleus is fused to an enucleated egg and essentially reprogrammed to create ES cells. An artificial blastocyst forms, and the inner cell mass again provides the ES cells for subsequent

**Figure 45.2** Somatic cell nuclear transfer provides an alternative to embryonic stem cells. Somatic cell nuclear transfer can create an artificial blastocyst for a source of embryonic stem cells. In this method, the somatic cell nucleus is transplanted into an enucleated egg. Upon activation, the early events in embryonic development are initiated and a blastocyst forms. This blastocyst can provide the source of embryonic stem cells without the necessity of destroying a human embryo. At this stage, the blastocyst can also be transferred into a receptive uterus to form a fetus (albeit at low efficiency). When transferred to a uterus, this is now termed *reproductive cloning*.

manipulation or alternatively reproductive cloning (discussed later). Culture conditions are developed to induce ES cells to differentiate into functional somatic tissues/cells and then transplanted. The technique requires a substantial number of donated eggs from an IVF laboratory and can be technically challenging. Infertile couples seeking to conceive a child by IVF face significant personal expense, and there is a high demand for oocyte donation to other infertile couples attempting to conceive. Thus, with current methodologies, these caveats are likely to limit this approach to the few privileged and capable of affording this technology.

As mentioned earlier, although the goal of somatic cell nuclear transplantation is to generate cells, tissues, or organs for transplantation, the success of reproductive cloning in animals (such as Dolly the lamb (Wilmut *et al.*, 1997)) brings new concerns regarding this technology. Prior to the cloning of Dolly, the rules governing stem cell research were nonspecific, limiting only federal funding of research on human embryos for *in vitro* fertilization (IVF). During this time, research funds were limited to those approved by a congressionally appointed ethics advisory board. In 1996, the Dicky Amendment completely banned the use of federal funds for any human embryo research.

Development of the first human embryonic stem cell line by Thomson *et al.* in 1998 pushed the debate over stem cell usage back into center court. In 1999, the National Institute of Health announced that current U.S. law did not ban federal support for the use of embryonic stem cells, instead stating that support could not be used for the isolation of stem cells but could be used on stem

cells once obtained. This opened the floodgates for ethical debate over the issue of extraction versus research. The National Bioethics Advisory Committee released a statement supporting the federal funding for both the isolation and use of embryonic stem cells stating the inability to ethically separate the two.

In a report in *Science* in 1999, Pittenger *et al.* described the novel isolation of a multipotent cell derived from adult human tissue. This served only to reinforce the debate against embryonic stem cell research, arguing that adult stem cells (discussed later) are adequate for research purposes. The wavering under the Clinton administration was firmly halted when President Bush took office. On August 9, 2001, President Bush announced that federal funding would be allowed for research on human embryonic stem cells, but only on those lines that had been derived before the date of announcement. At that time more than 60 lines were estimated to be available for research; since then the number of NIH available lines has dropped to 22.

Although President Bush's policy does allow some research to proceed, it fails to address research in private or nonfederally funded sources. In November of 2004, California's voters passed Proposition 71, which authorizes \$3 billion in state funds to support stem cell research in California. Other states are expected to follow, and currently, bills are continually being introduced in individual states regarding the legality of collaborations, with researchers using such funds and prohibiting one or all forms of cloning research. Funding and laws are not the only factors prohibiting stem cell research from advancing.

Of the 60 to 75 lines originally available for federally funded stem cell research in 2001, scientists have encountered several problems with their use. To date, as noted, there are actually only 22 lines available from the NIH. These cell lines are degrading with time, becoming more vulnerable to chromosomal abnormalities. Also, the cell lines lack the genetic diversity required for broad-spectrum disease treatment, and there is an absence of disease-specific lines. Within the private sector, these problems are being circumvented by creating a variety of new lines from wide genetic backgrounds, but limitations on the freedom of scientists in the United States to work and publish on these cell lines has hindered any real progression toward disease treatments. Not only do investigators have difficulty obtaining functional cell lines, but also the exact mechanism for cell culture has yet to be discovered. One of the vital components of ongoing work is determining the conditions required to sustain undifferentiated stem cells as well as differentiating them along defined pathways. Determining what the right signal is at the right time will better allow scientists to manipulate the stem cell fate, and controlling this is what ultimately leads to powerful medical therapy.

Indeed, the fear of human cloning (illegal in the United States and a number of other countries) has led to many

countries banning research on this technology. Because of these restrictions over the use of ES and primordial germ cell lines, some researchers have focused their studies on adult stem cells, reexamining their potential regenerative potential and cell type plasticity.

### **Application of Stem Cell Technologies for Rejuvenation of Aging Tissues: Embryonic and Adult Stem Cells**

Unique cells with regenerative potential in the adult include spermatogonial and Leydig cells, stem cells in the testis, mesenchymal progenitors of muscle, neural stem cells, hematopoietic stem cells, bone, spleen, and those of the gastrointestinal system. These adult stem cells are described next, in more detail. We discuss the potential applications of both embryonic and adult stem cells to rejuvenate failing organ function associated with aging.

#### **THE STEM CELLS OF THE HEMATOPOIETIC SYSTEM ARE USED THERAPEUTICALLY TODAY**

Hematopoietic stem cells (HSC) are widely studied, well-characterized, and currently used for patient care. The studies of Till and McCullough (Till *et al.*, 1961), which provided the basis for subsequent studies, focused on the identification and enrichment of a population of bone marrow-derived cells capable of self-regeneration and repletion of the entire hematopoietic cell line (Blau *et al.*, 2001; Weissman, 2000).

A heterogeneous mix of stem cells exists in the bone marrow composed of HSC and mesenchymal stem cells (MSC). MSC are readily separated from the HSC based upon their characteristic adherence to plastic (Poulsom *et al.*, 2002). There are two types of HSCs: long term (LT-HSC) and short term (ST-HSC). The potential long-term cells offer is most important, defined by their ability to self-renew for life, and also to give rise to the short-term cells, which in turn self-renew for a period of about eight weeks. The short-term cells can give rise to differentiated or multipotent progenitors that subsequently differentiate into the various blood cell types (Morrison *et al.*, 1997).

Researchers focused on methods to enrich the HSC from bone marrow using protocols that rely on the presence of cell surface proteins and using this approach to remove cells expressing markers of maturity. First identified in a mouse model, human HSC are Thy-1 and CD34 positive, but Lin and CD38 negative (Uchida *et al.*, 1998). With current technologies, hematopoietic stem cells can be enriched about 10,000 fold (Morrison *et al.*, 1994). Despite stringent criteria for cell separation and great enrichment potential, some enriched cells cannot replete the blood cells, reinforcing the notion that stem cell markers are not completely identified or understood.

Transplantation of highly enriched, histocompatible HSC offers the potential of complete reconstitution of the entire hematopoietic system in patients after whole body radiation or chemotherapy. Not surprisingly, transplantation of allogeneic HSC induces a graft-versus-host (GVH) and tumor responses. Transplantation of enriched allogeneic HSC reduces the incidence of the GVH response because the transplant patient later develops tolerance to donated cells (Burdon *et al.*, 2002).

#### *Hematopoietic stem cells: chemotherapy strategies for older patients*

The application of standard-dose chemotherapy to elderly patients usually results in a higher rate of treatment-related deaths compared to that of their younger patient counterparts (Gaynor *et al.*, 1994). The mechanisms underlying the changes within the hematopoietic system that result in reduced tolerance to chemotherapy is unclear. Age-related changes of the hematopoietic system are probably irrelevant for normal aging function, but under several courses of chemotherapy, the stress becomes clinically evident. This suggests hematopoietic stem cell (HSC) exhaustion. In order to effectively treat older patients, the mechanisms by which this occurs and the strategies for HSC treatment and renewal must be discovered.

#### **NEURAL STEM CELLS ARE PRESENT IN THE ADULT BRAIN**

The ability of the central nervous system (CNS) to repair itself following injury or age-related disease is limited, and previous development of therapeutic approaches focused only on preserving at-risk neuronal populations. Yet these strategies are limited to patients where substantial neuronal loss has not already occurred. Hope for the targeting of new neurons into injured regions of the brain or expanded neural cells grafted into regions of degeneration has stemmed from the observation of endogenous generation of new neurons in the adult brain. Although once thought to be restricted to prenatal development, emerging evidence suggests that neurogenesis continues through adult life.

Researchers were surprised to learn that stem cells were present in the adult brain, an organ long thought to comprise nonrenewable neurons. The subventricular zone and the subgranular zone of the dentate gyrus of the hippocampus have the highest concentrations of dividing cells (Cameron *et al.*, 1994). Neuronal stem cells isolated from fetal and adult brains and then cultured were induced to differentiate into the three distinct neuronal cell types—astrocytes, oligodendrocytes, and neurons (Gage *et al.*, 2000). After transplantation, cultured stem cells engrafted into developing fetal and adult brains migrated throughout the nervous system and differentiated into tissues ranging from the hippocampus to the olfactory bulb (Gage *et al.*, 1995; Suhonen *et al.*, 1996). Neuronal stem cells are classified by their

## 45. Therapeutic Potential of Stem Cells in Aging-Related Diseases

expression of a number of cell surface markers (CD133 positive, CD34 negative, and CD45 negative) (Uchida *et al.*, 2000). Following expansion of adult neuronal stem cells *in vitro*, transplantation, and engraftment into rat brains, neural function was apparent based upon the presence of synaptic electrical activity (Auerbach *et al.*, 2000).

Neural stem cells are defined by their ability to differentiate into the three major cell types of the CNS—neurons, astrocytes, and oligodendrocytes—*in vitro*. The mechanism by which this occurs *in vivo* has yet to be elucidated. Regulation of transcription, via Rel silencing transcription factor mediated recruitment of histone deacetylases, is critical in the transition from neural stem cell to mature neuron (Ballas *et al.*, 2005). Cooperation between the Smad and STAT signaling pathways is involved in gene expression and suppression during astrocyte differentiation (Sun *et al.*, 2001). Oligodendrocytes, the myelinating glial cell type of the CNS, differentiate from a common neural-oligodendrocyte precursor through coexpression of Olig2, a basic helix-loop-helix transcription factor, and Nkx2.2 (Zhou *et al.*, 2001). It is through a delicate interplay of transcriptional activators and repressors that neuronal stem cell fate is decided. The therapeutic potential of neural stem cells for the aging brain makes determining these factors essential.

*In vitro*, neural stem cells have the potential to ubiquitously give rise to neurons. In the adult brain, neurogenesis is spatially restricted to two areas, the sub-ventricular zone and the hippocampal dentate gyrus (Cameron *et al.*, 1994). Under normal conditions, newly generated neurons are restricted to defined pathways of migration followed by highly regulated, sequential steps to integration. Although these steps are equivalent to those undergone during early development, neurogenesis in the adult brain occurs in a less permissive environment, with new adult neurons having to integrate into preexisting circuits. The quest for producing an effective therapy from induced neurogenesis relies on the discovery of several factors. These include identifying the cellular cues that are responsible for a neurogenic niche becoming permissive for neurogenesis and how the proliferation of adult neural stem cells is regulated.

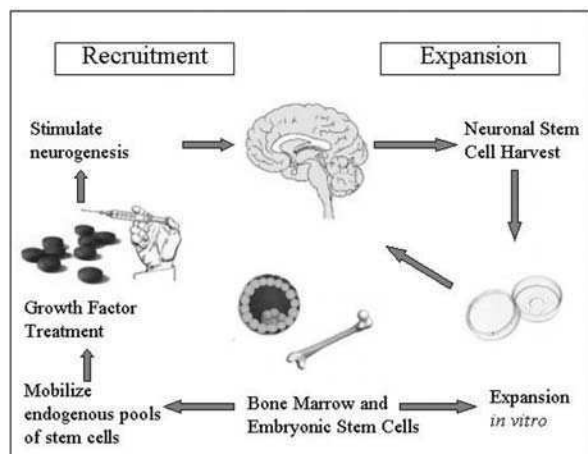

### *Neural stem cells as therapeutic agents for age-related brain repair*

The prevalence of stem cells in the nervous system appears to decline with age, as is true for a number of organ systems. The aging brain also is characterized by reduced neurogenesis. Several diseases and injuries of the brain also consist of acute neuronal loss. Parkinson's disease is distinguished by progressive loss of dopaminergic neurons in the substantia nigra zona compacta. A leading cause of death and disability, acute ischemic stroke causes a loss of neurons, astrocytes, and oligodendrocytes. Decreased neurogenesis in the adult

hippocampus has been genetically linked to Alzheimer's disease, a neurodegenerative disorder of the CNS. Alzheimer's has also been linked to age-related structural deterioration and cellular senescence of the neuroprotective microglia.

Though understanding the basis for age-related reduction of neurogenesis would be necessary to determine the functional contributions of newly generated neurons, preliminary studies suggest a link between neuronal replacement and phenotype recovery for disease models. In a rodent model of Parkinson's disease, treatment with TGF $\alpha$  and a mitogen for stem cells caused an improvement of behavioral deficits and the appearance of new neurons (Fallon *et al.*, 2000). In a study examining the combined effects of FGF-2 and EGF on a degenerative hippocampal model, the authors observed a significant number of new neurons believed to be integrated into the hippocampal circuitry (Nakatomi *et al.*, 2002). Behavior studies showed improved behavior recovery after growth factor treatment. Implantation of neural stem cells into the midbrains of aged mice was associated with reconstitution of neural depleted areas (Ourednik *et al.*, 2002). Not only did this study show that aged brains can support engraftment and extensive migration of neural stem cells, but also that neural stem cells migrate more readily in the aged mouse brain than in the intact young brain.

Neural stem cells may prove to be a useful pool for age-related brain injury or disease that could be recruited or expanded in culture for transplantation to repopulate regions of neuronal loss (see Figure 45.3).

**Figure 45.3** Approaches to stem cell therapy for age-related injury or disease. There are several defined therapeutic targets for using stem cells to treat age-related injury or disease. Strategies include the isolation or recruitment of stem cells (shown in this figure are models for neural and hematopoietic stem cells) as well as targeted differentiation of embryonic stem cells. Research needs include the development of techniques for the enrichment and expansion of the stem cells *in vitro*, control of differentiation and cell function, as well as methods to stimulate the growth of new neurons (i.e., for neurogenesis in the brain).

In order for a recruitment strategy to become a viable therapy, scientists must find a way to overcome age-related loss of progenitors. Recruitment strategies must also incorporate factors involved in guided migration of newly generated neuronal progenitors to areas of injury. The alternative method, expansion of neural stem cells *in vitro* with subsequent transplantation, is limited by the extent to which an aged brain can tolerate grafting surgeries. Another challenge is discovering the environmental cues necessary for successful survival, differentiation, and functional integration. Certainly the field of neural stem cell research has many obstacles to overcome, but with the promise of potential therapies for neurodegenerative diseases that affect many, the light at the end of the tunnel remains a driving force.

#### THE LIVER HAS REGENERATIVE CAPACITY: HEPATIC STEM CELLS

The liver is an organ that exhibits significant regenerative capacity; the entire organ can regrow from as little as a third of its original tissue (Vessey *et al.*, 2001). The resting hepatocytes can undergo cell division—up to 12 to 16 divisions per cell providing the basis for this regenerative capacity (Sell, 2001). Evidence of liver stem cells capable of forming both hepatocytes and bile ducts has been demonstrated in a rodent model. Administration of a hepatotoxic agent (carbon tetrachloride) to rats pretreated with N-2-acetylaminofluorene (an agent used to block hepatocyte proliferation) creates hepatocellular injury, simultaneously blocking the normal hepatocyte proliferative response following toxic injury (Petersen *et al.*, 1998).

Liver regeneration is believed to occur through three mechanisms: replication of existing hepatocytes, differentiation of oval cells, or hematopoietic stem cells. After a 70% hepatectomy, liver regeneration requires no more than two rounds of hepatocyte replication (Fausto, 2004). Hepatocytes have enormous proliferative potential, but there is evidence of diminished replicative activity with injury and disease. Due to the ability of liver regeneration to occur through fully differentiated hepatocytes, initial arguments were against the need or existence of a hepatic stem cell. Observations in the 1950s first indicated that another source of hepatocytes existed, termed oval cells (Farber, 1956). Oval cells refer to single cells or clusters of cells that form a ductule. They arise after toxic insult to the liver stem cells, located along the canal of Herring, and are identified based upon the expression of OV-6 (Thorgeirsson, 1996). These cells arise from an intrahepatic stem cell niche corresponding to the canals of Hering and terminal bile ductules of the adult liver.

Even though the term *oval cell* often is used synonymously with hepatic stem cell, whether or not they are one and the same remains in dispute. Certainly oval cells give rise to multiple cell lineages in the liver, but the oval cell may be an activated progeny of stem cells in

the liver. One of the challenges facing researchers today is the lack of definitive markers of hepatic stem cells. Candidate markers include OV6, CD34, c-kit, cytokeratins CK 7 and CK-9, chromogranin-A, and the cell adhesion molecule N-CAM (Dunsford *et al.*, 1989; Roskams *et al.*, 1998). Improved protocols are continuously emerging for the purification and culture of hepatic stem cells (Lazaro *et al.*, 1998).

Some markers expressed by oval cells are also hematopoietic stem cell markers. This suggests a relationship between a liver-derived stem cell population and a circulating bone marrow-derived stem cell fraction. In fact, in sex-mismatched bone marrow transplantation experiments, oval cells and hepatocytes were found from bone marrow origin (Petersen *et al.*, 1999). Similar findings revealed the interchangeability of tissue stem cells after transplanted bone marrow side population cells, stem cells purified on the basis of their ability to efflux Hoechst 33342 dye, could be isolated in hepatic side population cells and were recruited to repair liver damage (Wulf *et al.*, 2003). Although there is clear evidence of cells originating from the bone marrow contributing to the formation of hepatocytes, this transformation is a rare event. Much of this work supports the phenotypic plasticity of stem cells in response to a microenvironment, but it has yet to be seen if these relatively rare events could play a noteworthy part in human liver or tissue damage repair.

#### *Hepatic stem cells: hope for liver transplantation*

The immense regenerative potential of the liver makes the resident stem cells a target for cell-based therapies for a variety of liver diseases. Hepatocyte transfusion may provide a short-term solution for patients awaiting liver transplantation (Strom *et al.*, 1997). Transfusion of cultured hepatocytes has realized some success for the treatment of metabolic conditions such as ornithine carbamoylase deficiency (Strom *et al.*, 1997), homozygous familial hypercholesterolemia (Raper *et al.*, 1996), and Crigler-Najjar syndrome type I (Fox *et al.*, 1998).

#### *Hepatic stem cells and aging*

Although the rate of liver regeneration declines with age, the regenerative capacity remains unchanged. The aged liver is more vulnerable to injury from toxins, viruses, and ischemia. A decline in hepatic clearance of certain drugs leads to a marked increase in the frequency of adverse drug reactions in geriatric patients. The development of cell therapy strategies for liver failure and metabolic diseases has become a necessity due to limitations on rates of regeneration in the aged population as well as shortage of donor livers. The availability of *in vitro* expandable progenitors would facilitate studies on cell engraftment and serve as a model for clinical applications.

Currently, cell transplantation for the treatment of liver failure is restricted to the transplantation of primary

## 45. Therapeutic Potential of Stem Cells in Aging-Related Diseases

hepatocytes. Due to shortage of donor human hepatocytes, liver stem cell research must be aimed at expanding a progenitor population *in vitro*. Another potential avenue for cell-based therapies includes discovering a potential functional role for bone marrow-derived cells in hepatic tissue transplant. Human fetal tissue remains a promising source of bipotential stem cells. Providing this tissue type remains accessible, these cells could be more efficient than adult hepatocytes for the repair of liver damage. At the present rate of progress, transplantation is a goal achievable within the foreseeable future.

### MUSCLE STEM CELLS

Muscle satellite cells, located in the periphery between the muscle fiber sarcolemma and the surrounding basement membrane, provide the basis for the repair and regeneration of muscle tissue (Goldring *et al.*, 2002; Mauro, 1961). These cells are rare, accounting for only 5% of the nuclei present in muscle fiber (Schultz *et al.*, 1982). Muscle satellite cells are critical to understanding the role of adult stem cells in myogenic growth and regeneration. Of note, stem cells of other tissue origins, bone marrow (Lipton *et al.*, 1979; Wakitani *et al.*, 1995), neural (Galli *et al.*, 2000), or even skin (Pye *et al.*, 2001) can contribute to muscle regeneration. Muscle progenitors offer great hope for the treatment of primary muscle diseases such as muscular dystrophy, and these may reach clinical reality in the future.

#### *Muscle stem cells: Regeneration for primary muscle diseases and maintenance of blood vessels*

Cardiovascular disease is the number one cause of death in the United States. Although many risk factors associated with cardiovascular disease can be managed, the aging process and hereditary predisposition cannot be changed. Current pharmacological agents fail to address the cell loss associated with heart failure. Cardiac muscle of the adult heart is unable to repair itself following loss of cardiac function due to severe disease or injury. Although once thought to be a post-mitotic organ, recent support for the regeneration of myocytes shows cardiac muscle replenished with newly generated cells. A resident cardiac stem cell population is thought to be capable of limited repair, but may be ineffective for thorough restoration of function after severe injury. Adult as well as embryonic stem cells have been shown to differentiate into cardiomyocytes, providing a new type of treatment for patients. Evidence suggests that adult stem cells of the bone marrow and adipose tissue can be a source of *de novo* cardiomyocyte population. In fact, when GFP expressing hematopoietic stem cells were purified and injected directly into the myocardium of infarcted mouse hearts, over 50% of all new myocytes, confirmed as maturing and functional, expressed GFP (Orlic *et al.*, 2001). The transplanted bone marrow stem cells were able to acquire a cardiomyocyte phenotype and regenerate

considerable amounts of contractile myocardium. Though bone marrow stem cells are the most widely studied source of stem cells, they are by no means the only source or the most abundant. The large volume of adipose tissue makes it an attractive alternative to study stem cell plasticity as it relates to cardiac failure. Rangappa *et al.* showed differentiation into cardiomyocytes from adipose derived cells in 2003. Coculture and the addition of the proper signaling molecules relay the external cues required for differentiation of human mesenchymal stem cells into cardiomyocytes. These studies suggest that extra cardiac stem cells can repopulate the myocardium and participate in myocardial repair, but considerable controversy exists regarding the rate at which this occurs *in vivo*.

Increasing the number of functional cardiomyocytes has obvious therapeutic potential. Circulating multipotent and resident cardiac stem cells have demonstrated the potential to contribute to cardiac repair and recovery, but this does not preclude the importance and promise of embryonic stem cell-derived cardiomyocytes. ES cells can easily be genetically manipulated through fusion gene transfection to produce a highly differentiated, 99% pure cardiomyocyte culture (Klug *et al.*, 1996). The ES-derived cardiomyocytes exhibit normal contractile sensitivity to calcium and display many of the physical attributes observed in endogenous populations (Metzger *et al.*, 1994). Upon grafting into adult mice hearts, ES-derived cardiomyocytes formed suitable intracardiac grafts for as long as seven weeks. Embryonic stem cells hold promise for cellular engraftment and tissue engineering. Through simple genetic manipulation, relatively pure cultures of cardiomyocytes from ES cells can be used for successful intracardiac grafts. If this therapy can be translated to patients through the generation of cardiogenic human ES cell lines, the factor that limits the number of heart failure patients from receiving life-saving procedures would be nearly eliminated.

### TESTICULAR STEM CELLS

Spermatogonial stem cells are a unique population of stem cells due to their ability to genetically contribute to the next generation. In 1994, Brinster and Zimmerman described a novel method to isolate and transplant the spermatogonial stem cell. Stem cells are isolated from the testes of mice carrying the  $\beta$ -galactosidase transgene. This allows transplantation and colonization to be followed by visualizing blue staining cells; donor cells of fluorescently labeled mice, such as GFP, could also be used. The isolated cells are then microinjected into a germ cell deficient host via efferent duct or rete testes. After an incubation period equivalent to the time needed to undergo normal mouse spermatogenesis, the testes are harvested and stained with  $\beta$ -gal to identify the presence of spermatogenesis and blue staining seminiferous tubules, indicative of transplanted spermatogonial stem cells. The development of this technique and the ability to successfully repeat it, including by our

own lab, have opened the door to a range of therapeutic possibilities. Xenogenic transplants are possible and are looking at the complex relationship between the Sertoli cells and the resident stem cell (Franca *et al.*, 1998). The development of male mouse spermatogonial stem cell long-term culture conditions by Konatsu-Shinohara *et al.* in 2004 will allow scientists to determine the signals that regulate the self-renewal division of spermatogonial stem cells along with those factors that signal differentiation.

Leydig cells are the steroid-producing cells of the interstitial tissue of the testis. Their primary function, the production of androgen, is essential for spermatogenesis and development of the male phenotype. Throughout development the lineage of Leydig cells changes; five classifications of Leydig cells have been identified. Although the population of progenitors is relatively small, Leydig cell turnover is maintained with age, and therefore, the ability to isolate this population offers a novel technique to restore androgen synthesis.

Leydig cell progenitors can be isolated from adult testes as shown by Lo *et al.* in 2004. Making use of a technique developed by Goodell *et al.* with hematopoietic stem cells, Leydig progenitors are enriched through flow cytometry analysis of the Hoechst dim side population (see Figure 45.4).

**Figure 45.4** Enrichment of Leydig cell progenitors by flow cytometry analysis of the Hoechst dim side population. Goodell and colleagues reported the use of Hoechst dye exclusion to select for a population of stem cells based upon their ability to exclude the dye via the multidrug resistance transporter protein. The cells are sorted into SP (side-population), which extrudes the dye, and non-SP which retains the dye. The SP fraction represents about 0.9% of the total population. Briefly, after the Hoechst dye staining, the cell solution is excited with the UV laser at 350 nm. Duo-wavelength filters in the flow cytometer are used to detect the resulting fluorescence (Dakocytometry, Carpinteria, California).

Lo *et al.* were able to identify successful transplantation of Leydig stem cells by restoration of spermatogenesis and a significant increase in the levels of circulating testosterone in infertile mice. The ability to isolate Leydig progenitor offers a powerful method to study the adult testicular Leydig stem cell, characterize the phenotype, and discover what signals regulate differentiation, which will ultimately lead to human reproductive therapies.

Recent work by Davidoff *et al.* describes the progenitors of Leydig cells as vascular smooth muscle cells (VSMCs) and pericytes (PCs). Using an *in vivo* model of EDS treatment, Leydig cell regeneration was preceded by a proliferation of VSMCs and PCs and their subsequent conversion into steroidogenic Leydig cells. As advances in reproductive technology allow us to isolate and transplant testicular stem cells into infertile men and cancer patients, the ethical responsibility to the patient and society cannot be disregarded. Considerations for all involved parties, including unborn children, must be in place before human therapies can be implemented.

#### *Testicular stem cells and andropause*

Aging is described as “the progressive loss of function accompanied by decreasing fertility and increasing mortality with advancing age” (Kirkwood *et al.*, 2000). Androgen secretion by the testis progressively declines with age. Currently, a variety of drugs are on the market for replacement of testosterone in hypogonadal aging men (AndroGel, Androderm). Similarly, loss of fertility due to chemotherapy or radiotherapy (as well as other infertility problems) is a deficiency that cannot be corrected with any available treatment, but recent work with testicular stem cells has given hope for therapies. Specifically, the findings of Atala and colleagues (Machluf *et al.*, 2003) that encapsulated transplanted Leydig cells or granulosa cells (Yoo *et al.*, 2000) can provide the basis for natural hormone replacement in aging. Similarly, germ cell transplantation may allow for restoration of fertility.

#### BONE MARROW STEM CELLS

The vast majority of bone mass is achieved in the human adult by the age of 18, with a small amount accumulated up to the age of 30. In a healthy adult, bone remodeling is a balance between bone resorption, via osteoclasts, and bone formation, by osteoblasts. Changes in levels of endogenous hormone and mechanical load, due to age-related changes in physical activity, determine the extent of bone remodeling.

#### *The prospect of bone repair and prevention*

Reduced activity of osteoblasts observed with aging is due in part to estrogen and progesterone deficiency. Loss of bone mass, also attributed to reduced activity of

## 45. Therapeutic Potential of Stem Cells in Aging-Related Diseases

osteoblasts, is responsible for enhanced risk of fractures and reduced bone fracture repair. Of those over the age of 70, only 31 to 36% are predicted to have normal bone mass. Many people in the aging population are affected by hip fractures: up to 20% of hip fracture patients die within the first year, and only 30% ever regain prefracture function (Akeson *et al.*, 2003). A major consequence of the aging population is the inability to replace or repair aging tissue. The bone marrow contains stem cells that are progenitors for osteoblasts, capable of forming bone cartilage and other connective tissue. Osteoprogenitor cells may provide a potential therapy for bone repair, reconstructing bone tissue in the area of injury.

Mending broken or damaged bones through bone grafts is a common practice performed by doctors in the United States every year. Although not all patients are eligible for this commercial process, including aged patients whose quality and quantity of bone are not sufficient, there is hope for these patients. Bone engineering has made great strides in developing therapies that colonize damaged areas and form new bone. A group in China has recently shown that engraftment of bone marrow stem cells was capable of repairing segmental bone defects in sheep metatarsus (Li *et al.*, 2005). Bone marrow stem cells were enriched over a Percoll density gradient and implanted with porous-TCP in a sheep metatarsus defect. Compared to controls, the stem cell implants healed the bone defect more efficiently and quicker. The use of a biological scaffold, a hydrogel, in concert with bone marrow stem cell cultures also provided new bone formation when transplanted into a region of bone defect (Srouji *et al.*, 2004). A three-dimensional hydrogel scaffold that contained an osteogenic subpopulation of bone marrow stem cells was transplanted into rat tibia and examined six weeks postimplantation. Due to the decrease in skeletal bone formation and rate of fracture repair seen with aging, the fact that the scaffold and stem cells induced bone repair is promising as a potential therapy. If bone tissue could be engineered to interchange senescent or apoptosing cells with a fresh supply from stem cells, the effects of aging on bone could be mitigated.

### STEM CELLS OF THE SPLEEN

Diabetes is an insulin insufficiency disease that affects over 6% of the U.S. population. People with diabetes are at higher risk for heart disease, blindness, kidney failure, and other chronic conditions. Diabetes cost the United States an estimated \$132 billion in 2002 in direct medical and indirect expenditures (Hogan *et al.*, 2003). Pancreatic  $\beta$ -cell death directly leads to Type I diabetes, causing a misregulation of glucose homeostasis. Patients with Type I, insulin-dependent diabetes require exogenous insulin therapy to regulate glucose levels. Neogenesis of  $\beta$ -cells could lead to an important mechanism of islet cell repopulation and restoration of normoglycemia. Two strategies for producing human islet cells have made

significant advances in the past few years: the transformation of pancreatic cells into new islet cells and the isolation and development of stem cells into insulin-producing islet cells. Acquiring renewable sources of cells, either from embryonic or adult stem cells, may overcome problems related to obtaining sufficient numbers of islets for transplant. Specifically, stem cells of the spleen, an organ previously not thought to harbor pancreatic stem cells, have been demonstrated to mature into fully functional islet cells (Kodama *et al.*, 2003). Islet replacement, via adult and embryonic stem cells, represents a promising cure for diabetes.

### *Regeneration of islet cells for the treatment of diabetes*

Although the onset and progression of Type I diabetes can be managed through intensive insulin therapy, this type of therapy does not liberate the patient from insulin dependence. Restoring  $\beta$ -cell function through regenerating  $\beta$ -cells from islet cell precursors is an attractive alternative to transplantation of exogenous  $\beta$ -cells. Problems with scarcity of material and immunological rejection are circumvented by the use of embryonic stem (ES) cells, which can differentiate into a variety of cell lineages *in vitro*. Soria *et al.* made use of a cell-trapping system to generate an insulin-secreting cell clone from undifferentiated ES cells (Soria *et al.*, 2000). ES-implanted animals reached a normalized weight by four weeks postimplantation, and implantation led to correction of hyperglycemia within one week. ES-derived insulin-containing cells are able to normalize blood glucose in diabetic mice, but using this technology in human therapies involves first solving problems with ES cell use, including overcoming political obstacles and potential tumor development.

Kodama *et al.* identified endogenous adult precursor cells of the spleen that can reconstitute functional islets and restore normoglycemia in the pancreas (Kodama *et al.*, 2003). By utilizing flow cytometry sorting against CD45, a surface marker absent on precursor cells, treatment of prediabetic mice with splenic precursor cells prevents diabetic onset, whereas their untreated littermates became diabetic. The donor precursor splenocytes contributed to *de novo* islet regeneration and rescue of damaged islets. These findings implicate the endogenous adult population of stem cells in therapies to reverse diabetes without the ethical issues associated with the use of ES cells.

### CONTROVERSY: POTENTIAL PLASTICITY OF ADULT STEM CELLS

The idea that adult stem cell lineage is restricted to their resident tissue has recently been challenged. The transplantation of a single hematopoietic stem cell resulted in reconstitution of hematopoietic tissue and the generation of epithelial cells in the liver, skin, lungs, and gastrointestinal tracts (Krause *et al.*, 2001). The plasticity

of several known adult stem cells is being questioned along with the possibility of resident stem cells in every human tissue. It is such possibilities that show promise for tissue repair and regeneration using adult stem cells from the patient.

Using adult stem cells to screen drugs represents another potential use that could drastically reduce the time it takes to get a drug to market. Embryonic stem cells represent a more promising source of therapies due to their pluripotent nature. These cells represent a novel approach to exploring human development. By being able to discover how cells become differentiated, the potential for cell-based therapies becomes real. Human embryonic stem cells have been grown into heart muscle, nerves, pancreas, liver, bone, cartilage, and several other tissue types. With the knowledge of how to send stem cells along the path toward differentiated tissue, there is great possibility to prevent and treat several diseases including Alzheimer's, heart disease, diabetes, arthritis, Parkinson's, and numerous others. The potential for stem cells is immense, but several obstacles must first be overcome in order to make stem cell-based therapy a reality.

## Conclusion

As of yet, we do not know what causes aging, but we do know that the rate at which aging occurs can be altered through nature and intervention. Cell turnover and replacement is routine in many tissues and does not cause tissue dysfunction when cells are adequately replaced. Changes in aging tissue include cellular senescence and apoptosis, which results in reduced numbers of fully functional cells. The use of stem cells to replace or renew these populations could lead to the treatment of several aging-related diseases; the fate lies in the hands of the scientists. The explosion of information on stem cells and their newly emerging potential holds great promise for the understanding and treatment of many diseases; however, the excitement requires tampering with careful and detailed examination of the data as well as adherence to strict criteria to form a solid basis for future work. The message from the stem-cell research community has been a resounding call for more research on both adult and ES cells in animal models of human disease. It will be years before human therapies emerge from the stem cell research, but the potential is undeniable.

# Nuclear Transfer and Cloning: Preservation or Expansion of Proliferative Lifespan?

Keith E. Latham

*Cloning of animals by somatic cell nuclear transfer has provided the potential for undertaking therapeutic cloning to produce stem cells that can be used to treat human disease. This chapter considers limitations in the ability of the oocyte to restore replicative potential to adult somatic cell nuclei. Specifically, questions related to somatic mutation load and aneuploidy, mitochondrial replacement, and telomere restoration are considered. Additionally, the feasibility of therapeutic cloning in humans is addressed.*

## Introduction

Complex organisms are comprised of two fundamental lineages, the germ cell lineage and the somatic lineage. The germ cell lineage produces during each generation the gametes that are required for reproduction, and thus must be immortal. This lineage must undergo meiotic recombination but remains genetically intact, and must retain full replicative potential, reflected, for example, in elongated telomeres and robust mitochondria, so that each new generation begins at the same starting point. A general feature of development of most animals, marking its unique place in the life cycle, is that the germ line forms quite early, often before the major differentiative milestones of the soma.

The somatic lineage, by contrast, is required to grow and develop in order to form the vessel for carrying the germ line, provide the mechanical means for accomplishing reproduction, and provide some measure of early support to the resulting progeny. The multitude of sizes, morphologies, and behaviors seen among organisms comprise specific adaptations to enable the soma to complete its mission. Once its reproductive mission has been accomplished, the soma becomes evolutionarily expendable, to a degree that varies with the degree of support of the offspring early in their lives. The endurance of the soma is affected by a variety of factors, primarily disease, environmental factors, and the genetically programmed onset of senescence as individuals age.

For most organisms, maximum lifespan is established at birth, being determined by the individual genotype.

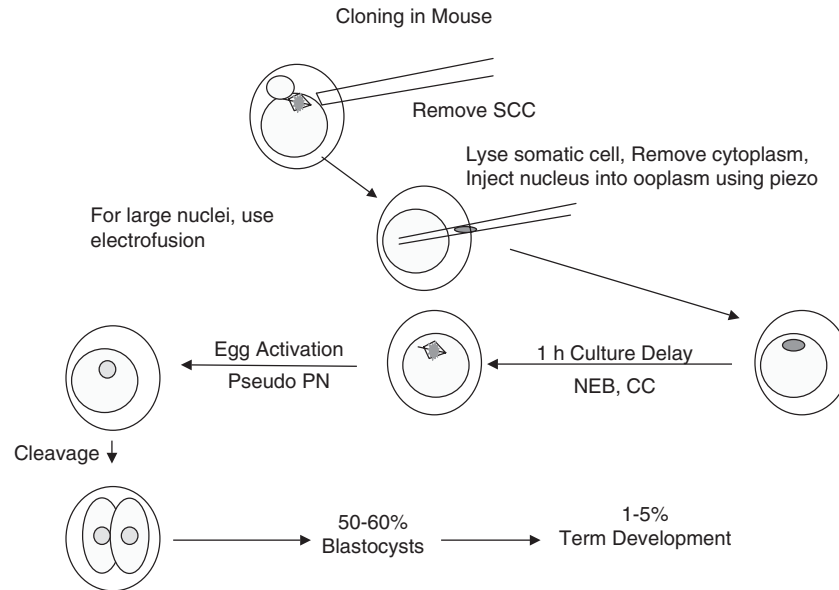

For the first time in history, however, *Homo sapiens*, unique among all other organisms, may possess the potential to modify an individual's maximum lifespan, by manipulating the long-term fate of the somatic component, effectively overcoming the preordained limits imposed by the individual genotype. This potential has arisen out of the new and exciting technology known as mammalian somatic cell nuclear transfer (SCNT), wherein nuclei from somatic cells are transplanted into oocytes, followed by the activation and development of the resulting construct. With this technology, it is now possible, in theory at least, to derive stem cells that are genetically identical to any individual. These stem cells can be manipulated in culture to correct genetic defects, and made to differentiate along specific pathways in order to produce cells for tissue repair.

This exciting new technology has raised a myriad of ethical and moral issues. These will not be addressed here. Instead, this review will address the question: To what degree can stem cells derived by the SCNT method and associated technologies modulate the lifespan of an individual? In addressing this question, three fundamental restrictions of cellular proliferative lifespan will be evaluated, namely, somatic mutation load, mitochondrial fitness, and replicative potential of the genome as reflected in telomere length.

## Overview of SCNT Method

The cloning method requires the substitution of a somatic cell genome in place of a normal embryonic genome (see Figure 46.1).

Early efforts to accomplish this using fertilized 1-cell cytoplasts as recipients failed to produce advanced development. It is now clear that the oocyte possesses a myriad of activities that mediate important early events that normally prepare the incoming sperm-derived nucleus for function. One such activity is the ability to disrupt the nuclear envelope (nuclear envelope breakdown, or NEB) (Latham, 1999). Another is the ability to exchange chromatin proteins. Normally, protamines must be removed and replaced with histones.

**Figure 46.1** Basic steps of cloning in mice. The MII stage oocyte genetic material is first removed along with the second meiotic spindle. A donor nucleus is lysed with a narrow bore pipet and the nucleus injected into the oocyte using a piezo pipette drill to assist. If donor cells are larger and have larger nuclei, electrofusion can be employed. During the following hour, the nuclear envelope breaks down, chromosomes condense, and a new spindle forms. The oocyte is then activated to initiate cleavage development. As indicated, development to term remains somewhat inefficient.

Additionally, oocyte-specific chromatin proteins typically are assembled onto the incoming sperm DNA (e.g., oocyte-specific histones; Latham (1999); Gao and Latham (2004)). Another activity is the ability to direct nuclear envelope formation and DNA decondensation, leading ultimately to the transcriptional activation of the genome (Latham, 1999). All these activities are developmentally regulated, and essentially lost within a few hours of oocyte activation (Latham, 1999).

Somatic cell nuclei need to recapitulate the same sequence of events as does the incoming sperm nucleus, but when zygote stage recipients are employed, these activities are no longer present, the corresponding processes do not occur, and embryos fail to develop. For this reason, oocytes are most often employed for nuclear transfer, and this typically involves the use of metaphase II (MII) stage oocytes. The first step in the procedure is to remove the oocyte genome, typically by aspirating the spindle-chromosome complex (SCC) into a small glass micropipette. This can be accomplished by a variety of means, each particularly suited to a given species. It should be noted that this procedure eliminates not only the oocyte DNA, but also other factors that are specifically associated with the SCC. After SCC removal, the donor cell nucleus can be introduced. There are three basic kinds of methods employed for nuclear transfer to MII stage oocytes. One involves fusion of the entire donor cell to the oocyte. Fusion is accomplished most often by electrofusion, wherein one or more electrical pulses are delivered in order to induce membrane fluidity changes that lead to fusion. Some alternative fusion methods involve the use of inactivated Sendai virus, or chemicals

such as polyethylene glycol coupled with the use of phytohemagglutinin. Fusion methods have the advantage of being somewhat noninvasive, but the disadvantages are that the entire contents of the donor cell are transferred to the oocyte, and that the efficiency of cell fusion is reduced by smaller donor cell size, which reduces physical contact between donor cell and oocyte. The second method of nuclear transfer involves simple injection of the nucleus into the oocyte. This works with some species, but not with all (e.g., rodents), due to an increased propensity for the oocyte to lyse after injection. The third method, first applied in rodents, is to employ a piezo-assisted pipette driver, which permits microinjection of nuclei, for example, into rodent oocytes, without lysis. With the injection methods, the donor cell can be lysed and repeatedly aspirated and expelled in order to remove the bulk of the cytoplasm before injection.

Once the nuclear transfer has been accomplished, typically one hour or more is permitted for the ooplasm to act upon the nucleus, bringing about NEB and then condensation of chromosomes (CC) and their assembly on a newly formed spindle. Then, the nuclear transfer construct is activated to begin development, whereupon pseudo-pronuclei form and the embryo eventually undergoes cleavage. Activation can be accomplished either as a result of electrical pulses (in some cases delivered at the time of fusion) or the use of chemical treatments, such as the use of ionophores, cycloheximide, 6-dimethylaminopurine (DMAP), or strontium chloride in calcium-free medium. Recent studies in fertilized embryos revealed a potentially important role for sperm-induced calcium oscillations in long-term

embryo viability, with particular relevance on the amplitude, number, and frequency of such oscillations (Ducibella *et al.*, 2002). As such oscillations likely are not recapitulated during artificial oocyte activation, cloned embryos may be initially disadvantaged relative to fertilized embryos due to an absence of correct calcium signaling and downstream events.

Once the cloned constructs are activated, they must be cultured *in vitro* for some period before being returned to the reproductive tract of a suitable foster mother for continued gestation. Recent studies reveal that cloned embryos have radically different culture medium requirements as compared with fertilized embryos (Latham, 2004). This is most likely the result of continued expression of genes from the donor cell nucleus. Reprogramming of gene expression appears to be a rather prolonged process, possibly continuing until just before the time of gastrulation. As a result, when gene transcription commences in the early cloned embryo, many somatic cell-expressed genes will be aberrantly expressed in the embryo. The products of these aberrantly expressed genes likely alter basic processes of osmoregulation, homeostasis, and metabolism (these processes differ substantially between somatic cells and normal fertilized embryos). Thus, although traditional embryo culture media have been most widely employed for culturing cloned embryos, such media are likely to be grossly suboptimal. In fact, somatic cell formulations have produced superior results in several instances (Latham, 2004). The cloning technique is thus faced with a fundamental problem: in order to achieve continued development, embryos must be returned to the reproductive tract, and yet the environment there is likely optimized for fertilized embryos and thus poorly suited to cloned embryos. If we accept the possibility that nuclear reprogramming continues up through the time of gastrulation, then it is likely that the exposure of the cloned embryos to a suboptimal environment, either *in vitro* or *in vivo*, inhibits the reprogramming process and reduces clone viability.

The overall outcome of the cloning procedure is that only about 1 to 5% of all nuclear transfer constructs develop to term. About half of all constructs can complete preimplantation development, and then there are additional waves of loss during the peri-implantation period, and around the time of gastrulation (Yanagimachi, 2002). From the standpoint of contemplating therapeutic uses for cloning, it is fortunate that a substantial number of constructs can form blastocysts and eventually give rise to an inner cell mass population, from which can be derived embryonic stem cells (ESCs).

### The Question of Donor Cell State

One theoretical uncertainty that besets all cloning studies is the precise phenotypic state of the donor cells from which the rare surviving clones are obtained. Typically,

adult or fetal tissues are dissociated into single-cell suspensions. Various enrichment procedures might be employed to favor isolation of a particular cell type. The operator then selects from that suspension cells of a particular type. For example, the operator might select the smallest size cells present, presumably because such cells should be in the G1 stage of the cell cycle, if MII stage oocytes are employed as recipients and polar body extrusion is prevented during oocyte activation. Alternatively, G2/M phase cells may be selected if polar body extrusion is to be permitted. The cell cycle status of cultures can be manipulated (e.g., by serum starvation/stimulation) to enrich for cells of particular cell cycle stages. If no further enrichment methods are applied, the donor cells are thus selected from a population that is to some degree heterogeneous. Within that population of cells may reside somatic stem cells. Whether such rare stem cells in fact contribute preferentially to live clone births has not been thoroughly studied. There are two circumstances in which the presence of stem cells probably does not contribute to cloning outcome. First, differentiated cells expressing specific molecular markers can be employed. In such cases, cloning success rates are about an order of magnitude lower than observed with primary cell sources (Hochedlinger and Jaenisch, 2002), an outcome that could reflect the differentiated state, absence of stem cells, or simply a differential response of clones made with those particular cell types to the *in vitro* cloned embryo culture system. The second circumstance wherein stem cell contamination would not affect outcome would be in cases where clonally selected cell lines are established following genetic manipulation (e.g., gene knockout or transgenesis).

Whether stem cells contribute preferentially to the production of clones that develop to term could affect conclusions derived from the study of cloned progeny. Stem cells can differ from differentiated cells in fundamental respects such as the number of past rounds of cell division, telomere length, and telomerase expression. Because reprogramming is slow, these phenotypic differences between stem cells and differentiated cells will likely persist to some degree in cloned embryos. Thus, conclusions regarding somatic mutation load, mitochondrial fitness, and replicative potential of the genome as reflected in telomere length in the context of cloned embryo and cloned stem cell derivation need to account for possible effects of donor cell state.

### Somatic Mutations and Effects on SCNT

#### ANEUPLOIDY AND POLYPLOIDY ARISING DURING CLONING

Recent studies reveal that a large proportion of cells in cloned blastocysts are aneuploid or polyploid (Nolen *et al.*, 2005; Booth *et al.*, 2003; Shi *et al.*, 2004). Thus, although a large proportion of cloned constructs can

attain blastocyst stage and be used to generate ESCs, the genetic integrity of the ESCs obtained must initially be suspect. This places obvious restrictions and requirements on plans to employ clone-derived ESCs for therapy.

When does this aneuploidy arise? We might argue that this most likely occurs during the early cleavage divisions of the cloned constructs, on the premise that the somatic cells should initially be predominantly euploid. In a recent study of aneuploid in cloned bovine embryos, completely euploid constructs comprised only 22% of the total blastocyst population based on the analysis of two chromosomes; the remaining embryos were either polyploid or mixoploid (Booth *et al.*, 2003). A significant rate of polyploidy/aneuploidy was also observed in mouse cloned blastocysts, although less than the rate seen in the bovine study (Nolen *et al.*, 2005). If we assume that at most only a small fraction of somatic cells would be aneuploid or polyploid, then these results suggest that aneuploidy/polyploidy in cloned embryos likely arises due to mitotic errors during cleavage.

It has been suggested that cloning in primate species may be hindered by the removal of proteins associated with the SCC (Simerly *et al.*, 2003, 2004). Studies in mice reveal spindle defects in SCNT embryos (Miyara *et al.*, 2006). Other studies reveal that removal of the SCC likely depletes the embryo of factors that otherwise could modulate its phenotypes (i.e., tetraploid constructs prepared by SCNT without SCC removal appear more like fertilized embryos than do diploid clones) (Gao and Latham, 2004).

It is also possible that aneuploidy in clones is the result of aneuploidy in the donor cells. In a study of developing brain, one-third of neuroblasts were aneuploid (Rehen *et al.*, 2001). Aneuploidy was also detectable in adult neurons, which displayed more than 1% aneuploidy for sex chromosomes.

With respect to producing ESCs for therapy, it appears likely that a stringent selection may operate, such that clones with a greater degree of aneuploidy/polyploidy tend to have smaller numbers of cells (Booth *et al.*, 2003), and thus may be less likely to form a healthy inner cell mass from which to derive an ESC line. This may account for why the one clone-derived human ESC line is euploid (Hwang *et al.*, 2004), despite evidence from bovine clones of a high rate of aneuploidy.

### SOMATIC MUTATIONS IN CLONING

Somatic mutation and somatic recombination following DNA damage and repair could affect the outcome of cloning procedures. Exposure to mutagenic chemicals and radiation can obviously damage somatic cells. Nondividing stem cells within adult tissues could be less susceptible to damage by transient exposures. Cloning with somatic cells bearing *de novo* mutations would then give rise to cloned embryos displaying either lethality

or aberrant phenotypes later in life. Recombination-based repair of DNA damage, as well as aberrant mitoses can lead to loss of heterozygosity or uniparental disomy for entire chromosomes or chromosome regions. Loss of heterozygosity could lead to phenotypic exposure of recessive traits, whereas uniparental disomy could lead to abnormal phenotypes associated with imprinted regions of the genome.

### CLONING WITH CANCER CELLS

Cancer cells display characteristics of continued cell growth, lack of crisis or senescence in culture, altered growth properties (e.g., anchorage independence), and an arrest or reversion of cellular differentiation. These characteristics can arise through a combination of somatic oncogenic mutations and loss of genomic integrity, including gene duplication/amplification and loss of heterozygosity. An obvious question made approachable by the SCNT method is whether the oocyte can reprogram the nuclei of such cells to an embryonic state. Additionally, we can ask whether the oncogenic mutations in particular cancer cells would predispose the cloned animal to only a single form of cancer, or to cancer in multiple tissues.

Cloning with cancer cells recently has been reported. Hochedlinger *et al.* (2004) reported that cloning with several types of cancer cells (leukemia, lymphoma, breast cancer) led to the formation of blastocysts, but not to development of inner cell masses (ICMs), the early progenitor of the embryo proper and ESCs. However, ESCs were established from clones made with nuclei from a RAS-inducible melanoma cell line, and these were subsequently used to produce chimeric mice using the tetraploid complementation method. The chimeric mice were predisposed to cancer, with an expanded spectrum of tumorigenesis. This result reveals that, although developmental pluripotency can be conferred upon cancer cell nuclei by the cloning method, the genetic factors that originally induced carcinogenesis predispose the clone to develop tumors of the same type as the donor, as well as other cell types that can respond to that genetic defect.

It is interesting that cloning by SCNT provides a novel means of exploring the transforming potential of various carcinogenic genetic changes by providing a situation in which the effects of those genetic lesions can be examined during the formation of all the cell lineages of the body. Blelloch *et al.* (2004) produced ESCs from clones made with embryonal carcinoma cell nuclei. These ESCs behaved much like the embryonal carcinoma cells themselves, with respect to developmental potential, a result that appears to be related to specific genetic lesions in the embryonal carcinoma cells. Shi *et al.* (2003) found that bovine immortalized cell nuclei were unable to support clone development to the blastocyst stage, even following a number of treatments applied in order to try to expand developmental potential. Sheep clones made

with nuclei from nontransformed fibroblasts immortalized with the human telomerase (hTERT) gene can display significant postimplantation development (Cui *et al.*, 2003).

Although elevated telomerase expression maintained telomere length and prevented senescence in the donor cell cultures, no term development was achieved (Cui *et al.*, 2003). This could reflect a cell-line specific or insertion site-specific defect, or could reflect an inhibitory effect of immortalization and elevated hTERT expression on development. It is interesting that fetal development was achieved in the study of Cui *et al.* (2003) but not that of Shi *et al.* (2003). This may reflect the activity of additional genetic lesions in the cells employed by Shi *et al.* (2003), rather than an effect of immortalization specifically. Species-specific differences also must be considered. Further studies defining the effects of various immortalizing or transforming mutations on the ability to establish pluripotency should prove interesting.

## Mitochondrial Fitness

### MITOCHONDRIAL CHANGES DURING AGING

The preceding section illustrates that genetic alterations in the somatic cells employed as nuclear donors for SCNT exert effects on cloned embryo phenotypes. What of the mitochondrial genome? The mitochondrial theory of aging holds that mitochondria accumulate mutations as a result of damage by reactive oxygen species they generate, and that the accumulation of defective mitochondria leads ultimately to cellular senescence and tissue degeneration. The rate of repair relative to the incidence of DNA damage would affect the overall rate of accumulation of damaged mitochondrial genomes.

### MITOCHONDRIAL FATE AFTER SCNT

If cells harboring these mutant mitochondria are selected for SCNT, several possible fates might await them. As “foreign” (i.e., not oocytic) mitochondria, they might actively be eliminated, much as sperm mitochondria typically are eliminated. They might fail to replicate and thus be eliminated by attrition. They might persist in the embryo, leading to mitochondrial heteroplasmy. Last, they might experience a replicative advantage over endogenous ooplasmic mitochondria, and thus become the predominant mitochondria in the cloned animal.

In one study, a mouse model was employed in which mitochondrial dysfunction was associated with telomere shortening and genomic instability (Liu *et al.*, 2002). Using nuclear transfer to transfer nuclei from cells with defective mitochondria to oocytes with normal mitochondria alleviated these defects. This suggests that mitochondrial defects related to aging might be eliminated by nuclear transfer. To what extent replacement of “aged”

mitochondria by “young” ooplasmic mitochondria would occur is not clear. A variety of nuclear transfer studies have described diverse results concerning the fate of mitochondria after various micromanipulations involving oocytes.

Oocytes are designed to eliminate the mitochondria that are transmitted via the sperm (Kaneda *et al.*, 1995). These paternal mitochondria carry ubiquitin tags that seem to target them for elimination by the ooplasm (Sutovsky *et al.*, 2000). Interestingly, with interspecies crosses, paternal mitochondria can avoid elimination (Kaneda *et al.*, 1995), indicating that there exists species specificity to the recognition of the sperm ubiquitinated proteins by the ooplasm. Cell type specificity also exists. Injection of *Mus spretus* spermatid or liver mitochondria into oocytes of *Mus domesticus* revealed that the liver mitochondria persisted to birth, whereas spermatid mitochondria were gradually eliminated and then were not detected in progeny (Shitara *et al.*, 2000). It is therefore unlikely that donor cell mitochondria would be eliminated in cloned embryos by the same mechanism that eliminates sperm mitochondria, as the donor cell mitochondria would not be expected to carry the appropriate ubiquitinated tags.

If not actively eliminated, then to what degree might donor cell mitochondria in SCNT embryos be eliminated by attrition, persist at a low level, or assume a replicative advantage over endogenous mitochondria? Mitochondrial heteroplasmy was not observed in sheep clones (Evans *et al.*, 1999). In SCNT embryos made with *Bos indicus*, donor nuclei transferred to *Bos taurus* oocytes, donor cell mitochondria were nearly undetectable in cloned fetuses (Hiendler *et al.*, 2003) and calves (Meirelles *et al.*, 2001). However, donor cell mitochondria were not eliminated in monkey-to-rabbit or panda-to-rabbit NT embryos (Chen *et al.*, 2002; Yang *et al.*, 2003). Mitochondrial heteroplasmy was also reported for nuclear transfers made between Holstein and Luxi Yellow cow (Han *et al.*, 2004), and in other studies involving bovine species (Takeda *et al.*, 2003; Steinborn *et al.*, 2002). Embryonic blastomere nuclear transfer in *Macaca mullatta* produces offspring with mitochondria from both the recipient oocyte and the donor blastomere (St. John and Schatten, 2004). In this case, both maternal and paternal mitochondria derived from the donor embryonic blastomere were detected, indicating that the sperm mitochondria were not eliminated as expected, revealing a possible defect in the process of paternal mitochondrial elimination in cloned constructs. Similarly, with ooplasm transfer approaches in human infertility treatment, mitochondrial heteroplasmy can be detectable in the resulting children (Barritt *et al.*, 2001). Collectively, the results obtained to date indicate that mitochondrial heteroplasmy is likely to accompany the application of SCNT methods in the human.

The persistence of mitochondrial heteroplasmy to birth indicates that the donor cell mitochondria replicate

following SCNT. In some cases, the donor cell mitochondria may actually have a replicative advantage. In the panda-to-rabbit NT embryos, donor cell mitochondria, in fact, can become the predominant organelle by fetal life (Chen *et al.*, 2002). In bovine NT studies, donor cell mitochondria can account for as much as 40% of the total (Takeda *et al.*, 2003), again indicating a replicative advantage over recipient mitochondria at some point during development. It is worth noting that, although it is often assumed that donor cell mitochondria might be eliminated due to incompatibilities with recipient cell nuclear genomes, these observations indicate that this need not always be the case. It is thus of interest that mitochondria carrying mutated genomes can be unevenly distributed within adult tissues, consistent with a clonal expansion (both intracellular and cellular) during aging (Khrapko *et al.*, 2003). The ability of such mutated mitochondria from aging cells to expand within adult tissues might also result in their expansion, and possibly a replicative advantage, in SCNT embryos.

## Replicative Potential

### TELOMERE LENGTH CHANGES DURING DEVELOPMENT AND *IN VITRO* CULTURE

With the exception of stem cells, the replicative potential of somatic cells is limited due to the eventual onset of cellular senescence. It is widely thought that progressive shortening of telomeres during DNA replication contributes to the aging process, so that after a sufficient number of rounds of replication, the telomeres shorten below a critical point needed to maintain genomic integrity. Overexpression of telomerase can be associated with cellular immortalization and may contribute to cancer, although other events leading to uncapped, shortened telomeres are also associated with cancer (Cui *et al.*, 2003; Wai, 2004). During normal development, telomerase activity may decline with age. Shorter lived species display a rapid loss of telomerase activity during development, whereas longer lived species delay this decrease in telomerase activity (Haussman *et al.*, 2004). Increased telomere length in *Caenorhabditis elegans* correlates with increased life span (Joeng *et al.*, 2004). Oxidative DNA damage from reactive oxygen species, irradiation, and various forms of stress are believed to shorten telomeres prematurely, leading to accelerated aging (Kawanishi *et al.*, 2004; Liu *et al.*, 2002).

### SERIAL NUCLEAR TRANSFER

One striking result to come from SCNT studies is the apparent extension of replicative potential that accompanies the process. This is most apparent where serial nuclear transfer has been undertaken. This is the process of producing cloned embryos or progeny, recloning using donor cells from that cloned individual, and repeating the process for a number of generations.

This has been performed in both cattle (Stice and Keefer, 1993; Puera and Trounson, 1998) and mice (Wakayama *et al.*, 2000). An additional type of serial NT indicative of expanded replicative potential involves not repeated rounds of NT, but rather the derivation of NT ESCs, which are then employed as nuclear donors for cloning. Thus, with nuclear transplantation, it is possible to entice adult somatic cell genomes to undergo extensive replication, illustrating an expanded replicative potential relative to the original donor cells.

### PRESERVATION VERSUS ELONGATION OF TELOMERE LENGTH IN CLONED ANIMALS

The expanded replicative potential demonstrated by serial NT indicates that progressive diminishment of telomere length may be halted following the initial NT step in order to permit an expanded replicative potential. It is also possible that telomere lengths become expanded during cloning, under the influence of reactivated expression of telomerase, thus restoring an authentic embryonic cellular replicative potential. A third possibility relates to the inherent uncertainties about donor cell origins, and the low efficiency of success of the cloning procedure; specifically, that the rare donor cell nuclei that give rise to the rare surviving clones represent stem cell contaminants in the donor cell population. Stem cells would likely possess longer telomeres than differentiated cells, and yet this greater telomere length would be undetectable by typical Southern blot hybridization of the whole cell population. Stem cells may also possess a greater capacity to activate telomerase expression after SCNT and restore telomere length to counter aging effects evident in differentiated cells (Allsopp *et al.*, 2003). The first of these two possibilities have been examined extensively in a variety of studies of clones of many different species, but the third possibility related to stem cell donor nuclei remains to be examined.

The Wilmut laboratory reported that nuclear transfer can lead to telomere elongation of late-passage donor cells (fibroblasts) used for cloning in sheep, but that the telomeres do not become fully restored relative to early passage cells (Clark *et al.*, 2003). Dolly was reported to have shorter than normal telomeres (Shiels *et al.*, 1999), consistent with incomplete restoration of telomere length (Clark *et al.*, 2003). Observations in cattle indicated that cloned calves could be obtained from senescent fibroblasts, suggesting an ability to elongate telomeres and thus restore replicative potential (Lanza *et al.*, 2000). Other studies (Tian *et al.*, 2000; Betts *et al.*, 2001) reported cloned calves made using fibroblast nuclei possessed telomeres that were not different from those of control calves, indicating restoration of telomere length relative to donor nuclei. Kato *et al.* (2000) reported that the observed telomere lengths of clones depended on the cell type assayed; telomere length in ear cells of cloned calves were similar to those of ear cells of the nuclear donor animal, but that telomere length was shorter in white

blood cells of clones. Miyashita *et al.* (2002) reported that donor clones made with muscle and fibroblast cell nuclei had telomeres longer than those of the donor animal, but similar to control calves, whereas clones made with cumulus, mammary epithelial, and oviductal cell nuclei had telomeres shorter than those of control animals. Clones made with embryonic stem cell nuclei appeared to have expanded telomeres. Thus, a donor cell type effect on subsequent telomere length appeared to occur.

The results of Miyashita *et al.* (2002) may reflect the continued expression of the donor cell program in the early cloned embryo, so that different nuclear donor cell types may direct different levels of expression of telomerase and other factors required for telomere elongation. An alternative explanation for the apparent effect of donor cell type is that the different populations contain different proportions of some form of undifferentiated stem cell. If the donor cell gene expression program continues after nuclear transfer, and includes telomerase expression, then such a donor cell nucleus could direct the expression of telomerase and expansion of its own telomeres. The variability seen among different tissues of cloned animals bears further study. Additionally, species-dependent differences in replicative potential, which varies with adult size (Hausmann *et al.*, 2003), could contribute to diversity in observations obtained with different model organisms. Overall, it appears that cloning by SCNT can lead to telomere expansion, but the degree of that expansion is affected by a variety of factors, most notably donor cell type.

#### GENETIC MANIPULATION OF TELOMERE LENGTHS OF DONOR NUCLEI

One approach that has been applied recently to cloning in animals is to try to manipulate genetically the donor cell genome so that it becomes more efficient for SCNT. Cui *et al.* (2003) performed SCNT with telomerase-immortalized cells. The nuclei from these cells supported significant development, but were unable to support term development. It is thus not clear whether such genetic manipulation of telomerase expression confers sufficient advantage to offset the risk associated with mutagenesis of the genome.

#### Conclusion

Cloned animals that are born and survive beyond the neonatal period and appear generally of good health seem to be capable of lifespans that are normal for the species. Dolly was born in mid-1996 and died in 2003. A majority of cloned mice of otherwise apparently normal phenotypes display normal lifespans (Yanagimachi, 2002). These results illustrate that reproductive cloning is possible, without profound restrictions on lifespan. Serial NT studies further illustrate the ability of SCNT to drive somatic cell genomes to extended replicative

potential. It seems clear, therefore, that SCNT methods can expand the proliferative lifespan of the donor cell genome. The degree to which this occurs, however, appears to be affected by such parameters as the donor age, the donor cell type, and the differentiated state of the donor cell. In a broader context, SCNT may provide the means necessary for preserving individual lifespan as well.

The potential for SCNT to be employed to derive ESCs for therapeutic purposes has been demonstrated in both animal models and in humans (Rideout *et al.*, 2002; Hwang *et al.*, 2004; review, Latham, 2004). Additionally, the ability of cloned ESCs to rescue phenotypic defects has been shown in mice, effectively illustrating the principle of therapeutic cloning (Rideout *et al.*, 2002). In moving forward with devising strategies for therapeutic cloning, several pertinent questions arise. One is the issue of mutation load. It may be advantageous to restrict donor cell types to those that may experience the least risk of somatic mutation or aneuploidy. Of course, two kinds of mutations must be considered: mutations that affect donor cell phenotype, and thus may be detectable using methods that could permit the exclusion of mutant cells, and “silent” or “masked” mutations that do not immediately affect the donor cell phenotype because they arise in unexpressed genes, or because additional mutations would be needed to allow penetrance. In the latter case, ESCs derived by therapeutic cloning might bear some measurable increase in risk of cancer development if they harbor oncogenic mutations. Selection for stem cells from adult tissues may be worth considering, because stem cells may have less risk of accumulating genetic mutations, as a result of active DNA replication and associated expression of DNA repair proteins, selective partitioning of newly replicated DNA strands (Potten *et al.*, 2002; Merok *et al.*, 2002), and apoptosis of cells with damaged DNA. Additionally, stem cells may confer advantages with respect to mitochondrial phenotype and telomerase expression.

Another consideration is whether the age of the donor individual/patient affects the likely outcome of therapeutic cloning. Will cells from older versus younger individuals display differences in the quality of ESCs that can be produced? Might there arise analytical methods to enrich for the appropriate population of cells, making it possible to avoid such an age effect? Might cells from older individuals require serial NT procedures in order to eliminate defective mitochondria or to achieve suitable telomere lengths? Will younger recipients/patients require higher quality or “younger equivalent” ESCs to be produced, with respect to mitochondria or telomere lengths?

Epigenetic changes may also be problematic, as cloned embryos often display defects in DNA methylation and regulation of imprinted genes (Latham, 2004). During cloning in animals, clones with severe epigenetic changes are likely to die during gestation, and thus be eliminated.

Cloning to produce ESCs, however, would not require this level of selection, because the embryos are converted to ESCs before this is likely to happen. It may thus be necessary to characterize ESCs thoroughly with respect to methylation state and expression of imprinted genes before using in therapeutic applications.

Given that cloning has been successful in so many different mammalian species, it seems likely that therapeutic cloning should be feasible in humans. However, recent studies indicate that cloning may be more difficult in primates and may not be possible using the protocols described to date. Cloned rhesus monkeys were produced using blastomere nuclei (Meng *et al.*, 1997), and an additional advanced pregnancy was again achieved later (Mitalipov *et al.*, 2002). Cloned rhesus monkeys have not been produced successfully using adult or fetal somatic cell nuclei (Mitalipov *et al.*, 2002; Simerly *et al.*, 2003). It appears that this limitation may reflect an inability of adult somatic cell components, in particular the centrosome, to substitute for authentic sperm-derived components, as indicated in studies by Simerly *et al.* (2003, 2004) and Miyara *et al.* (2006). This deficiency could lead to incorrect mitotic segregation of chromosomes and aneuploidy, which would account for the failure to obtain live progeny. The use of cloned human embryos to produce ESCs (Hwang *et al.*, 2003) was clearly a milestone with respect to illustrating the feasibility of the approach. Further research will be needed to identify, and hopefully correct, potential pitfalls in applying this technology in medicine.

## ACKNOWLEDGMENTS

The author thanks Carmen Sapienza for critical comments on the manuscript. The work in the author's laboratory is supported in part by grants from the NIH/NICHD (HD38381, HD43092).

# Human Models of Longevity

Thomas Perls

*Centenarians, though rare at a prevalence of approximately one per 10,000 in industrialized countries, are among the fastest growing segment of our population. Familial studies indicate that exceptional longevity runs strongly in families, but as of yet, few genetic variations have been found to account for this survival advantage. It is likely that the prevalence of centenarians is increasing because achieving exceptional old age is multifactorial. A number of factors important to such longevity are becoming more prevalent with modern public health measures and interventions. Such a multiple trait model would predict that the more extreme the phenotype, the more likely discernible environmental and genetic characteristics are to be discovered that are important to achieving very old age, much of it disability-free. Thus studies of families highly clustered for longevity or studies of supercentenarians, people age 110 and older, hold promise of facilitating such discoveries.*

## Introduction

People vary a great deal in terms of how they age. Some seem to age relatively quickly and develop age-related illnesses such as heart disease or stroke in their 40s and 50s, whereas others appear to age very slowly, and if they do develop age-related illnesses it may only be toward the end of their very long lives. Within these two extremes are the majority of people who, at least in industrialized nations, have an average life expectancy in their late 70s. Much of the variation around this average appears to be due to differences in environment, behavior, and luck. As in the case of the Seventh Day Adventists, if one has good health habits, they are quite likely to live to an age that many humans appear to be capable of achieving, their late 80s (20 years beyond the age of 60!) (Fraser and Shavlik, 2001). Distinguishing themselves from most Americans, the behavioral traits that lead to such a survival advantage are regular exercise, a frugal vegetarian diet, not smoking, and perhaps having a religious faith is also helpful.

However, what does it take to live to even longer, beyond the nonagenarian years, to age 100 and older? First, it appears that a resistance to disability is necessary. One study retrospectively found that nearly 90% of centenarians were independently functioning at an

average age of 92 years (Hitt, Young-Xu, Silver, and Perls, 1999). On the other hand, many of these very old individuals can live with age-related illness(es) for a long period of time (unlike many other older people who die of those diseases) (Evert, Lawler, Bogan, and Perls, 2003). Thus, achieving exceptional old age, with its compression of disability toward the relative end of life, would appear to be a true advantage to which most people would aspire. So, what does it take to live to 100?

## Demographic Selection

There has been significant debate among demographers as to what happens to the rate of mortality at extreme old ages. The answer has important ramifications for deciphering the factors that are important to survival to extreme old age. An important possibility is that demographic selection occurs at very old age, yielding a select, relatively healthy cohort at even older ages. Demographic selection describes the process of old frail individuals dying, leaving behind a more fit surviving cohort (Vaupel *et al.*, 1998). The observation by some research groups that the incidence of AD plateaus at very old ages is consistent with this phenomenon. Ritchie and Kildea (1995) performed a meta-analysis of nine epidemiological studies, finding that the rate of increase in dementia prevalence fell off among octogenarians and plateaued at approximately 40% at age 95. In a longitudinal study of older people living in Cache County, Utah, the incidence of both dementia and AD increased almost exponentially until ages 85 to 90, but declined after age 93 for men and age 97 for women (Miech, 2002).

A genetic example of demographic selection is the decreased frequency of the apolipoprotein E epsilon-4 (ApoE  $\epsilon$ -4) allotype in the oldest old. Individuals who are homozygous for ApoE  $\epsilon$ -4 have 2.3 to 8.0 times greater risk of developing AD than the general Caucasian population (Corder, 1993). The allelic frequency of ApoE  $\epsilon$ -4 drops off dramatically in the oldest age groups, presumably because of its association with AD and vascular disease (Schachter *et al.*, 1994). Interestingly, the effect of ApoE allotype upon AD incidence appears to decrease with age at these very old ages (Sobel, 1995).

These examples notwithstanding, the phenomenon of demographic selection occurring at extreme old ages

remains controversial. Some argue that because of marked improvements in medical care and public health measures, such selection no longer occurs. In this case, decreased mortality due to improved health care could lead to an increased prevalence of frailty among older survivors because treatment of existing diseases simply postpones death to older ages (Carnes, 2001).

## Gender Differences

Save for a very few exceptions, in most populations, the vast majority of centenarians are women and generally, in industrialized nations, they comprise 85% of centenarians. In Sardinia, Italy, Michel Poulain has reported that approximately 50% of centenarians, particularly those living in the mountainous region of the island, are male (Poulain, 2004). But again generally speaking, female centenarians outnumber males almost nine to one. Despite the fact that many more women achieve exceptional longevity than men, among centenarians the men generally have better functional status. One explanation for this may be that men must be in excellent health to achieve such extreme old age (Perls, 1998). Women on the other hand, may be better adept at living with age-associated illnesses, and thus they can achieve exceptional old age even with significant chronic disability, particularly compared to men of similar age.

These observations might indicate a demographic crossover in which women are better off than men in younger old age and men, although fewer in number, are functionally better off in extreme old age. The underlying reasons why women generally live longer than men and are, at least before menopause, significantly less likely to develop heart disease and stroke are unclear. Estrogen, which might be a powerful antioxidant, has been implicated as an important reason. However it has been noted that premenopausal women who undergo hysterectomy but not oophorectomy experience an increased risk for vascular disease that is similar to men (Kiechl, 1997). Another possible reason is that women, because of menses, are relatively iron-deficient compared to men for a 30- to 40-year period. Iron is a crucial catalyst in mitochondrial production of free radicals as a byproduct of metabolism. Perhaps a reduction in available iron leads to less free-radical production. For example, iron deficiency has been associated with significant reductions in levels of oxidized low-density lipoprotein (LDL) cholesterol, an essential component of atherosclerotic plaque production (Sullivan, 1989). In addition, diets high in heme have been associated with significantly increased risk of heart disease (van der A, 2005).

Another potential female advantage studied by scientists relates to the fact that males possess one X chromosome and women have two. Women thus have the prospect for somatic cell selection with advancing age where the more fit of two somatic cell population survives. Stem cell populations that give rise to highly proliferative

cell populations (for example, intestinal and skin epithelium, leukocytes) would be particularly prone to such selection. Among the genes on the X chromosome that are of particular interest are those that affect telomere length, in part because those cell populations that resist oxidative stress better might have longer telomeres (Aviv, 2005). Increased telomere length has been associated with both improved proliferative capacity and decreased mortality.

## The Familiarity of Exceptional Longevity

### HERITABILITY ESTIMATES

Twin studies have estimated the heritability of life expectancy to range between 25 and 30% (McGue, Vaupel, Holm, and Harvald, 1993). These twin studies cannot infer the heritability of living to extreme old age because the oldest subjects in these studies are only octogenarians. In contrast, centenarians who live an additional 15 to 20 years beyond average life expectancy may require more than an advantage in their habits and environment. They may require a genetic advantage that translates into a significant inherited component to exceptional longevity. Some estimates are higher when the phenotype is more specific, as in the case of cognitive function at very old age (McClearn, 1997). Centenarians and their family members may have or lack certain genetic characteristics that result in a significant survival advantage.

### FAMILIARITY OF EXCEPTIONAL LONGEVITY

Perls, Wilmoth, and colleagues (2002) analyzed the pedigrees of 444 centenarian families in the United States that included 2,092 siblings of centenarians. Survival was compared to 1900 birth cohort survival data from the U.S. Social Security Administration. As shown in Figure 47.1, female siblings had death rates at all ages that were about one-half the national level; male siblings had a similar advantage at most ages, though diminished somewhat during adolescence and young adulthood.

The siblings had an average age of death of 76.7 for females and 70.4 for males compared to 58.3 and 51.5 for the general population born around the same time. Even after accounting for race and education, the net survival advantage of siblings of centenarians was found to be 16 to 17 years greater than the general population. Relative survival probabilities (RSP) for these siblings increased markedly at older ages, reflecting the cumulative effect of their mortality advantage throughout life (see Table 47.1). Compared to the U.S. 1900 birth cohort, male siblings of centenarians were 17 times more likely to attain age 100 themselves, and female siblings were 8.2 times more likely.

The analysis of death rates indicates that the siblings' mortality advantage does not grow as they get older. Rather, their relative probability of survival is a cumulative measure and reflects their life-long advantage

## 47. Human Models of Longevity

**Figure 47.1** Relative mortality rate, siblings of centenarians compared with their 1900 birth cohort for ages 20 to 100.

**TABLE 47.1**  
RSP with 95% confidence intervals (CI) of siblings of centenarians versus U.S. 1900 cohort

Age	MALES			FEMALES		
	RSP	Lower 5% CI	Upper 95% CI	RSP	Lower 95% CI	Upper 95% CI
20	1.00	1.00	1.00	1.00	1.00	1.00
25	1.00	0.99	1.01	1.01	1.00	1.02
60	1.18	1.15	1.21	1.12	1.09	1.14
65	1.29	1.25	1.33	1.16	1.13	1.19
70	1.48	1.42	1.53	1.24	1.21	1.28
75	1.68	1.60	1.77	1.36	1.31	1.41
80	2.03	1.90	2.16	1.54	1.47	1.60
85	2.69	2.47	2.91	1.83	1.73	1.93
90	4.08	3.62	4.54	2.56	2.39	2.74
95	8.35	6.98	9.71	4.15	3.73	4.57
100	17.0	10.8	23.1	8.22	6.55	9.90

over the general population born about the same time. Such elevated RSP values support the hypothesis that these family members have genetic variations in common that are important to achieving exceptional longevity. Furthermore, mortality rates of different groups (e.g., gender, race, education, physical activity, socioeconomic status) converge at very old age, and thus such a sustained advantage is unusual. The substantially higher RSP values for men at older ages might reflect the fact that male disease-specific mortality is significantly higher than for females at these older ages, and thus the males experience a greater relative advantage from beneficial genotypes compared with women. Another possibility could be

that an even greater, and thus more rare combination of genetic and environmental factors are required for men to achieve extreme age compared to women. Either possibility could explain why men comprise only 15 percent of centenarians.

Richard Cutler, in what is now a classic paper in gerontology, proposed that persons who achieve extreme old age do so in part because they have genetic variations that affect the basic mechanisms of aging and that result in a uniform decreased susceptibility to age-associated diseases (Cutler, 1975). Persons who achieve extreme old age probably lack many of the variations (the “disease genes”) that substantially increase risk for premature death by predisposing persons to various fatal diseases, both age-associated and non-age-associated. More controversial is the idea that genetic variations might confer protection against the basic mechanisms of aging or age-related illnesses (the “longevity-enabling genes”). Centenarians may be rare because a complex set of environmental and genetic variables must coexist for such survival to occur. Based upon studies of centenarian pedigrees, it appears that family members are more likely to have such combinations of factors in common than the general population.

### CHILDREN OF CENTENARIANS

Offspring of centenarians have been found to have lipid profiles associated with lower risk for cardiovascular disease (Barzilai, Gabriely, Gabriely, Iankowitz, and Sorkin, 2001). Other findings show that middle-aged sons of long-lived parents had better systolic pressures, cholesterol levels, and decreased frequencies of the apoE  $\epsilon$ -4 allele, compared to middle-aged sons of shorter-lived parents. Using a questionnaire-based cross-sectional study design, Terry and colleagues (2004) assessed the

health histories of a nationwide sample of centenarian offspring ( $n = 176$ ) and controls ( $n = 166$ ). The controls consisted of offspring whose parents were born in the same years as the centenarians but at least one of whom died at age 73, the average life expectancy for that birth cohort. The average age at death of the other parent was 77 years, the same as the spouses of the centenarians. Centenarian offspring were found to have a 56% reduced relative prevalence of heart disease, a 66% reduced relative prevalence of hypertension, and a 59% reduced relative prevalence of diabetes in multivariate analyses that controlled for age, gender, years of education, annual income, IADL score, ethnicity, marital status, exercise, smoking, and alcohol use. There were no significant differences in the prevalence of a number of other age-related diseases including cancer, stroke, dementia, osteoporosis, cataracts, glaucoma, macular degeneration, depression, Parkinson's disease, thyroid disease, and COPD. The lack of differences for these diseases may be a function of the sample size, the choice of controls, or it may be that families with exceptional longevity do not have differential susceptibility to these diseases. For the offspring of centenarians who did report hypertension, the age of onset was significantly later when compared to controls. Similar delays were noted for the age of onset of coronary heart disease, diabetes, and stroke.

#### GENES PREDISPOSING TO EXCEPTIONAL LONGEVITY

The discovery of genetic variations that explain even 5 to 10% of the variation in survival to extreme old age could yield important clues about the cellular and biochemical mechanisms that affect basic mechanisms of aging and susceptibility to age-associated diseases. Until recently, only one genetic variation had been reproducibly associated with exceptional longevity, but even this might vary with ethnicity and other, as yet unknown sources of stratification. Schachter and colleagues (1994) from the French Centenarian Study noted that the Apolipoprotein E  $\epsilon 4$  allele becomes markedly less frequent with advancing age. One of its counterparts, the  $\epsilon 2$  allele, becomes more frequent with advancing age in Caucasians (Rebeck *et al.*, 1994).

Nir Barzilai and colleagues (2003), studying Ashkenazi Jewish centenarians and their families, recently investigated a cardiovascular pathway and gene that is differentiated between centenarians and controls. In this study, controls were spouses of the children of centenarians. Barzilai and colleagues noted that high-density lipoprotein (HDL) and low-density lipoprotein (LDL) particles were significantly larger among the centenarians and their offspring, and that particle size also differentiated between subjects with and without cardiovascular disease, hypertension, and metabolic syndrome. In a candidate-gene approach, the researchers then searched the literature for genes that affect HDL and LDL particle

size, and hepatic lipase and cholesteryl ester transfer protein (CETP) emerged as candidates. Compared with a control group representative of the general population, centenarians were three times as likely to have a specific CETP gene variant (24.8% of centenarians had it vs. 8.6% of controls), and the centenarians' offspring were twice as likely to have it.

Discovering genes that could impart the ability to live to old age while compressing the period of disability toward the end of life should yield important insight into how the aging process increases susceptibility to diseases associated with aging, and into how this susceptibility might be modulated. Human longevity enabling genes are likely to influence aging at its most basic levels, thus affecting a broad spectrum of genetic and cellular pathways synchronously. The centenarian genome should also be an efficient tool for ferreting out disease genes. Comparing single nucleotide frequencies implicated in disease in centenarians with frequencies in persons with the disease should show clinically relevant polymorphisms. Another approach that researchers are in the early stages of understanding is differential gene expression in models suspected of slowing the aging process, such as caloric restriction. This might prove to be another potent tool for discovering longevity-enabling genes. The hope, of course, is that these gene discoveries will help in identification of drug targets and creation of drugs to allow persons to become more "centenarian-like" by maximizing the period of their lives spent in good health.

#### A Multifactorial Model for Exceptional Longevity

The fact that siblings maintain half the mortality risk of their birth cohort from age 20 to extreme age suggests a multifactorial model for achieving exceptional longevity. For example, socio-demographic advantages may play key roles at younger ages, whereas genetic advantages may distinguish the ability to go from old age to extreme old age. Undoubtedly exceptional longevity is much more complicated, with temporally overlapping roles for major genes, polygenic, environmental, and stochastic components. Such a scenario would be consistent with a *threshold model*, where predisposition for exceptional longevity can be measured on a quantitative scale. Figure 47.2 illustrates the standard threshold model proposed by Falconer (Falconer, 1965), where it is predicted that the proportion of affected relatives will be highest among the most severely affected individuals.

In the case of exceptional longevity, perhaps severity may be measured by additional years beyond a certain age (threshold) or in further years of delay in the case of exceptional survival phenotypes such as age of onset of disability or certain diseases.

Examples of phenotypes fitting the threshold model are early onset breast cancer or Alzheimer's disease (AD),

**Figure 47.2** Threshold model of a multifactorial trait.

where relatives of patients who develop these diseases at unusually young ages are themselves at increased risk or liability. Thus, a 108-year-old's "liability" or predisposition for exceptional longevity is further beyond the threshold than someone more mildly affected, for example, a person who died at age 99 years. One interpretation of data indicating the higher RSP of male siblings of centenarians compared to female siblings is that the males carry a higher liability for the trait given the presence of the requisite traits. The model predicts that if a multifactorial trait is more frequent in one sex (as is the case with exceptional longevity, which is predominantly represented by females), the liability will be higher for relatives of the less susceptible sex (males, in the case of exceptional longevity) (Farrer, 1998). Although we have not yet looked at RSP of siblings of male versus female probands (something that certainly needs to be done), these elevated risks for male versus female siblings are interesting in this context. The model also predicts that the risk for exceptional longevity will be sharply lower for second-degree relatives compared to first-degree relatives, another observation we hope to test by having access to many expanded pedigrees.

Important questions to pursue in light of this proposed model are:

Are siblings of males with exceptional longevity (EL) more likely to achieve EL themselves compared to siblings of females with EL?

Does this risk for EL in siblings and offspring increase with the age of the proband of either sex? What are the quantitative differences of such liability with or without accounting for the gender of the proband?

The ramifications of this model holding true for EL include:

The older the subject, the better for discovering traits predisposing for EL.

There are gender-related differences in both relatives and probands in liability for EL given the presence of specific traits conducive to EL.

## Conclusion

Genetic findings related to human longevity have primarily been related to vascular health. This is not surprising given that vascular disease is the number one killer among older people, including centenarians. We would expect that the oldest old would have to have some genetic advantages regarding a relative resistance to vascular disease in order to survive to their extreme ages. More elusive has been the search for genetic variations that impact upon the basic biology of aging that could impact upon the rate of aging and susceptibility to a broad range of age-related diseases. Discovering such so-called longevity-enabling genes might entail the study of the extreme of the extreme such as supercentenarians, those who live to 110 years old and older or those who achieve extreme old age despite habits that would otherwise be associated with high mortality and age-associated disease risk.

# Computational Models of Mitochondrial DNA in Aging

David C. Samuels

*In this chapter we present simulation methods for modeling the development of somatic mitochondrial DNA mutations over a human lifetime. The simulation method descriptions are intended for the advanced undergraduate, the graduate student, or the researcher planning to develop simulations in this field, and for the general biomedical reader. Different modeling methods that we have used are described, and their strengths and weaknesses are compared.*

## Introduction

In this chapter we will be using a different meaning of *model* than is used in the rest of this book. Here we discuss the use of *computational* models of mitochondrial DNA (mtDNA) applied to aging research. Computational models have unique advantages for investigating the aging process. With a simulation we can follow the changes over a full human lifetime in a single cell, or in a group of dividing cells. We can do this nondestructively, and we can do this down to the level of single DNA molecules or even to the level of individual genes on each DNA molecule. The computational model should be thought of as a way to determine the consequences of explicit assumptions and hypotheses. Given the long time scales involved in human aging, and the important role of random processes in mtDNA maintenance and mutation, these consequences are often nonintuitive. The primary use of our simulations has not been to calculate exact numerical values. Instead, we are more concerned with understanding the qualitative behavior of the system. Based on this increased understanding of the simulated system we can propose new hypotheses, which can then be tested in the lab, completing the circle between theory and experiment that is fundamental to the scientific method.

Our purpose in this chapter is to discuss the different simulation methods that we have used in our work on mtDNA dynamics (Chinnery and Samuels, 1999; Elson *et al.*, 2001; Chinnery *et al.*, 2002; Capps *et al.*, 2003). We will discuss two general methods of modeling: DNA-molecule level simulations and cell level simulations. Each method has its strengths and weaknesses,

and each is suitable for investigating different types of questions about the dynamics of mtDNA.

## Acquired mtDNA Mutations, Clonal Expansion, and Their Relationship with Aging

Dysfunctional mitochondria and mutated mtDNA are associated with the aging process in a wide range of species, from *C. elegans* to humans. A recent experiment showed that mice with a mutated mitochondrial polymerase had an increased rate of mtDNA mutation and suffered from accelerated aging (Trifunovic *et al.*, 2004). This was the first experiment to deliberately manipulate the rate of mutation of mtDNA in an organism and to show a direct effect on the rate of aging.

The general idea of the mitochondrial theory of aging is that mitochondrial dysfunction increases with time, causing a decreased rate of ATP production and the eventual loss of function of cells throughout the organism. Our work focuses on mitochondrial dysfunction due to mtDNA mutations. Mitochondrial DNA is not well protected against mutation and has few mutation repair mechanisms. Furthermore, mtDNA is located near the primary source of ROS in the cell, the electron transfer chain (ETC) in the mitochondrial inner membrane (for more on ROS production see Chapter 16). This combination of little mtDNA protection or repair in a high ROS environment causes a very high mutation rate in mtDNA, much higher than is found in the nuclear DNA.

For more on the relationship between mitochondrial DNA mutations and aging, refer to Chapter 41 and to several recent review papers (Alexeyev *et al.*, 2004; Barja 2004; Huang and Manton, 2004; Skulachev, 2004). However there is one feature of mtDNA that I must point out in preparation for the following discussion. Each mitochondrion contains several copies of mtDNA (roughly 5 to 10 copies). Therefore there are a large number of mtDNA molecules in just a single cell. This number depends on cell type and ranges from a few

**Figure 48.1** Two alternate mechanisms for the increase over time of the mutated mtDNA in the cell.

hundred in skin cells to 100,000 in oocytes. A typical number for our simulated cells is 1,000 to 10,000 mtDNA per cell. The purpose of our simulations is to model the dynamics of this population of mtDNA molecules within a cell. Generally we model the changes over time in the number of wild-type and mutant mtDNA molecules in a single simulated cell.

To design a simulation model of mtDNA mutation in aging we must first choose the hypotheses on which we will base the model. There are two basic hypotheses on this subject that you will find in the literature (see Figure 48.1).

By far the most commonly presented is the *error cascade hypothesis*. In this hypothesis, mutations of mtDNA cause a disruption of either the production or the function of one (or more) of the proteins that make up the ETC. This disruption slows the transfer of electrons through the ETC, increasing the risk that the electrons may be diverted to form ROS. The increased ROS production in the mitochondrion then raises the rate of mutation of mtDNA, resulting in a vicious cycle of increasing ROS production and increasing mtDNA mutation.

The error cascade hypothesis is reasonable, and there is little doubt that this process does actually occur in cells. However, there is doubt that this process plays a significant role in aging, at least in humans. The problem is that the error cascade process would result over time in the formation of a large number of *different* mutations in the mtDNA of a single cell. This is not what is observed in the cells of elderly humans. Instead, it is found in the elderly that cells with large numbers of mutated mtDNA generally contain many copies of a single mutation (Taylor *et al.*, 2001; Nekhaeva *et al.*, 2002), not the wide range of different mutations that would be expected from the error cascade mechanism. Different cells in the same tissue may contain different mtDNA mutations, so this effect is detectable only if measurements of mtDNA mutation are done at the single-cell level, not at the tissue sample level.

This observation that a single cell tends to have only one mtDNA mutation present in large numbers has led to the *clonal expansion hypothesis* (see Figure 48.1). In this hypothesis only a single mutation event is responsible for all of the identical mutated mtDNA found in the elderly cell. Over time this mutated mtDNA was copied

more often than the other mtDNA molecules, either through some replicative advantage or simply through chance (genetic drift). Other mtDNA mutation events may have occurred, but those mutated mtDNA molecules were eventually lost from the population within the cell, again either through a replicative disadvantage or by random genetic drift.

Our simulation work began as a computational test of the random genetic drift version of the clonal expansion hypothesis (Chinnery and Samuels, 1999). The question was whether purely random drift, with no replicative advantage or disadvantage, could lead to clonal expansions of mutant mtDNA in a reasonable population size of 1,000 mtDNA per cell, within a reasonable timescale of 50 to 80 years. Therefore our modeled mechanisms and methods are aimed at this question, not at the error cascade hypothesis. This means that no model of ROS production is used in these particular simulations, as ROS production is not central to the clonal expansion hypothesis, and that, in general, we do not consider any replicative advantages to the mutant mtDNA molecules. Now we will discuss the mechanisms that are included in our mtDNA simulations and the computational techniques that we have used to model these mechanisms.

## Modeling the Basic Processes: mtDNA Replication, Degradation, and Cell Division

The two fundamental mechanisms that must be included in all simulations of the population of mtDNA molecules within a cell are mtDNA replication and degradation. We begin with degradation, since this is the simplest process.

### mtDNA DEGRADATION

Given the high ROS environment of the interior of the mitochondrion, it is no surprise that the lifetime of mtDNA is relatively short. A typical measurement of the half-life of mtDNA in mammals is approximately 10 days, with some reported values as high as 30 days. It is possible that this measured degradation actually reflects the degradation of the entire organelle. As is generally the case in simulations involving molecular degradation, we model this as a random process. Given a half-life of  $T_{half}$ , the probability that a given mtDNA molecule will degrade within a time  $\Delta t$  is

$$P_d = 1 - \exp(-\ln(2)\Delta t/T_{half}). \quad (1)$$

With a population of  $N$  mtDNA molecules in a cell, the number of degradation events,  $n_d$ , that would occur within a time span of  $\Delta t$  is given by a cumulative Poisson distribution.

$$n_d = \text{Poisson}(N \times P_d). \quad (2)$$

The quantity  $N \times P_d$  is the mean number of degradation events expected, and the Poisson function returns a

number that has random fluctuations about this mean. When  $\Delta t \ll T_{half}$ , the mean number of degradation events  $\langle n_d \rangle$  is given by

$$\langle n_d \rangle = N \ln(2) \Delta t / T_{half}. \quad (3)$$

For details on the cumulative Poisson distribution and the binomial distribution used in the next section, I highly recommend the series of Numerical Recipes books (Press *et al.*, 1988), and refer you to the books for details on programming these functions. As a concrete example of the degradation rate, for a population of 10,000 mtDNA molecules with a half-life of 10 days, over a time  $\Delta t$  of one hour, the mean number of mtDNA molecules degraded would be 29. The actual number returned from the Poisson routine would fluctuate about that mean value.

### mtDNA REPLICATION

To balance the loss of mtDNA molecules by degradation, mtDNA must be continually copied. This replication is independent of the cell cycle, and occurs in all cells, including postmitotic cells. The total number of mtDNA molecules replicated,  $n_{copy}$ , in a time span  $\Delta t$  must be equal to the mean number lost to degradation plus any additional growth,  $n_{grow}$ , which would be needed in dividing cells.

$$n_{copy} = \langle n_d \rangle + n_{grow} = N(\ln(2)\Delta t/T_{half}) + n_{grow} \quad (4)$$

Little is known about the control of the mtDNA replication rate, so for the modeling we generally choose the simplest possible model, a constant replication rate. For examples of simulations with a variable mtDNA replication rate, see Chinnery and Samuels (1999) and Capps *et al.* (2003).

Equation 4 gives the total mtDNA replication rate. We are usually simulating conditions where the cell contains a mixture of wild-type and mutant mtDNA. The total number of replicated mtDNA molecules is split into two parts,

$$n_{copy} = W_{copy} + M_{copy} \quad (5)$$

where  $W_{copy}$  is the number of wild-type mtDNA copied in the time  $\Delta t$  and  $M_{copy}$  is the number of mutant mtDNA copied. If more than one type of mutant mtDNA is being modeled in the simulation, then the term  $M_{copy}$  can be further subdivided into these mutation subtypes. Based on the assumption that there is no replicative advantage to the mutants, we model the number of wild-type and mutant copied as a binomial process. Let  $W$  be the number of wild-type mtDNA and  $M$  be the number of mutant, with the total number of mtDNA  $N = W + M$ . Then we can write

$$\begin{aligned} W_{copy} &= \text{binomial}(n_{copy}, W/N) \\ M_{copy} &= n_{copy} - W_{copy} \end{aligned} \quad (6)$$

where the notation  $\text{binomial}(n_{copy}, W/N)$  means that a total of  $n_{copy}$  objects are being chosen from a population

where a fraction  $W/N$  of the objects are wild-type mtDNA. The *binomial* function (Press *et al.*, 1988) returns the random number of wild-type mtDNA chosen to copy, with  $W_{copy} \leq n_{copy}$ . Note that only one call to the routine *binomial* is needed to calculate both  $W_{copy}$  and  $M_{copy}$ . By using a binomial routine, the values  $W_{copy}$  and  $M_{copy}$  will have natural random variations that are an important driving force behind the random genetic drift in the system.

### CELL DIVISION

We model cell division by periodically dividing the mtDNA within the simulated cell into two subpopulations, representing the two daughter cells. Since the division will not be exactly even, we again use a Poisson model for the division of the mtDNA between the two daughter cells. We must determine separately the number of mutant and wild-type mtDNA that end up in each daughter cell. Let  $W_0$  represent the number of wild-type mtDNA in the parent cell and  $W_1$  and  $W_2$  the number in the two daughter cells, with  $W_0 = W_1 + W_2$ . Similar definitions are made for the mutant mtDNA. Then we have the following.

$$\begin{aligned} W_1 &= \text{Poisson}(W_0/2) \\ W_2 &= W_0 - W_1 \\ M_1 &= \text{Poisson}(M_0/2) \\ M_2 &= M_0 - M_1 \end{aligned} \quad (7)$$

### ACQUIRED mtDNA MUTATIONS

We have used two slightly different computational models to represent the somatic mutations that occur in mtDNA as part of the aging process. One method is to tie mutation to the replication process, to represent mutations that arise from replication errors. In this case, at every mtDNA replication event there is some probability  $P_{mut}$  that a new mtDNA mutation will be created. An alternative method is to model mutation formation independent of the mtDNA replication process. Then, over every time interval  $\Delta t$  there is a probability  $P_{mut}$  that a mtDNA molecule may be converted to a new mutation. Unless the replication rate is varying with time in the model, there is little significant difference between these two models for *de novo* mtDNA mutation formation. The parameter  $P_{mut}$  can also be made a function of time to represent changing mutation conditions, such as periods of increased radiation exposure, for example.

Models of acquired mtDNA mutations based on the mechanisms of mtDNA replication and degradation have a particular behavior that must be considered in the design of the simulation. Just after a new mutation forms, the population of mtDNA within the simulated cell will have only one copy of that mutation and about 1,000 other mtDNA molecules that are wild-type or different mutations. In simulated postmitotic cells

(where the cellular mtDNA population is not growing with time) there is a 50% chance that this particular mutant mtDNA molecule will be degraded before it is copied, thus removing the new mutation relatively quickly from the cell. Even if the mutated mtDNA does manage to be copied, then you have only two copies of the new mutant and it is still very likely that you will lose both of those copies to degradation. So you should expect that the majority of *de novo* mutations will survive in the simulated cell for only a short time (Elson *et al.*, 2001), and the data structures and memory management of your simulation design should be made with this point in mind to avoid wasting memory on the many mutations that transiently appear in the simulated cell.

### COMPLEMENTATION OF MUTATIONS

It can be useful to model the effect of mtDNA mutations at the level of individual genes, instead of just counting the number of mutated mtDNA molecules in the cell. To see why, consider a cell with 100% mutated mtDNA consisting of clonal expansions of two different mutations that have occurred on different genes. Call the mutants A and B. Mutant A may have a nonfunctional ND1 gene whereas mutant B has a nonfunctional tRNA-W gene. Even though all the mtDNA molecules in the cell are mutated in some way, all the mutant A mtDNA molecules contain functioning tRNA-W genes and all the mutant B molecules contain functioning ND1 genes, so the two mutant mtDNA molecules still complement each other and the cell function would be normal. To allow for this complementation of different mutant mtDNAs, we can assign to each mutation a profile indicating which genes, if any, are deleteriously affected by that mutation. We can do this with a logical vector with 37 elements (22 tRNAs, 13 protein genes, and 2 rRNAs). Table 48.1 gives an example of this for three specific mutations: the common

deletion, the A3243G point mutation, and any silent point mutation. The columns of the table are arranged in the gene order on the human mtDNA genome, for simplicity in representing deletions that affect multiple genes. In the examples shown in Table 48.1, the common deletion removes a wide swath of genes, the relatively common A3243G point mutation affects only the L1 tRNA gene, and a neutral mutation affects no gene products.

The specification of the gene products affected by the simulated mutant will allow you to be more specific in the modeling of COX cells. COX staining is a very common laboratory method of detecting mitochondrial dysfunction in tissue samples. However, the COX staining only directly detects the presence of complex IV of the respiratory chain. This complex will be directly affected by mutations in the genes CO I, CO II, CO III, and also by any tRNA or rRNA mutation (see Table 48.1). This includes the majority of all known pathogenic point mutations and deletions, but not all. Specifying the gene products affected by the mutation allows the possibility of pathogenic mutations that will not produce COX- cells. By including this detail in your simulation you allow a very valuable comparison between the simulation and clinical data.

### Choosing the Scale of Your Simulation Design

The design of every simulation begins with a choice of scale. What is the smallest level of detail that you will attempt to simulate, and what is the largest level of organization to be included? Biological questions often cover a wide range of scales, from the molecular to the organism level. This is also true of our mtDNA simulations. A list of the possible levels that can be included in these simulations is given in Table 48.2.

TABLE 48.1

Three examples for a data structure to represent mutations: a deletion (the common deletion), a point mutation (the 3243 mutation), and a neutral mutation. "1" indicates the gene product is not affected and "0" indicates that the gene product is defective or not produced. Single letter column headings denote the 22 tRNA genes

Mutation	F	12S	V	16S	L1	ND1	I	Q	M	ND2	W	A	N	C
Common Deletion	1	1	1	1	1	1	1	1	1	1	1	1	1	1
A3243G	1	1	1	1	0	1	1	1	1	1	1	1	1	1
Neutral	1	1	1	1	1	1	1	1	1	1	1	1	1	1
Mutation	Y	CO I	S	D	CO II	K	ATP8	ATP6	CO III	G	ND3			
Common Deletion	1	1	1	1	1	1	0	0	0	0	0			
A3243G	1	1	1	1	1	1	1	1	1	1	1			
Neutral	1	1	1	1	1	1	1	1	1	1	1			
Mutation	R	ND4L	ND4	H	S2	L2	ND5	ND6	E	CytB	T	P		
Common Deletion	0	0	0	0	0	0	0	1	1	1	1	1		
A3243G	1	1	1	1	1	1	1	1	1	1	1	1		
Neutral	1	1	1	1	1	1	1	1	1	1	1	1		

## 48. Computational Models of mtDNA in Aging

TABLE 48.2

The range of potential levels of complexity of simulations of mitochondrial DNA in aging

Levels of simulation
Base pairs
Mitochondrial genes
MtDNA molecules
Nucleoids
Mitochondrion
Cell level
Tissue or organ level
Organism level
Pedigree (maternal relatives)
Mitochondrial haplogroups

We have used almost all these levels in various simulations that we have created, but you can expect to cover no more than two or at most three levels of scale in any one simulation.

For aging simulations we have focused on the smaller scales given in Table 48.2, generally around the cellular level. However, this still leaves a wide range of scales to consider, too wide a range for a single simulation design to handle efficiently. We have dealt with this multiple-scale problem by developing two types of simulation. The *mtDNA Molecule Level simulation* can deal with the scales from the mtDNA molecule level to the cellular level. The *Cell Level simulation* deals with the scales from the cellular level only to the small tissue level. The practical upper limit (with the current computers) on the Cell Level simulation is a few tens of millions of simulated cells over a time span of 100 years. Each of these two simulations has its strengths and its limitations. In the following we describe the computational methods for each simulation model separately, and then we compare the computer requirements of each model.

### THE mtDNA MOLECULE LEVEL SIMULATION

The lowest level represented in these simulations is the individual mtDNA molecule. The basic data structure is a vector of integer values, with each element of the vector representing a particular mtDNA molecule in the simulated cell. Call this data structure  $DNA(1, \dots, N)$ . A typical simulation will have 1,000 to 10,000 mtDNA molecules (in one cell). The integer values of the vector are used to represent the mutation state of that mtDNA molecule. A value of “0” denotes a wild-type mtDNA molecule; higher integer values denote various mutations. The coding of the mutations depends on the particular application of the simulation, but for an aging simulation, typically “1” represents the first acquired mutation to appear and is carried by all the descendants of that

molecule, the value “2” denotes the second mutation to appear, and so on.

If you wish to define any characteristics of each acquired mutation, such as the list of genes affected as in Table 48.1, then this can be handled by a separate data structure. The important design point is that these *mutation characteristics* should not be recorded directly in your data structure  $DNA(1, \dots, N)$ , since we expect that many of the elements of this data structure will be clonal expansions of one or two separate mutation events, and that would waste memory space and slow the simulation. Instead the mutation characteristics should be stored in a separate array that can be indexed by the integer value stored in the vector  $DNA(1, \dots, N)$ , recording the identity of the original mutation event.

One mutation characteristic that we have found very useful to record is the time of the original mutation event. With this data we were able to look at the mutations found in the simulated cell at age 80 years and determine the distribution of ages when the original mutation event occurred. The surprising result was that the majority of the mutations found in the simulated 80-year-old cell were acquired before the age of 20 years (Elson *et al.*, 2001). The ability to “tag” individual DNA molecules with information such as the mutation date allows you to gather data that is simply impossible to acquire in a real experiment.

The modeling of mtDNA replication, degradation, and cell divisions in the mtDNA level simulations is fairly simple. The number of each event occurring in a time-step of length  $\Delta t$  is calculated from Eqs. 1 through 7. Typically we use a time step of one hour (so that 100 years requires less than 1 million time steps, a reasonable amount). For example, say that in one time step 23 mtDNA molecules are destroyed and 27 are copied. First, we would randomly choose 23 elements of the data structure  $DNA(1, \dots, N)$  to remove, modeling degradation. The data structure is then compressed from  $N$  elements to  $N-23$  elements, to remove the empty spaces. Then, 27 elements of the vector  $DNA(1, \dots, N)$  are chosen at random for replication. The new mtDNA molecules are added at the end of the vector, and their attributes such as the mutation value are copied from the parent mtDNA molecules. Any acquired mutations are calculated at this point, resulting in a change of the mutation state between the parent and offspring mtDNA molecules.

Note that there is no need to separate out the degradation or replication processes into mutant and wild-type mtDNA in this model. This occurs naturally through the random choice from the elements of the  $DNA(1, \dots, N)$  vector, which contains both the mutant and mtDNA molecules.

Since the mtDNA replication and degradation processes are fundamentally random, the results for any one simulated cell are also stochastic. Therefore simulating a single cell is not sufficient. One must simulate a

number of cells, and take statistics over the set of simulated cells. For the mtDNA Level simulations, the practical limit of the simulations is on the order of 1,000 simulated cells, over a time scale of one century for aging studies.

### THE CELL LEVEL SIMULATION

To model larger numbers of cells in a reasonable time requires a change in the level of the simulation. Details at the DNA molecule level must be sacrificed to allow the simulation to extend to higher levels of organization (see Table 48.2). For this we have designed simulations where the lowest level of detail represented is the level of a single cell (Capps *et al.*, 2003; Rajasimha *et al.*, 2004). In the most basic form of this model each simulated cell, is now represented by just two integer values.  $W$  is the number of wild-type mtDNA molecules in the cell, and  $M$  is the number of mutant mtDNA. Over a time step  $\Delta t$  the changes in the values  $W$  and  $M$  are given by the following integer difference equations.

$$\begin{aligned} W(t + \Delta t) &= W(t) - W_{\text{loss}}(t) + W_{\text{copy}}(t) \\ M(t + \Delta t) &= M(t) - M_{\text{loss}}(t) + M_{\text{copy}}(t) \end{aligned} \quad (8)$$

The number of wild-type and mutant mtDNA lost to degradation is calculated from the following equations.

$$\begin{aligned} W_{\text{loss}} &= \text{Poisson}(W \times P_d) \\ M_{\text{loss}} &= \text{Poisson}(M \times P_d) \end{aligned} \quad (9)$$

Acquired mutations are represented by decreasing  $W$  and increasing  $M$ . For example, if the probability of *de novo* mutation within a time step  $\Delta t$  is set at  $P_{\text{mut}}$ , then mutation terms are added to Eq. 8 to give the following.

$$\begin{aligned} N_{\text{mut}} &= \text{Poisson}(W(t) \times P_{\text{mut}}) \\ W(t + \Delta t) &= W(t) - W_{\text{loss}}(t) + W_{\text{copy}}(t) - N_{\text{mut}} \\ M(t + \Delta t) &= M(t) - M_{\text{loss}}(t) + M_{\text{copy}}(t) + N_{\text{mut}} \end{aligned} \quad (10)$$

This description of the Cell Level simulation lumps all mutant mtDNA together in a single category. To follow different mutations separately is more complicated in the Cell Level simulation than it was in the mtDNA Molecule Level model. To include more than one mutation type we must extend the basic data structure to  $W(t)$ ,  $M_1(t)$ ,  $M_2(t)$ ,  $\dots$ ,  $M_n(t)$ . Each variable  $M_i(t)$  represents the number of mtDNA molecules with a specific mutation. The simulation may be set up to represent a set of predefined mutations, or each new mutation event may define a new mutation type. In the latter case, since we expect most mutations to appear only transiently in the cell before being lost to random drift, it is best to remove any data structure  $M_i(t)$  that falls to zero and reuse that data structure for the next new mutation to occur. Otherwise you will end up with a large number of empty data structures. From our experimental and simulation work on human colon crypt cells we found

that some crypt cells contained three mtDNA mutations at detectable levels (Taylor *et al.*, 2003), and most crypt cells contained fewer than three different mutations. These experimental results indicate that only a few different mutation data structures would be needed to simulate the range of mtDNA mutations found in a single aging human cell.

### Comparison of the mtDNA Molecule Level Model and the Cell Level Model

When you are preparing to build a simulation model of mtDNA in aging, how do you choose the level of detail for the model? The ability to follow individual mtDNA molecules in the mtDNA Molecule Level model makes this approach flexible. It is easier to add new mechanisms to this model, and it is easier to make the characteristics of the mtDNA molecules variable, such as including a replicative advantage to a deletion mutation but not for a point mutation, for example. The price is that the mtDNA Molecule Level simulations require more computation resources than the Cell Level simulations. The mtDNA Molecule Level models are practically limited to simulating a few thousand cells over 100 years.

The Cell Level simulations can model up to a million cells over a time span of a century. This ability to model large numbers of cells is their main advantage. The disadvantage is that adding lower level detail, such as distinguishing between different mtDNA mutants, significantly increases the computational time required and is also difficult to implement. In my experience this type of model is less flexible than the mtDNA Molecule Level models. Also, the presentation of this type of model generally involves more mathematics, and that can be a barrier to communication with the intended biomedical audience.

The choice between the two levels of model often boils down to a practical consideration. Do you have enough computational power available to use the simple and flexible mtDNA Molecular Level model, or do you need the efficiency of the Cell Level simulations? As a guide in making this choice, we present some measurements of the computational time requirements of both models, as a function of the number of simulated cells and the average number of mtDNA molecules per cell. The simulation times were measured on a 2 GHz Pentium 4 CPU with 512 MB RAM running LINUX. Each simulation was run for 100 years, with approximately 1,000 mtDNA molecules in each cell (average value). For both simulation methods the computational time rises linearly with the number of simulated cells (see Figure 48.2).

However, the mtDNA Molecule Level simulation requires 54 seconds per cell per century, whereas the Cell Level model requires only 1.3 seconds per cell per century, a factor of 40 difference.

## 48. Computational Models of mtDNA in Aging

**Figure 48.2** Computational time required as a function of the number of compartments simulated for the two simulation methods. Each simulated cell containing approximately 1,000 mtDNA molecules. Simulations were run for 100 years, with a time step of one hour.

**Figure 48.3** Computational time as a function of the number of mtDNA molecules per cell. (A) mtDNA Molecule Level simulation. One cell was simulated for 100 years. The computational time requirements for this method are approximately 48 seconds per cell per century per 1,000 mtDNA molecules. (B) Cell Level simulation. One thousand cells were simulated for 100 years. In the plateau region for more than 10,000 mtDNA molecules per cell, the simulation requirements are approximately nine seconds per simulated cell per century.

In Figure 48.3 we show the dependence of the computation time on the number of mtDNA molecules per compartment.

The mtDNA Molecule Level simulation shows a linear increase in computational time with increasing numbers of mtDNA molecules per cell. This is expected since each mtDNA molecule is modeled separately in this simulation. For the Cell Level simulation (see Figure 48.3B) the behavior is more complicated. The change in behavior from a linear increase up to 10,000 mtDNA per compartment to a relatively constant computation time

for a higher number of mtDNA is due to a change in the numerical methods used to calculate the binomial and Poisson distributions (shifting from the direct method to the rejection method). This shift in methods is done automatically by the standard numerical methods described in detail in *Numerical Recipes in C* (Press *et al.*, 1988). The direct method is used when the number returned by the binomial or Poisson distribution subroutines is small, so the location of this switch in numerical methods depends on the time step used. The values in Figure 48.3 are for a time step of one hour. By coincidence, with this time step the computation time flattens out at about 10,000 mtDNA molecules per cell, so the computational requirements of this simulation method are insensitive to the number of mtDNA molecules per cell over an important physiological range (10,000 to 100,000 mtDNA molecules per cell).

Generally, the simulated cells do not interact with each other, and we are interested only in the statistics taken over a large number of independent cells. In this case I recommend that simulations of multiple cells be run sequentially, with each simulated cell run one at a time. Data may be saved at set time points along the simulation, and then statistics over the set of cells can be calculated at these time points after all simulated cells are run. By running the cells sequentially, instead of all at once, the RAM memory requirements of both simulation methods are negligible. However, in simulations where the cells interact in some way, the full set of simulated cells must be calculated simultaneously. For example, we have had to do this in simulations of cell cultures where the cell division rate depends on the number of cells in the simulated culture. In these cases, the Cell Level simulation is the only practical choice since less data must be stored per simulated cell in that method compared to the mtDNA Molecule Level models. On a PC with 512 MB RAM the memory requirements of the Cell Level simulation are not a limitation until the number of simulated cells reaches 8 million.

### ADVICE ON THE CHOICE OF SIMULATION METHOD

If you need to simulate either a large number of cells, or cells with more than about 10,000 mtDNA molecules, then the most practical choice is the Cell Level simulation. However, for simplicity and flexibility the mtDNA Molecule Level simulations are the best choice, but you will be limited to simulations of approximately 1,000 cells in order to complete a simulation of 100 years duration in a single day.

### Modeling mtDNA Mutations and Aging in Different Species

How do these computational models account for the radically different aging rates that occur in different

species? Our simulations show that the time required for the clonal expansions of mtDNA mutations by random drift is proportional to the number of mtDNA molecules per cell,  $N$ , and the mtDNA half-life,  $T_{half}$  (Chinnery and Samuels, 1999). However, neither of these parameters is believed to vary significantly across mammalian species. The simulations indicate that there is no biologically reasonable way to speed up the process of clonal expansion of mtDNA mutations in short-lived species. The long time scale necessary for clonal expansion by random drift leads us to reconsider the two hypotheses illustrated in Figure 48.1. Although the clonal expansion hypothesis may be the best explanation for the increase in mtDNA mutations with age in the long-lived species, such as humans, for the short-lived species we have to return to the error-cascade hypothesis.

The relative importance of the clonal expansion and error cascade mechanisms in the mtDNA aging simulations is controlled by the parameter  $P_{mut}$ , the probability of *de novo* mutation formation in mtDNA. At low mtDNA mutation rates clonal expansions dominate (Taylor *et al.*, 2003), whereas at high mutation rates the error cascade mechanism of enhanced ROS production should be included in the simulations. There is good reason to believe that the mtDNA mutation rate is higher in short-lived species than it is in humans. This has been repeatedly observed in experiments on aging in rodents (Wang *et al.*, 1997; Herrero and Barja, 1999). Finally, our own analysis of the mtDNA sequences of mammals indicates that the mitochondrial genomes of the short-lived species are physically more susceptible to mutations than are those in the long-lived species (Samuels, 2004, 2005).

## Conclusion

There are only a few other research groups that have recently worked on simulations of mtDNA dynamics and the aging process. The simulation research program of Tom Kirkwood (Kowald and Kirkwood, 1993; Kowald and Kirkwood, 2000; Sozou and Kirkwood, 2001; Kirkwood and Proctor, 2003) is based on a different general hypothesis than that of our modeling efforts. Their work uses the *delayed degradation* hypothesis, which assumes that mitochondria carrying a large fraction of mutated mtDNA suffer less damage and are thus degraded more slowly than the mitochondria with a larger proportion of wild-type mtDNA. This gives the mutant mtDNA a competitive advantage over the wild-type mtDNA. Another research group that is active in this area of simulation is headed by Konstantin Khrapko (Nekhaeva *et al.*, 2002; Kraytsberg, *et al.*, 2003). The simulations of this group follow the same general hypotheses as we do in our modeling.

For an idea of the future challenges to be dealt with in mtDNA simulations, take another look at Table 48.2. The simulation methods described in this chapter cover only

a small range of the scales important to the role of mtDNA in the aging process. In particular, building on simulations of aging at the cellular level to develop an understanding of the aging process at the organism level is a grand challenge.

There are significant challenges to be faced even within the scale range covered by these simulations, between the mtDNA molecule level and the cell level. The complicated spatial organization of mtDNA in separate organelles, and even further into nucleoids (small groupings of 1–5 mtDNA molecules), is a challenge to simulation. The simulations described here do not deal with these intermediate levels of organization, though those of Kirkwood do include the organelle level.

## Recommended Resources

Although there are many off-the-shelf simulation packages for biochemical models, there are few such packages available for the types of simulations described in this chapter. For this reason, the research in this area is still primarily done by writing original programs in either C or Fortran. Until a very flexible and general simulation package is available, I recommend that you write your own programs for this research. However, this does not mean writing every line of simulation code from scratch. Here are two excellent sources of code for basic simulation methods, such as the Poisson and Binomial routines used repeatedly in this chapter.

For advice on programming methods for simulation I recommend the very popular series of *Numerical Recipes* books (Press *et al.*, 1988), now available in Fortran, C, C++, and Fortran 90. These books take a very practical approach to numerical methods, not a theoretical one, describing routines that are both effective and relatively simple. The books contain example codes for each numerical method discussed. These codes can be used directly in your simulation for convenience, though often an expert programmer can improve on their efficiency.

For an alternative to the *Numerical Recipes* books, I recommend the GNU Scientific Library (or GSL), available for free download at [www.gnu.org/software/gsl](http://www.gnu.org/software/gsl). This software library contains over 1000 routines, in C and C++, which can be used as basic building blocks for developing simulation code. The most effective approach may be to read the *Numerical Recipes* books for an understanding of the methods, and use the GSL code in your programs.

Finally, for cross-species comparisons of mitochondrial genomes, the National Center for Biotechnology Information (NCBI), a part of the National Institutes of Health, is the standard repository for all sequenced mitochondrial genomes. These genomes are available at [www.ncbi.nlm.nih.gov/genomes/ORGANELLES/organelles.html](http://www.ncbi.nlm.nih.gov/genomes/ORGANELLES/organelles.html), in a convenient taxonomic organization. As of this writing (mid-2005), this database contained

complete mitochondrial genomes from 713 different species, including 639 metazoa species.

# Mouse Models of Accelerated Aging

Jan Vijg and Paul Hasty

*Mouse mutants displaying aging phenotypes much earlier in time than normal control animals offer the opportunity to develop and test interventions to reduce aging-related morbidity and mortality in humans. However, the few natural mouse mutants identified in the past as accelerated aging models have been criticized as less suitable for studying mechanisms of normal aging because neither the nature of the mutational defect nor the genetic background was accurately defined. A more general critique involved the perceived large variety of ways to reduce life span by causing pathologies similar to those normally occurring at late age. To address this problem one would ideally specifically design mouse models on the basis of known causes of aging. The validity of such models should then be demonstrated by showing that the genetic intervention accelerates a host of symptoms of normal aging rather than one or few.*

*Accumulation of DNA damage with age has been implicated as a major cause of aging, an hypothesis strongly supported by the discovery that most human segmental progeroid syndromes are caused by heritable mutations in genes involved in DNA repair and genome maintenance. There are now a number of mouse models, harboring engineered defects in various aspects of genome maintenance, which prematurely display a range of aging phenotypes. This strengthens the hypothesis that aging is driven by spontaneous DNA damage causing genomic instability and cellular stress responses, such as apoptosis and cellular senescence, eventually resulting in systems dysfunction at all levels. In this chapter we will review the recent developments in this field and discuss the validity of the aging phenotypes observed in the mouse models, with a focus on the possible implications with respect to DNA damage as a proximate cause of aging common to all mammals.*

## Introduction

Aging is poorly defined at the mechanistic level, even though in recent years much progress has been made by

studying genetic mutations altering life span and the onset of age-related characteristics (Vijg and Suh, 2005). Subjects of these analyses include yeast (*Saccharomyces cerevisiae*), nematodes (*Caenorhabditis elegans*), fruit flies (*Drosophila melanogaster*), and mice (*Mus musculus*). Intriguingly, in all these species, mutations downregulating activities of growth, reproduction, or nutrient sensing significantly increase longevity, possibly by interfering in the generation of somatic damage or through the upregulation of mechanisms that protect against such damage.

Although the mechanisms underlying age-related degeneration and death in these and other species still need to be uncovered, a consensus as to why and how we age has begun to emerge. It is now generally accepted that the time-dependent decrease in fitness in most multicellular organisms is nonadaptive; that is, it is not controlled by a purposeful genetic program similar to the control of development. Aging provides no specific advantage to the individual and most researchers now accept that age-related degeneration and death is ultimately due to the greater relative weight placed by natural selection on early survival or reproduction than on maintaining vigor at later ages. This decline in the force of natural selection is largely due to the scarcity of older individuals in natural populations owing to mortality caused by extrinsic hazards (Kirkwood, 2005). Because resources are limited, this strategy would not allow a maximization of somatic maintenance and repair, which is not required for periods of time that greatly exceed the time needed to reproduce. Under conditions of lower extrinsic mortality, permitting reproduction at later ages, the allocation of resources would shift toward somatic maintenance, thereby increasing life span. However, maintenance of the soma is never maximized since, according to the nineteenth-century biologist August Weismann, the soma merely provides the housing for the germline, seeing to it that the germ cells are protected, nourished, and conveyed to the germ cells of the opposite sex to create the next generation (Kirkwood and Cremer, 1982). With the soma being dispensable, the trade-off between growth and reproduction on the one hand and

somatic maintenance on the other, is biased toward reproduction.

This “disposable soma theory” not only provides a rationale for why we age, but also predicts the nature of its proximate cause; that is, the accumulation of unrepaired somatic damage (Kirkwood, 2005). This explanation, which is now supported by a large body of evidence, also explains the similarities in symptoms of aging, both within and across species, and the apparent universality of genetic pathways of life extension across different phyla. Indeed, rather than being programmed to age, animals are programmed to survive long enough to reproduce, possibly by using highly conserved cellular defense systems against somatic damage common to all or most species. Such damage may come from the environment e.g., radiation, infectious agents but also from inside the organism e.g., reactive oxygen species (ROS), normal by-products of metabolism.

### Mouse Models of Aging

Although it is now clear that life span is highly plastic and can be manipulated by metabolic switches that can affect the levels of spontaneous somatic damage or the proportional effort that is devoted to somatic maintenance, we still have only limited insight into the mechanisms of aging in different animal species. To elucidate human aging, mice are a good model system for several reasons. First, mice are positioned close to humans on the evolutionary scale. Second, their relatively short life span and small size permit extensive life span studies on an economic basis. Third, mouse genetics has closely emulated the progress in human genetics and is now almost equally powerful. Fourth, although in mice a full phenotypic characterization of aging is still far from the systematic catalogue of signs and symptoms of old age presently available for humans, the species ranks a solid second with rapid improvements underway.

Indeed, in the wake of the current explosion in genetically engineered mouse models, major coordinated efforts have emerged to obtain standardized and comprehensive databases for morphologic, biochemical, physiologic, or behavioral characteristics of various mouse strains (e.g., the mouse phenome project; <http://www.jax.org/phenome>). More recently, patterns of age-related pathology of the mouse have been made computationally accessible using ontologies—controlled vocabularies of terms—in the context of a federated database (e.g., [www.niehs.nih.gov/cm/gcc/dbmouse.htm](http://www.niehs.nih.gov/cm/gcc/dbmouse.htm)). Such progress greatly facilitates the development and use of mouse models of accelerated aging.

Mouse models of accelerated aging have been criticized in the past based on the argument that many of the degenerative phenotypes associated with aging could result from a variety of interventions and need not

necessarily involve the same causes that underlie natural aging. Although this is a valid argument, it should be realized that the use of model systems to study natural phenomena is a generally accepted approach in biology. For example, human cancer has been studied extensively using laboratory rodents subjected to treatment with a variety of genotoxic agents. Although we were all well aware of the fact that natural human cancers normally were not caused by such treatments, this approach nevertheless allowed us to obtain valuable information about the etiology of this disease. Of note, such rodent models for studying human cancer were based on the rationale that cancer is caused by DNA damage—hence, the use of DNA damaging agents to generate these model systems. By the same token, the most recent series of mouse models for human cancer is based on highly specific genetic alterations, known to increase human susceptibility to cancer. Hence, a logical approach in generating animal models for human aging is to develop specific interventions based on our increased knowledge of what causes human aging.

What can we say about the proximate causes of aging? The disposable soma theory predicts that aging is caused by the accumulation of unrepaired somatic damage (Kirkwood, 2005). There are strong arguments that DNA damage is the most important type of age-accumulated damage and a likely cause of many aging-related phenotypes. Among biological macromolecules, the DNA of the genome is unique in view of its role in transferring genetic information from cell to cell and from generation to generation. A strong, logical argument to consider the DNA of the genome as the Achilles heel of an aging organism is the lack of a back-up template. This is in contrast to proteins, which at least in principle, can be easily replaced with the corresponding gene as template. Indeed, the maintenance of genomic DNA is of crucial importance to survival because its alteration by mutation is essentially irreversible and has the potential to affect all downstream processes. A logical approach for making mouse models for human aging, therefore, would be to inactivate genes involved in DNA repair and genome maintenance. Interestingly, nature itself has preceded us, in this respect, by creating natural human mutants displaying premature aging as a consequence of defects in DNA repair and genome maintenance. This is by itself a powerful argument that changes in DNA drive the aging process. Indeed, genetic defects in few, if any, other systems than DNA repair and genome maintenance have been associated with premature aging (Martin, 2005). The rationale for generating mouse models of human aging on the basis of genetic alterations in genome maintenance pathways is therefore strong but not without problems.

Next we will first discuss the validity of premature aging symptoms in such mouse models and then discuss a number of them in more detail.

### Validity of Accelerated Aging Phenotypes

Aging differs from all human diseases by its complexity. It is the most complex phenotype currently known and the only example of generalized biological dysfunction. Its effects become manifest in all organs and tissues, it influences an organism's entire physiology, impacts function at all levels and increases susceptibility to all major chronic diseases. Nevertheless, typical symptoms of aging, often similar across species, can and have been defined.

For human aging, valuable information has been gleaned from a century of clinical observations. It was on this basis that, as mentioned earlier, a series of life-shortening genetic alterations in humans were described over a century ago that appeared to accelerate multiple signs of normal aging (Martin, 2005). These so-called segmental progeroid syndromes, already briefly discussed, were described by the medical community well before the discovery of DNA, and are therefore not biased toward a DNA-based hypothesis of aging. So it is remarkable that so many of these syndromes are defective in genome maintenance. The most striking of the human progeroid syndromes are Werner Syndrome (WS) (Epstein *et al.*, 1965) and Hutchinson-Gilford Progeria Syndrome (HGPS) (Pollex and Hegele, 2004). WS is caused by a defect in a gene that is a member of the RecQ helicase family (Yu *et al.*, 1996). The affected gene, WRN, encodes a RecQ homologue whose precise biological function remains elusive, but is important for DNA transactions, probably including recombination, replication, and repair.

HGPS is caused by a defect in the gene LMNA, which through alternative splicing encodes both nuclear lamins A and C (Eriksson *et al.*, 2003). Nuclear lamins play a role in maintaining chromatin organization. Less striking segmental progeroid syndromes include ataxia telangiectasia, caused by a heritable mutation of the gene ATM (ataxia telangiectasia mutated), a relay system conveying DNA damage signals to effectors (Shiloh, 2003), Cockayne syndrome and trichothiodystrophy, diseases based on defects in DNA repair and transcription (Lehmann, 2003), and Rothmund Thomson syndrome, like Werner syndrome, based on a heritable mutation in a RecQ gene (Lindor *et al.*, 2000). There is evidence that each of these genes when defective can also lead to aging symptoms in the mouse, sometimes in combination with other gene defects (see later, and Hasty *et al.*, 2003).

Although in both humans and mice cancer incidence increases exponentially with age, the tumor spectrum in the two species differs significantly, with sarcomas and lymphomas predominant in the mouse and epithelial cancers in older humans (DePinho, 2000). Likewise, the spectrum of normal age changes (other than cancer) in mice and humans is not exactly the same, which

always needs to be kept in mind when using these models (Hasty and Vijg, 2004). Moreover, although cancer as a phenotype is generally undisputed, aging has diffuse characteristics, and includes cancer and a variety of degenerative phenotypes (see [www.niehs.nih.gov/cmccc/dbmouse.htm](http://www.niehs.nih.gov/cmccc/dbmouse.htm)). Progeroid genotypes are associated with an early onset of some, but not all, characteristics of senescence and must therefore be interpreted with caution.

Loose criteria that help identify genuine mouse mutants of accelerated aging are (1) the phenotype should present after development and maturation are complete; (2) the phenotype should be demonstrable in control populations at a more or less similar point in their survival curve; and (3) the genetic alteration should accelerate multiple aging phenotypes (Hasty and Vijg, 2004). None of these criteria is written in stone. Indeed, accelerated aging can occur even before development is complete, as in the case of HGPS. Such cases, however, are more difficult to recognize as authentic models of aging and may not be as valid as those that exhibit aging phenotypes after maturation. It is also easily imaginable that a genetic alteration accelerates certain symptoms of aging much more than expected on the basis of the survival curve. Such so-called exaggerated aging would be expected if, rather than a quantitative, chronological master switch, the mutation would affect only one critical pathway for somatic maintenance leading to severe imbalance of the survival network.

Interestingly, the single-gene mutations that increase life span in worms, flies and mice may do so through the upregulation of cellular defense systems, including DNA repair and antioxidant defense. Candidate genes implicated in the control of such a survival response are FOXO and SIRT1, which have been demonstrated in nematodes and fruit flies to control downstream targets of the pro-longevity mutations affecting nutrient sensing, reproduction, and growth (Vijg and Suh, 2005). Downregulation of these effector genes could then conceivably lead to an acceleration of all possible aging phenotypes. FOXO3a and SIRT1 knockout mice do not display apparent signs of accelerated aging, although it is possible that a progeroid phenotype will become visible after a more quantitative downregulation of these genes (Cheng *et al.*, 2003; Hosaka *et al.*, 2004).

It should be noted that the mutations that lead to increased longevity in nematodes, flies or mice are likely to do so only at the cost of some selective disadvantage, often not obvious under laboratory conditions (Jenkins *et al.*, 2004). For some of the mouse longevity mutants, such as the growth hormone deficient Ames dwarf mice, fitness costs are readily apparent in the form of infertility and hypothyroidism (Bartke and Brown-Borg, 2004). However, for another longevity mutant in the mouse, p66<sup>SHC</sup>, there is no obvious selective disadvantage

(Migliaccio *et al.*, 1999). At this time the only known consequence of deleting p66SHC is increased life span; thus, we presume the laboratory environment masks any disadvantage. For example, it is possible that p66SHC functions to increase cellular ROS to initiate cellular destruction as a part of our defense system against infectious agents. This potential disadvantage would be masked in the p66SHC-mutant mice since they are housed in a pathogen-free environment. We currently lack the detailed phenotypic comparisons to confirm that longevity-conferring mutations do so by retarding all possible symptoms of aging equally. Hence, though it is clear that mutations in single genes can activate survival pathways conferring increased longevity, the concept of master regulator genes to control the rate of aging is doubtful.

### Defects in Genome Maintenance: Observations for Aging and Cancer

Embryonic stem cells and gene targeting technologies have been instrumental in confirming during the last decade the general prediction that genome maintenance systems are critical for suppressing tumor formation (Hoeijmakers, 2001). The data show that mutation of a single gene can increase genomic instability, leading to cancer. Of note, the cancer spectrum in such mutants, as in human cancer hereditary syndromes, is segmental even though these DNA repair pathways function in many cell types that are not predisposed to cancer. Importantly, while focused on cancer, several investigators have found that mutating some genome maintenance genes causes progeroid syndromes. Currently there are a number of mouse lines harboring specific genetic alterations that present with a shortened life span and precocious aging phenotypes (for an exhaustive listing, see Lombard *et al.* (2005)). In each of these mouse models some aspect of genome maintenance is affected. Next, we will briefly discuss the most prominent models with some details of the aging-related phenotypes they affect and their possible link to one or more causal factors. It should be noted that none of these models has been subjected to standardized, objective phenotyping, only some of them were compared side-by-side with littermate controls, and the genetic background may be different from model to model, making comparisons difficult.

#### THE p53 ANTI-TUMOR RESPONSE AS A CAUSE OF AGING

Defects in cell cycle control have been demonstrated to cause premature aging in mice, most notably mutations in the p53 gene. The p53 tumor suppressor is a transcription factor that controls a network of genes that regulates responses to DNA damage (Vogelstein *et al.*, 2000). The p53 protein inhibits cell cycle progression, facilitates DNA repair, and activates both cellular senescence and

apoptosis pathways (Campisi, 2005). Two mutant alleles of p53 have been described, which, in combination with a wild-type allele, result in multiple symptoms of aging and a shortened life span. The p44 allele, a naturally occurring, splice variant first described in 1987, lacks the first transactivation domain (Maier *et al.*, 2004). The other mutant allele, termed M, is a deletion of the 5' region of the p53 gene, lacking both transactivation domains (Tyner *et al.*, 2002). Both mutants display prominent signs of premature aging, but the two animal models differ, mainly in the severity of the symptoms. The first symptoms of aging in the M mutant become apparent only at 18 months, whereas the p44 animals already show aging-related mortality as early as five months. Severity is probably correlated with the expression level of the mutant allele, which is very low in the case of the M allele. In the p44 model it has been demonstrated that with increasing p44 expression symptoms become much more severe.

Both models display early osteoporosis and kyphosis, major forms of aging-related pathology in both mice and humans. The p44 mice show early fertility loss, to some extent caused by a breakdown of the reproductive axis (H. Scrable, personal communication). This loss of the hypothalamic pituitary gonadal axis is very similar to the situation in natural human and mouse aging (Wise *et al.*, 1997). This loss of fertility is not observed in the M mutant, but again, the symptoms in that model are generally much less severe. Both mouse models suffer from a typical aging-related redistribution of fat resulting in loss of subcutaneous fat. Other typical aging-related phenotypes in these mice are skin problems and various forms of atrophy.

Surprisingly, in both mutants cancer incidence was lower than in the controls. Of note, mice expressing additional copies of wild-type p53 under the control of its own promoter do not show signs of premature aging, but do show lower cancer incidence (Garcia-Cao *et al.*, 2002). In this case, the normal p53 gene dosage is minimally increased (i.e., by one additional copy), resulting in an increased response to DNA damage without affecting basal levels of p53. By contrast, in the two accelerated aging mutants, p53 may be constitutively activated through an interaction of a truncated p53 with a full-length polypeptide. This apparently results in postnatal growth impairment of the animals, possibly caused by a reduced cell proliferation rate as observed in cultured fibroblasts from these animals (Maier *et al.*, 2004). It is also supported by the observation of a two-fold increase of senescent cells in tissue sections of liver and spleen in the p53+/M mice, as compared to control animals (Dumble *et al.*, 2004), a modest rise in comparison to the increase in the number of senescent cells in both mutant and control animals during aging, which was more than ten-fold in these tissues. (Cellular senescence is the irreversible cessation of cell division, which can be observed with all normal mammalian cells in culture.

## 49. Mouse Models of Accelerated Aging

Senescent cells can be identified by staining for  $\beta$ -galactosidase at pH6.0.)

Of note, increased rates of apoptosis (programmed cell death) in these two mutant mouse models have not been observed (H. Scrable and L. Donehower, personal communication). Indeed, the hyperactive p53 protein most likely causes its effects through increased cell cycle arrest, leading to a general inhibition of cell proliferation. This may explain many of the premature aging phenotypes. For example, impairment of osteoblast proliferation, a likely natural cause of osteoporosis in the elderly, may cause the increased, premature osteoporosis in these mutant mice.

Overall, therefore, abnormally enhanced p53 activity appears to promote many aging-related phenotypes through the inhibition of normal regenerative processes that are essential for adult animals to survive and maintain organ function. As the guardian of the genome, p53 is supposed to inhibit cell growth and proliferation, but only in response to DNA damage, when extra time is needed for repair. Though cancer is also a major aging-related phenotype, enhanced p53 activity would be expected to greatly suppress tumor formation due to its inhibition of normal cell proliferative activities. It is conceivable that in normal mice p53 responses naturally increase with age due to the aforementioned increased load of DNA damage. This would then result in very similar phenotypes as in the p53 mutants, but later in life, as part of the normal aging process.

### THE IMPORTANCE OF DNA DOUBLE-STRAND BREAK REPAIR

Double-strand breaks (DSBs) in DNA are highly toxic lesions that can be created through a variety of mechanisms, including effects of reactive oxygen species. Double-strand breaks are repaired by either of two mechanistically distinct DNA repair pathways, homologous recombination (HR) or nonhomologous end-joining (NHEJ) (van Gent *et al.*, 2001). A key factor

of DSB repair by NHEJ is the DNA-end-binding Ku70/Ku80 heterodimer. Mice harboring a null mutation in the Ku80 gene have a significantly shorter life span and display a range of premature aging phenotypes (Vogel *et al.*, 1999). For this mouse model the age-related phenotypes have been compared to those of their littermate controls in a side-by-side study in an identical environment (same air, same food, same bedding, same cage). Figure 49.1 shows the survival curve of the Ku80 mutant mice, indicating a significantly shorter life span than their littermate controls.

One of the most prominent aging-related phenotypes occurring early in the mutants is lordokyphosis, the lateral curvature of the spine that is also present in the p53 mutants (see Figure 49.2). Lordokyphosis in these mice is likely due to osteoporosis because histology showed the older Ku80-mutant and control bones to exhibit osteopenia (thinning of the bone and reduced trabeculae). Figure 49.3 shows growth plate closure, a well-known age-related phenotype that is a part of maturation, not senescence, in humans. Mice are different

**Figure 49.1** Life span and mortality of Ku80-mutant and control mice (Vogel *et al.*, 1999). The survival curve begins after weaning (three weeks), because ku80<sup>-/-</sup> pups are less able to compete than their bigger littermate controls for mother's milk, and often die within the first two weeks (Nussenzweig *et al.*, 1996). Symbols are shown at the points of 100%, 50%, and 0% survival. Number of mice observed: 47 control mice represented by a filled box and 89 ku80<sup>-/-</sup> mice represented by an open circle.

**Figure 49.2** Lordokyphosis in control (+/+ and +/-) and ku80<sup>-/-</sup> (-/-) mice (Vogel *et al.*, 1999). **A.** Mice at 2.5 wk. No kyphosis. **B.** Mice at 31 wk. Kyphosis in only ku80<sup>-/-</sup> mouse. **C.** Mice at 75–79 wk. Kyphosis in only ku80<sup>-/-</sup> mouse. **D.** Control mice at 120 weeks (ku80<sup>-/-</sup> mice do not live this long). Kyphosis observed.

**Figure 49.3** Growth plate closure (Vogel *et al.*, 1999). Growth plates look the same for both cohorts between 1 and 15 weeks. However, by 20–45 weeks, compared to controls, the number of chondrocytes is reduced, and the columnar organization of chondrocytes is lost for the *ku80*<sup>-/-</sup> epiphysis. This same phenotype is observed for control mice by 70 weeks. Section of epiphysis from control (**A**, **C**, **E**) and *ku80*<sup>-/-</sup> (**B**, **D**) mice. (**A**, **B**), 1–15 weeks (shown are one-week old growth plates). (**C**, **D**) 20–45 weeks (shown are 22-week-old growth plates). (**E**) Greater than 70 weeks of age. Only the control is shown because very few *Ku80*-mutant mice survive to this age.

from humans in that growth plates do not close until well after maturation. Here, growth plates close much earlier in Ku80-mutant mice than in control mice. Figure 49.4 illustrates skin atrophy, a well-described age-related phenotype in both mice and humans. Again, skin atrophy was observed earlier in Ku80-mutant mice than in their littermate controls. In addition, various other aging-related phenotypes were observed in Ku80-mutant mice, well before they appeared in their littermate controls (forms of liver degeneration, reactive immune responses). Even though these phenotypes occur earlier in Ku80-mutant mice than in the controls, they all occur at about the same point in their biological life spans (the latter half of their survival curve). Despite these similarities, there are differences; most obvious is the difference in cancer incidence (cancer incidence is much lower in Ku80-mutant mice than in their littermate controls).

The most straightforward explanation for the accelerated aging phenotypes in Ku80 null mice is increased genomic instability resulting from erroneous or inefficient repair of DNA double-strand breaks in the absence of NHEJ. Such increased genomic instability would trigger apoptosis and interfere with normal cell growth and tissue regeneration. Whereas increased genomic instability normally would be expected to promote tumor formation, the increased rate of apoptosis in the presence of an intact p53 checkpoint is likely to restrain tumor development. This scenario is supported by actual observations. Ku80 mutant mouse cells display growth impairment, increased susceptibility to apoptosis, and a marked increase in chromosomal aberrations, including breaks, translocations, and aneuploidy (Difilippantonio *et al.*, 2000). Results from our laboratories indicate increased genomic instability at a lacZ reporter locus in liver, and, especially, in spleen, already at five months of age. In liver of 10-month-old mice, increased numbers of TUNEL or caspase 3 positive cells were observed, indicating a higher rate of spontaneous apoptosis (Y. Suh and P. Hasty, unpublished results).

Hence, though the inability of the Ku80 mutant mouse to repair DNA damage leads to excessive genome rearrangements, the resulting increase in cell death or dysfunction becomes manifest as impaired proliferation and regeneration, resulting in diminished cancer and accelerated age-related organ and tissue degeneration. This situation may be very similar for two other mouse models with defects in double-strand break repair: mice with defects in DNA-PK<sub>CS</sub>, the catalytic subunit of the Ku70/Ku80 complex, and mice harboring a hypomorphic mutation in the BRCA1 gene, a major player in HR. In DNA-PK<sub>CS</sub> null mice the situation resembles the Ku80 null model: the absence of intact NHEJ promotes genomic instability leading to impaired tissue growth and regeneration (Espejel *et al.*, 2004). Complete loss of BRCA1 is embryonically lethal, and the same is true for the homozygous BRCA1 hypomorph, lacking exon 11. However, the homozygous hypomorph can be

rescued completely in a p53 heterozygous background. In a p53-homozygous mutant background, these mice exhibit a high incidence of cancer. In the p53 heterozygous background, BRCA1 hypomorphic mice exhibit a long list of premature aging phenotypes and a significant reduction of life span, probably caused by the activity of the remaining p53 allele, which is triggered by genomic instability to prevent normal cell proliferation (Cao *et al.*, 2003).

Thus far, there is no evidence that inactivation of Ku80's partner in NHEJ (i.e. Ku70) is causing accelerated aging (Gu *et al.*, 1997). However, Ku70 null mice have never been studied as an aging cohort over longer periods of time in parallel with their littermate controls. Such studies are now underway and should soon reveal if there really is a difference between the Ku80 and Ku70 mutants. It is possible that each of these two key players in DSB repair has other, tissue-specific functions that confound their role in suppressing aging.

#### AGING, DNA REPAIR, AND TRANSCRIPTION

Another type of DNA repair defect associated with premature aging involves transcription-related nucleotide excision repair (NER). NER removes a broad range of helix-distorting lesions, from UV-induced DNA damage and numerous chemical adducts to oxidative damage produced by endogenous metabolism (Hoeijmakers, 2001). Within NER two subpathways are recognized, differing in damage recognition but sharing the same repair machinery: global genome NER (GG-NER) for the removal of distorting lesions anywhere in the genome and transcription-coupled NER (TC-NER) for the elimination of distorting DNA damage blocking transcription. Two mouse models with defects in NER have been reported to display premature aging symptoms: the Xpd hypomorph (de Boer *et al.*, 2002) and the Ercc1 knockout or hypomorph (Weeda *et al.*, 1997).

In humans, a heritable mutation in the XPD gene is responsible for the disorder trichothiodystrophy (TTD). TTD shows no predisposition to cancer, but leads to severely impaired physiological and neurological development, including retarded growth, cachexia, sensorineural hearing loss, retinal degeneration and its hallmark features of brittle hair, nails, and scaly skin (Lehmann, 2003). TTD patients have a strongly reduced life span, and the disease often is considered as a segmental progeroid syndrome. The helicase encoded by the XPD gene is one of the 10 subunits of basal transcription factor IIIH (TFIIH), which is required for multiple processes: GG-NER, TC-NER of NER and non-NER lesions, as well as transcription initiation by RNA polymerase I and II.

An Xpd-deficient mouse model was generated by mimicking a human mutation that causes TTD (de Boer *et al.*, 1998). This mutation does not ablate but rather alters the normal activity of Xpd. These mice have impaired transcription and mildly impaired NER.

**Figure 49.4** Skin atrophy (Vogel *et al.*, 1999). Section of skin (dorsal region over cranial to mid-thorax) from control (**A, C, E**) and *ku80*<sup>-/-</sup> (**B, D**) mice. Skin looks the same for both cohorts between 1 and 15 weeks. However, by 40 weeks, compared to control, all subcutaneous elements, including superficial collagen, subcutaneous adipose and skeletal muscle are atrophied for *ku80*<sup>-/-</sup> skin. This same phenotype is observed for control mice by 70 weeks.

## 49. Mouse Models of Accelerated Aging

TABLE 49.1  
Aging-related phenotypes in *Xpd* mutants and C57BL/6 control mice (Wijnhoven *et al.*, 2005)

	C57BL/6		<i>Xpd</i> TTD	
	Incidence	Severity	Incidence	Severity
Osteoporosis femur	88.2	3.3	97.1	4.1
Hepatic lipofuscin accumulation	85.0	1.6	97.1	3.1
Hepatic intranuclear inclusions	10.0	0.1	28.6	0.5
Hepatocellular atrophy	5.0	0.1	34.3	0.5
Renal karyomegaly	17.9	0.2	38.2	0.7
Renal tubular dilatation	30.8	0.5	85.3	2.2
Renal hyaline glomerulopathy	15.4	0.3	52.9	1.1
Aortic sarcopenia	5.6	0.1	87.9	2.0
Lymphoid depletion spleen	30.8	0.4	85.7	2.0
Lymphoid depletion thymus	82.8	2.6	100	3.7
Skin reduced hypodermal fat	18.9	0.5	85.7	2.9
Heart lipofuscin accumulation	100	1.9	100	2.3

These characteristics closely resemble those of humans with the disorder, including brittle hair. At this time, *Xpd* mice have been exhaustively characterized side-by-side with their littermate controls in a similar C57BL/6 genetic background. The results indicate a host of premature aging symptoms (see Table 49.1), but also a limited number of TTD-specific phenotypes (Wijnhoven *et al.*, submitted). Life span was reduced in this model by about 10%.

Are the accelerated aging characteristics observed in the *Xpd* mutant mice due to defective DNA repair alone? *Xpd* is important for repairing DNA in association with transcription, so the exact way in which it delays age-related decline is difficult to determine. Complete abrogation of NER, accomplished by mutating *Xpa*, has not yet been shown to cause premature aging in mice (de Vries *et al.*, 1995). Thus, defective NER, which leads to an accumulation of DNA mutations, is unlikely to be the sole cause of early senescence in *Xpd* mutant mice. However, defective DNA repair apparently does contribute to premature senescence in these animals. This can be derived from the observation that a much more severe phenotype is obtained by crossing the *Xpd* mutants with an *Xpa*-knockout mouse (Jan Hoeijmakers, Harry van Steeg, personal communication).

It is conceivable that a response to stalled transcription at sites of DNA damage is responsible for early aging in the *Xpd* mutant mice. In this scenario, a defective TFIIF results in stalled transcription that decreases gene activity and leads to a mild accumulation of DNA damage. Cells respond by undergoing apoptosis, which may cause the early organismal senescence in these mice. In the absence of *Xpa* alone (with a fully functional *Xpd* protein), transcription from a damaged DNA template can still take

place, possibly because the amount of spontaneous damage subject to NER is low. (Base excision repair, not NER, is the main pathway for removing the most abundant forms of spontaneous DNA damage, such as oxidative lesions.) In combination with the *Xpd* mutation, however, the complete absence of *Xpa* would exacerbate the suboptimal performance of TFIIF, leaving the DNA lesion exposed for a greater period of time; this would result in a further decline in gene activities and an enhanced response. Thus, the premature aging symptoms in the *Xpd* mutant mouse may be primarily the result of a cellular response to impaired TFIIF at the site of a spontaneous DNA lesion, rather than the accelerated accumulation of DNA damage or mutations. Indeed, mutation frequencies at a *lacZ* reporter locus in this mouse model were not elevated as compared to control animals of the same age (Dollé *et al.*, in press). The role of p53 responses as a possible causal factor in the aging phenotypes displayed by *Xpd* mutant mice is unknown.

Another NER-defective mouse model showing symptoms of premature aging involves the gene *ERCC1*. The ERCC1-XPF complex forms an endonuclease, which is required for the 5' incision to remove the damage-containing oligonucleotide during NER, but also essential for interstrand crosslink repair (ICLR). Hence, *Ercc1* knock-out (*Ercc1*<sup>-/-</sup>) mice are deficient in GG-NER, TC-NER, and ICLR. These mice show a severe phenotype including runted growth, progressive neurological abnormalities, kyphosis, a short life span of about three weeks, and liver and kidney dysfunction (Weeda *et al.*, 1997). At the cellular level the *Ercc1* defect leads to accelerated nuclear polyploidization. The combination of a knock-out allele with a truncated *Ercc1* allele

(*Ercc1<sup>-m</sup>*), resulting in a protein lacking the last seven amino acids, delays the onset of the premature aging phenotype and extends the maximal life span to about four to six months (Weeda *et al.*, 1997). Similar to the Xpd mutant, the premature appearance of aging symptoms is not caused by the defect in NER (which may contribute), but mainly to the defect in the removal of the highly toxic interstrand crosslinks. In the hypomorphic *Ercc1* mutant mouse an increased level of genomic instability at a lacZ reporter locus was observed at four months of age (Dolle *et al.*, in press). Although this mouse model may ultimately appear as a valid model of accelerated aging, the fact that severe symptoms already appear before development is complete makes this less suitable for modeling aging phenotypes that normally appear only in adult animals.

### WRN, ATM, AND TELOMERES IN MICE AND MEN

At least three other mouse mutants harboring defects related to DNA repair have been identified as models of accelerated aging. The first of these models that should be mentioned is the WRN-defective mouse. In most of the preceding cases the mouse mutants of genome instability were generated primarily for studying cancer, but the WRN gene defect was modeled on its own account as an accelerated aging model (Lebel and Leder, 1998; Lombard *et al.*, 2000). Human WS patients prematurely exhibit signs of senescence including atrophic skin, graying and loss of hair, osteoporosis, malignant neoplasms, diabetes, and shortened life span (Goto, 1997). Furthermore, increased genomic instability at the HPRT locus has been reported in peripheral blood lymphocytes from these patients (Fukuchi *et al.*, 1989). Mice deleted for *Wrn* exhibit no obvious phenotype, suggesting redundancy with another RecQ helicase or differences in threshold levels or nuclear localization (Lebel and Leder, 1998; Lombard *et al.*, 2000).

However, the fact that *Wrn*-mutant mice do not recapitulate WS as seen in humans does not diminish the potential importance of the human phenotype with regard to aging or the importance of mouse models. Similar cases, in which the mouse model failed to recapitulate the human phenotype, have been observed many times for genes that suppress cancer in humans. However, at a closer look, the proteins involved were found to perform remarkably similar biochemical functions with the same physiological significance in both species. For example, the retinoblastoma protein (pRb) is a tumor suppressor that in humans prevents the formation of tumors in the retina. However, in Rb-deficient mice, retinoblastoma does not occur. Instead, adenomas develop in the intermediate pituitary gland. However, retinoblastomas will develop in Rb mutant mice after reducing the expression of an Rb family member, p107 (Robanus-Maandag *et al.*, 1998). Thus, the difference in phenotype between mouse and human is due simply

to different levels of expression of Rb family genes. Therefore, tumor suppressor genes perform remarkably similar functions in mice and humans at both the biochemical and physiological levels.

An important confounder of modeling human cancer and aging in the mouse involves telomere instability. Telomeres are the nucleoprotein complexes that occur at the ends of eukaryotic linear chromosomes. In the mammalian genome they consist of several kilobase pairs of repetitive DNA sequences (TTAGGG) that attract a number of sequence- and structure-specific binding proteins. These chromosomal caps prevent nucleolytic degradation and provide a mechanism for cells to distinguish natural termini from DNA double-strand breaks, which signal DNA damage, resulting in cell cycle arrest, senescence, or apoptosis. Telomeres terminate in 35-600 bases of single-stranded TTAGGG at the 3' end (the 3' overhang). This 3' overhang folds back into the duplex TTAGGG repeat array forming a so-called t-loop. Telomeres are also thought to buffer the internal coding regions of the genome from the consequences of the end replication problem, that is, the inability to complete the 5' end by lagging strand synthesis. Although this may temporarily protect the genome against attrition, cells would inevitably lose terminal DNA with each cell division. However, telomere attrition can be countered by elongation mechanisms. The most important of these elongation mechanisms is telomerase, a reverse transcriptase composed of a protein component and an RNA (complementary to the telomeric single-stranded overhang) that can synthesize telomeric DNA directly onto the ends of chromosomes. Telomerase is present in most fetal tissues, normal adult male germ cells, inflammatory cells, proliferative cells of renewable tissues, and in most tumor cells (for a recent review on telomeres and telomerase, see Blackburn (2005)).

Telomerase null mice have been made by ablation of the RNA component of the enzyme, *Terc* (Blasco *et al.*, 1997). The enzyme is less important in mice than in humans because mice have very long telomeres. This is thought to be the reason that mice are more prone to sarcomas and lymphomas whereas humans are more prone to epithelial tumors (DePinho, 2000). Indeed, late-generation (i.e., fifth to eighth generation) of telomerase knockout mice display a more human tumor spectrum (Artandi *et al.*, 2000). Progressive telomere erosion in *Terc* null mice of somewhat earlier generation has been found associated with premature aging symptoms, but these represented far from a full spectrum of classical pathophysiological symptoms of aging. In these mice, age-dependent telomere shortening and increased genetic instability were associated with shortened life span as well as a reduced capacity to respond to stresses such as wound healing and hematopoietic ablation (Rudolph *et al.*, 1999).

As mentioned earlier, the ataxia-telangiectasia mutated (ATM) gene, when defective, causes a segmental

progeroid disorder in humans. ATM stimulates cell cycle responses to the highly toxic DNA double-strand breaks. One of its targets is actually p53, which can also be activated via ATM-independent mechanisms. Premature aging in ataxia telangiectasia is not that obvious (Chun and Gatti, 2004), and in its mouse counterpart progeroid symptoms are even less prominent (Xu *et al.*, 1996) unless they are bred into a *Terc*-deficient background. Against the background of eroding telomeres, the double null mice exhibited a general growth and cell proliferation defect, probably causing the extensive organ dysfunction observed in this mouse model (Wong *et al.*, 2003). In contrast to the p53 mutants, the cause of the problems in these mice is likely to be increased genomic instability and an elevated apoptosis rate. This is typically observed in the *Atm* and *Terc* mutants separately, but greatly accelerated by the combined defect. It results in diminished stem cell reserve in several organ systems, and, similar to the situation in the p53 mutants, this impairment in regenerative capacity results in premature aging, exemplified by lordokyphosis, reduced muscle and fat mass, and several other aging-related phenotypes. Hence, in the combined *Terc/Atm* mutants the accelerated aging phenotype is much more convincingly expressed than in each mutant separately.

Similar to the *Atm* mutants, bringing the *Wrn* defect into a *Terc*-deficient background dramatically uncovered an array of premature aging phenotypes reminiscent of the human syndrome (Chang *et al.*, 2004). After four to six generations, during which the initially long telomeres of these mice become progressively shorter, mice were obtained of shorter life span displaying premature aging symptoms at 12 to 16 weeks. Symptoms included hair loss, cataract formation and hypogonadism, osteoporosis, type II diabetes and lordokyphosis, which are typical for Werner syndrome patients. Since Werner syndrome patients display high levels of spontaneous genome instability in their peripheral blood lymphocytes, bone marrow metaphases in the late-generation double knock-out mice were examined and showed similar, marked genomic instability. Increased genomic instability was also observed in embryonic fibroblasts from these mice as well as a reduction in their replicative life span. A marked increase in apoptosis rates was observed in intestinal crypt cells. Although not prominently cancer prone, the earlier generation *Terc* null mice succumbed to osteosarcomas and soft tissue sarcomas, typical for Werner syndrome patients but not for mice.

It is known that WRN, like ATM, plays a role in telomere maintenance, and the conclusion could easily be drawn that the *Wrn* mutation mainly reinforces the premature phenotype reported to be associated with the ablation of *Terc* alone. Conceivably, in mesenchymal tissues, which are mainly affected in the *Terc/Wrn* double knockouts, intact WRN is able to compensate for the lack of telomerase. It may be able to do that through its role (like ATM) in HR, a repair process known to be involved

in the maintenance of eukaryotic telomeres (Tarsounas and West, 2005). Ultimately, the cause of the accelerated aging phenotypes is likely to be very similar to the one discussed for the *Terc/Atm*, *Ku80*, and *Brca1* defective mice, namely, increased genomic instability resulting in impairment of cell proliferation. The same probably would apply to a third “accessory DNA repair”-defective mouse model, the topoisomerase III $\beta$  deficient mouse model.

It is known that topoisomerases interact with RecQ helicases (Laursen *et al.*, 2003). Even though there is virtually no phenotype in *Wrn* mutant mice, deletion of the helicase domain of *Wrn* increases the mutation frequency at the *Hprt* locus and reduces proliferation of embryonic fibroblasts from these mice. Both cellular phenotypes are exacerbated by inhibition of topoisomerase I (Lebel and Leder, 1998). The *Wrn* defect also increases tumor formation in a p53 defective background, much more than the p53 defect by itself (Lebel *et al.*, 2001; Lombard *et al.*, 2000). The combined defect also resulted in tumors, such as sarcomas, which do not normally develop in a p53 null mouse model. Based on the increased sensitivity to topoisomerase inhibition of cells from the *Wrn* defective mice (which has also been demonstrated for lymphoblastoid cells derived from Werner syndrome patients Poot *et al.*, 1999) it is possible that the *Wrn* defect is to some extent caused by impaired interaction with topoisomerases. This is supported by the observation of some aspects of premature aging in mice with a topoisomerase defect, that is, topoisomerase III $\beta$  null mice. Such mice develop normally but exhibit a shortened life span with an age-related phenotype that includes a marked increase in ulcerative dermatitis (Kwan and Wang, 2001). Analyses of yeast cells suggest that the topoisomerase III $\beta$  phenotype is influenced by RecQ helicase activity. Yeast cells deleted for the topoisomerase III homologue, TOP3, exhibit slow growth, hyper-recombination, genomic instability, impaired sporulation and increased sensitivity to genotoxic agents (Wallis *et al.*, 1989). Interestingly, this phenotype is suppressed by deletion of *Sgs1*, a RecQ helicase, indicating that *Sgs1* creates a deleterious topological substrate that needs to be resolved by TOP3 (Gangloff *et al.*, 1994). Conceivably, ablating the *Top3 $\beta$*  gene may impair the RecQ family members causing the symptoms of aging, which *Wrn* inactivation alone, at least in the mouse, cannot accomplish.

## NUCLEAR STRUCTURE

Attention was drawn to the importance of maintaining nuclear organization as a longevity assurance system once it was demonstrated that Hutchinson Gilford Progeroid Syndrome (HGPS) is caused by *de novo* mutations in the gene LMNA, encoding both lamin A and lamin B through alternative splicing (Eriksson *et al.*, 2003). A *de novo* mutation activates a cryptic splice site,

effectively resulting in a protein with a 50 amino acid deletion near the C-terminus of lamin A. This deletion allows farnesylation but prevents proteolytic cleavage of the prelamin A to generate the final product. The resulting mutant lamin A acts in a dominant fashion (patients are heterozygous), and the aberrant protein is called progerin. Although mouse models accurately mimicking the human defect are now being generated in different laboratories, two potentially relevant mouse models deserve some discussion. The first is a null mouse for the gene *Zmpste24* metalloproteinase, an enzyme involved in the proteolytic processing of prelamin A. Apart from nuclear abnormalities, this model shows growth retardation, alopecia, bone fractures, muscle weakness, and early cardiac dysfunction (Bergo *et al.*, 2002). More recently, accelerated aging in these mice has been linked to p53 signalling activation, supporting the concept that hyperactivation of the tumour suppressor p53 may cause accelerated ageing (Varela *et al.*, 2005). The second model originally was aimed at mimicking a mutation in LMNA that in humans normally results in Emery-Dreifuss muscular dystrophy (EDMD). (Heritable mutations in lamin A/C or lamin-binding proteins cause various diseases other than HGPS. For example, mutations in emerin, a lamin-binding protein, or LMNA cause EDMD, and mutations in LMNA can also cause Dunnigan-type partial lipodystrophy. The mutations that cause these diseases are nonoverlapping, and it is unclear as to how different mutations in the same gene can cause different diseases.) The homozygous EDMD mutation in the mouse causes death in four to six weeks. The mice develop severe growth retardation and a number of other symptoms reminiscent to HGPS patients (Mounkes *et al.*, 2003). In neither of the two mouse models have genomic instability, cell growth rate, or apoptosis rate been studied thus far. In interpreting these results, keep in mind that HGPS is an early-onset segmental progeroid syndrome that occurs before reproductive maturation. Hence, it is unrealistic to expect an adult-onset type of premature aging.

Is it possible to ascribe HGPS to a defect in genome maintenance? Lamins at the nuclear periphery and throughout the nucleoplasm are thought to maintain nuclear shape. However, they may also contribute to tissue-specific gene expression, through their role as key elements in nuclear architecture (Gruenbaum *et al.*, 2005). Regions of chromatin appear to be anchored to the lamina, and, at least *in vitro*, lamins have been demonstrated to bind directly to chromatin. In this respect, the actions of a gene are not only influenced by its position in the one-dimensional DNA sequence, relative to regulatory elements, but also by its particular location in the nucleus. Such position effects may include not only transcription, but also replication, repair, and recombination. For example, when DNA undergoes more than one double-strand break the spatial proximity of the broken ends is positively correlated with the

probability of illegitimate joining. Hence, it is of the utmost importance to faithfully maintain lamin organization, defects that are likely to result in genomic instability. Indeed, it was recently found that *Zmpste24*-deficient mouse embryonic fibroblasts show increased DNA damage and chromosome aberrations and are more sensitive to DNA-damaging agents (Liu *et al.*, 2005).

#### MITOTIC SPINDLE CHECKPOINT AND THE ROLE OF ANEUPLOIDY

Before mitosis, the mitotic spindle checkpoint allows every chromosome to send a stop signal, arresting cell growth until all the chromosomes are appropriately distributed. Defects in this checkpoint provoke chromosome missegregation and aneuploidy (gain or loss of chromosomes), which can have adverse functional consequences, including cell death, but also cancer. For example, defects in different components of the mitotic spindle checkpoint have consistently been observed in cancer cells, characterized by chromosomal instability (Hanks and Rahman, 2005). Recently, a mouse model was made based on partial inactivation of the gene *BubR1*, encoding a spindle assembly checkpoint protein. These mice have a median life span of only six months and display a host of premature aging symptoms, including lordokyphosis, cataracts, and muscle atrophy (Baker *et al.*, 2004). They developed aneuploidy from the age of two months onward that increased as the mice aged further. There was a strong correlation between the degree and severity of the chromosome number instability and the onset and progression of the aging phenotypes. Increased apoptosis in several tissues from these animals at one year of age was not found. However, senescence-associated  $\beta$ -galactosidase activity was high as compared to control mice. This observation of increased cellular senescence *in vivo* was further supported by an accelerated rate of senescence of embryonic fibroblasts cultured from these mice, which also correlated with the degree of aneuploidy observed in these same cells. Hence, the progressive aneuploidy was assumed to be the underlying cause of both *in vitro* senescence and the premature aging symptoms *in vivo*. Interestingly, *BubR1* expression declines in tissues of normal mice with age (Baker *et al.*, 2004). Hence, it is conceivable that increased aneuploidy, which has been observed in aging animals, contributes to normal aging as well.

A somewhat unexpected finding in this study was the virtual lack of spontaneous tumors in the mutants, in spite of the fact that aneuploidy is one of the hallmarks of cancer. In this respect, it is possible that the severity of the aneuploidy, while initially promoting the genesis of cancer cells, eventually prevents further tumor progression, similar to the situation in the aforementioned *Atm/Terc* mutant mice. This could be a direct effect of ongoing polyploidization or facilitated through the activation of an aneuploidy checkpoint.

## BACK TO MITOCHONDRIA

Another example of a mouse model with a defect in genome maintenance especially designed to test the hypothesis that genomic instability is involved in aging is the PolgA proofreading-deficient mouse model. PolgA, the catalytic core of the mitochondrial DNA polymerase gamma (Polg), is a mtDNA polymerase, encoded in the nuclear genome. Hence, proofreading defects in this gene would be expected to lead to increased mutations in the mitochondrial genome. Mutations in both nuclear and mitochondrial DNA have been demonstrated to accumulate with age in a tissue-specific pattern (Arnheim and Cortopassi, 1992; Vijg and Dollé, 2002). Hence, in the PolgA deficient mouse we would expect to see the premature appearance of aging-related phenotypes, which turned out to be correct. Apart from a three- to five-fold increase in mtDNA mutations in brain, heart, and liver, and respiratory chain dysfunction in the heart, a host of premature aging symptoms was observed in this mutant, including osteoporosis, lordokyphosis, alopecia, a growth defect, reduced subcutaneous fat, hypertrophy of the heart, and anemia (Trifunovic *et al.*, 2004). Life span was reduced by about 50%. Interestingly, the enhanced mitochondrial mutation load in these mtDNA mutator mice already was established at two months and did not dramatically increase thereafter. This suggests that once present, somatic mutations can continue to exert adverse physiological effects even without any further dramatic increases. It is possible that the premature aging phenotypes arise through increased ROS production as a consequence of respiratory chain dysfunction in these mice. However, in a more recent study, in which a similar mouse model was generated and studied, evidence for increased oxidative stress was not found. Instead, accumulation of mtDNA mutations was found to be associated with increased apoptosis (Kujoth *et al.*, 2005).

## Conclusion

We have reviewed a range of genetically engineered mouse models, harboring specific defects in genome maintenance and exhibiting a common array of aging-related phenotypes, even though the mutated genes represent a diverse range of pathways. As discussed, the most convincing models undergo normal development and then prematurely exhibit such an impressive array of common aging features that it is difficult to maintain that these mutants do not faithfully mimic aspects of the normal aging process. At this point in time, the question is no longer whether the premature aging phenotypes in these mice are genuine, but rather why different genetic defects in some aspect of the complex network of genome maintenance all lead to very similar endpoints in aging. To the best of our knowledge, genome maintenance is the only system in which such a wide variety of defects leads to such a

recognizable pattern of phenotypic changes. Before discussing the most logical explanation of this phenomenon, we will first address two specific caveats of accelerated aging models.

The first caveat involves the lack of mouse models recapitulating all possible aging symptoms in an accelerated fashion. We could argue that only gene defects that accelerate all possible symptoms of normal aging are likely to truly intervene in its core mechanisms. In this respect, it is important to realize that it is unknown if some of the aforementioned mouse mutants do not display a full complement of aging characteristics, like their littermate controls. First of all, in a typical population of humans or mice, there is not a single individual displaying all possible symptoms of aging. Although it is indeed very likely that human progeroid disorders are in fact segmental (Martin, 2005), the number of patients is often too small to exclude the possibility that other aging-related phenotypes also are accelerated. In mice, the situation is seriously confounded due to the variation in genetic background. It is very possible that a particular phenotype that is associated with normal aging in one genetic background is not observed in others. However, the expectation of mutants accelerating or decelerating all aspects of normal aging is probably unrealistic.

We have already alluded to the lack of evidence for pacemaker genes orchestrating all the critical aspects of the fundamental mechanisms of normal aging. Because of its very nature as a byproduct of evolution, the post-maturational changes considered as aging are ill-defined, with major confounders in the form of genetic, environmental, and stochastic variation. It seems highly unlikely that the many different individual phenotypes of aging, which may be related and/or interact with each other, are controlled by one or few genes. Therefore, it is not to be expected that single-gene mutations accelerate all aging symptoms characteristic for the normal population. Indeed, if DNA damage would be the single most important cause of aging, the hundreds of genes directly involved in its metabolism immediately refute the possibility of a simple genetic control center specifying each and every aging-related phenotype. Mutations in only one of these genes may cause one or few aging symptoms, but will never accelerate all possible signs of aging that are characteristic for the population under study.

On the other hand, there is abundant evidence that multiple cellular defense systems can be upregulated in concert, to increase stress resistance and survival in a diverse range of organisms (Tatar *et al.*, 2003). This is exemplified by the identification of a wealth of mutants in nematodes, flies, and mice, downregulating pathways of growth, reproduction, and energy metabolism, resulting in significant increases in life span as well as increased stress resistance, including resistance to oxidative stress. We do not know if in all these mutants, in different

species, increased survival is controlled in the same way, by the same mechanism, but it is possible that in some way they all reflect the selective advantage of temporarily delaying reproduction and maximizing survival in times of famine, awaiting better times. There is no convincing evidence that this could also work the other way around, although, for example, growth hormone overexpressing mice have been found associated with at least some symptoms of accelerated aging (Bartke *et al.*, 2002). A logical conclusion therefore would be that DNA damage is a major proximate cause of aging and only direct interference at that level uncovers accelerated aging phenotypes. Any upstream interference would probably have too many side effects or require a much more sophisticated type of genetic engineering than we currently have available.

A second caveat in using mouse models of accelerated aging is the potential misinterpretation of a life-shortening effect of early diseases as signs of an acceleration of fundamental mechanisms of normal aging. It often is argued that mouse models with a mutation that accelerates aging simply are showing some disease that has nothing to do with normal aging. Based on the aforementioned evolutionary basis of aging we could say that all genetic variations that exclusively manifest after the age of first reproduction are by definition part of the aging phenotype. How likely is it that a random germline change would give rise to a phenotype that can superficially be diagnosed as aging (i.e., adversely affects post-maturation fitness)? The first results of mouse ENU mutagenesis programs in which the effects of many different randomly induced germline mutations are assessed suggest that aging phenotypes are rare. The phenotypes observed in ENU mutagenesis screens are, to a large extent, developmental, and very few if any have been defined as aging-related (Kile *et al.*, 2003). In addition, very few mouse knockouts exhibit aging phenotypes. Thus, genetic alterations rarely impact aging. In view of the convincing array of aging phenotypes in the genome maintenance mutants discussed, the point is probably moot, but it remains useful to point out the difference between a disease and an aging phenotype.

Consider the well-known genetic diseases, cystic fibrosis and sickle cell anemia. These genetic alterations reduce life span by impairing the function of a vital system independent of normal aging. The negative impact of both these diseases is apparent very early in life, and neither disease is observed in the elderly. On the other hand, arteriosclerosis and its sequelae, such as coronary and cerebrovascular disease, is an age-related disease process. Used by Williams as a theoretical example of the effect of a pleiotropic aging gene, late-life arteriosclerosis could be promoted by depositions of calcium in the arterial wall, a possible pleiotropic effect of a gene variant causing enhanced calcium deposition in the bones, offering a selective advantage at a young age (Williams, 1957). A similar reasoning could be applied to diseases,

such as diabetes, osteoporosis, and cancer. Although none of these diseases occurs exclusive in the elderly, the high incidence in this segment of the population is compelling, and it is very difficult to argue that they are not genuine aging phenotypes. Hence, in interpreting accelerated aging symptoms it is critically important to correctly diagnose the phenotype. On this basis it should be possible to differentiate between genuine aging phenotypes and phenotypes related to disorders unrelated to aging.

How can so many clinical end points of aging undergo acceleration as a consequence of genetic defects in a set of functional pathways that superficially have no relationship to the original function that is impaired—for example, bone metabolism, functional skin mass, neuronal activity, growth? As already alluded to, this observation points toward a key role of the network of genome maintenance genes as the last line of defense against aging by removing damage induced by metabolism-related reactive oxygen species.

The key consideration here is that aging is characterized by progressive system dysfunction as a consequence of the loss of functional cells, ultimately driven by the accumulation of DNA damage. This could reflect two major underlying processes. First, organ and tissue dysfunction could be caused by cellular responses to DNA damage, including apoptosis and cellular senescence. Second, cells could degenerate by a process of intrinsic aging, possibly driven by increased genomic alterations. Although the former would mainly result in various forms of tissue atrophy and loss of regenerative capacity, increased genomic instability at old age is likely to contribute to the well-documented exponential increase in cancer during aging. Indeed, hyperplastic and neoplastic lesions can comprise as much as 50% of all pathological lesions observed at old age (Bronson and Lipman 1991). However, an increased load of genomic mutations, including sequence alterations and methylation changes, also could lead to a progressive increase in the number of dysfunctional cells, without causing them to die immediately or become transformed. We can call such cells *senescent* cells, and they may include permanently arrested cells, as a consequence of replicative senescence (for a discussion of the phenomenon of cell senescence and its implications for *in vivo* aging, see Campisi 2005). Similar to increased cell death, an increased fraction of dysfunctional cells would be expected to lead to organ dysfunction.

As we have seen, in all mouse models of premature aging, the genetic defect leads to increased impairment of growth and cellular proliferation, either through cell cycle arrest, or other elicited DNA damage responses, such as replicative senescence and apoptosis. In many of these mutants we also see an increase in mutations—irreversible changes in DNA sequence due to misreplication or misrepair. This increased genomic instability promotes the emergence of cancer cells but is so dramatic

## 49. Mouse Models of Accelerated Aging

that it ultimately represses tumor progression, due to increased anti-cancer responses, such as apoptosis. Indeed, deletion of p53 rescues the accelerated aging mutants from the premature replicative senescence that is often observed in their tissue culture cells. This suggests that many of the premature aging phenotypes in mice with defects in genome maintenance are caused by cellular responses to DNA damage, including the activity of a p53-dependent cell cycle checkpoint.

Are these same cellular responses, identified in the mouse models as a likely cause of their accelerated aging, also responsible for normal aging? There can be no doubt that loss of cells *per se* contributes to normal aging and various forms of atrophy are common among older mice. Hence, part of normal aging is also likely to be due to the adverse effects of cellular responses to DNA damage. Of note, it has been demonstrated that SIRT1, the aforementioned candidate master regulator of life extension, is capable of deacetylating Foxo3a, the ortholog of the main longevity effector gene DAF16 in nematodes, increases its ability to induce cell cycle arrest, raises its resistance to oxidative stress, but inhibits its ability to induce cell death (Motta *et al.*, 2004). However, normal aging generally is not associated with the dramatic forms of growth reduction, tissue atrophy, and loss of organ functional mass as observed in many of the accelerated aging models. For example, Table 49.1 indicates symptoms of aging in the Xpd mouse model that are much more severe than would be expected from their biological age as derived from the survival curve. Indeed, these data were obtained by complete histopathology at the end of life. Hence, we would expect to see an incidence and severity level very similar to the control animals, but this is not the case. Hence, it is possible that accelerated aging in many of these models is caused mainly by excessive cellular responses to genomic stress, in contrast to normal aging, which is more likely due to a gradual accumulation of persistent DNA damage or mutations. Indeed, the bursts of DNA damage necessary to evoke, for example, an apoptosis response must be quite rare during normal aging, as can be derived from the extremely low number of apoptotic cells in tissues of normally aged animals.

Normal steady-state levels of DNA damage, such as 8-oxo-guanine, are extremely low (Hamilton *et al.*, 2001) and therefore also unlikely to directly cause aging-related degenerative defects. However, DNA damage can be turned into mutations by erroneous processing of DNA damage. Evidently, the frequency of such events is low, as exemplified by the normally low frequency of neoplastic transformation. However, it is likely that many mutations of different kinds (from point mutations to large genome rearrangements and aneuploidy) are needed to generate a tumor cell. Most of such mutations do not involve actual genes, but gene regulatory sequences. Indeed, rather than a catalog of useful genes interspersed with functionless DNA, each chromosome is now viewed as

a complex information organelle with sophisticated maintenance and control systems. In this concept of a genome, each part has a function, even its nonprotein-coding parts. Such a holistic view of the genome would assign a variety of functions to noncoding DNA (e.g., structural maintenance, gene regulation). The continuous process of irreversible alteration of the DNA sequence organization of the genome would lead to a mosaic of cells, with each individual cell in a tissue bearing a different pattern of genomic scars (Vijg and Dollé, 2002). Rather than the inactivation of unique genes with unique functions, which has thus far been given primacy, a scenario of an initially tolerable loss of genome structural integrity is more likely. This could lead to increased loss of function, highly variable from cell to cell, thus contributing to increased organ dysfunction. Hence, whereas age-related systems dysfunction in premature aging may predominantly involve cellular responses evoking proliferation impairment and programmed cell death, normal aging could be due to the gradual accumulation of persistent genomic or epigenomic alterations, leading to a progressive increase of dysfunctional cells. Both scenarios would result in organ and tissue dysfunction. Figure 49.5 schematically depicts the hypothetical causes of aging as driven by DNA damage for (1) accelerated aging, mostly due to adverse effects of cellular responses to DNA damage; (2) normal aging, with a reduced role of cellular responses, and (epi)genomic alterations as the main cause of cell and organ dysfunction; and (3) delayed aging with reduced cellular responses as well as reduced accumulation of irreversible, (epi)genomic alterations.

It would be premature to consider DNA damage as the sole driving force of aging in all multicellular organisms. However, based on the model systems now available, it accounts for a significant number of the observations that have been made. Of note, DNA damage as the original driver of a universal process of aging

**Figure 49.5** DNA damage, mainly resulting from oxidative stress, byproducts of normal growth and metabolism, as the hypothetical main driver of the aging process, in accelerated aging, normal aging, and delayed aging conditions. The trade-off between somatic maintenance and growth and reproduction is from Kirkwood (2005).

has some inherent logic. After all, damage to nucleic acids is the most ancient example of damage accumulation in the living world. Ever since the first replicators, genetic damage posed both a fundamental problem and an opportunity for living systems. This is a problem, because genetic damage essentially prevents the perpetuation of life, since it interferes with replication (and transcription); it is also an opportunity, because it allows the generation of genetic variation through errors in the replication of a damaged template, thereby facilitating evolutionary change. Genetic stability in somatic cells of metazoa has become part of the trade-off between the allocation of scarce resources to either reproduction or somatic maintenance and is not expected to be maximized. Though the concept of DNA damage as a main driver of aging is intuitively attractive, evolutionary logic dictates that other causes of aging would have emerged over evolutionary time. Indeed, it is likely that age-related deterioration and functional decline is synchronized across different organismal functions. This would imply that given a molecular machinery of limited endurance, all bodily functions would adapt, and under such conditions a variety of harmful physiological late-life effects, unrelated to DNA damage, can be expected to develop.

## ACKNOWLEDGMENTS

The authors are grateful for support from NIH grants AG 17242, AG20438, ES11044 (JV), and R01 CA76317-05A1 (PH). We thank Drs. Yousin Suh, Judith Campisi, Jan Hoeijmakers, and Harry van Steeg for stimulating discussions, and John David Garza for creating Figure 49.5 and for his help with the manuscript.

# Models, Definitions, and Criteria of Frailty

David B. Hogan

*This chapter will examine the current state of research on frailty. A number of competing and complementary models for its development will be described. This will be followed by a working definition of frailty. Finally, criteria for the identification of frailty in older individuals will be discussed. Promising future directions for research will be noted throughout the chapter. The aim is to provide useful background information about frailty for researchers interested in the field. It is an area of inquiry still early in its evolution.*

## Introduction

In a radio broadcast on October 3, 1939, Sir Winston Churchill said about Russia that, "It is a riddle, wrapped in a mystery, inside an enigma." The same can be said about frailty.

The term *frail elderly* is defined in the National Library of Medicine's MeSH database as "Older adults or aged individuals who are lacking in general strength and are unusually susceptible to disease or to other infirmity." The concept that aging is associated with declining resiliency goes back to the dawn of western medicine, and likely, before. The Hippocratic tradition held that aging was caused by a progressive loss of the body's store of heat, which resulted in a depletion of vitality and increased vulnerability (Thane, 1993). At birth it was assumed that we were granted a finite supply of energy. During childhood it was used for growth. At maturity we were to maintain a balance with our environment, but in old age we decayed as our remaining energy was spent. Benjamin Rush, a signer of the Declaration of Independence, stated that the loss of vitality led to a "predisposing debility." The older individual became unable to remain in balance with the world (Haber, 1986).

In this short overview of frailty I'll deal first with select models and mechanisms for the development of frailty. I'll then present a working definition followed by an examination of the currently favored criteria for the identification of frail older persons.

## Models and Mechanisms

### KNOWLEDGE DISCOVERY FROM DATASETS

Mathematical models can simulate and predict the behavior of systems. Many biomedical researchers, though, are more comfortable with verbal or visual models of complex phenomena. Various mathematical models for frailty have been reviewed elsewhere (Rockwood *et al.*, 2002). An example of the knowledge discovery from the dataset approach would be the work of Drs. Mitnitski and Rockwood. Using large databases, they developed a *frailty index* consisting of a number of variables including symptoms, attitudes, illnesses, and function that can be used to predict the likelihood of mortality (Mitnitski *et al.*, 2002).

This approach has been used to produce highly predictive models for certain outcomes associated with frailty but will not necessarily further our understanding of it. The most readably available outcomes for database research—death, disability, and institutionalization—do not arise solely from frailty and/or only capture a subset of all frail individuals. Although the presence of frailty makes death more likely, not all deaths in old age are "frail" deaths. Between 20 and 47% of deaths in old age have a *frail trajectory* (Lunney *et al.*, 2002, *et al.*, 2003). Likewise there is more than one pathway to disability. It can arise in a catastrophic or a progressive manner (Ferrucci *et al.*, 1997). Older individuals with frailty commonly show an insidious development of disability (Gill *et al.*, 2004). Ferrucci found that approximately half (51.6%) of older individuals who developed a severe disability over two to three years did so in a catastrophic manner (Ferrucci *et al.*, 1997). The risk factors and outcomes of the two modes of disability onset are different (Ferrucci *et al.*, 1997; Guralnik *et al.*, 2001). Although most residents in long-term care facilities are frail, only a subset of frail individuals reside in institutions. Defining frailty as being in a long-term care residence would be specific but not sensitive (Rockwood *et al.*, 1996).

### SENESCENCE AND FRAILITY

Are frailty and aging (or more accurately senescence) the same? Senescence refers to the time-dependent changes seen in living organisms that have cumulative and deleterious effects (Yates, 1996). A senescent organism

lacks resiliency, and, as will be seen later in this review, increased vulnerability is a hallmark of frailty. I feel that at some very advanced, but currently unspecified age, a degree of frailty will become universal. Others argue that frailty is not inevitable with aging but is due to a distinct biological pathway (Kolata, 2002). I would agree that few if any frail individuals currently develop the state *solely* because of senescence. Other factors (e.g., behaviors, life-styles, diseases) typically play a role. Even though very advanced age is arguably a sufficient cause of frailty, it isn't a necessary one.

## ROLE OF GENES

Saying that the frailty phenotype arises from gene-environment interactions doesn't move us very far forward as these interactions are pervasive throughout biology. Nonetheless, the emerging work on the genetics of aging, age-associated diseases, and age-associated functional decline will become increasingly relevant to our understanding of frailty (Johnson *et al.*, 1996; Hamet *et al.*, 2003; Gurland *et al.*, 2004; Martin 2005; Hadley *et al.*, 2005). Although genes likely influence the development of frailty, environmental influences probably predominate. For example, a twin study of the genetic contribution to late-life disability found that although genetic factors did play a significant role, environmental factors were more important (Gurland *et al.*, 2004). Genetic influences will operate partially, if not primarily, through the mechanism of susceptibility to diseases.

A few studies about the potential relationship between genetic polymorphism and frailty have been published. The Apolipoprotein E (ApoE) gene has been referred to as a *frailty gene* (Gerdes *et al.*, 2000). Epsilon 2 carriers are more likely to survive to extreme old age, but epsilon 4 carriers are less likely. The differential mortality rates for the various ApoE genotypes extend into extreme old age (Corder *et al.*, 2000). Genetic influences on immune and muscle function will likely be relevant to frailty research, but no consistent picture has emerged yet. Genetic variation in interleukin-6 (IL-6) was not associated with frailty in older women (Walston *et al.*, 2005), but a significant genetic association with the IL-10 promoter gene has been found (van den Biggelaar *et al.*, 2004). In the latter study, those genetically predisposed to lower cytokine production seemed predisposed to frailty. As will be seen, this seems to go against the prevailing thinking about the pathogenesis of frailty. Polymorphism in the insulin-like growth factor-2 (IGF2) was modestly associated (only 1% of the variance was attributable to IGF2 genotype) with grip strength in men aged 64 to 74 (Sayer *et al.*, 2002). Those with the AA genotype were marginally stronger than those with the GG genotype. Angiotensin-converting enzyme (ACE) gene polymorphism is associated with response to physical training (Montgomery *et al.*, 1999). Low ACE activity was associated with a greater response

to intensive physical training in young white male British Army recruits.

Interestingly, other studies have shown that the use of ACE-inhibitors for hypertension is associated with maintained muscle mass, muscle strength, and walking speed in older individuals (Onder *et al.*, 2002; Di Bari *et al.*, 2004). The issue of age-dependent regulation of gene expression requires study. Transcriptional profiling of human frontal cortex from individuals aged 26 to 106 showed both reduced expression of certain genes (e.g., involved with synaptic transmission and vesicular transport) and the induction of genes (e.g., involved with stress response and DNA repair) after the age of 40 (Lu *et al.*, 2004). The greatest diversity in gene expression was seen between 40 and 70 when a switch-over in genetic expression seems to occur. Middle and early old age may represent a critical period for the development of frailty in our later life.

## ALLOSTATIC LOAD AND HORMESIS

The concepts of allostasis and hormesis deal with the relationship between an organism and its environment. They may have particular relevance to frailty and could explain how early life events could have late-life consequences. Allostasis (literally meaning "achieving stability through change") is a dynamic regulatory process that allows the organism to adapt to the challenges of its environment. It is an extension of the concept of homeostasis (the ability or tendency of an organism or a cell to maintain internal equilibrium by adjusting its physiological processes). Many physiologic parameters do not remain constant but vary significantly in response to perceived stress. The neuroendocrine, autonomic nervous, and immune system responses, though beneficial in the short run, can be damaging long term if not shut down when no longer needed. Allostatic load refers to the price of the chronic overactivation of these regulatory systems (McEwen, 2003; McEwen, 2004). Although there are no studies showing a direct association with frailty, a summary measure for allostatic load was found to be an independent predictor of functional decline in the MacArthur studies of successful aging (Karlamañgla, *et al.*, 2002). Hormesis refers to the beneficial effects of low doses of potentially harmful substances. It is becoming apparent that environmental stress does more than "cull the herd" by eliminating the weakest individuals (Semenchenko *et al.*, 2004). A number of mild stresses (e.g., cold, heat, irradiation, caloric restriction) have been found to be associated with increased longevity in various animal models. The proposed mechanism is that the stress induces stimulation of maintenance and repair pathways (Tattan, 2004; Radek *et al.*, 2005). Frailty may be the long-term outcome of a complex interaction between the type, severity, and timing of environmental stresses and the nature (and consequences) of the response to these stresses.

### SYSTEM DYSFUNCTION

Dysfunction of key organ systems might explain the phenomenon of frailty. This would include musculoskeletal abnormalities (e.g., sarcopenia) (Marcell 2003; Doherty 2003; Vanltallie 2003), endocrine deficiency states (e.g., gonadal hormones, DHEA, growth hormone/IGF-1) (Morley *et al.*, 2005), or immune dysfunction (e.g., high levels of inflammatory markers like TNF- $\alpha$  and IL-6) (Cohen 2000). It is not felt, though, that frailty arises from a single system problem (i.e., frailty  $\neq$  sarcopenia). There is widespread agreement that a core feature of frailty is the dysfunction of *multiple* physiologic systems. Different investigators have proposed various combinations of the following abnormalities as underlying frailty: diminished aerobic capacity; abnormalities in the neurological system (e.g., cognition, balance, and gait); musculoskeletal problems; precarious or deficient nutritional states; endocrine-metabolic dysfunction; stimulation of the immune system; and cardiovascular concerns (Buchner *et al.*, 1992; Lipsitz *et al.*, 1992); Lipsitz, 2002; Bortz, 2002; Campbell *et al.*, 1997). Endocrine-immune dysregulation is a particularly favored partnering (Walston, 2004; Joseph *et al.*, 2005; Ferrucci *et al.*, 2003). At the present time there are no widely accepted animal models for frailty.

### LIFE COURSE APPROACH

Life course epidemiology studies the long-term effects on later health- or disease-risk of physical or social exposures during gestation, childhood, adolescence, young adulthood, and later adult life (Kuh *et al.*, 2003). It allows the integration of biological, behavioral, clinical, psychological, and social processes that interact across a person's life (Ben-Shlomo *et al.*, 2002). This is not a new concept in aging research. Over 50 years ago Nathan Shock wrote, "In the broadest sense, problems of growth, development, and maturation are as much a part of gerontology as are those of atrophy, degeneration, and decline" (Baker *et al.*, 1992). He emphasized the need to examine aging over the entire life span.

The likelihood of developing certain chronic conditions (e.g., type 2 diabetes, ischemic heart disease) appears to depend in part on the early environment (Gluckman *et al.*, 2004). A noxious stimulus at a critical, sensitive period earlier in life may lead to permanent structural, physiologic, and/or metabolic changes (Godfrey *et al.*, 2001). These changes in the young organism might confer immediate survival advantages but at a subsequent cost, especially if there is a mismatch between the developmental and adult environments (e.g., constrained fetal growth followed by exposure to high-calorie foods after birth). This is not to deny the importance of adult risk factors—life course epidemiology allows the joint study of both early life and adult factors. Understanding the biological, clinical, psychological, lifestyle, and social factors that influence physical

performance in midlife may provide clues to the origin of frailty in old age.

Whether frailty risk accumulates or there is a required chain of events is unknown (Kuh *et al.*, 2003). It is also unknown whether there are critical or sensitive periods for the development of frailty; middle-age might be a critical period (Lu *et al.*, 2004). Confounding, mediating, and modifying factors will require consideration. The very complexity of the life course approach in the study of frailty would be an attraction—it would allow the consideration of a mix of both early and late risk factors as well as biomedical and psychosocial influences.

The Alameda County Study looked at risk factors for frailty over the previous three decades in an older cohort (Strawbridge *et al.*, 1998). It was found that (listed alphabetically) depression, fair or poor self-rated health, heavy drinking, physical inactivity, prevalence of chronic conditions, prevalence of chronic symptoms, and smoking were adult risk factors that predicted the occurrence of what they defined as frailty (i.e., problems in two or more of the following domains—physical functioning, nutritional status, cognition, sensation).

Although we have no direct evidence linking early life factors and frailty, suggestive data are becoming available. Muscle weakness typically is included as one of its characteristics. Grip strength is often used in epidemiological studies to measure this attribute. The Medical Research Council National Survey of Health and Development found a positive relationship between birth weight and grip strength at the age of 53 (Kuh *et al.*, 2002). The Hertfordshire cohort study found that grip strength in the mid-60s was significantly associated with birth weight (Sayer *et al.*, 2004). A suggested mechanism for the association is that birth weight is related to the number of muscle fibers at birth. Because of the loss of muscle fibers with aging, a deficit in the number at birth could predispose an individual to sarcopenia later in life.

Other early life factors that may be associated with the development of late-life frailty include exposure to infections and chronic stress. The induction of chronic inflammation might explain the relationship between early-life infections and late-life morbidity and mortality. The reduction in lifetime exposure to infectious diseases and other sources of inflammation may be contributing to the decline we've seen throughout the developed world in late-life mortality (Finch *et al.*, 2004). As noted previously, activation of the immune system may play a role in the etiology of frailty. An interesting and potentially testable hypothesis is whether lifetime exposure to infectious diseases influences the incidence of frailty. A recent study found that chronic cytomegalovirus infection was associated with the presence of frailty (Schmaltz *et al.*, 2005). High IL-6 levels increased the strength of the association.

Challenging social conditions (e.g., having a relatively lower social standing) over the life course can be

associated with chronic stress and increased susceptibility to various disease states (Brunner, 1997). When survivors of the Whitehall Study were resurveyed after a 29-year gap, men in clerical or manual jobs at middle age were four times more likely to report poor physical performance than senior administrators (Breeze *et al.*, 2001). It was estimated that at most 20% of this could be explained by baseline differences in cardio-respiratory disease and risk factors. Chronic stress has been shown to be associated with a variety of biological effects including increases in IL-6 levels (Kiecolt-Glaser *et al.*, 2003) and accelerated telomere shortening (Epel *et al.*, 2004).

**PROPOSED MODEL**

Figure 50.1 presents a descriptive model based on a life course approach for the development of frailty.

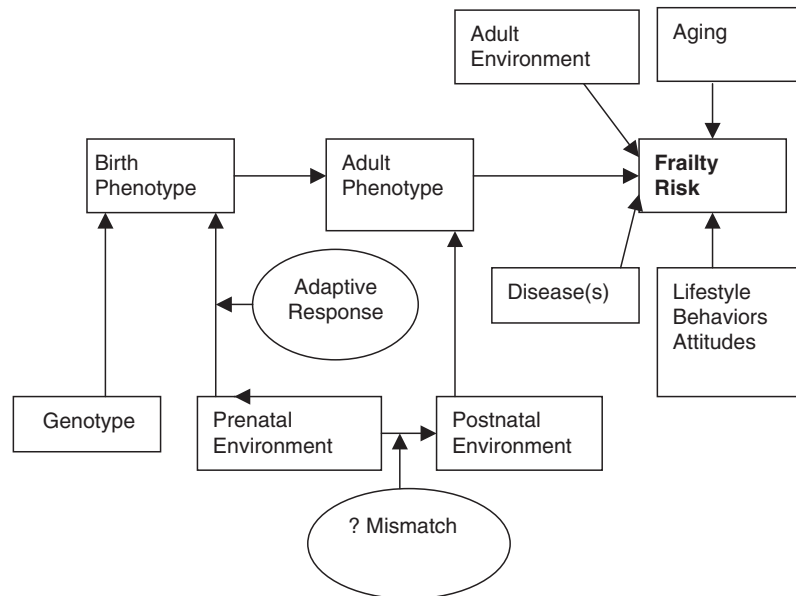

Genotype and prenatal environment will determine the birth phenotype. The specific nature of the prenatal environmental could lead to development plasticity, predictive adaptive responses, and developmental disruption (Gluckman *et al.*, 2004). When there is a mismatch between the prenatal and the predicted postnatal environment (e.g., predicted postnatal food restriction versus abundant postnatal food availability), the risk of problems down the road might be increased. After maturity is reached, aging, the physical and social environment, coping strategies, affect, lifestyle/behavioral choices, and the presence of disease(s) can contribute to the onset of frailty in the aged individual. In this model disability and healthcare utilization would be a consequence of frailty and modified by the relative assets and deficits of the individual. Although more complex, I think a life course

approach will be required to comprehensively understand this entity.

**Definition**

**CORE FEATURES**

There is agreement that frailty is a syndrome encountered in older individuals that is marked by increased vulnerability to a number of adverse outcomes. Other hallmarks are the presence of multisystem impairment (see preceding section) and the concept of a gradient. Although vulnerability is present to a degree in all of us, frailty is marked by a greater than normal susceptibility. In studies we will likely continue to treat frailty as either a dichotomous value (frail/ not frail) or categorize it on a short ordinal frailty scale (e.g., not present, mild, moderate, and severe frailty) in order to make the data easier to manage and understand. There is likely a diverse mix of predisposing, precipitating, enabling, and reinforcing factors (see Table 50.1). It is hoped that a characteristic clustering of characteristics will allow for its accurate identification (see Table 50.2). The consequences of frailty in a given individual will depend on their particular balance of assets and deficits (see Table 50.3). The physical and social environment of the older person coupled with how they cope with their limitations will be modifiers of outcomes. As can be seen, there is some overlap between Tables 50.1 and 50.2 as well as between Tables 50.2 and 50.3. This arises because of our current uncertainty about the pathogenesis, manifestations, and consequences of frailty. Ultimately there should be a clear distinction between the three.

**Figure 50.1** Life course model for frailty.

## 50. Models, Definitions, and Criteria of Frailty

TABLE 50.1  
Candidate predisposing, precipitating, enabling, and reinforcing factors

Community-based services
Physician visits
Access to care
Insurance coverage
Use of medical devices

#### RELATIONSHIP WITH DISABILITY AND DISEASES

Frailty was used initially as another term for disability (Hogan *et al.*, 2003). Although frailty has been disentangled from ADL disability (Fried *et al.*, 2004), there is considerable overlap between frailty and both instrumental ADL (IADL) limitations and mobility disability (Fried *et al.*, 2001). In the Cardiovascular Heart Study (CHS), 27.4% of those categorized as frail had an ADL, 59.7% had an IADL, and 71.7% had a mobility disability (Fried *et al.*, 2001). To further complicate the relationship, disability can be an outcome of frailty. If frailty is the cause of disability for an individual (Albert *et al.*, 2002), frailty doesn't disappear with the onset of the disability.

Diseases alone (e.g., subclinical cardiovascular disease (Newman *et al.*, 2001), chronic renal insufficiency (Shiplak *et al.*, 2004), or in combination (i.e., comorbidity)) are associated with frailty. In the CHS study, only 7.3% of frail subjects had no chronic disease compared to 23.2% in those who were not frail (Fried *et al.*, 2001). Sixty-eight percent of frail individuals had two or more chronic conditions compared to 40% in the not frail group (Fried *et al.*, 2001). It should be noted, though, that it was a small proportion of those with comorbidities (10.5%) who were also frail (Fried *et al.*, 2001). Nearly all frail individuals will have at least one chronic condition, and most will have two or more. The presence of comorbidities, though, is not specific for frailty.

#### Criteria

##### IDENTIFICATION OF FRAIL OLDER INDIVIDUALS

Over 30 criteria have been proposed for identifying frail older individuals (Hogan *et al.*, 2003). The set that has attracted the most interest is the one developed by Dr. Linda Fried and her colleagues (Fried *et al.*, 2004). They categorized older individuals as being frail if they have three or more of the following five characteristics: diminished grip strength (compared to peers); complaints of fatigue/exhaustion; limited physical activity (compared to peers); slow gait (compared to peers); and unintentional weight loss. In a validation study, both those who were frail by these criteria and those who were intermediate (presence of one or two of the characteristics) had worse outcomes than nonfrail subjects (those with none) (Fried *et al.*, 2001).

##### UNSETTLED QUESTIONS

Although an important step forward, there are questions about these criteria. First, were the components selected essential to the recognition of frailty? They are not specific for frailty. A number of chronic diseases can have similar manifestations. Chronic Obstructive Pulmonary Disease, for example, is associated with diminished grip strength (Rantanen *et al.*, 1998), complaints of fatigue (Walke *et al.*, 2004), limited physical activity (Garcoa-Aymerich *et al.*, 2004), slow gait speed (Butcher *et al.*, 2004), and weight loss (Schols, 2000). Fried and her colleagues recognized the nonspecific nature of their criteria. In their validation study, they excluded individuals with significant cognitive impairment/Alzheimer's disease, depression, and Parkinson's disease as "these conditions could potentially present with frailty characteristics as a consequence of a single disease" (Fried *et al.*, 2001). The late Pope John Paul II, because of his Parkinson's disease, would not have been considered frail in this study. In their subsequent writings they have suggested secondary frailty due to diseases as a subtype of frailty (see Table 50.4). Primary frailty, from their perspective, would arise from aging-associated processes such as changes in gene expression, oxidative DNA damage, and telomere shortening (Walston, 2004). They theorize that there is substantial interaction between primary and secondary mechanisms in the development of frailty. Of the five characteristics proposed by Fried and her colleagues, weight loss seems the most problematic. Frailty is not necessarily a wasting condition. Obese seniors appear to have a high prevalence of frailty (Villareal *et al.*, 2004). The combination of sarcopenia and obesity (the sedentary obese) delineate a group at particularly high risk for functional decline (Pierson, 2003).

The second major question deals with what was not included as a component. It is debatable that the Fried criteria captured all the essential clinical characteristics of frailty. Cognition, depressive symptoms, psychological

## 50. Models, Definitions, and Criteria of Frailty

TABLE 50.4  
Subtypes of frailty (listed alphabetically)

---

Cognitive: The presence of demonstrable cognitive decline or being at risk for significant cognitive deterioration; it is the opposite of <i>cognitive vitality</i> (Fillit <i>et al.</i> , 2002).
Dynamic and Static: Dynamic frailty would be a significant worsening over time on one or more preselected marker(s) of frailty; static frailty occurs when subjects are found to be in the lowest quintile, at a point in time, on preselected frailty markers; dynamic frailty requires longitudinal data collection, whereas static frailty is based on cross-sectional data (Puts <i>et al.</i> , 2005).
Global and Intrinsic: Global frailty includes <i>intrinsic frailty</i> (see following) and <i>consequences</i> (i.e., changes in functional independence, social roles, psychosocial factors, and healthcare utilization) (Studenski <i>et al.</i> , 2004). Intrinsic is defined as “physiologically based organ system impairments and physical performance limitations, such as losses of strength, endurance, balance, body weight, and mobility” (Studenski <i>et al.</i> , 2004).
Physical: Defined as impairments in the physical abilities needed to live independently (Hogan <i>et al.</i> , 2003). Described as “a final common pathway, in which the effect of disease, disuse, and aging across organ systems contribute to further decline and adverse events or states” (Studenski <i>et al.</i> , 2004); operational criteria used to identify subjects with physical frailty range from looking at a single attribute (e.g., slow gait speed) (Hardy <i>et al.</i> , 2004) to utilizing a battery (e.g., manifesting 2+ of low-peak aerobic power, self-reported difficulty, or need for assistance with two instrumental activities of daily living or one basic activity of daily living, and modified Physical Performance Test score of 18 to 22) (Villareal <i>et al.</i> , 2001).
Physiologic: Incorporates the concepts of age-associated declines in physiological systems/reduced physiologic reserve and vulnerability (Farquharson <i>et al.</i> , 2001; Hawkes <i>et al.</i> , 1998; Katz <i>et al.</i> , 1994).
Primary and Secondary: Primary causes of frailty would be age-related mechanisms (e.g., changes in gene expression, oxidative DNA damage, telomere shortening) and secondary causes would be diseases (e.g., congestive heart failure, depression, hypothyroidism, malignancy) (Fried <i>et al.</i> , 2004; Walston, 2004).
Psychosocial: Equated to the presence of depressive symptoms; de Jonge wrote that “Subjects experiencing depressive symptoms before the onset of a somatic event may have fewer resources to deal with a stressful event . . . Depressive symptoms reported before by elderly people may thus signal psychosocial frailty” (de Jonge <i>et al.</i> , 2004); Katz elaborated upon this and stated that “(late-life) depression is a state associated with cognitive dysfunctions that interfere with coping, adaptation, and resilience” (Katz, 2004).

---

attributes (e.g., positive affect; Ostir *et al.* (2004)) and others are also candidate criteria (see Table 50.2). The origin of the factors included by Fried was a survey of like-minded individuals—academic geriatricians (Fried *et al.*, 2004). A more diverse group would have added other perspectives (Surowiecki, 2004). For example, older patients and their caregivers, when considering frailty, prioritized emotional and social factors higher than clinicians (Studenski *et al.*, 2004). Excluding cognitive and psychological attributes in the definition of frailty has been justified by stating that the inquiry is limited to “physical” frailty (see Table 50.4) (Hogan *et al.*, 2003; Studenski *et al.*, 2004; Hardy *et al.*, 2004; Villareal *et al.*, 2001; Gill *et al.*, 2002; Hadley *et al.*, 1993). The wisdom of proposing a Cartesian mind–body dualism is debatable. For example, predisposing or enabling factors underpinning physical frailty may also be associated with impaired cognition. Chronic inflammation is felt to play a central role in the pathogenesis of frailty, and increased inflammatory proteins have been found to be associated with an increased risk of developing dementia (Englehart *et al.*, 2004). A correlation between cognitive processing speed and physical performance measures has been shown (Binder *et al.*, 1999). A brief instrument for the identification of frailty, the Frailty Scale (that predicted

both mortality and institutionalization), included cognition as an essential feature (Rockwood *et al.*, 1999). There are data linking depressive features and subsequent physical functioning. Depressive symptoms at baseline predicted a decline in physical performance measures (standing balance, walking speed, chair rises) in four years time (Pennix *et al.*, 1998). Compared to nondepressed individuals and those with transient symptoms, older subjects with persistent depressive symptoms were at an increased risk for a worsening of their functional abilities (Lenze *et al.*, 2005). Other instruments proposed for the identification of frailty, such as the Groningen Frailty Indicator (Schuurmans *et al.*, 2004), include cognition and affect as core characteristics.

### FUTURE DIRECTIONS

The various criteria proposed for frailty should be examined and compared. Do they describe the same group of individuals? The answer is, “probably not.” How do they compare in predicting the outcomes associated with aging? Can their components be linked to a common pathogenesis? The respective validity, reliability, sensitivity to change, and practicality of the available criteria should be examined and contrasted. I suspect we will move away from clinical characteristics to the use of

biomarkers (alone or in combination with clinical features) in identifying frail older individuals.

The challenges in establishing criteria for frailty are analogous to those faced in establishing the diagnostic criteria for the metabolic syndrome (also known as syndrome X, the dysmetabolic syndrome, the insulin resistance syndrome, and the deadly quartet). This is a cluster of abnormalities (glucose intolerance, obesity, hypertension, dyslipidemia) that are well-documented risk factors for cardiovascular disease in themselves (Eckel *et al.*, 2005). The grouping of certain characteristics known to independently predict adverse outcomes can be justified only if they are synergistic in their effect or have a common etiology (Domanski *et al.*, 2004). This appears to be the case in the metabolic syndrome. Whether a similar synergistic effect on outcomes will be seen with the components of frailty requires confirmation.

## Conclusion

There is potential harm in labeling an older person as frail. Although it is a term frequently used *about* seniors, it is rarely used *by* them when discussing their status. Labeling a person can adversely change how they view themselves and how others view them. Studies have shown that priming older individuals with stereotypes can influence decision-making about life-prolonging interventions (Levy *et al.*, 1999–2000), performance on memory testing (Levy, 1996), and gait speed (Hausdorff *et al.*, 1999). An examination of the underinvestigation and undertreatment of cancer in old age concluded that it could not be wholly explained by appropriate adjustments for the condition of individual patients (Turner *et al.*, 1999). The adjective “frail” was often used to describe older patients, but it was not clearly defined. Older patients must not be inappropriately denied (or prescribed) interventions on the basis of a specious diagnostic label.

Frailty is both one of the more exciting and frustrating research areas in clinical gerontology. What leads to it, how best to recognize frailty, and ultimately what we can do to prevent or treat it are uncertain. To date there has been a “Blind Men and the Elephant” quality to frailty research. In order to achieve clarity on frailty, a concerted effort to integrate concepts and disciplines will be required. Otherwise as John Godfrey Saxe wrote, we’ll

Rail on in utter ignorance  
Of what each other mean,  
And prate about an Elephant  
Not one of them has seen!

# Fertility and Aging Men: An Introduction to the Male Biological Clock

Puneet Masson, Sarah M. Lambert, Peter N. Schlegel, and Harry Fisch

*Data obtained in the past decade suggested a worldwide decline in male fertility. The increase in paternal age is both a personal problem for couples and a public health problem because of the simple fact that male fertility declines with age. Journal articles by Kidd and Ford demonstrate that men over the age of 35 are twice as likely to be infertile as men younger than 25. In addition, a study of couples undergoing fertility treatments found that the amount of time it takes for a man to achieve a pregnancy rises significantly with age.*

*The levels of sex hormones in men decline with age. The roughly 1% per year decline in testosterone levels after age 30 has been termed andropause, or “symptomatic hypogonadism in the aging male.” Rhoden and Morgentaler estimate that between 2 and 4 million men in the United States alone suffer from hypogonadism, but only 5% of men are getting treatment for their symptoms.*

*Although increasing maternal age has long been known to be associated with an increased incidence of birth defects, new data show that the age of the male does matter and the genetic quality of sperm does decline with age. Several studies have demonstrated that older men are at higher risk of fathering a child with various genetic diseases such as schizophrenia and Down Syndrome, to name a few. Additionally, there has been an increased risk of miscarriage with increasing paternal age.*

*This review discusses the relationship between advanced paternal age and male infertility. Continuing this dialogue will improve the sexual and reproductive health of aging males.*

## Introduction

Say “biological clock,” and most people immediately think, “women.” Female fertility, after all, “strikes midnight” with the cessation of menses. This occurs in association with distinct—and dramatic—declines in estrogen production. And as women age, the genetic quality of their eggs declines and the subsequent increased proportion of genetically damaged embryos leads to an increased risk of genetic problems in their offspring.

This triad of declining fertility, declining hormone levels, and increasing risk for genetic problems is what most people mean when they say “biological clock.”

Until recently, that is. Although it is an idea that has not yet filtered down to the general public, we now know that men have biological clocks, too. And those clocks involve the same physiological triad experienced by women. Male fertility and male sex hormones *do* decline with age. And the genetic quality of sperm *does* decline, leading to an increased risk of genetic problems in offspring above and beyond any contributed by the female. The object of this review is to describe these features of male aging and, hence, to expand the notion of the “biological clock” to include *both* sexes.

## Conceptions of Fertility

It is a well-established fact that a reduction in fertility status happens with increasing age. In women, we recognize that a decline in oocyte production occurs in their late 30s to early 40s. Men, on the contrary, can continue to father children well beyond their 40s, and to date there is no significant limit with respect to spermatogenesis. As paternal age continues to increase, many investigators have explored the effect of age on seminal parameters with the central question: Is advanced paternal age associated with diminished semen quality and a higher risk of infertility?

In a mouse model, studies have demonstrated that aging is correlated with histologic changes in testes and a decline in semen quality. Tanemura *et al.* (1993) demonstrated that older mice (at the age of 18 months) have several age-related changes, including an increased number of vacuoles in germ cells and a thinner seminiferous epithelium. By the age of 30 months, extremely thin seminiferous epithelia with very few spermatocytes or spermatids were found. In another study, Wang *et al.* (1993) found that total sperm production was significantly reduced in 22- and 30-month-old rats. Further studies also documented an increased incidence of preimplantation losses, mutation frequencies, and aneuploidy in the offspring

of older male mice (Serre *et al.*, 1998; Walter *et al.*, 1998; Lowe *et al.*, 1995).

With the abundant evidence on the association between aging and male infertility in mice, the appropriate question is whether such a correlation exists in men. A comprehensive review by Kidd *et al.* (2001) evaluated the effects of male aging on semen quality in men; they looked at all studies in published literature between January 1 1980 and December 31 1999, and examined the outcome parameters of semen volume, sperm concentration, sperm motility, sperm morphology, pregnancy rate, and time to pregnancy/subfecundity (Kidd *et al.*, 2001).

The overall consensus in the stated literature demonstrated a decrease in semen volume with increasing age. There have been 16 major studies examining semen volume with respect to advanced age. Though individual studies have varied with respect to the setting in which they were conducted (i.e., infertility clinics versus sperm banks), Kidd's meta-analysis of the results provides a comprehensive overview of the effect of male age on seminal parameters. Out of the 16 studies analyzed, 11 reported decreases in semen quality with increasing age. Two of these studies adjusted for the confounder of duration of abstinence and found that a statistically significant correlation still exists between decreasing semen volume and increasing age; they reported decreases of 0.15 to 0.5% for each increase in year of age (Fisch *et al.*, 1996; Andolz *et al.*, 1999). The duration of abstinence has been correlated with semen volume in a time-dependent fashion (Mortimer *et al.*, 1982). Out of four studies showing no association between age and semen volume, only one study adjusted for duration of abstinence, and this study had a maximum patient age of 50 years (Schwartz *et al.*, 1983). One study reported a slight increase (0.01mL/year) in semen volume with increasing age; however, this effect disappeared when adjusted for year of birth. Therefore, there is abundant evidence linking decreased semen volume with increased age, which becomes more significant in men over 50 years of age. When comparing men under the age of 30 with men aged 50 or older, most of the studies document decreases of 20 to 30% in semen volume between the two groups (Kidd *et al.*, 2001). The correlation between advanced paternal age and semen volume suggests that age contributes to a decline in semen quality necessary for fertilization.

Unlike semen volume, the relationship between increasing age and sperm concentration was found to be inconclusive. Kidd *et al.* (2001) reviewed 21 studies examining the association between age and decreased sperm concentration and found no clear relationship between these parameters. Five studies documented decreasing sperm concentration with increasing age. However, only one study controlled for abstinence and year of birth as potential confounders; this study found a decrease in sperm concentration of 3.3% per year of age

and also a 66% decrease in concentration from age 30 to 50 (Auger *et al.*, 1995). Six studies found little or no association between age and sperm concentration, and none of these studies adjusted for duration of abstinence. Eight studies documented that with increasing age, sperm concentration had linear increases from 0.03 to 3.3% per year of age. Only two of these studies adjusted for duration of abstinence as a confounder and, interestingly enough, the increase in sperm concentration per year of age was found to be minimal (Fisch *et al.*, 1996; Andolz *et al.*, 1999). Based on the review by Kidd *et al.* there is substantial inconsistency among the studies exploring the relationship between sperm concentration and age. Even the results of the studies adjusting for duration of infertility are conflicting, suggesting that there is no clear association between sperm concentration and increasing paternal age.

Sperm motility, on the other hand, was found to be strongly linked to age as a substantial decline in sperm motility went hand-in-hand with increasing age. Kidd *et al.* (2001) reviewed 19 studies examining the relationship between the percentage of motile sperm and age; the majority of these studies (17/19) used visual assessment of sperm motility by light microscopy. Thirteen of the 19 studies found a decrease in sperm motility with increasing age; five of these studies adjusted for duration of abstinence, and the observed changes were statistically significant (Fisch *et al.*, 1996; Rolf *et al.*, 1996; Schwartz *et al.*, 1983; Auger *et al.*, 1995; Henkel *et al.*, 1999). When these studies compared men age 50 or older to men under the age of 30, they reported a 3 to 37% decline in motility. Four studies reviewed by Kidd *et al.* found no association between age and sperm motility, and two studies reported a positive correlation; none of these studies adjusted for duration of infertility. Thus, the extensive body of evidence suggests that an inverse correlation exists between age and sperm motility: there is a decline in sperm motility with increasing male age.

Likewise, an adverse correlation exists between sperm morphology and age. Kidd *et al.* (2001) reviewed 14 studies examining the relationship between age and sperm morphology. There were nine studies documenting a decrease in the percent of normal sperm with increasing age, five of which were found to be statistically significant. Controlling for the potential confounders of duration of abstinence and year of birth, Auger *et al.* (1995) reported that the percent of normal sperm decreased by 0.9% per year of age, and Andolz *et al.* (1999) reported a decline of 0.2% per year of age. When studies utilized age as a categorical variable, there was an observable trend with increasing age group and decreasing percent normal sperm. Five studies found no association between percent normal sperm and age, and none of these studies were found to be statistically significant. Despite the variation among morphological criteria to assess sperm abnormalities, there was

a substantial amount of evidence linking increasing age to decreasing percent normal sperm.

The associations between increasing age and decreasing semen volume, sperm motility, and sperm morphology suggest that semen quality diminishes in the aging male. Whether age is analyzed as a continuous or categorical variable, the body of evidence suggests that a trend exists between increasing male age and decreasing semen quality based on these parameters. Aging in the human male results in degenerative changes to the prostate, such as a decrease in protein and water content (Schneider, 1978); these may contribute to the decrease in seminal volume and sperm motility. Additionally, age-related degenerative changes to the germinal epithelium can impact sperm morphology (Johnson, 1986). Though we recognize that advanced paternal age affects semen quality, it is necessary to study the impact of increasing age on fertility itself.

In his extensive analysis, Kidd *et al.* (2001) also studied the impact of increasing age on pregnancy rate, defined as the percent of male subjects whose partners achieved a pregnancy over a period of time, and subfecundity, defined as the percent of couples remaining infertile at a defined time point. Kidd *et al.* (2001) reviewed nine studies that examined the association between male age and pregnancy rate. The study population consisted of participants from infertility and assisted conception clinics. Seven of these studies reported a correlation between decreasing pregnancy rates and increasing age, and five of them reached statistical significance. However, four of the seven studies did not adjust for female age in the analysis, and female age is a well-established independent predictor of achieving pregnancy. Two of the studies that controlled for female partner age found that, after stratifying the study population into men under 30 and men over 50, the pregnancy rate in the cohort of older men was 23 to 38% lower (Rolf *et al.*, 1996; Mathieu *et al.*, 1995). One study did not find an effect of male age on pregnancy rates when female age was less than 35 years (Dondero *et al.*, 1985), and another study reported lower pregnancy rates for couples where the man was over 30 years compared to those where the man was under 30 (van der Westerlaken *et al.*, 1998); neither study determined the statistical significance of these differences. Overall, we see that there is an extensive amount of evidence linking increased paternal age and decreased pregnancy rate, with more substantial declines in men over the age of 50.

Kidd *et al.* (2001) also reviewed 11 studies evaluating the association between male age and subfecundity. Nine of these studies found that the time to pregnancy increases with male age, and four of the nine studies employed a proportional hazard analysis, which adjusted for varying lengths of observation before pregnancy was achieved. Seven of the nine studies reporting a direct correlation between paternal age and time to pregnancy reached statistical significance. In these studies,

the increased risks of subfecundity with older age groups ranged from 11 to 250%. Only one study by Mathieu *et al.* (1995) adjusted for duration of infertility and irregular ovulation; Mathieu *et al.* found that after stratifying men into cohorts of age 35 or greater and less than age 30, there was a 60% decrease in the chance of initiating a pregnancy for the older men. Since this study was conducted for couples undergoing intrauterine artificial insemination, female age was found to be a poor prognostic value in predicting risk of pregnancy. There were two studies that did not show an association between male age and time to pregnancy; neither of these studies showed statistically significant differences (Kidd *et al.*, 2001). Thus, the weight of the evidence suggests a strong correlation between paternal age and time required for a couple to achieve pregnancy.

A landmark study by Ford *et al.* (2000) explored the effect of paternal age on the likelihood of delayed conception. With a study population of 8515 planned pregnancies, the study found that older men were significantly less likely to impregnate their partners in less than six or less than 12 months, compared to their younger counterparts. After adjusting for various confounding factors such as age of the female partner, BMI, smoking, passive smoke exposure, education, duration of cohabitation, duration of oral contraceptive use, and paternal alcohol consumption, paternal age still remained highly significantly associated with conception within six or 12 months. If paternal age was treated as a continuous variable, there was a statistically significant linear relationship; the odds ratio for conception within six months decreased by 2% per year of age, and for conception within 12 months decreased by 3% per year of age. After comparing their study with the existent literature, Ford *et al.* concluded that the probability that a fertile couple will take greater than 12 months to conceive nearly doubles from approximately 8% when a man is less than 25 years old to approximately 15% when he is greater than age 35.

Kidd's review and Ford's study include a vast body of articles with variable evaluations and diverse patient populations. Additionally, the studies also vary in their adjustment of potential confounders as well as age-group stratifications. For these reasons, there can be no single conclusion about the linearity of the relationship between male age and semen parameters and/or fertility. Nevertheless, advanced paternal age is associated with a decline in semen quality and fertility status. As paternal age continues to increase in industrialist societies, it is worthwhile to continue engaging in a dialogue about the risks of infertility associated with a population of aging potential fathers.

### Testosterone Decline

As with women, the levels of sex hormones in men decline with age (Harman *et al.*, 2001). The drop is not as steep

or as sudden as that associated with menopause, but it can be equally significant for fertility and overall well-being. Recently, there has been a lot of interest in declining testosterone levels in men. The roughly 1% per year decline in testosterone levels after age 30 has been termed andropause and is associated with a plethora of congenital and acquired disease-syndromes (McLachlan, 2000).

Previous longitudinal studies have demonstrated that abnormally low testosterone levels are present in elderly men (Sparrow *et al.*, 1980; Harman *et al.*, 2001; Feldman *et al.*, 2002). Several large-scale studies in healthy, fertile men have evaluated mean values for serum testosterone (Ferrini *et al.*, 1998). Additionally, there have been numerous cross-sectional investigations documenting lower concentrations of total testosterone and/or free testosterone in older men (Vermeulen *et al.*, 1972; Gray *et al.*, 1991). Most recently, the Massachusetts Male Aging Study, a large population-based random-sample cohort, reported that in a cohort of 1,709 healthy men aged 40 to 70 with a mean age of 55.2 years, the mean total testosterone value was 520 ng/mL. In follow-up data approximately a decade later, another cohort of 1,156 healthy men with a mean age of 62.7 years had a mean total testosterone value of 450 ng/mL (Feldman *et al.*, 2002). This is a decline in testosterone in the same population of men sampled approximately 10 years later. Feldman *et al.* quantified the decreasing testosterone levels as a cross-sectional decline of 0.8%/year of age and a longitudinal decline of 1.6%/year within the follow-up data. Other aging studies also have reported a longitudinal decline in serum testosterone (Rodriguez-Rigau *et al.*, 1978; Morley *et al.*, 1997). Additionally, Feldman *et al.* reported that the rate of decline was the same in apparently healthy men as well as men reporting a chronic illness, obesity, alcoholism, prescription medication, or prostate problems.

The decline in testosterone with age puts a greater number of elderly men at risk for developing hypogonadism. Rhoden and Morgentaler estimated that between two and four million men in the United States alone suffer from hypogonadism (defined as serum total testosterone levels lower than 325 ng per deciliter) (Rhoden *et al.*, 2004). More alarmingly though, the same study reported that only 5% of these men are getting treatment for their symptoms, which include decreased libido and erectile dysfunction, loss of muscle mass and strength, weight gain, and declining cognitive function. Hypogonadism is also associated with type II diabetes, musculoskeletal frailty, cardiovascular disease, and the metabolic syndrome.

Because of the increasing prevalence of abnormally low levels of testosterone in elderly men, it is worthwhile to assess the relationship between hypogonadism and aging. The Baltimore Longitudinal Study on Aging, a large-scale study measuring total and free testosterone levels in 890 healthy men without any reported fertility

or varicocele complications, found that using total testosterone, the frequency of detection of hypogonadal testosterone levels increased to about 20% of men over 60, 30% over 70, and 50% over 80 years of age (Harman *et al.*, 2001). The study also found that 78% of men identified as hypogonadal by a single testosterone determination had low total testosterone levels on all subsequent samples. Additionally, a multivariate analysis confirmed that age is an independent predictor of a longitudinal decline in both total and free testosterone. Testosterone also decreased with increasing body mass index (BMI), independent of age.

To rectify the increased prevalence of hypogonadism in the aging male, treatments such as exogenous testosterone replacement and stimulation of endogenous testosterone production are gaining tremendous popularity. Sales of prescription testosterone products have soared more than 500% since 1993 and continue to increase (Bhasin *et al.*, 2001). This enormous increase is not without risks; indiscriminate use of testosterone supplements can raise the risk of prostate problems, blood disorders, and infertility.

It has been established that there is a natural decline in serum testosterone as a process of aging; however, it demands to be explored if there are subsets of men with lower serum testosterone levels at an earlier age. Varicoceles are a well-established condition causing infertility. Varicoceles affect sperm function, and several studies suggest that they may contribute to testicular dysfunction and induce a subhypogonadal or hypogonadal state. Animal experiments have demonstrated an association between varicoceles and decreased serum testosterone biosynthesis (Rodriguez-Rigau *et al.*, 1978). However, such studies in humans have not shown as strong an association. Gorelick and Goldstein reported that infertile males with varicoceles have a mean serum testosterone level that is within the limits of normal (Gorelick *et al.*, 2000). Yet, Younes (2000) reported that mean serum testosterone was substantially decreased in male infertility patients with varicoceles compared to controls. Though there have been several further studies examining the testosterone profile of infertile men with varicoceles, results continue to be conflicting (Nagao *et al.*, 1986; Comhaire *et al.*, 1975).

At Columbia University Medical Center, we retrospectively reviewed testosterone levels of 237 men presenting with male factor infertility and clinical varicoceles between 1994 and 2004 who underwent varicocelectomy. For the entire cohort of men, the median age was 36.0 years, and the average testosterone level was 389.7 ng/mL. Out of our sample, 30.3% (72/237) patients were found to be hypogonadal (testosterone < 300 ng/mL). When stratified into groups, the student's *t* test of independent samples showed that infertile men with varicoceles under the age of 30 had a mean testosterone level of 420.3 ng/mL and those age 50 or older had mean testosterone level of 342.1 ng/mL ( $p = 0.05$ ); men between

the ages of 30 and 49 had a mean testosterone level of 389.2 ng/mL (Shah *et al.*, 2005). This is the largest study to date reporting the testosterone profile of infertile men with varicoceles. Infertile men with varicoceles have a much lower serum testosterone level than was previously anticipated, with almost one-third being hypogonadal. With increasing age, we found a trend indicating that older men have even lower testosterone levels than younger men. A similar study by Su *et al.* (1995) confirmed this trend and demonstrated that correction of the varicocele can improve testosterone levels for infertile men with varicoceles.

The lower testosterone levels observed in older men compared to younger men in our study population may implicate progressive local damage of the varicocele on testicular function. Previous studies suggest that various mechanisms may account for the testicular dysfunction associated with varicoceles (Howards, 1995). Both intrascrotal and intratesticular temperatures are higher in men with varicoceles compared to controls (Zorgniotti *et al.*, 1979). However, not all investigators have found an association between higher intratesticular temperatures and varicoceles (Tessler *et al.*, 1966). As a result, nonthermal mechanisms have been suggested to account for the effect of a varicocele on testicular function; reflux of renal and adrenal metabolites from the renal vein, decreased blood flow, and hypoxia have all been postulated, and there is substantial evidence that smoking augments varicocele-induced testicular dysfunction (Comhaire *et al.*, 1974; Saypol *et al.*, 1981; Chakraborty *et al.*, 1985; Klaiber *et al.*, 1987). It is now accepted that infertility in the varicocele patient may be multifactorial, and the associated testicular dysfunction appears to worsen with age. Our data suggests this as well. Chehval and Purcell reported that varicoceles have a progressive effect on semen quality, which has also been reported by other studies (Chehval *et al.*, 1992). Though there is abundant evidence that varicoceles are associated with lower semen quality over time, there is limited data available discussing the progressive effect that clinical varicoceles have on testosterone status. For this reason, further studies need to explore this trend as it may lead to hypogonadism in a substantial population of men. Additionally, it is worthwhile to investigate whether repair of the varicocele can improve testosterone levels in these hypogonadal men.

### Advanced Paternal Age and Reproductive Capacity

Population studies within the United States reveal a significant increase in paternal age, with many couples postponing childbearing until their mid-30s to mid-40s. According to the CDC birth statistics, the average maternal age in 2003 was 25.1, which represents an increase from the average maternal age of 21.4 years

in 1974. A trend toward advanced parental age is simultaneously occurring in American men. The birth rate among men 25 to 44 years has been steadily increasing since the 1970s, whereas the birth rate of men less than 25 years has been decreasing (Hamilton *et al.*, 2003). An improved understanding of the effects of increased parental age on the developing fetus and newborn is imperative for counseling older couples preparing for childbearing. Advanced paternal age has been suggested to result in increased spontaneous abortions, autosomal dominant disorders, trisomy 21, and recently, schizophrenia.

Women aged 35 years or greater are at higher risk than younger women for adverse reproductive events including infertility, abortion, congenital abnormalities, and perinatal mortality. Paternal age often correlates with maternal age and can confound the effects of advanced maternal age. The first connection between spontaneous abortion and paternal age was raised during an analysis of fetal death certificates in 1939 (Yershalmy, 1939). Recent data confirms the association between advanced paternal age and the risk of spontaneous abortion. A prospective study of 5,121 American women revealed that the risk of spontaneous abortion increased with advanced paternal age (Slama *et al.*, 2005). A prospective analysis of 23,821 women from the Danish National Birth Cohort further demonstrated that pregnancies fathered by men 50 years or older had almost twice the risk of spontaneous abortion when compared with pregnancies with younger fathers after adjustment for maternal age, reproductive history, and maternal lifestyle during pregnancy (Nybo Andersen *et al.*, 2004). Although the correlation between advanced paternal age and spontaneous abortion is well demonstrated, there remains debate within the current literature regarding which trimester is at greatest risk with advanced paternal age. De La Rochebrochard and colleagues (2002) utilized the unique single variable "couple age" to elucidate the interaction between maternal and paternal age and the risk of spontaneous abortion. The retrospective data collected from this multicenter European study revealed that the effects of advanced paternal age and maternal age are cumulative; the risk of spontaneous abortion is highest if both partners are advanced in age. It is theorized that this increased risk of spontaneous abortions associated with advanced maternal or paternal age reflects chromosomal abnormalities in the developing fetus.

In this regard, advanced parental age is a recognized risk factor for many genetic abnormalities in the developing newborn. In men, advancing age decreases semen volume, percent normal sperm, and sperm motility (Rolf *et al.*, 1996). Though these factors adversely affect fertility, the genetic integrity of the sperm is also at risk. In contrast to oogenesis, spermatozoa are continuously produced and undergo lifelong replication, meiosis, and spermatogenesis (Evans, 1996). This continued replication allows for spontaneous mutations within the paternal

cell line. Apoptosis of sperm with damaged DNA is an essential aspect of spermatogenesis that ensures selection of normal sperm DNA (Roosen-Runge, 1973). As men age, the rate of genetic abnormalities that occur during spermatogenesis increases. Investigation of advanced paternal age in the murine model reveals age-dependent effects on the meiotic and premeiotic phase of sperm development. These abnormalities in replication result in both aneuploidy and structural abnormalities in male germ cells (Lowe *et al.*, 1995). Additionally, the frequency of these numerical and structural aberrations in sperm chromosomes increases with increasing paternal age in humans (Sartorelli *et al.*, 2001). This age-related increase in sperm cells with highly damaged DNA results from both increased double-strand DNA breaks and decreased apoptosis during spermatogenesis (Singh *et al.*, 2003).

As a result, advanced paternal age is associated with many autosomal dominant disorders such as Apert syndrome, achondroplasia, osteogenesis imperfecta, progeria, Marfan syndrome, Waardenburg's syndrome, and thanatophoric dysplasia (Lian *et al.*, 1986). Apert syndrome results from an autosomal dominant mutation on chromosome 10, mutating the fibroblast growth factor receptor 2 (FGFR2). The incidence of sporadic Apert syndrome increases exponentially with paternal age, resulting in part from an increased frequency of FGFR2 mutations in the sperm of older men (Glaser *et al.*, 2003). Achondroplasia results from an autosomal dominant mutation on FGFR-3. Data from clinical achondroplasia registries reveal that 50% of affected children were born to men 35 years or older. In addition, the rate of achondroplasia increased exponentially with increasing paternal age (Orioli *et al.*, 2004). The Muenke-type craniosynostosis results from an autosomal dominant mutation in FGFR-3 resulting entirely from the paternal allele. The average paternal age of children with Muenke-type craniosynostosis has been reported as 34.7 years (Rannan-Eliya *et al.*, 2004). Therefore, men as young as 35 years are at higher risk for many autosomal dominant disorders, most notably costochondrodysplasias.

In addition to structural errors and resultant autosomal dominant disorders, aneuploidy errors in germ cell lines also occur at higher rates with advanced parental age. Trisomy 21 or Down syndrome is a common aneuploidy error that affects 1/800 to 1000 newborns (Cunningham *et al.*, 2001). The association of advanced maternal age and trisomy 21 was first documented as early as 1933 (Fisch *et al.*, 2001). Further amniocentesis data from the European collaborative study of Ferguson-Smith and Yates determined that the rate of trisomy 21 increases exponentially from a maternal age of 35 years (Ferguson-Smith *et al.*, 1984). Although the correlation between trisomy 21 and advanced maternal age is well documented, it is only recently that the

effects of advanced paternal age have been elucidated. Investigation of the meiotic nondisjunctional error in trisomy 21 reveals the origin of the extra chromosome 21 to be paternal in 5 to 20% of cases (Antonarakis, 1991; Jyothy *et al.*, 2001). Despite this recognized paternal origin, to our knowledge no chromosomal studies evaluating parental origin of chromosomal defects in offspring and paternal age are available.

Early studies from the 1970s and 1980s failed to demonstrate a consistent effect related to advanced paternal age. Initial epidemiological studies utilizing city and state birth registries failed to show any correlation between trisomy 21 and advanced paternal age while confirming the effect of advanced maternal age (Erickson, 1978; Hook, 1987). In contrast, an evaluation of the Medical Birth Registry of Norway from 1967 to 1978 that included 685,000 total births and 693 cases of Down syndrome revealed an increased risk of Down syndrome with a paternal age of 50 years or greater (Erickson *et al.*, 1981). As parental age is increasing in the United States, recent studies provide more men of advanced age to evaluate. The New York State Department of Health congenital malformations registry containing 3,419 trisomy 21 births was analyzed from 1983 to 1997 and demonstrated a 111% and 60% increase in women and men over 35 years, respectively. This contemporary evaluation revealed no effect of parental age on trisomy 21 until 35 years. A paternal age effect was apparent in association with a maternal age of 35 years or greater and was most pronounced when maternal age was 40 years or greater. The rate of Down syndrome with a combined parental age greater than 40 years was 60/10,000 births that represents a six-fold increase compared with parents less than 35 years (Fisch *et al.*, 2003). Advanced paternal age in interaction with advanced maternal age significantly increases the risk of trisomy 21 and may possibly explain the exponential increase in trisomy 21 in women greater than 35 years.

In contrast to the effects of combined parental age in trisomy 21, schizophrenia is associated with spontaneous mutations arising in the paternal germ cells. Although schizophrenia is a complex disease of unclear etiology, there is substantial evidence for a genetic component (Kendler *et al.*, 1993). Since most individuals with schizophrenia are born to unaffected parents and have reduced reproductive activity, it is unclear how the disease is maintained within the population (Fananas *et al.*, 1991). Early studies from the 1960s and 1970s suggested an association between advanced paternal age and the development of schizophrenia (Hare *et al.*, 1979; Gregory, 1959). Recent studies have confirmed this association between advanced paternal age and schizophrenia in large population-based studies (Zammit *et al.*, 2003). A 12-year evaluation of the Jerusalem birth registry and the Israel psychiatric registry that included 658 individuals with schizophrenia revealed that the risk

## 51. Fertility and Aging Men

of schizophrenia increased monotonically with increasing paternal age. This increased risk culminated in a relative risk of 2.96 (95% confidence interval, 1.60–5.47) for offspring of men 50 years or greater (Malaspina *et al.*, 2001). Conversely, maternal age demonstrated no effect on the development of schizophrenia. A Swedish birth registry study revealed that the association between paternal age and schizophrenia was present in families without previous history of the disorder, but not in those with a family history. Based upon the stronger association between paternal age and schizophrenia in people without a family history, the authors suggested that accumulation of *de novo* mutations in paternal sperm contributed to the risk of schizophrenia (Sipos *et al.*, 2004).

Men of advanced paternal age, much like their female counterparts, are at greater risk for spontaneous abortion and genetic abnormalities. The continually replicating spermatogonia and the decreasing apoptotic rate are likely causes of the amplified meiotic and premeiotic errors in the male germ cell line. These chromosomal abnormalities increase in the aging male and potentially result in spontaneous abortion, autosomal dominant disorders, trisomy 21, and schizophrenia. In light of the trend toward delayed childbirth, the potential deleterious effects of advanced parental age become increasingly important. Therefore, appropriate prenatal counseling of older couples regarding the effects of advanced parental age on the developing fetus and newborn is imperative.

### Conclusion

This brief discussion of the aging male demonstrates an unappreciated reality: men have biological clocks that affect their fertility, hormones levels, and the genetic quality of their sperm. This clock plays a role on a personal level (when couples must grapple with infertility or birth defects) and on a public health level (when society must decide policies governing, for instance, insurance coverage for advanced fertility treatments such as *in vitro* fertilization). Women should no longer be viewed as solely responsible for age-related fertility and genetic problems. Infertility is not just a woman's problem, and with the new awareness of a new male biological clock, couples and their physicians can much more accurately proceed with proper testing, diagnosis, and (if needed) treatment of the male. The field of male-factor infertility is still very young and much more research is needed to fully characterize risks and to find more effective treatments. We also need to better understand the cellular and biochemical mechanisms of "gonadal" aging in order to find safe, effective ways to delay this process and, in effect, "rewind" the male biological clock. Doing so will lessen the potential for adverse genetic consequences in offspring, improve the sexual and

reproductive health of aging males, and increase a woman's chance of having healthy children by correcting defects in the male reproductive machinery (Fisch, 2005).

# Benign Prostatic Hyperplasia

Peter Celec

*Benign prostatic hyperplasia is a common disease of aged males. It is associated with low urinary tract syndrome and can result in serious complications including renal failure. The main pathophysiological factors, and consequently, therapeutic targets, are sex hormones and sympathetic activity. Testosterone, dihydrotestosterone, and estradiol play crucial roles, and their effects are influenced by several genetic factors.*

*The models of benign prostatic hyperplasia can be divided into in vivo and in vitro models. Animal models include spontaneous and hormonally or pharmacologically induced prostatic hyperplasia, as well as newly generated transgenic models. Cell cultures are simple and cost effective, but the research in vitro is difficult to interpret for human pathology.*

*The number of various models indicates that an ideal model of benign prostatic hyperplasia does not exist. Thus, further improvements are awaited to enhance the biomedical research with clinical outcome on this entity.*

## Introduction

Male aging is accompanied by several prostate diseases including prostate cancer and prostatitis. However, by far the highest incidence and prevalence is reached by benign prostatic hyperplasia (BPH). Despite huge scientific and clinical effort, this entity is still an important biomedical problem, as neither the understanding of pathophysiology nor the currently applied therapy are satisfying. Research focused on BPH, thus, clearly is needed and should be supported by appropriate models of BPH. Nevertheless, the wide spectrum of models indicates that there is no clear winner of the race—no ideal model of BPH.

Although the existence of a female prostate is more or less accepted (Zaviacic and Ablin, 1998, 2000), this chapter will focus on male prostate hyperplasia, as the incidence of diseases of female prostate seems to be low and no specific animal or cell culture models exist for research on female prostate.

The contemporary view on the pathophysiology of BPH is presented, as it implies several different internal

as well as external factors that influence prostate growth. This divergence can also explain the number of different available BPH models and the related problems regarding the interpretation of the results of various studies, both clinical and experimental. There is a need for further development of new models that would be closer to human pathology.

## Epidemiology

About 50% of men over 60 years have a pathologically increased prostate (see Figure 52.1).

The huge prevalence of BPH in men over the age of 80 years of more than 90% makes BPH “an inescapable phenomenon” for the male population if taking into account the contemporary rise of life expectancy in the developed world (Berry *et al.*, 1984; Lepor, 2005). The volume and weight of prostate tissue is increasing from 20 g in 40 years to 60 g in 80 years of age (Oesterling *et al.*, 1993). The hyperplasia of the prostate is not a life-threatening condition per se; however, BPH causes serious and dangerous complications. These include acute urinary retention as the most frequent complication, recurrent infections, chronic urinary retention, and even renal failure (Thorpe and Neal, 2003).

Most patients with BPH are asymptomatic and undiagnosed. The most prominent complication is so-called LUTS—low urinary tract syndrome (see Table 52.1). LUTS and bladder outlet obstruction bring the patient to the clinician, but although the prevalence of LUTS also increases with age, the relationship between BPH and LUTS is complex (see Figures 52.2 and 52.3).

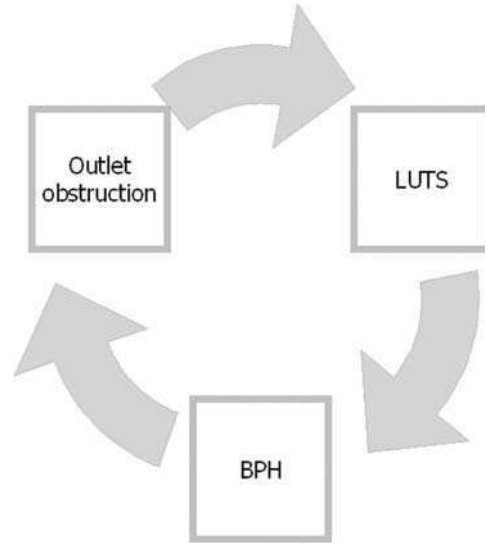

The severity of LUTS, for example, does not depend linearly on prostate size, although further research is needed (Girman, 1998). To distinguish between BPH, obstruction syndrome, and LUTS is difficult in epidemiologic studies because the borders are unclear. However, this clinical feature is mostly not a part of the BPH models for research.

The mortality from BPH decreases steadily during the last 50 years. Bias caused by better diagnostics and differences in the inclusion criteria cannot be excluded. However, the increase in mortality in Eastern Europe and some other parts of the world is a warning signal that should not be overlooked (Levi *et al.*, 2003).

**Figure 52.1** Prevalence of BPH in male population based on the results of several epidemiological studies.

**Figure 52.3** BPH, LUTS, and outlet obstruction are associated, and the relations are not linear.

TABLE 52.1  
Low urinary tract syndrome—LUTS symptoms

Voiding	
	Prolonged urination
	Post-micturation dribbling
	Poor urinary flow
	Incomplete bladder emptying
	Delay in onset of micturation
Storage	
	Urge incontinence
	Nocturia
	Frequent urination

**Figure 52.2** BPH is causing LUTS and outlet obstruction.

### Pathophysiology

There are many factors influencing the so-called aging male. Androgens and other sex hormones that decrease in elderly men definitely belong to these factors; this condition is called PADAM—partial androgen deficiency of the aging male (Schulman and Lunenfeld, 2002). The role of androgens in the pathogenesis of BPH is common to their role in the prostatic carcinogenesis (Parnes *et al.*, 2005). The relationship between prostate cancer and BPH is a matter of debate, which is out of scope of this chapter. Nevertheless, it should be noted that the BPH does not represent a clear premalignancy and the pathogenesis of both entities is divergent, although androgens play an important role in both pathologies.

Androgens affect the static part of BPH pathophysiology—the size of the prostate. The other group of factors is related to the dynamic tension of prostatic smooth muscles (see Figure 52.4).

In general, currently used therapy of BPH involves antiandrogenic treatment (reducing the prostate size) and alpha adrenergic blockade (relaxing of smooth muscle inside the prostate). The finding that alpha adrenergic blockade improves the symptoms of patients three-fold in comparison to antiandrogenic treatment does not ultimately mean that the adrenergic stimulation is more important in the pathogenesis of BPH. Other studies have shown the opposite, if longer observation periods were chosen. Moreover, many clinically important symptoms might be caused by conditions other than BPH, including functional denervation or detrusor dysfunctions, and these conditions might be affected by the alpha adrenergic blockade (Skolarikos *et al.*, 2004).

## 52. Benign Prostatic Hyperplasia

**Figure 52.4** Two major factors participating in BPH pathogenesis. The static component is represented by the antiapoptotic and proliferative effects of androgens. The dynamic component is represented by the action of sympathomimetics on smooth muscle cells in the fibromuscular stroma of the prostate.

The hormonal influence on the pathogenesis of BPH is undoubted. Castrated males do not develop BPH. Sex hormones have been shown to be a major factor in normal physiological development of prostate, but also in the pathological hyperplasia. However, the detailed mechanism of their effects is not clear (Roberts *et al.*, 2004).

Besides *androgens*, recently the role of estrogens in prostate growth is also discussed, although previously, *estrogens* were thought to act protectively against BPH.

A common precursor of steroids is cholesterol, and the specific precursor of androgens is dehydroepiandrosterone (Celec and Starka, 2003). The main metabolic pathways of androgens are shown in Figure 52.5.

Nevertheless, testosterone and dihydrotestosterone (DHT) seem to be of major importance. Both steroids are recognized by the intracellular androgen receptor, but the activation of this transcription factor via DHT is stronger by a factor of 10 in comparison to testosterone. The production of DHT from testosterone is mediated by the enzyme 5-alpha reductase. Inhibiting this catalytic activity pharmacologically is one of the major therapeutic approaches currently used in the treatment of BPH. The levels of testosterone slightly increase due to the inhibition of 5-alpha reductase, but the clinical outcome is clearly a reduction of prostate size, so it seems that testosterone plays a secondary role in BPH pathogenesis. It may be explained by the fact that only 1% of testosterone is bioavailable for the activation of androgen receptors. The rest is bound to plasma proteins, specifically to sex hormone binding globulin (SHBG), and nonspecifically to albumin. As the concentrations of SHBG rise with age, the proportion of bioavailable free

**Figure 52.5** Metabolic pathways of androgens.

testosterone decreases. Moreover, the production of testosterone in Leydig cells in testes also decreases; thus, the absolute concentration of free testosterone decreases considerably. However, there are other receptors for testosterone than androgen receptor; some of them are membrane bound, and some of them even recognize testosterone bound to SHBG. Their role in prostate growth is currently unknown and is expected to be of less importance, but future research will make this clear.

An interesting question is the role of estrogens in the pathogenesis of BPH. Estradiol is produced from testosterone, and this one step-one direction reaction is catalyzed by *aromatase* (see Figure 52.6).

Although the presence of aromatase in the prostate tissue is a matter of discussion, and the results of molecular studies are divergent and puzzling, the production of estradiol affects prostate growth independently from the site of its production (Risbridger *et al.*, 2003). Estradiol increases the production of SHBG and thus decreases the free fraction of plasma testosterone available for the DHT production by 5- $\alpha$  reductase. This fact would explain a protective role of estrogens in BPH, but the last decade of research has shown that estrogens play the opposite role—they stimulate the growth of prostate tissue, particularly in a highly

**Figure 52.6** Aromatase catalyzes the aromatization of testosterone to estradiol.

androgenic environment (Roberts *et al.*, 2004). The molecular aspects of estrogen action include the upregulation of androgen receptor expression. Thus, the sensitivity of the tissue to androgens is increased and the response to testosterone and also to DHT is enhanced. The effects of estradiol on prostate growth are age- and dose-dependent. The most prominent influence has been shown for low-dose estradiol during fetal life (vom Saal *et al.*, 1997). Interestingly, estrogens and androgens act synergistically in BPH pathogenesis (see Figure 52.7), even if some effects are contradictory if these hormones are applied alone (Fujimoto *et al.*, 2004).

There are several genetic factors that affect the actions of sex hormones in the prostate. The androgen receptor undergoes alternative splicing, and a longer version of the protein is more sensitive to DHT. Various polymorphisms have been associated with altered function of the androgen receptor. A CAG repeat in the first exon is the best described short tandem repeat (STR) in the androgen receptor gene. Normal number repeats is 10 to 40; a higher number is associated with a rare neurodegenerative Kennedy disease, and the activation of androgen receptor is weaker. Lower number of repeats is related to increased androgenity—increased response to androgens, and this condition is clinically associated with an increased risk of Alzheimer's, breast and prostate cancer, and BPH.

Similarly, the gene encoding 5- $\alpha$  reductase includes several polymorphisms important for the activity of the enzyme; best studied is the A49T polymorphism that increases the activity of 5- $\alpha$  reductase five-fold. Aromatase is encoded by a gene with a single nucleotide polymorphism C1558T and several STRs. Besides sex hormone receptors and metabolic enzymes, other genes and their polymorphisms are associated with BPH in humans, but their role in the etiology of BPH is unclear. It has been reported that the expression of a potential tumor suppressor protein p27Kip1 is very low or undetectable in BPH tissue in contrast to control prostate tissue (Cordon-Cardo *et al.*, 1998).

**Figure 52.7** Androgens and estrogens act synergistically on the pathogenesis of BPH.

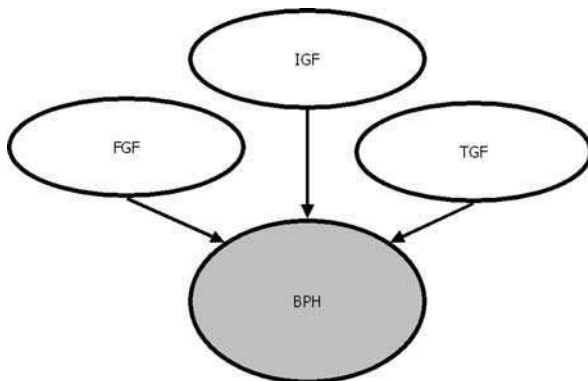

## 52. Benign Prostatic Hyperplasia

Although the prostate is an exocrine gland, BPH is caused mainly by proliferative changes of the fibromuscular stroma. The histological classification distinguishes stromal and epithelial origin of BPH. The stromal BPH accounts for cca 80% and is further divided into proliferative processes of the fibrous tissue (40%) and smooth muscle (40%). Cell culture studies have provided evidence for the hypothesis that on a molecular level an important role in the pathogenesis of BPH is played by several growth factors (see Figure 52.8).

These growth factors include fibroblast growth factors (FGF) 2 and 9, insulin-like growth factors (IGF) I and II, and also transforming growth factor beta 1 (TGF), although the latter affects stromal cells of the prostate differentially according to its concentrations—stimulatory at lower and inhibitory in higher concentrations (Eaton, 2003). The effects of TGF are especially interesting as it induces apoptosis in epithelial cells but the opposite in stromal cells. The influence of growth factors on prostate is dependent on the presence of appropriate receptors at the surface of cell membranes as well as on the intracellular response pathway. Molecular biology and its modern methodological improvements like microarray experiments will facilitate the detailed understanding of BPH pathophysiology (Prakash *et al.*, 2002).

### *In vivo* Models

Best described and widely used *in vivo* models include rodent, canine, and primate models (see Table 52.2). These can be either spontaneous or induced using various hormonal application regimes. Modern genetic technologies allow the production of several new transgenic mice models. Another approach is to use transplantation of the prostate tissue, either embryonic or pathologically hyperplastic. Some of the aspects of BPH can be studied in alternative models, for example, in the phenylephrine-induced increase of intraurethral pressure (Akiyama *et al.*, 1999).

**Figure 52.8** Several growth factors are participating on the growth regulation of prostate tissue.

TABLE 52.2  
Comparison of animal species used in BPH models

Animal model	Similarity to human BPH		Availability	Costs
	Anatomy	Histology		
Rodent	+	+	Very good	Low
Canine	+	++	Fair	Moderate
Primate	+++	+++	Poor	High

### SPONTANEOUS BPH MODELS

Dogs and chimpanzees are the only experimental animal species that develop BPH spontaneously. In both species the BPH occurs in an age-dependent manner, but there are important differences from the human BPH.

Nonhuman primates represent the best model for most human diseases when it comes to similarity to human pathology. BPH is not an exception. Chimpanzee prostate is anatomically very similar to the human prostate (Steiner *et al.*, 1999). It is divided into two lobes—caudal, which resembles the human transition and peripheral zone, and cranial, which resembles the central zone in the human prostate. The age dependence of BPH in chimpanzees does not differ from human BPH, and histological evaluation has shown that the epithelium/stroma ratio is also similar. Is chimpanzee BPH an ideal model? No, but it is currently the best available. The problems lie just in the availability, as primates are available for research use only in specialized primate research centers. Spontaneous BPH occurs in chimpanzees at their elderly age—cca 30 years. Furthermore, the prostate-specific antigen is present only in very low concentration; thus, to follow the development of BPH in primates biochemically is complicated. On the other hand, the presence of outlet obstruction enables functional evaluation.

Canine prostate lacks a capsule, and its growth is oriented not to the urethra, but to the pelvic cavity due to anatomical relations, including the lack of a fixation to symphysis. This explains why BPH in dogs does not result in LUTS but is mostly asymptomatic or it causes defecation problems due to rectal obstruction. Canine prostate is not divided into clear morphological subunits; similarly, canine BPH does not resemble the nodular pathogenesis of human BPH. Moreover, the histological picture of canine BPH involves epithelial proliferation in contrast to human BPH, where fibrostromal proliferation is usually present. This might be explained by the finding that the activity of 5-alpha reductase is higher in the epithelium than in the stroma. Several other biochemical differences have been described, including the expression of prostate-specific antigen and prostate-specific esterase. Nevertheless, canine spontaneous BPH is a widely used

model of human BPH, and if differences are taken into account, pathophysiologic and therapeutic studies can make use of this model.

### INDUCED BPH MODELS

Spontaneous models of BPH are closer to human pathology, but these models are difficult to obtain due to the slow aging process. BPH pathogenesis can be induced or accelerated in dogs, as well as in standard laboratory rodents like mice and rats. Dogs have an androgen responsive prostate tissue; thus the application of androgens can induce BPH. It has been experimentally shown that a regime involving androstanediol and estradiol application induced BPH. DHT and testosterone were not able to induce BPH in dogs if applied alone. Combinational treatment with DHT and estradiol applied subcutaneously daily usually during 14 or 28 days induces BPH in dogs (Yokota *et al.*, 2004). Similarly, eight-months-long daily treatment with testosterone and androstenedione induced a canine BPH even in young animals (Ito *et al.*, 2000). The problematic anatomy of canine prostate described earlier is still a problem in modeling the human BPH using hormonal induction. This problem can be overcome using a surgical approach, where the canine prostate is enveloped by a mesh that does not allow growth into the peritoneal cavity. This is currently the only way to induce BPH in dogs that is accompanied with urethral obstruction seen in human BPH.

The rodent prostate differs considerably from the human prostate in anatomy and physiology. Rodent prostate consists of anterior, ventral, and dorsolateral lobes. Only the dorsolateral lobe has been reported to be comparable to human prostate. The main factor in BPH induction is the long-term application of high doses of androgens and estrogens. Some studies report an induction of BPH using only chronic testosterone treatment, but this model suffers from several limitations (Mitra *et al.*, 1999). The response is strain specific; however, some rat strains do not develop BPH after this treatment, and classic strains like Wistar or Sprague-Dawley are responsive. Except for sex hormones, chronic applications of prolactin or sympathomimetic phenylephrine also lead to BPH in rodents (Van Coppenolle *et al.*, 2000; Marinese *et al.*, 2003). However, this model is used only sporadically as the use of sympathomimetic drugs affects not only the urogenital system, but notably other systems as well (Golomb *et al.*, 1998). Reports of spontaneous development of BPH in rodents are lacking; normal rodent prostate tissue even undergoes an age-dependent atrophy. Exceptions are the brown Norway rats (Banerjee *et al.*, 1998; Banerjee *et al.*, 2001) and spontaneously hypertensive rats (Zhang *et al.*, 2004). However, the mechanism of BPH etiology in these strains is specific and does not resemble the multifactorial origin of human BPH.

Besides hormonal treatment there is an additional approach for the induction of BPH—the so-called mouse prostate reconstitution model. Fetal urogenital tissue is transplanted into the prostate of an adult animal. Without androgen treatment only epithelial proliferation is induced, but additional androgen application results in BPH (Guo *et al.*, 2004). It can be expected that specific growth factors in the transplanted tissue are responsible for the induction of proliferation, but the identification of the active compounds is not complete. Nevertheless, previously mentioned growth factors like FGF, IGF, and TGF might be involved. Xenografting of human BPH tissue into immunodeficient mice or rats is also possible. However, the survival of this tissue is limited, and the use of such models is currently questionable, although biochemically the transplants produce prostate-specific enzymes. Another possibility is to implant prostate tissue cell lines ectopically (e.g., under the renal capsule) in recipient animals (Takao *et al.*, 2003). This model however, resembles *in vitro* more than *in vivo* models.

### Transgenic Models

Transgenic animals present a totally new approach for modeling human diseases. They are very important for the study of the pathogenesis of diseases, mostly the role of specific genes and gene products. However, their use in finding and evaluating potential therapeutics is limited, and the results of such studies must be taken with caution. BPH, like most other so-called civilization diseases, has a multifactorial etiology and thus cannot be reduced to a deficiency or overexpression of one protein. Nevertheless, transgenic animals represent an invaluable tool for BPH research. Based on the known pathophysiology of BPH, these animals are genetically modified to overexpress growth factors like FGF and IGF in a more or less prostate-specific manner. The organ specificity of expression is guaranteed by the use of prostate-specific promoters. Interestingly, another endocrine factor can be added to the pathogenesis of BPH after research using transgenic mice—prolactin. Mice overexpressing prolactin have been shown to develop BPH with high histological similarity to human BPH (Dillner *et al.*, 2003). The role of prolactin in BPH remains uncertain, as its overproduction was associated with higher androgen levels and an altered expression of several metabolic genes in the transgenic rodents (Dillner *et al.*, 2002).

*In vitro* studies show that prolactin alone can have a proliferative or at least antiapoptotic effect on prostate tissue. As mentioned previously, the tumor suppressor protein p27Kip1 might be involved in the pathogenesis of BPH. This has been shown on p27Kip1 knock-out mice that develop an enlarged prostate. This model might also explain the puzzling relationship between BPH and prostate cancer (Cordon-Cardo *et al.*, 1998). Of the transgenic animals currently described as models of BPH prolactin, overexpressing mice seem to develop

## 52. Benign Prostatic Hyperplasia

a histological picture that is closest to the human BPH, though with several shortcomings. The generation of mice with prolactin overexpression restricted to the prostate tissue has improved the potential of this model considerably (Kindblom *et al.*, 2003).

### *In vitro* Models

In part due to the pressure from ecologic organizations, cell culture models are used more and more by researchers. It is difficult to study BPH in Petri dishes, but it is possible. The advantages are the generally assumed advantages of all cell culture models—easy reproducibility, virtually unlimited material for experiments, very good control over the cell growth conditions, no ethical problems. On the other side, cell cultures, especially in the case of BPH, are a very distant model. The biggest problem is the interaction between epithelial and stromal cells that plays a crucial role in the BPH pathogenesis *in vivo*. This interaction is lacking in classic pure cell culture models. Most cultures are derived from clinical specimens obtained during prostatectomy or transurethral resection. An important issue in the evaluation of cell cultures for research is the ability of the cells to express the androgen receptor, 5-alpha reductase, and the prostate-specific antigen. On the functional level, this means that the cells must retain their androgen responsiveness. Caution must be paid to cell cultures derived from prostate carcinoma. These tumor cell lines have a different phenotype, and research on these cells is difficult to interpret for BPH, although many studies have been published using these cell lines. Nontumorigenic cell cultures are few, and some of them are prepared from prostate tissue of various experimental animals. Similar to the *in vivo* models, cell cultures from rats or mice differ considerably from canine or primate cell lines.

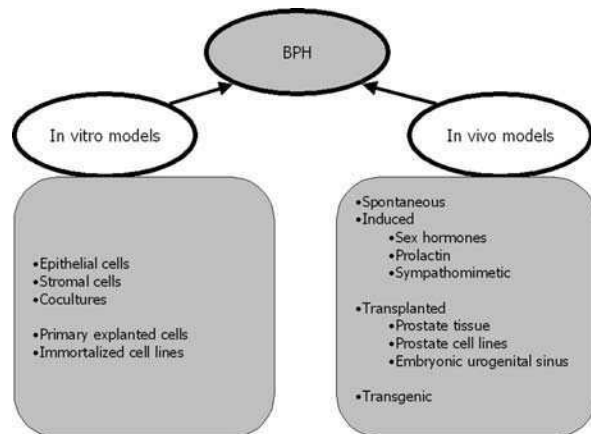

Some problems of classic mono-layer cell cultures can be overcome by using a 3D histoculture—sponge-gel-supported or the so-called total-immersion histoculture (Olbina *et al.*, 1998). The problem of a lacking interaction between different cell types is partially solved by using a coculture model where primary cell lines of prostate fibroblasts and epithelial cells are cultured

together, separated by a porous membrane that enables the diffusion of soluble factors produced by the one or the other cell type. It must be noted that this—although definitely an improvement—is still a virtual interaction that only partially resembles the situation *in vivo*. A detailed description of such a coculture model was published repeatedly (Bayne *et al.*, 1998; Habib *et al.*, 2000).

### Conclusion

The wide spectrum of available models shows that there is still no ideal model for BPH research (see Figure 52.9 and Table 52.3).

On one site, there is the need to make the model as close as possible to the human pathology; this is true for the spontaneous model of BPH in chimpanzees. On the other site, there is a need for simple, reproducible, and relatively cheap models; this is true for some of the cell culture models. It is probable that an ideal model will never exist and the knowledge about BPH will be composed of numerous puzzle pieces from many studies on various models as is the case today. One possibility to get closer to the ideal is to generate transgenic animals

**Figure 52.9** *In vivo* and *in vitro* models of BPH pathogenesis described in this chapter.

TABLE 52.3  
Comparison of practical applications of BPH models

Model	Variability	Reproducibility	Availability	Costs	Similarity to human BPH	Applicability for research on	
						Pathogenesis	Therapy
Spontaneous	High	Poor	Fair	High	+++	++	+++
Induced	High	Moderate	Very good	Low	++	+	++
Xenografts	High	Poor	Poor	High	+	+	++
Transgenic	Low	Very good	Fair	High	+	+++	+
Cell culture	Low	Very good	Good	Low	–	+	++

with several genetic alternations. This would be at least closer to the real multifactorial etiology of BPH in humans. On the other hand, the clinically relevant biological variability of human BPH can be reached only in spontaneous animal models, but the species-related differences to human BPH should always be kept in mind (Mahapokai *et al.*, 2000). Tough major advances in this field of biomedical research are due to the cooperation of specialists—urologists, molecular biologists, and others. The hormonally induced BPH in rodent and canine animals will still be the most popular and most often used model at least for the next few years.

# Murine Models of Infectious Diseases in the Aged

Kevin P. High

*Immune responses typically wane with age in both humans and mice. This phenomenon is termed immune senescence and renders older adults more susceptible to many infections and less likely to respond to vaccines. Murine models of immune senescence offer a window into the mechanisms that increase the incidence and severity of infection with advanced age and have furthered our understanding of host defenses. Strain differences between inbred mice and limited availability of genetically heterogeneous populations limit some of these findings, but overall, these models accurately reflect many human conditions and allow critical variables to be isolated by appropriate experimental design. In a few instances, older mice are actually more resistant to infection than are young mice, suggesting there may be immune mechanisms that remain intact or are even enhanced with advanced age. This might be exploited to improve vaccine responses and host defense in older adults.*

## Introduction

It is widely accepted that older adults are more susceptible to infectious diseases when compared to young adults, and infection is a major cause of morbidity and mortality in the elderly (High, 2004). Animal models are frequently used to assess the impact of age on infectious diseases, and to gather preclinical data on preventive strategies such as novel vaccine preparations. This chapter will focus on murine models of infection across the age spectrum, utilizing specific examples to illustrate general considerations when using these models.

## Limitations of Murine Models in the Study of Infection in the Aged

Murine models of aging have distinct limitations for infectious diseases research that are important to recognize in order to place these models in the context of the human condition. The limitations outlined mandate that findings in murine models be validated in other animal model systems and, whenever possible, in humans.

However, despite the limitations, murine models can be invaluable for studying infection in the aged by allowing manipulation of genes, diet, immune function, route of infection, and other control variables important in study design.

## INBRED MOUSE STRAINS

There is a general waning of immunity with age, termed immune senescence. This phenomenon is discussed in depth in other chapters of this text. Although murine immune senescence is similar in many ways to the waning of immunity experienced by older humans, there are marked interspecies differences (Miller, 1996). A major difference between murine and human models is that most studies in mouse models utilize inbred strains or F1 crosses of inbred strains. Though there are human populations of relative genetic homogeneity (e.g., the Amish), the diversity of most human populations raises distinct issues as to whether inbred mouse strains can appropriately model human disease and host defense (Miller, Austad *et al.*, 1999; Miller, Harper *et al.*, 2002). Inbred strains were originally produced for rapid maturation and large body size, likely significantly changing the gene pool and selecting for mutations that might shorten life span. Outbred mice live longer and have fewer tumors than inbred strains, traits associated with lower levels of insulin growth factor-1 (IGF-1) in young adulthood (Miller *et al.*, 2002).

There are four inbred mouse strains (BALB/cBy, CBA, C57BL/6, DBA/2) and three F1 hybrid strains (CB6ByF1, B6C3F1, B6D2F1) available from the mouse colony of the National Institute of Aging (NIA) ([www.nia.nih.gov/ResearchInformation/ScientificResources](http://www.nia.nih.gov/ResearchInformation/ScientificResources)). All these strains have been widely used in infectious diseases research, but each inbred strain has a distinct median life span, markedly different Th-orientation of immune response, and varied susceptibility to specific infectious agents (see Table 53.1). This can lead to very different conclusions when aged mice of one strain are compared to others with regard to the influence of age on disease outcome. For example, an old female DBA/2 mouse may be only 16 to 18 months of age, whereas C57BL/6 mice of this age would still

TABLE 53.1

Comparison of the median life span, Th-orientation and susceptibility to selected infectious agents for four inbred mouse strains available from the National Institute of Aging's mouse colony (+ relatively resistant; ++ modestly susceptible; +++ susceptible; ++++ highly susceptible). Data summarized from [www.informatics.jax.org/external/festing/mouse/docs](http://www.informatics.jax.org/external/festing/mouse/docs)

	BALB/cBy	CBA	C57BL/6	DBA/2
Median life span (months)	Males: 18 Females: 19	Males: 17.5 Females: 17.5	Males: 22.5 Females: 23	Males: 20.5 Females: 18
Th-orientation	Primarily Th2	Mixed (Th1 > Th2)	Primarily Th1	Mixed (Th2 > Th1)
Susceptibility to infection with:				
Influenza	+++	++++	+++	++++
<i>Leishmania</i> spp.	++++	++	+	++
<i>Listeria monocytogenes</i>	+++	+++	+	+++
<i>Mycobacterium</i> spp.	+++	+++	++	++++
<i>Plasmodium bergheia</i>	++	++++	+++	+++
<i>Pseudomonas aeruginosab</i>	++	No Information	+++	++++
<i>Salmonella</i>	++++	++	++	+++

<sup>a</sup>Relative susceptibility depends on outcome measured (e.g., parasitemia vs. cerebral symptoms).

<sup>b</sup>Lung infection susceptibility is shown; differences exist with regard to corneal and other sites of infection.

be considered middle-aged or mature; old C57BL/6 mice are usually in the 22- to 24-month range. The condition in which mice are housed also affects life span. Specific pathogen-free (SPF) conditions result in decreased life span in some (e.g., BALB/cBy), but increased life span in others (e.g., C57BL/6) ([www.informatics.jax.org/external/festing/mouse/docs](http://www.informatics.jax.org/external/festing/mouse/docs)).

Strain-specific changes in immunity and life span may underlie much of the variability and contradictions in the literature. An excellent example of this is shown in Figure 53.1, demonstrating strain- and age-related changes of *B. microtiii* parasitemia in murine models (Vannier *et al.*, 2004).

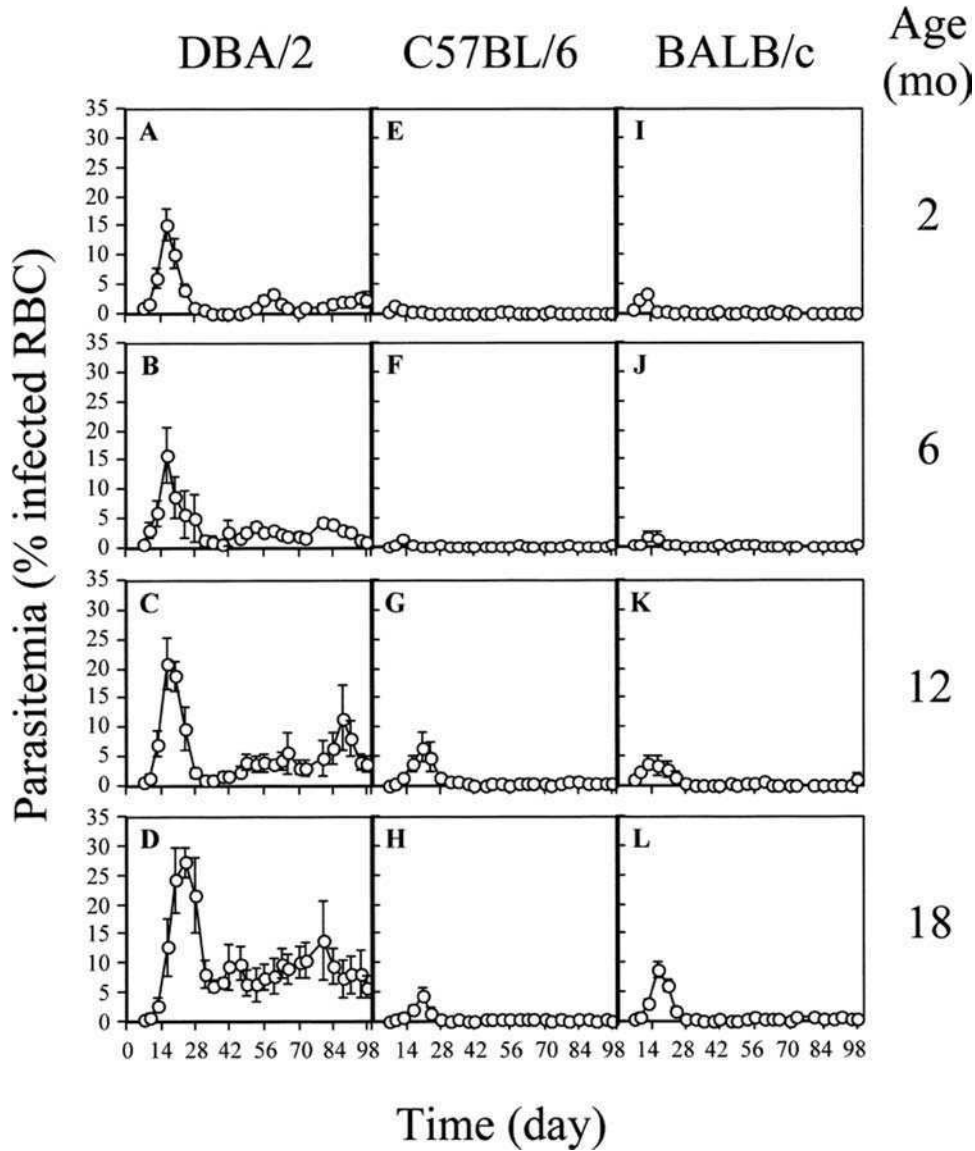

In the cited study, age-related differences of susceptibility were attributed to strain specificity (i.e., DBA/2 mice were assessed to experience an age-related decline in susceptibility to babesiosis, whereas C57BL/6 and BALB/c were not), and there are clearly strain-related differences with young DBA/2 mice showing greater susceptibility than the other two strains. However, as evidenced by the lower panels in Figure 53.1, outcomes in 18-month-old mice show some age-related changes in strains other than DBA/2, particularly in BALB/c mice. It is possible that age-associated declines in immunity render old C57BL/6 mice more susceptible to babesiosis as well, but that 18 months is not old enough for that particular strain to demonstrate statistically significant changes. Thus, it is important to try to match the stage of human life we are attempting to replicate in an inbred strain of mouse. This concept is illustrated in Figure 53.2 (Turnbull *et al.*, 2003).

## PHYSIOLOGIC AGE VS. CHRONOLOGIC AGE

Although aging occurs in all organisms, the inter-individual variability of entering old age is marked. There are old 70-year-old humans and young 70-year-old humans. The same is undoubtedly true for animals, but there is no standard way to assess the physiologic age of mice. In older humans, frailty, disability, comorbidity, and other contributing factors to disease risk have been defined and their inclusion in infectious diseases research encouraged (High *et al.*, 2005). Correlates of these measures in animal studies would be a tremendous advance. There are some data in F1 hybrid rats that indicate reproducible physical and cognitive measures can predict survival in rodent models of aging (Carter *et al.*, 2002). There have not been any data published using murine models, but initial studies are being done in mice and should be forthcoming (personal communication, C.S. Carter).

## STUDYING AGING VS. OBESITY/INACTIVITY

Aging mice in a caged environment is quite different from rodents aging in the wild. Apart from the obvious climate control, group housing, lack of predators, and so on, two major factors previously shown to impact age-related changes in physiology and life span are profoundly altered by the caged environment: diet and exercise. Caged animals have more fat, and many changes in immunity that are associated with obesity mimic immune senescence. Both states are associated with underlying constitutive activation of inflammatory pathways (most strikingly noted as an increase in NFκB

**Figure 53.1** Parasitemia in DBA/2, C57BL/6 and BALB/c mice of various ages after experimental infection due to *Babesia microti* expressed as a percentage of red blood cells infected. Reprinted from Vannier (2004) with permission.

activation in the absence of any particular stimulus, i.e., constitutive activation), perhaps mediated by IGF-1 and its receptor (Quarrie, 2004). Caloric restriction extends life in virtually every species investigated to date, including mice, and reversal of suspected physiologic changes by caloric restriction is often viewed as confirmation of an age-related phenomenon (Quarrie, 2004). However, given the convergence of IGF-1, leptin, cortisol, and other hormones in both aging and obesity, investigators are cautioned that age-related alterations in host defense that reverse with caloric restriction may reflect body composition or activity level-dependent phenomena rather than age itself.

### Age-related Differences in Common Infection Models

#### SEPSIS/OVERWHELMING INFECTION: MODELING CLINICALLY RELEVANT HUMAN PHENOMENA

Many investigators have determined that older mice are more likely to die from overwhelming infection and sepsis than are young adult mice. Two examples are shown to illustrate this fact and demonstrate important outcomes relevant to the study of infection in the aged. Sepsis can be induced by various methods, but direct injection of bacterial lipopolysaccharide (LPS) is most widely used

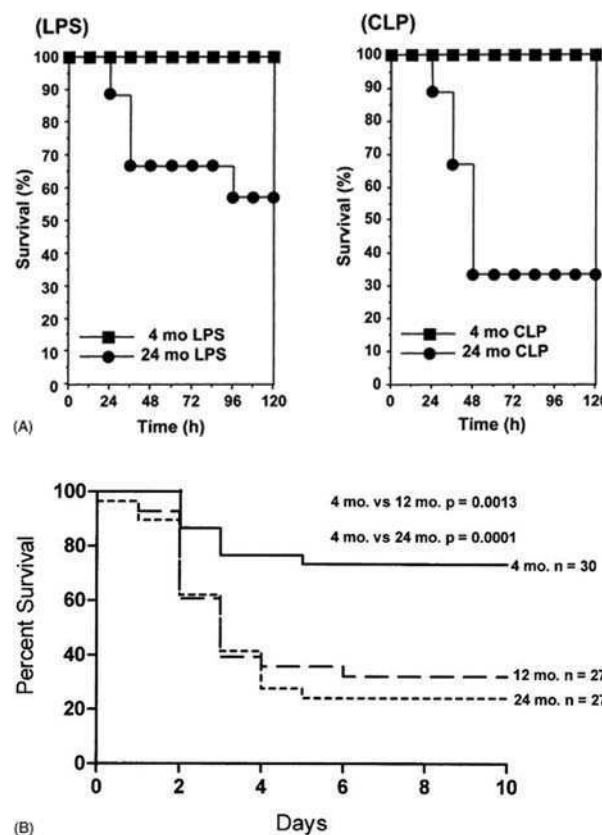

**Figure 53.2** Human and murine (C57BL/6) survival curves by age expressed as years for humans and months for mice. Reprinted from Turnbull *et al.* (2003) with permission.

and cecal ligation and puncture (CLP) is used as a more physiologically relevant method to induce overwhelming bacterial infection. As shown in Figure 53.3, both LPS injection and CLP reveal markedly impaired host defense in older C57BL/6 mice when compared to young adult mice (Saito, 2003).

Based on these data, we might assume very advanced old age is a risk factor for increased mortality in sepsis. However, data from other investigators using the CLP method (Turnbull *et al.*, 2003) suggest the change in risk occurs sometime during mature adulthood, not merely in advanced age (see Figure 53.3B). A 12-month-old C57BL/6 mouse is roughly equivalent to a 40-year-old human (see Figure 53.1), and it is possible that the change in sepsis mortality risk occurs as early as six months (about age 20 years in humans). Further, whatever change occurs between four and 12 months, there appears to be no further decline in host defense after 12 months as assessed by this model since 12-month and 24-month-old mice appear to respond similarly. This illustrates a general tenet that studies of aging should investigate animals across the age spectrum. If we study only the extremes of age, the pattern of change over the entire life span of the organism is lost and may lead to erroneous conclusions.

The example of overwhelming sepsis also demonstrates that many physical exam and laboratory findings can efficiently replicate human phenomena in murine models. Older mice and humans demonstrate a lower baseline body temperature than young adults, and older humans admitted with infection have a much higher risk of mortality if hypothermia is present (Bender and Scarpace, 1997). Figure 53.4A shows that the CLP model can mimic this event and accurately predict survival in murine models. Further, hypothermia after LPS administration or CLP correlates with the degree of inflammation as measured by serum interleukin-6 (IL-6)

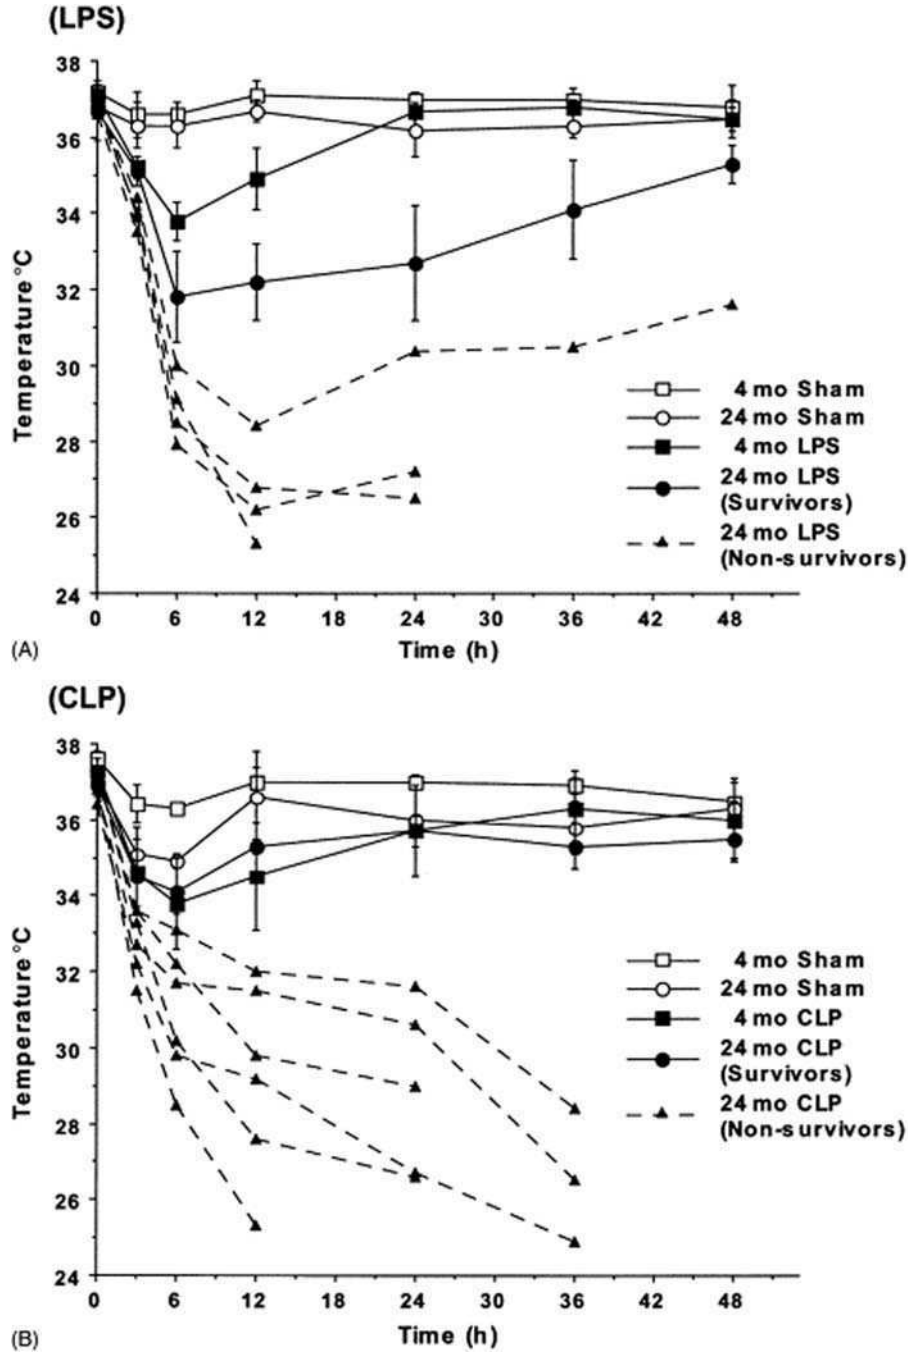

**Figure 53.3** (A) Survival after injection of lipopolysaccharide (LPS) or cecal ligation and puncture (CLP) in C57BL/6 mice aged 4 or 24 months. Reprinted from Saito (2003) with permission. (B) Survival after CLP in 4-, 12-, and 24-month-old C57BL/6 mice. Reprinted from Turnbull *et al.* (2003) with permission.

(see Figure 53.4B), indicating that the CLP procedure is an excellent correlative model of human sepsis (Saito, 2003).

#### TUBERCULOSIS: THE IMPORTANCE OF ROUTE OF INFECTION, USE OF MULTIPLE STRAINS, AND LIMITATIONS OF KNOCKOUT MODELS

Tuberculosis is one of the prototype infections in which the elderly are disproportionately affected (Rajagopalan, 2001). The enhanced disease rate in older adults is due to both reactivated and newly acquired *Mycobacterium tuberculosis*. The cohort of aged adults is more likely to have encountered the organism in childhood or young adulthood due to increased population prevalence at that time of their lives, but the risk is also greater for this group since older adults often reside in nursing homes or other domiciliary settings that increase exposure risk (Rajagopalan, 2001). Waning immunity with advanced age is also widely suspected of contributing to this risk, but the data are mixed. A series of elegant experiments by Orme and colleagues over 20 years has shed light on

**Figure 53.4** (A) Survival as a function of body temperature in 4- or 24-month-old C57BL/6 mice either injected with lipopolysaccharide (LPS), or (B) after cecal ligation and puncture (CLP) or Sham CLP. Temperature in C57BL/6 mice with sepsis induced by LPS or CLP as a function of serum IL-6. As serum IL-6 increases, body temperature declines. Reprinted from Saito (2003) with permission.

Figure 53.4 Continued.

this issue and provides an excellent example of how different infection models can be confusing but also complementary (Cooper *et al.*, 1995; Orme 1987; Turner *et al.*, 2002; Turner and Orme, 2004).

Early data suggested that older mice (F1 offspring of an A/Tru  $\times$  C57BL/6) were more susceptible to a challenge with *M. tuberculosis* than were young adult mice (Orme, 1987). Transfer of splenocytes from young, infected mice was able to protect the old mice, suggesting a defect in adaptive immunity was responsible for the age-related decline in host defense. The model employed in those studies utilized intravenous administration of a high inoculum ( $10^5$  organisms). However, intravenous injection is not a typical route of acquisition for *M. tuberculosis*, and Orme and colleagues later attempted to examine a more physiologic model using a low inoculum (50–100 organisms/lung) delivered via aerosol inhalation. In those studies, overall survival of old mice was comparable to that of young mice. However, older mice actually were found to have *increased* resistance early in mycobacterial infection when compared to young adult mice (Cooper *et al.*, 1995). Importantly, the investigators went on to demonstrate that this phenomenon was common to two different in-bred murine strains (C57BL/6, BALB/c) and an hybrid F1 strain (B57BL/6  $\times$  Cd8a) (Turner *et al.*, 2002). Old mice of a murine knockout strain that results in disruption of CD8+ T cells lost the enhanced capacity to control early tuberculosis infection (Turner *et al.*, 2002). Other knockout mouse models suggest this immune response is dependent upon interferon- $\gamma$ , but not type I interferons (Miller *et al.*, 2002). In those studies knockout mice were aged until they reached very late adulthood, providing a powerful tool

to examine specific mechanisms. However, a note of caution: a mouse aging throughout 18 to 24 months in the absence of a specific immune mechanism is likely to develop alternate immune responses (see Miyamoto *et al.* (2003) for an example), but it is possible, perhaps likely, that those mechanisms do not contribute to host defense to the same degree in wild-type mice in old age. Techniques currently in their infancy, such as whole animal siRNA (Buckingham *et al.*, 2004), may allow studies of old wild-type mice with silencing of genes just prior to experimental infection, which is likely to better model host defenses in the aged than are knockout models.

#### INFLUENZA AND RESPIRATORY SYNCYTIAL VIRUS (RSV): AGE-RELATED CHANGES IN Th PARADIGM AND VACCINE MODELS

Viral infections frequently cause morbidity and mortality in older adults, and winter-time illnesses including influenza and RSV bring annual threats that excessively affect the elderly (Thompson *et al.*, 2003). Since viruses are obligate intracellular pathogens, Th1-biased immunity (i.e., cell-mediated immunity) is critical for host defense. Th1 responses are characterized by reduced production of the cytokines IL-4, IL-10 and enhanced production of IFN- $\gamma$ . Th2 responses show the opposite relationship. Immunoglobulin subtypes also indicate Th-specificity with IgG2a primarily associated with Th1 responses, IgG1 with Th2 responses, and the IgG1:IgG2a ratio is often used to assess the degree of Th1 vs. Th2 response. Although exceptions exist, aged mouse models generally reveal a shift of immune responses away from Th1 toward a mixed Th1/Th2 response in advanced age in response to viral infections such as RSV (Zhang *et al.*, 2002) or vaccines such as the influenza vaccine (Asanuma *et al.*, 2001). This shift is hypothesized to contribute to the increased susceptibility of older mice to viral infections when compared to young adult mice (Asanuma *et al.*, 2001; Bender and Small 1993; Hirokawa and Utsuyama 2002; Zhang *et al.*, 2002).

The shift in Th-bias may also underlie impaired vaccine responses found in older humans and animals; influenza vaccine is discussed in greater detail to illustrate this issue. Most data support efficacy of the currently available influenza vaccine for reducing infection-related death (Bridges *et al.*, 2002) and influenza-induced decompensation of underlying disease in older adult humans (Nichol *et al.*, 2003). However, other studies clearly show limited protection in the very old and frail vs. young, healthy adults, and have questioned the utility of influenza vaccine in older adults, particularly the frail elderly who need protection most (Simonsen *et al.*, 2005). Many other vaccines are less effective in older adults as well; thus, improved vaccine responses are a priority area of research for older adults, and influenza and RSV are specifically targeted organisms.

### 53. Murine Models of Infectious Diseases in the Aged

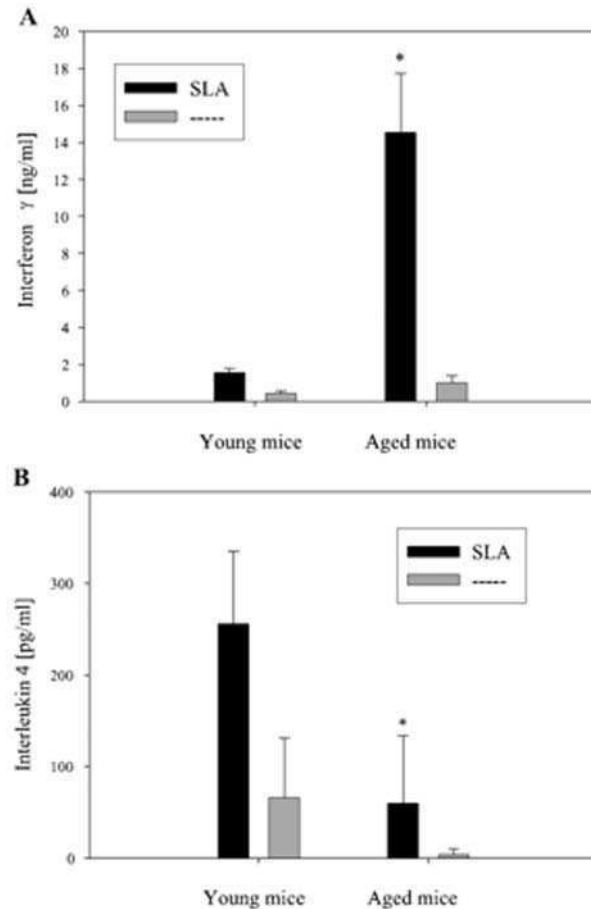

Murine models of both influenza and RSV, and vaccine strategies aimed at these organisms have been widely published. Vaccine strategies employed have included subunit vaccines, alternate routes of immunization, DNA vaccines, hybrid live-virus vaccines, and others. Recently, there has been great interest in new adjuvants. Only alum is currently FDA-approved as an adjuvant in humans, and this compound has minimal adjuvant activity in older adults. Adjuvant biology has been greatly advanced by the discovery of a strong link between Toll-like receptors (TLRs) and adaptive immunity (Pasare and Medzhitov, 2004). An extensive discussion of TLRs and their influence on vaccine responses is beyond the scope of this chapter; however, examples illustrate several key points.

Specific TLR agonists can modulate the aged immune response back toward Th1 responses (Ichinohe *et al.*, 2005; Manning *et al.*, 2001). For example, the addition of CpG, a TLR-9 agonist, can greatly enhance vaccine responses and induce mucosal immunity in older mice (Manning *et al.*, 2001). This boost is associated with a concomitant shift in the IgG1:IgG2a ratio from a clearly Th2-predominate 63:1 toward a Th-1/Th-2 mixed response ratio of 8:1 in older mice. The latter ratio closely reflects that seen in immunized young adult mice. Despite early success with TLR-agonists in murine models, it should be noted that TLR expression, regulation, and cellular distribution vary from mice to humans (Heinz *et al.*, 2003; Rehli 2002), and the road to human vaccines from murine models is littered with previous failures.

#### LEISHMANIASIS: ADVANCING AGE SOMETIMES LEADS TO IMPROVED HOST DEFENSE

Though many immune responses wane with age, some elements of host defense appear to actually be enhanced with advanced age. The resistance early in experimental tuberculosis noted earlier (Cooper *et al.*, 1995; Turner *et al.*, 2002; Turner and Orme, 2004) is one example, but others exist. The most clearly documented and mechanistically determined example is leishmaniasis (Ehrchen *et al.*, 2004). As previously outlined (see Table 53.1), BALB/c mice generally respond to immune challenges with a Th-2 response, whereas C57BL/6 mice are oriented toward a Th-1 response. Since Th1 immunity more effectively controls leishmaniasis, C57BL/6 mice have less severe disease than do BALB/c mice. However, as the mice age, BALB/c, but not C57BL/6, demonstrate an increased Th-1 response vs. *L. major* (see Figure 53.5) that leads to disease more closely resembling that of C57BL/6 with lower levels of parasites in the spleen and reduced footpad swelling (see Figure 53.6).

Further studies of the mechanism of enhanced host defense in old BALB/c mice demonstrated strong, age-related increases in IL-12 secretion in the absence of any stimulus. This spontaneous release of IL-12 by macrophages was present whether mice were raised in SPF or conventional conditions, but was augmented

**Figure 53.5** Production of the Th-1 cytokine interferon- $\gamma$  and the Th-2 cytokine interleukin-4 by splenocytes isolated from young (8–10 weeks) or old (18 months) BALB/c mice stimulated with soluble leishmania antigen (SLA) 12 weeks after infection with *Leishmania major*. Reprinted from Ehrchen *et al.* (2004) with permission.

if animals were exposed to pathogens throughout life (Ehrchen *et al.*, 2004). It is likely that C57BL/6 already have such a marked Th-1 orientation that the same age-related shift would have little effect on disease and be undetectable using measures employed even if present.

We have demonstrated that older DBA/2 mice have enhanced resistance to infection due to attenuated or fully virulent strains of *Brucella abortus* (unpublished observation), similar to the findings outlined for leishmaniasis. Although *Leishmania* spp., *Brucella* spp., *Salmonella* spp., *Mycobacteria* spp., and viruses are all intracellular pathogens, they have vastly different immune evasion strategies and intracellular survival mechanisms. The differences outlined earlier demonstrate that we cannot predict age-dependent susceptibility or resistance in the absence of specific data. Examining the immune responses active against organisms in which older mice have augmented resistance is likely to elucidate pathways that

**Figure 53.6** (A) Foot pad swelling 12 weeks after infection with *L. major* in old (18 months; top) or young (8–10 weeks; bottom) BALB/c mice. The old mouse demonstrates marked healing by 12 weeks whereas the young mouse shows a large crusted ulcer. (B) Foot pad swelling in young or old *L. major* infected BALB/c or C57BL/6 mice. No age-related difference is seen in C57BL/6 mice, but there are marked differences in BALB/c mice by age at time of infection. Reprinted from Ehrchen *et al.* (2004) with permission.

remain intact into advanced age. It may be possible to exploit these mechanisms to improve host defense and/or vaccine responses in seniors.

### Senescence-Accelerated Murine Models of Chronic, Degenerative Infectious Diseases

Senescence accelerated-prone (SAMP) and -resistant (SAMR) mouse strains have been widely used to investigate a variety of disorders common with advancing age, and recent data suggest these may be relevant models for chronic infectious diseases such as prion disease (Carp *et al.*, 2000). SAMP and SAMR mice were derived from a cross between an unknown mouse strain and the AKR strain of mice known to be infected with an endogenous murine retrovirus called murine leukemia virus (MuLV). Interestingly, SAMP mice demonstrate infection with MuLV, typically with high viral titers in multiple organs including brain, whereas SAMR mice are MuLV negative or have extremely low MuLV titers (Carp *et al.*, 2000). SAMP mouse brains demonstrate changes that mimic scrapie-infection in non-SAM mice. Further, experimental scrapie infection in AKR, SAMP, and SAMR mice results in enhanced MuLV titers in AKR > SAMP, but not in SAMR mice. Brain pathology consistent with scrapie is eventually found in all three strains, but the incubation period is markedly different and parallels MuLV titer (i.e., the higher the MuLV titer, the shorter the incubation). This suggests there may be an interaction between microbes and the transmissible agents of prion disease. Senescence-accelerated mice may provide important insight into this relationship.

### Conclusion

Murine models have greatly advanced the study of infectious diseases in the aged and can accurately model many human conditions. In general, immune responses shift from a Th1-predominate paradigm in young adulthood to a more mixed (Th1/Th2) model in advanced age, but exceptions to this general rule exist. In a few instances older mice are even more resistant to some pathogens than are young adult mice. When designing investigations of aging and infection, it is important when possible to include multiple murine strains, utilize physiologically relevant routes of infection, and assess underlying immune responses across the age spectrum to elucidate mechanisms. The growing field of TLR biology and the role of TLR agonists as vaccine adjuvants hold great promise for enhancing vaccine responses and protection in older adults, and murine models are likely to be the foundation for human studies.

# Studying Infection in the Elderly: Physiopathology, Clinical Symptoms and Causative Agents of Pneumonia

Jean-Paul Janssens

*Pneumonia is a major threat to older individuals, with a high mortality. Aging is associated with a high rate of atypical clinical presentations (delirium, falls, incontinence, absence of fever, or cough) that may delay diagnosis. In this chapter, pneumonia will be discussed as a model of infection in older subjects. The normal age-related changes in respiratory physiology (such as decrease in forced expiratory volumes, respiratory muscle performance, and mucociliary clearance efficacy) and their relevance for explaining the higher susceptibility of older subjects to infection of the lower respiratory tract are detailed.*

*The main mechanisms leading to community-acquired and nursing-home acquired pneumonia are reviewed, with an emphasis on the importance of micro-aspiration, on risk factors such as colonization of the oro-pharyngeal flora by pathogenic organisms, and risk associated with artificial enteral feeding (nasogastric tube or percutaneous gastrostomy). Immunosenescence and its relevance to lower respiratory tract is discussed elsewhere, in Chapter 65. Particularities of the clinical presentation of pneumonia in this age group, as well as prognostic indicators as to short-term and long-term outcome, are described. The most important pathogenic organisms and their epidemiological and clinical characteristics are reviewed, as well as more unusual organisms and their specificities. Alternative diagnoses to be considered in the situation of nonresponsive pulmonary infiltrates are also discussed.*

## Introduction: Epidemiology of Pneumonia in the Very Old

The annual incidence of pneumonia increases with aging and is higher in institutionalized subjects than in community-dwellers. In noninstitutionalized older subjects, incidence of community-acquired pneumonia (CAP) is estimated at between 25 and 44 per 1000 population—up to four times that of patients less than 65 years of age.

Incidence of nursing-home acquired pneumonia (NHAP) has been reported as high as 137 cases per 1000 population per year (Fein, 1994; Sund-Levander *et al.*, 2003). Mortality rates for older patients in hospital-based studies of CAP (up to 30%) are correlated with comorbidities, nutritional and functional status, and presence of cognitive disorders (delirium) (Kaplan *et al.*, 2002; Janssens *et al.*, 2004; Torres *et al.*, 2004). For NHAP, mortality rates may reach 57%. Hospitalization for community-acquired pneumonia (CAP) per se is associated with a high risk of hospital readmission and a high mortality within the following year (Bohannon *et al.*, 2004).

The diagnosis of pneumonia in this age group is often delayed because of the frequent absence of fever, the paucity or absence of cough, and changes in mental status (delirium), further contributing to the high morbidity and mortality. Cognitive impairment (dementia), present in 20% of subjects aged over 80, is a risk factor for nonspecific presenting symptoms of CAP or NHAP (such as weakness, falls, and delirium), and thus delayed diagnosis and poor prognosis (Johnson *et al.*, 2000; Morrison *et al.*, 2000; Sund-Levander *et al.*, 2003).

## Age-related Changes in Respiratory Mechanics

### IMPACT OF NORMAL AGING ON COMPLIANCE OF THE LUNG PARENCHYMA AND CHEST WALL, AND PERFORMANCE OF RESPIRATORY MUSCLES

Normal aging is associated with changes in the respiratory system that have important consequences on the ability of older subjects to cope with the decrease in lung compliance (infiltration by inflammatory cells related to infection) and increase in airway resistance (bronchial edema, secretions) caused by lower respiratory tract infection (LRTI).

When compared to younger individuals, elastic recoil of the lung, compliance of the chest wall, and strength of respiratory muscles are all decreased in older subjects.

Age-related alterations in lung parenchyma (enlargement of alveoli, also referred to as *ductectasia* or *senile emphysema*) explain the decline in elastic recoil of the lung and the resulting increase in functional residual capacity (FRC). Indeed, FRC (lung volume at the end of a quiet expiration) is determined by the equilibrium between two opposite forces: the elastic recoil of the lung parenchyma and that of the chest wall, the latter tending to expand the chest. Thus a decrease in elastic recoil of the lung increases the FRC: older patients breathe at higher lung volumes, increasing the workload imposed on respiratory muscles.

Decreased compliance of the chest wall (i.e., “stiffening” of the chest wall) is explained to some extent by calcifications and other structural changes within the rib cage and its articulations. Changes in the shape of the thorax as a result of osteoporosis and vertebral fractures, resulting in dorsal kyphosis and increased antero-posterior (AP) diameter (barrel chest), also affect chest wall compliance. Indeed, prevalence of vertebral fractures in the aged is high and increases with age: in Europe, for female subjects aged over 60, the prevalence of vertebral fractures is 17% in the 60 to 64 age group, increasing to 35% in the 75 to 79 age group (Cummings *et al.*, 2002). Males also have an increase in vertebral fractures with age, but rates are approximately half those of the female population. The increase in AP diameter of the chest decreases the curvature of the diaphragm and has a negative effect on its force-generating capabilities. Respiratory muscle performance in older subjects is thus limited by the increase in FRC, the decrease in chest-wall compliance, and geometric changes in the rib cage (Janssens *et al.*, 1999).

Respiratory muscle strength is also affected by nutritional status, often deficient in the elderly, and by the age-related decrease in muscle mass (sarcopenia) (Enright *et al.*, 1994; Tolep *et al.*, 1995; Polkey *et al.*, 1997). Indeed, normal values for maximal inspiratory pressure in subjects aged over 80 are below the threshold defined in an adult population for clinically relevant respiratory dysfunction (Enright *et al.*, 1994). Situations in which an additional load is placed on the respiratory muscles, such as decreased parenchymal compliance (pneumonia, congestive heart failure) or increased airway resistance (presence of tracheal or bronchial secretions and inflammation, asthma), may lead to hypoventilation and hypercapnic respiratory failure. Patients with pre-existing structural changes in lung mechanics (such as COPD, interstitial lung disease, or Kyphoscoliosis) are, of course, at increased risk of hypercapnic respiratory failure.

Respiratory muscle function also depends on energy availability (i.e., blood flow, oxygen content); indeed, decreased respiratory muscle strength has been described in patients with chronic heart failure (CHF), a frequent occurrence in older subjects (Nishimura *et al.*, 1994; Evans *et al.*, 1995). Presence of CHF with a New York

Heart Association (NYHA) functional class 3 or 4 was shown to be associated with a 30% decrease in maximal mouth inspiratory pressure ( $PI_{MAX}$ ) compared to control subjects. Furthermore, a significant relationship was demonstrated between cardiac index (CI) and  $PI_{MAX}$ , the latter decreasing when CI decreased (Nishimura *et al.*, 1994). Other frequent clinical situations decreasing respiratory muscle function in the elderly include Parkinson’s disease and sequelae of cerebral vascular disease. Indeed, in hemiplegic patients, limitation of thoracic excursions caused by weakness and uncoordination of the chest muscles may lead to decreased chest wall compliance and compromise respiratory muscle function (Annoni *et al.*, 1990).

#### AGING, FORCED EXPIRATORY VOLUMES, AND PEAK FLOW: IMPLICATIONS FOR COUGHING AND CLEARANCE OF AIRWAY SECRETIONS

Forced expiratory volumes and peak expiratory flow show an age-related linear decrease, probable reflecting structural changes, and chronic low-grade inflammation in peripheral airways (Enright *et al.*, 1993). Indeed, for a male subject with a height of 180 cm, between the ages of 25 and 75, forced expiratory volume in 1 sec (FEV1) drops by 32%, forced vital capacity (FVC), by 24%, and peak expiratory flow (PEF), by 22% (Quanjer *et al.*, 1993). In the very old, both the decrease in forced expiratory flow rates and in lung elastic recoil may compromise the efficacy of clearing airway secretions by coughing. Critical values for PEF have been reported, under which the risk of pneumonia markedly increases (Tzeng *et al.*, 2000). In patients with neuromuscular disorders, a PEF below 270 L/min is associated with an increase in risk of pulmonary infection, and at PEF values < 160 L/min, cough is ineffective for clearing secretions from the airways (predicted PEF for an 80-year-old woman, measuring 160 cm, is 300 L/min). Coughing requires a precise coordination of laryngeal and respiratory muscle function: after a rapid inspiration, airways are submitted to a compression phase in which active glottic closure and abdominal contraction are critical, before the “explosive” expiratory phase. A decrease in expiratory muscle strength may thus compromise the efficacy of the cough reflex. The efficacy of glottic closure depends on the integrity of laryngeal muscle function and complex integrated reflexes that may be altered in the elderly by transient or permanent neurological disorders (cerebro-vascular disorders, extra-pyramidal, or cerebellar disorders). Indeed, ischemic stroke increases markedly the risk of pneumonia: in a large series of 13440 patients, pneumonia was the most frequent and serious complication, causing 31% of all deaths (Heuschmann *et al.*, 2004). Glottal gap related to unilateral vocal cord paralysis is a potentially reversible sequel of acute cerebro-vascular events that

may also increase the risk and frequency of aspiration (Fang *et al.*, 2004).

Mucociliary clearance (progression of mucus layer lining the tracheal and bronchial epithelium) is also affected by the aging process. Even in the healthy non-smoking aged population, mucociliary clearance rates are slowed in comparison with the young. Nasal mucociliary clearance and frequency of mucosal ciliary beat are decreased in older subjects; aging also is associated with ultrastructural changes in microtubules of ciliae of the respiratory epithelium. Indeed, both smoking and non-smoking elderly have reduced tracheal mucus velocity compared with younger individuals (Ho *et al.*, 2001). Dehydration, frequent in older debilitated subjects, may further compromise mucociliary clearance.

#### SENSITIVITY OF RESPIRATORY CENTERS AND CLINICAL SYMPTOMS

Lower sensitivity of respiratory centers to hypoxia or hypercapnia in older subjects results in a diminished ventilatory response in case of acute disease such as heart failure, infection, or airway obstruction, and thus delays important clinical symptoms and signs such as dyspnea and tachypnea, which are important for the diagnosis of pneumonia and appreciation of its severity (Kronenberg *et al.*, 1973; Peterson *et al.*, 1981). Aging is also associated with a decreased perception of added resistive loads, such as that induced by asthma or increased airway secretions. Indeed, older subjects have a lower perception of methacholine-induced bronchoconstriction when compared with younger subjects (Cuttitta *et al.*, 2001).

#### Pathogenesis of Infection of the Lower Airways

Mechanisms implicated in the pathogenesis of infection of the lower airways are essentially aspiration of oropharyngeal secretions or gastric contents, inhalation of pathogenic organisms (i.e., viral or mycobacterial infections), and hematogenous dissemination (either iatrogenic or from a distant infectious focus). Among these mechanisms, aspiration of oro-pharyngeal secretions is probably the most prevalent.

#### ASPIRATION

Approximately half of all healthy adults aspirate small amounts of oropharyngeal secretions during sleep. The low burden of virulent bacteria in normal pharyngeal secretions, together with forceful coughing, active ciliary transport, and normal humoral and cellular immune mechanisms, protect the airways from repeated clinical infection. However, defense of the airway is impaired in the elderly by decreased mucociliary clearance, alteration in respiratory mechanics, and, in some cases, concomitant illnesses that predispose to aspiration. Furthermore, normal aging is associated with impaired oro-pharyngeal

deglutition. This has been attributed to an increased neural processing time (Tracy *et al.*, 1989). Indeed, there is a high incidence of silent aspiration in elderly patients who develop pneumonia: 71% of patients with CAP vs. 10% of the control subjects (Kikuchi *et al.*, 1994). Cough reflex sensitivity may also be altered in older subjects with recurrent pneumonia. Conversely, intensive oral care for one month has been shown to enhance cough reflex sensitivity, in a controlled randomized trial of older nursing home patients (Niimi *et al.*, 2003; Watando *et al.*, 2004).

As previously mentioned, aspiration pneumonia is a frequent complication of acute ischaemic stroke. Aspiration pneumonia was documented in 13.6% of 1455 patients during the three months following the acute event; associated risk factors were male gender, age, and diabetes; furthermore, pneumonia was associated with a higher mortality, and a lower functional status at three months (Barthel Index, Rankin scale) (Aslanyan *et al.*, 2004). In a large study of 13440 patients with ischemic stroke, in-hospital mortality was 4.9%; pneumonia accounted for 31% of all deaths (Heuschmann *et al.*, 2004).

#### UPPER AIRWAY COLONIZATION

Colonization of the upper respiratory tract by both Gram-negative (GNB; *Enterobacteriaceae*, *P. aeruginosa*) and Gram-positive bacteria (*S. aureus*) is more prevalent in the elderly and is related more to the severity of systemic illness and level of care than to age *per se* (Johanson *et al.*, 1969; Valenti *et al.*, 1978). Factors leading to colonization of the lower and upper respiratory tract include antibiotic therapy, endotracheal intubation, smoking, malnutrition, surgery, and any serious medical illness. Decreased salivation such as that induced by antidepressants, antiparkinsonian medications, diuretics, antihypertensives, and antihistamines also contributes to oropharyngeal GNB colonization.

Periodontal disease and dental plaque are clearly identified risk factors for the development of nursing-home acquired aspiration pneumonia. Recent studies have focused on the relationship between oral hygiene, colonization of dental plaques, and subsequent risk of pneumonia (El-Solh *et al.*, 2003; El-Solh *et al.*, 2004). A high plaque index and/or evidence of periodontal disease has been associated with presence of anaerobic bacteria in broncho-alveolar lavage (BAL) samples (Imsand *et al.*, 2002). In a study of 49 older patients from chronic long-term facilities requiring intensive care for a lower respiratory tract infection (LRTI), El-Solh *et al.* (2004) assessed dental status (plaque index, culture of dental plaques) upon admission to the ICU; BAL was performed in 14 subjects. The study showed a high rate of colonization of dental plaque by aerobic bacteria (*S. aureus*: 45%; *P. aeruginosa*: 13%; other GNB: 42%). Furthermore, pathogens recovered from BAL matched the micro-organisms recovered from dental plaques in

61% of subjects. Dental plaque colonization thus appears as a potential reservoir for LRTI. Indeed, earlier studies have shown the potential benefit of oral care to reduce the incidence of pneumonia in elderly nursing home residents (Terpenning *et al.*, 2002; Yoneyama *et al.*, 2002). The risk of aspiration pneumonia is also reduced in edentate subjects.

In summary, there is an increased number of pathogenic bacteria in the upper respiratory tract of sick and institutionalized elderly patients, which increases the risk of pneumonia following aspiration of oropharyngeal secretions.

#### ASPIRATION PNEUMONIA VS. ASPIRATION PNEUMONITIS

The term *aspiration pneumonia* has been used to define two different clinical conditions: aspiration of gastric contents into the lung (chemical injury with a subsequent inflammatory response), also referred to as *aspiration pneumonitis*, and aspiration of oropharyngeal content into the lung with resultant bacterial infection. Aspiration pneumonitis is not infectious in its initial stage, and many episodes of aspiration pneumonitis may resolve with supportive care, without antibiotherapy. It is frequently associated with naso-gastric tube feeding; in fact, tube feeding has been shown to be an independent predictor of gastric content aspiration (Marik, 2001). It is associated, however, with a high risk of secondary bacterial infection after more than 24 hours (Mylotte *et al.*, 2003).

#### ASPIRATION AND FEEDING TUBES

Feeding tubes do not protect from bronchoaspiration; this is true for naso-gastric tubes (NGT) and percutaneous enterogastric (PEG) tubes. In fact, feeding tubes are associated with an increased rate of pneumonia and death from pneumonia (Strong *et al.*, 1992; Croghan *et al.*, 1994; Marik, 2001).

The use of a NGT or a PEG tube appears to alter the oro-pharyngeal ecosystem, and increases upper airway colonization by *P. aeruginosa*, other GNB, and *S. aureus* (Leibovitz *et al.*, 2003a; Leibovitz *et al.*, 2003b; Leibovitz *et al.*, 2003c). In a study of 215 nursing-home patients (78 patients with a NGT, 57 with a PEG, and 80 patients fed orally), *P. aeruginosa* was recovered from the oropharyngeal flora of 31% of patients with NGT, and 10% of those with PEG, vs. 0% of controls; GNB were recovered from 71% of patients with NGT, 44% of those with PEG vs. only 7.5% of controls. Globally, the upper airways of 81% of patients with NGT were colonized by potential respiratory pathogens vs. 51% of patients with PEG, and 17.5% of controls. Decreased mechanical clearance of organisms by chewing and swallowing, and appearance of a bio-film on the NGT itself probably contribute to upper airway colonization by GNB. The biofilm may facilitate growth and colonization by *P. aeruginosa*. The reason for the important upper airway

colonization by *S. aureus* and GNB in patients with PEG is unclear.

In summary, aspiration is an important pathogenic mechanism for pneumonia in the elderly; in patients with neurologic impairment of the glottic barrier, the use of a NGT or PEG does not abolish and may in fact increase the risk of pneumonia.

#### Prognostic Indicators and Outcome

Items associated with a higher risk of in-hospital or 30-day mortality for older patients hospitalized with pneumonia are NHAP vs. CAP, bedridden status, altered mental status, absence of fever ( $<37^{\circ}\text{C}$ ), absence of cough or chills, tachypnea ( $\text{RR} > 30/\text{min}$ ), systemic hypotension ( $\text{SBP} < 90 \text{ mmHg}$ ), respiratory failure,  $\text{CRP} > 100\text{mg/L}$ , multilobar involvement, pleural effusion, radiological signs of cavitation, suspicion of aspiration, presence of swallowing disorders, hypo-albuminemia, hyperphosphoremia, renal failure, liver disease, and Gram-negative pneumonia (Janssens *et al.*, 2004).

Factors associated with a prolonged length of hospital stay are age, delirium, NHAP vs. CAP, roentgenograms suggestive of aspiration, cyanosis, leucocytosis, and presence of band forms in blood smears (Janssens *et al.*, 2004).

Hospitalization for CAP is associated with a high rate of readmission (53–62%) and a high mortality in the year following discharge (24–41%) (Kaplan *et al.*, 2002; Bohannon *et al.*, 2004; Torres *et al.*, 2004). Aspiration pneumonia and total number of comorbidities were identified as predictive of readmission within a year of discharge. In the large study by Kaplan *et al.* (2003), 1-year mortality increased from 29% for patients without comorbidities to 57% in patients with  $\geq 3$  comorbidities. Factors reported as significantly related to death were Barthel Index scores (quantifying dependence in activities of daily life), peripheral muscle strength (handgrip), and absolute number of comorbidities.

A recent French prospective case-control study focused on risk factors for nosocomial pneumonia (NP) in a geriatric hospital; 75 cases were identified, with a complication rate of 58% and a 12% mortality (Rothan-Tondeur *et al.*, 2003). Most significant risk factors for NP were prior NP, oxygen therapy, NGT feeding, and malnutrition.

#### Clinical Presentation of CAP and NHAP

Among the most common symptoms of CAP and NHAP, cough (40–81%), sputum (37–66%), chills (8–58%), and pleural pain (9–43%) are reported less frequently in NHAP than in CAP; conversely, elderly patients present more often with altered mental status (delirium) when hospitalized for NHAP (53–77%) than CAP (12–45%) (Janssens *et al.*, 2004). Fever (12–76%) is frequently absent in elderly subjects with pneumonia.

Tachypnea (respiratory rate >20/min) and tachycardia (>100/min) is found in about two-thirds of elderly with pneumonia and may precede other clinical findings by three to four days (Fein *et al.*, 1991). The classical triad of cough, fever, and dyspnea was present in only 56% of 48 elderly veterans admitted for CAP, and 10% of patients had none of these symptoms (Harper *et al.*, 1989). Subtle clinical manifestations of CAP in the very old, such as unexplained falls, incontinence, failure to thrive, or sudden aggravation of a preexisting comorbidity (i.e., diabetes, congestive heart failure, Parkinson's disease) have to be actively sought after.

The regular (monthly) use of pulse oximetry has been suggested as a simple parameter to help detect pneumonia in nursing home patients. In a study of 67 older nursing home patients, an oxygen saturation (SaO<sub>2</sub>) < 94% had a sensitivity for pneumonia of 80%, a specificity of 91% and a positive predictive value of 95%; a drop in SaO<sub>2</sub> of >3% had a sensitivity for pneumonia of 73%, but a specificity and positive predictive value of 100% (Kaye *et al.*, 2002). Clearly, alternative diagnoses must also be considered in the presence of decreased SaO<sub>2</sub>, but LRTI is probably the most frequent cause of desaturation in this setting.

## Microbiology of Pneumonia in the Elderly

### BACTERIAL PNEUMONIA

In recent clinical studies of older patients with either CAP or NHAP, the most frequently identified microorganisms were *S. pneumoniae*, *H. Influenzae*, Enterobacteriaceae, and *S. aureus*.

*S. pneumoniae* is by far the predominant pathogen isolated in hospital-based studies of elderly patients with either CAP (up to 58%) or NHAP (up to 30%) (Riquelme *et al.*, 1996; Lieberman *et al.*, 1997; Marrie *et al.*, 1997; Riquelme *et al.*, 1997; Lim *et al.*, 2001; Kaplan *et al.*, 2002; Zalacain *et al.*, 2003). In older subjects treated in the ICU, *S. pneumoniae* reportedly causes 14% of CAP and 9% of NHAP (El-Solh *et al.*, 2001). The presence of *S. pneumoniae* is associated with coexisting lung disease, hepatic disorders, or alcohol abuse.

*H. influenzae* is reported in up to 14% of older patients with CAP or NHAP, and was identified in 7% of elderly subjects with severe pneumonia leading to admission to an ICU (El-Solh *et al.*, 2001). *H. influenzae* is frequently linked to exacerbations of COPD and bronchiectasis and thus should be considered as a potential pathogen in these patients.

*Staphylococcus aureus* was documented in up to 7% of patients with CAP and 4% of patients with NHAP. One study shows an even higher occurrence of *S. aureus*-related pneumonia. Of 104 elderly patients with severe CAP or NHAP admitted to an ICU, 17% had (mostly methicillin-sensitive) *S. aureus* as causative agent (El-Solh *et al.*, 2001). In this study, *S. aureus* was identified in 29%

of the patients with severe NHAP (78% methicillin-sensitive) vs. 7% of those with CAP (all methicillin-sensitive). Because of the increasing rate of MRSA colonization in the nursing home population, and the relatively high probability for MRSA carriers of developing symptomatic infection, MRSA pneumonia is likely to become a more frequently encountered entity. *S. aureus* is associated with lung abscess, empyema, and secondary bacterial pneumonia after viral respiratory infection.

### Enteric Gram-negative bacteria (GNB)

Both colonization by, and infection with, GNB is a function of the number and severity of comorbidities (Valenti *et al.*, 1978). The likelihood of GNB pneumonia increases in nursing home patients and in patients with decreased functional status. In a community setting, GNB infection occurs primarily in debilitated and chronically ill patients. The presence of *Pseudomonas* suggests bronchiectasis (Fein *et al.*, 1994). If appropriate, the presence of bronchiectasis should be investigated by high-resolution computed tomography; indeed, the presence of bronchiectasis warrants prolonged treatment for LTRI (14 to 21 days).

### AGENTS OF ATYPICAL PNEUMONIA

*M. pneumoniae* is seldom reported as a causative agent in CAP or LRTI in the very old (1–13%) (Janssens *et al.*, 1996; Marrie *et al.*, 1997; Riquelme *et al.*, 1997; Lim *et al.*, 2001; Kaplan *et al.*, 2002), and has not been identified in elderly patients admitted to the ICU for severe CAP (El-Solh *et al.*, 2001).

*C. pneumoniae* infection in the elderly generally is considered a mild disease and was reported in only 1% of patients admitted to ICU for CAP (El-Solh *et al.*, 2001). However, *C. pneumoniae* has been reported in up to 18% of NHAP and 28% of CAP. Occasional *C. pneumoniae* outbreaks in nursing homes have been associated with a high attack rate (44–68%) and high mortality (~35%) of confirmed cases (Troy *et al.*, 1997). *C. pneumoniae* has no specific clinical presentation but the combination of pharyngitis or hoarseness (laryngitis) and nonproductive cough should suggest *C. pneumoniae* infection. Duration of illness > 8 days before admission also increases the probability of *C. pneumoniae* infection (Socan *et al.*, 2004). A case-control study comparing older patients admitted for *C. pneumoniae* CAP vs. non-*C. pneumoniae* CAP, showed that residing in a nursing home vs. living at home was associated with a marked increase in the probability of *C. pneumoniae* infection. *C. pneumoniae* infection can be identified by direct fluorescent antibody staining, nasopharyngeal swabs (PCR or culture), or retrospectively by serology.

Prevalence of *L. pneumophila* in CAP shows important geographic variations, being in the range of 1.8 to 24% in hospital-based studies (Janssens *et al.*, 1996). In Switzerland, 261 cases of definite *L. pneumophila*

infection were reported between 1999 and 2001 (incidence: 1.7 per 10<sup>5</sup> inhabitants). Median age of patients infected was 61 years; that of patients dying from the infection was 67 years; 34% of subjects infected were aged over 70 (OFSP, 2003). *Legionella sp.* infection was community-acquired in 60%, travel-related in 27%, and hospital- or nursing home-acquired in 10% and 3% of cases, respectively (OFSP, 2003). Colonization of potable water in long-term care institutions and geriatric hospitals is a potential hazard for *Legionella sp.* infection.

Because of a low to moderate sensitivity of diagnostic tests, the incidence of *Legionella* infection may be underestimated in clinical studies. Indeed, sensitivity of serology ranges from 40 to 60%; that of direct fluorescent antibody staining of sputum is 30 to 70% (specificity of 94–99%), and sputum culture has a sensitivity of approximately 80% (Stout *et al.*, 1997). The most useful test, namely dosage of urinary *Legionella* antigen is highly specific (100%), yet has a sensitivity of 79 to 83%, increasing to 94% if only *L. pneumophila* serogroup 1 is considered (Stout *et al.*, 1997; Helbig *et al.*, 2001).

Infection by *Legionella* is frequently heralded by an abrupt onset of malaise, weakness, headaches, and myalgia (Bentley 1984). Most patients cough; hemoptysis occurs in one-third of patients. Mental status changes are reported in 25 to 75% of older patients. Other associated features are bradycardia, liver dysfunction, diarrhea, and hyponatremia, but none of these features are specific and all may occur with severe pneumonia of other etiologies.

The probability of *L. pneumophila* infection increases in severe CAP or NHAP and must definitely be considered in this setting (El-Solh *et al.*, 2001). Interestingly, in a study of older patients with pneumonia admitted to the ICU, *L. pneumophila* infection was strongly associated with immunosuppression: 60% of patients had been under prolonged corticosteroid therapy. In up to 65% of patients, radiographic findings initially worsen after treatment has been started, and even after 10 weeks of therapy, only 50% of chest radiographs are normal (Macfarlane *et al.*, 1984).

## VIRAL INFECTION

Viral infection (adenovirus, Respiratory Syncytial Virus (RSV), influenza, parainfluenza, rhinoviruses) may cause up to 42% of acute LRTI during the winter months in institutionalized elderly subjects, RSV being the most common viral pathogen in this setting (Falsey *et al.*, 1992; Falsey *et al.*, 1995). In community-acquired LRTI, a history of a familial flu-like illness, better functionality, and a lower leucocyte count (<10<sup>10</sup>/L) are predictive of viral infection (Flamaing *et al.*, 2003). Among patients admitted to a hospital for CAP or NHAP, viruses are the causative agents in 2 to 32% of patients admitted, influenza, RSV, and parainfluenza being the most commonly implicated (Falsey *et al.*, 1995; Janssens *et al.*, 1996; El-Solh *et al.*, 2001; Fernandez-Sabe *et al.*, 2003;

Zalacain *et al.*, 2003). In a recent prospective study of healthy elderly subjects, followed for up to two winter seasons, clinical RSV infection occurred in 3 to 7% of healthy elderly and 4 to 10% of high-risk elderly subjects. Although symptoms of RSV and Influenza A were similar, RSV led to less physician and emergency room visits than Influenza A and was associated with a lower use of antibiotics (Falsey *et al.*, 2005). Influenza A is reported in 1.5 to 26% of admissions for CAP or LRTI (Fernandez-Sabe *et al.*, 2003; Flamaing *et al.*, 2003; Saldias Penafiel *et al.*, 2003; Zalacain *et al.*, 2003; Torres *et al.*, 2004). Para-influenza and RSV were identified respectively in 1 to 1.3% and 0.6 to 3.6% of admissions (Fernandez-Sabe *et al.*, 2003; Flamaing *et al.*, 2003; Zalacain *et al.*, 2003).

## MYCOBACTERIAL INFECTION

Older subjects are today the main reservoir of tuberculosis infection in the indigenous population of industrialized countries. The incidence of tuberculosis in patients aged over 65 is higher than in all other age groups, except for HIV-infected subjects. In Switzerland, the incidence of tuberculosis in patients aged over 70 (20/10<sup>5</sup> inhabitants) is 2.5 times that of the general population. Comorbidities, immunosenescence, malnutrition, and immunosuppressive therapy all contribute to the higher incidence of tuberculosis in this age group.

Clinical presentations of mycobacterial infection in the elderly are often atypical, leading to delayed diagnosis. Thus, mortality of tuberculosis is much higher than in younger age groups, and increases with age. When compared to younger adults, elderly patients with active tuberculosis have less cough, fever, hemoptysis, and night sweats. Their tuberculin skin test is more often negative (32% vs. 10% in younger subjects) (Katz *et al.*, 1987; Korzeniewska-Kosela *et al.*, 1994; Mathur *et al.*, 1994; Chan *et al.*, 1995). On chest roentgenograms, older subjects have more frequent lower or middle lobe involvement, miliary tuberculosis, and atypical presentations (solitary nodules, pseudo-masses, and infiltrates resembling bronchopneumonia), and a lower incidence of cavitory lesions (Korzeniewska-Kosela *et al.*, 1994; Chan *et al.*, 1995). Finally, tuberculostatic treatment is associated with an age-related increase in side-effects (mainly hepatotoxicity).

## UNUSUAL ORGANISMS

Pulmonary cryptococcosis and nocardiosis have been reported in nonimmuno-compromised older patients (Laszlo *et al.*, 2001; Nadrous *et al.*, 2003). Chronic necrotizing pulmonary aspergillosis and actinomycosis must be considered in older patients with slowly evolving pulmonary infiltrates, malnutrition, weight loss, immunosuppressive therapy, and preexisting chronic pulmonary disorders. Atypical mycobacteria (mainly *Mycobacterium avium-intracellulare* complex) may cause a slowly evolving destructive pulmonary infection, occurring more

frequently in nonsmoking women (80%), who present with a chronic cough (86%), fatigue (42%), prolonged fever (10–14%), progressive weight loss leading to cachexia (14–52%), and nonspecific pulmonary infiltrates (Prince *et al.*, 1989; Kennedy *et al.*, 1994). Over the past years, several reports have drawn attention to the possibility of opportunistic infections (i.e., *P. Carinii* pneumonia, unusual presentations of tuberculosis), revealing unsuspected HIV infection in older patients (McMeeking *et al.*, 1989; Rosenzweig *et al.*, 1992; Chen *et al.*, 1998; Cloud *et al.*, 2003; Laszlo *et al.*, 2003).

### When the Pneumonia Doesn't Get Better

In patients who are poorly responsive to adequate antibiotic treatment, alternative diagnoses must be explored. Unusual pathogens and mycobacterial infection must be rapidly ruled out, whenever possible by fiberoptic bronchoscopy. Noninfectious disorders—which may mimic pneumonia—must be considered, such as pulmonary infarction, cryptogenic organizing pneumonia (previously referred to as idiopathic bronchiolitis obliterans organizing pneumonia, or BOOP), vasculitis (Wegener's granulomatosis, or Churg-Strauss Syndrome), bronchocentric granuloma, mucous plugging with infiltrates in allergic broncho-pulmonary aspergillosis, idiopathic acute eosinophilic pneumonia, chronic eosinophilic pneumonia, and carcinoma (mainly bronchoalveolar carcinoma). Cavitory lesions suggestive of pulmonary abscess in fact may be excavated primary pulmonary tumors, or vasculitis (Wegener's granulomatosis).

### Conclusion

In this chapter, we focused on the pathogenic mechanisms leading to pneumonia in older individuals. Aging is associated with important changes in respiratory mechanics (decreased compliance of the respiratory system and strength of the respiratory muscles, increased work of breathing for a given level of ventilation), which increase the vulnerability of the very old to any further aggression to the respiratory tract. Higher rates of aspiration occur in this age group, with frequently occurring risk factors such as cerebro-vascular events, or extrapyramidal disorders. Efficacy of mucociliary clearance mechanisms, including cough, tends to decrease in the very old. Aspiration of oro-pharyngeal secretions is the most important cause of LRTI: oro-pharyngeal flora is influenced by dental status and comorbidities. Increasing morbidity leads to colonization of upper airways by pathogenic micro-organisms such as GNB and *S. aureus*. As in younger subjects, *S. pneumoniae* remains the most frequently identified pathogen. Atypical organisms play a minor role in CAP or NHAP, although the contribution of *C. pneumoniae* may be underestimated.

Unusual organisms and alternative diagnoses must be rapidly considered and sought after in nonresolving pneumonia.

# Diabetes and Aging

Tamas Fulop, Anis Larbi, Daniel Tessier, and André Carpentier

*During the last decades, life expectancy has increased dramatically, leading to the augmentation of the number of elderly subjects around the world. This increase in the proportion of the elderly population is even more remarkable in those over 85 years of age. In the meantime, the incidence and prevalence of age-related diseases are also increasing markedly. The most common diseases associated with aging are infections, cancers, cardiovascular diseases, and type 2 diabetes. Approximately 20% of the adults in the United States have developed diabetes mellitus by the age of 65, according to the National Health and Nutritional Examination Survey (NHANES III). Type 2 diabetes is a multifactorial disease involving complex interactions of genetic and environmental factors. The three major pathophysiological features leading to type 2 diabetes are (1)  $\beta$ -cell dysfunction manifested by decreased insulin secretion; (2) impaired insulin-mediated glucose disposal associated with impaired muscle insulin signaling; and (3) enhanced hepatic glucose production.*

*Aging, most probably per se, is related to several physiological changes that will favor the appearance of these pathophysiological features. Thus type 2 diabetes as a model of aging as well as of premature aging may ultimately help us unravel the fundamental keys to the aging process. Although new breakthroughs in basic research will help us identify and design best-fitted interventions for our patients, more advances are also needed in translational research to gain maximal efficiency in implementing these new findings into clinical practice. This chapter will review the potential age-associated changes leading to increased type 2 diabetes mellitus incidence with aging.*

## Introduction

Life expectancy has increased markedly during the last century, which resulted in the augmentation of the elderly population. Among this elderly population the proportion of those over 85 years has increased even more dramatically. This phenomenon is accompanied by the enhancement of the incidence and prevalence of age-related diseases. The most common age-related diseases are infections, cancers, cardiovascular diseases and type 2 diabetes mellitus. Data from the epidemiological

studies show unequivocally that the incidence of type 2 diabetes mellitus rises steeply with age (Wilson *et al.*, 1986). Age is one of the most important variables influencing the prevalence of impaired glucose tolerance (IGT) and type 2 diabetes starting from 40 years of age (Finucane *et al.*, 2001). Type 2 diabetes has marked impacts on the aging subjects as it affects not only carbohydrate metabolism, but also lipid and protein metabolism. Over time, this disease has a profound influence on the development of dysfunctions of the cardiovascular system, the kidneys, the eyes, and the peripheral nervous system so common in the aging population. Thus, type 2 diabetes contributes heavily to the morbidity and mortality, and to the economic burden associated with aging of our population. This chapter will deal with the specific characteristics of the disease in relation to age.

## Definition, Diagnosis, and Epidemiology

The diagnosis of diabetes should be made on the basis of a fasting plasma glucose level of 126 mg/dL (7.0 mmol/L) or greater on at least two occasions (Standards, 2005; Halter, 1999). The diagnosis could also be made with an OGTT when the plasma glucose level is higher than 200 mg/mL (11.1 mmol/L) two hours post-challenge (Standards, 2005; Halter, 1999). These criteria have been chosen based on longitudinal studies demonstrating plasma glucose levels associated with an increased risk for retinopathy. Approximately 50% of the elderly population have impaired glucose tolerance (IGT) with normal fasting plasma glucose level. Impaired glucose tolerance (IGT) is defined as a glucose level over 140 mg/dL (7.8 mmol/L), but less than 200 mg/dL (11.1 mmol/L) two hours after a 75 g oral glucose tolerance test (OGTT) (Standards, 2005; Halter, 1999). This is an intermediate stage in the alteration of glucose metabolism and, as such, a strong predictor for the development of type 2 diabetes. The rate of conversion of IGT to diabetes was found to be between 3.6% for women and 8.7% for men per year (Yudkin *et al.*, 1993). Although individuals with IGT do not develop the microvascular complications associated with type 2 diabetes, they are at high risk of developing cardiovascular diseases and are also at higher risk of mortality attributable to cancer (Saydah *et al.*, 2003).

TABLE 55.1  
Risk factors for the development of type 2 diabetes

Advancing age
Increasing BMI
Central adiposity accumulation (larger waist circumference)
Physical inactivity
Having first-degree relatives with type 2 diabetes
Non-Caucasian ethnic origin
Prior delivery of a large for gestational age baby or previous diagnosis of gestational diabetes
Hypertension
Low HDL level—<0.35 mg/dl (0.9 mmol/L)
High plasma triglyceride level—>250 mg/dl (2.82 mmol/L)
Diagnosis of polycystic ovary syndrome
IGT or IFG
Presence of acanthosis nigricans
Known cardiovascular disease

Adapted from Wilson *et al.*, 1986.

Another intermediate stage between the normal metabolic state and type 2 diabetes is impaired fasting glucose (IFG), defined as a fasting plasma glucose between 100 and 125 mg/dl (5.6 to 6.9 mmol/L) (Standards, 2005). IFG is also associated with a higher risk of developing type 2 diabetes, although it is not as strong a marker for the risk of cardiovascular and cancer as IGT (Saydah *et al.*, 2003; Muntner *et al.*, 2004). Together, IGT and IFG (so-called pre-diabetes) can be found in approximately 12 million individuals aged between 45 and 75 years old in the United States (Benjamin *et al.*, 2003).

The ADA recommends that screening for diabetes begin at age 45 years and be performed at three-year intervals, but at a younger age and shorter intervals in high-risk patients such as overweight individuals (BMI  $\geq 25$  kg/m<sup>2</sup>) with one or more risk factors (see Table 55.1) (Standards, 2005). Nowadays the most useful and used diagnostic tool is the determination of fasting plasma glucose level. The OGTT is more cumbersome to apply to large populations and may be less reproducible than measurement of fasting plasma glucose. However, OGTT is also more sensitive than fasting plasma glucose level for the diagnosis of type 2 diabetes and has the advantage of identifying those individuals with impaired glucose tolerance.

Approximately 20% of the adults in the United States have developed diabetes mellitus by the age of 65, according to the National Health and Nutritional Examination Survey (NHANES III) (Harris *et al.*, 1987). This prevalence has progressively grown over the past 30 years. The prevalence of diabetes mellitus is approximately two per 1000 among those less than 45 years old, and steadily increases with age in subjects older than 75 (Harris, 1993; Meneilly *et al.*, 2001). Due to the

long, asymptomatic progression to type 2 diabetes, a large proportion of patients are unaware that they have this disease and may have developed end-organ damages by the time of diagnosis. Thus, the increasing prevalence of diabetes mellitus with age results in the several-fold increase of the well-known concomitant complications, including end-stage renal disease, loss of vision, myocardial infarction, stroke, peripheral vascular diseases, and peripheral neuropathy. The risk of lower extremity amputation is increased by 10-fold in the presence of diabetes mellitus. More strikingly, diabetes is associated with a 10-year reduction of the life expectancy and is associated with a higher mortality at any age (Halter, 1999).

Type 2 diabetes is a multifactorial disease involving complex interactions of genetic and environmental factors. The three major pathophysiological features leading to type 2 diabetes are (1)  $\beta$ -cell dysfunction manifested by decreased insulin secretion; (2) impaired insulin-mediated glucose disposal associated with impaired muscle insulin signaling; and (3) enhanced hepatic glucose production (Stumvoll *et al.*, 2005). Apart from age, overweight and central adiposity are important risk factors, associated with more than 80% of cases of diabetes in the adult population. Overweight and central adiposity accumulation are also associated with other classical cardiovascular risk factors including hypertension, dyslipidemia, impaired fibrinolysis, and pro-thrombotic state, which together are referred to as the metabolic syndrome. Recently, the role of adverse *in utero* environment associated with growth retardation and failure to thrive during the first year of life have been found predictive of the later development of IGT or type 2 diabetes (Jimenez-Chillaron *et al.*, 2005; McMillen *et al.*, 2005).

### Age-related Risk and Etiologic Factors for Diabetes Mellitus Type 2

Poor diet, genetic factors, obesity, and lack of exercise may partly explain the increased prevalence of glucose intolerance and type 2 diabetes with advancing age. Among the confounding factors for the development of type 2 diabetes associated with aging, the most important are increased body adiposity and reduced lean body mass. These changes are characteristic of the aging process, but individually can be found in many pathological states with similar untoward metabolic consequences. The concomitant occurrence of these body composition changes and aging *per se* probably has an important impact on the development of type 2 diabetes in elderly.

#### BODY COMPOSITION CHANGES AND OBESITY

Aging is characterized by a profound reshaping of the body composition (Hughes *et al.*, 2004). There is a typical decline in the lean body mass, while the fat cell mass is

increasing. The reduction of lean body mass is explained mainly by loss of muscle mass, a process called *sarcopenia* (Nair, 2005; Clarke, 2004). The decline of muscle mass has been estimated to be about 6% per decade between the age of 30 and 80. The exact cause of this decline is not known, but neuro-endocrine factors, reduced spontaneous and conscious physical activity, and intrinsic protein metabolic changes in muscles contribute to sarcopenia (Balagopal *et al.*, 1997). Reduced mitochondrial function in muscle associated with impaired production of ATP is felt to play an important role in the pathogenesis of age-associated sarcopenia (Nair, 2005). It is also of interest to note that reduced muscle production of ATP is present very early in young, insulin-resistant offspring of patients with type 2 diabetes (Petersen *et al.*, 2004), suggesting a link between mitochondrial dysfunction and muscle insulin resistance. However, mitochondrial dysfunction and biogenesis improve with aerobic training, whereas insulin sensitivity does not in the elderly (Short *et al.*, 2003). Why, then, is sarcopenia a serious risk factor for insulin resistance and consequently for type 2 diabetes in elderly subjects? The muscle is the primary site for insulin-mediated glucose disposal and, therefore, the reduction of muscle mass with aging may seriously affect glucose metabolism.

Furthermore, the frailty syndrome in the elderly is characterized by a frailty phenotype described by Fried *et al.* (2001) including sarcopenia, thus being a risk factor for insulin resistance. Moreover, as mentioned, the decreased supply in proteins and energy *in utero* and during the first year of life is a risk factor for IGT and type 2 diabetes. These factors associated with low birth weight also indicate a higher risk for frailty. Thus, the early growth retardation is a risk factor for both frailty and type 2 diabetes mellitus via perhaps the development of sarcopenia with aging.

Most dramatically, not only is there an increase in the fat cell mass but also its distribution is changing, because this enhancement is due to an enrichment at the abdominal site (central distribution). This central redistribution of the fat cell mass has dramatic consequences for the metabolic environment and is a risk factor for several obesity and age-related metabolic abnormalities. Thus, the frontier between aging and obesity is very thin (Harris, 1999). Interestingly, the normal relationship between total body fat mass and circulating leptin levels appears to be disrupted in the elderly, suggesting that abnormal secretion of this adipostat may play a role in body fat changes with aging (Moller *et al.*, 1998). The increase in visceral and central fat cell mass with or without reduction of peripheral fat mass has dramatic consequences for the metabolic environment and is a risk factor for several obesity and age-related metabolic abnormalities, such as hypertension and hyperlipidemias (Lewis *et al.*, 2002). Weight gain or central redistribution of fat clearly has been associated with the development of type 2 diabetes (Koh-Banerjee *et al.*, 2004).

This anatomical distribution is accompanied by an increase in plasma free fatty acid (FFA) levels (Raz *et al.*, 2005) and appearance rate, reduced adiponectin secretion, and the enhanced secretion of pro-inflammatory molecules (e.g., tumor necrosis factor (TNF)- $\alpha$  and interleukin-6) (Unger, 2003; Eckel *et al.*, 2005; Sharma *et al.*, 2005). Altogether, these changes favor the apparition of insulin resistance and may also have an untoward impact on beta cell function over time (Lewis *et al.*, 2002). However, as long as the pancreatic beta cell insulin secretory response can compensate for this increase of insulin resistance, euglycemia will be maintained. Once this compensation is overwhelmed, insulin resistance leads to a progressive reduction of glucose tolerance and, eventually, to type 2 diabetes.

#### LOW-GRADE INFLAMMATION

There are now accumulating data that aging is associated with a low-grade inflammation, coined InflammAging by Claudio Franceschi (Franceschi *et al.*, 2000). This status reflects an imbalance between the innate and the adaptive immune response. Whereas the pro-inflammatory cytokines such as IL-6, TNF- $\alpha$  are increasing, originating in particular from monocytes/macrophages as those infiltrating the various adipose tissues (Mazurek *et al.*, 2003; Weisberg *et al.*, 2003), those coming from the adaptive immune response are decreasing. In the meantime, as a compensatory mechanism, the anti-inflammatory cytokines originating from Th-2 cells of the adaptive immune response are also increasing. These changes add to the already increased production of pro-inflammatory cytokines by the increased abdominal fat cell mass (Unger, 2003; Eckel *et al.*, 2005; Sharma *et al.*, 2005). Indeed, central fat not only contributes to insulin resistance by direct secretion of pro-inflammatory cytokines, but also by the release of FFA, which, in turn, can stimulate the NF $\kappa$ B activation through the phosphorylation of I $\kappa$ B via IKK leading to the production of more pro-inflammatory cytokines. Thus, increased pro-inflammatory cytokine levels participate in the development of the insulin resistance. In this context IL-6 was also associated with the frailty syndrome leading to loss of independence and poor prognosis.

### Interactions between Type 2 Diabetes and Other Pathological States Associated with Aging

#### THE NEURO-ENDOCRINE DYSFUNCTION

Recently, epidemiological studies have demonstrated an increased prevalence of cognitive impairment associated with diabetes. In the Third National Health and Nutrition Examination Survey (NHANES III), type 2 diabetes, combined with hypertension, was significantly associated with impaired cognitive function in subjects younger than 60 years old (Pavlik *et al.*, 2005). Patients with

Alzheimer's disease suffer from a marked increase in prevalence of type 2 diabetes, whereas the presence of brain plaques in patients with type 2 diabetes correlates with the duration of diabetes (Janson *et al.*, 2004). Experimental models have suggested that the brain mitochondrial toxicity associated with neurotoxic agents such as beta amyloid deposits may be exacerbated by the presence of diabetes (Moreira *et al.*, 2003).

As described earlier, aging is associated with a low-grade inflammation. This manifests itself also at the neuro-endocrine level by a relative sustained increase of cortisol and adrenergic hormone levels in elderly subjects (Valenti, 2004). The stress hormones such as cortisol may contribute to the development of insulin resistance. In case of acute events, such as illnesses, the effect of these stress hormones may be accentuated, contributing to the occurrence of type 2 diabetes. The contributing effect of cortisol on impaired glucose tolerance or type 2 diabetes could be through its ill-defined age-dependent effects on the innate immune response or direct interference with insulin-mediated glucose disposal. The  $\alpha$ -adrenergic effect of catecholamines by inhibiting insulin secretion further accentuates the contribution of age-related hormonal changes to insulin resistance in diabetes mellitus. The activation of serine kinase via the catecholamine-mediated cAMP dependent kinase inhibits the tyrosine phosphorylation of the insulin receptor, contributing to insulin resistance with aging. Thus, the increase in cortisol and noradrenalin levels seen with aging may contribute in many ways to the development of IGT and type 2 diabetes.

Recently, the role of the enteroinsular axis was assessed in relation to the age-dependent glucose intolerance. Glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1), two gut hormones whose secretion is stimulated by the ingestion of glucose, are incretin hormones that potentiate insulin secretion. Their basal levels as well as their levels after OGTT have been found unchanged in elderly obese and nonobese healthy elderly individuals. A study using the hyperglycemic clamp technique showed that GIP sensitivity may be impaired in older subjects (Meneilly *et al.*, 1998). Recently, however, it has been shown that incretin-mediated muscle glucose uptake was markedly impaired in elderly type 2 diabetes patients (Chang *et al.*, 2003). Further studies are needed to establish more firmly the role of incretins in the beta cell defect and type 2 diabetes associated with aging.

#### ADIPOSE TISSUE DYSFUNCTION

There are only scarce data on the contribution of adipose tissue dysfunction to the etiology of diabetes mellitus type 2 in relation to aging. The role of the adipose tissue is well established in relation to the increased release of free fatty acids (FFA) interfering with insulin signaling in insulin-sensitive tissues (Lewis *et al.*, 2002). The loss of peripheral fat tissue in hereditary or acquired

lipodystrophic syndromes has been associated with intramyocellular and intrahepatic fat accumulation, profound insulin resistance, and type 2 diabetes (Lewis *et al.*, 2002). Recently, a cross-sectional study in a large cohort of elderly has shown an association between higher subcutaneous thigh fat and favorable plasma glucose and triglyceride levels, independent of visceral fat (Snijder *et al.*, 2005). However, there is almost no data to show how central adipose tissue redistribution with aging may contribute to increased pro-inflammatory cytokine production, including TNF- $\alpha$ , compared to that of the innate immune cells such as monocyte/macrophages. Moreover, the role of adipocytokine secretion is also controversial with aging (Ryan *et al.*, 2003; Kanaya *et al.*, 2004). Leptin is released from adipocytes and acts on the central nervous system to decrease appetite. Lower, higher, and no change in leptin levels have been reported in the elderly.

The strong positive correlation between fat mass and circulating leptin levels was found to be disrupted in elderly subjects (Moller *et al.*, 1998), suggesting an impairment of the feedback between peripheral fat stores and appetite regulation, which may contribute to the increased prevalence of obesity with age. Adiponectin has an insulin-sensitizing effect in the liver and skeletal muscles associated with the activation of AMP kinase (Ouchi *et al.*, 2000; Masuzawa, 2005). In obesity and insulin resistance, plasma adiponectin levels are decreased. Although data are very scarce concerning adiponectin level changes with aging, they seem to indicate an age-related decrease. Very recently, higher adiponectin levels were associated with lower odds of diabetes in older men and women (mean age 73 years) (Masuzawa, 2005). Furthermore, low adiponectin levels were associated with the development of the metabolic syndrome in healthy elderly Koreans (Choi *et al.*, 2004). In this context animal models of diabetes could have some contribution, but the study of diabetes and aging is rarely exploited together. This would be interesting to develop an aging model progressing to diabetes for the study of the adipose tissue contribution.

#### LIPOTOXICITY

Much attention has been turned recently on the role of free fatty acids in type 2 diabetes. As already mentioned, enhanced fat cell mass releases higher amounts of FFA, leading to enhanced plasma FFA flux and exposure of insulin-sensitive tissues (Lewis *et al.*, 2002). FFAs are known to interfere with insulin-mediated GLUT4 translocation to the sarcolemma and with glucose phosphorylation in muscles, leading to impaired insulin-mediated glucose disposal and insulin resistance. This could happen through the activation of the PKC pathway, which can phosphorylate IRS molecules on serine/threonine residues, thus reducing downstream signaling. FFA can also stimulate neoglucogenesis in the liver. Though FFA can also act on  $\beta$ -cells to sustain

insulin release during the fasting state, chronically elevated circulating FFA levels result in intracellular accumulation of long chain acyl CoAs (LC-CoAs) within the beta cells. These LC-CoAs interfere with the glucose-dependent closure of  $K_{ATP}$ -channel activity and impairs insulin secretion. FFAs also interfere with the physiological oscillation of calcium and insulin secretion granule exocytosis. The recent observation of a link between impaired fatty acid oxidation and other effects on beta cells could be the reduction of ATP formation leading to decreased insulin secretion and the induction of beta cell apoptosis (lipoptosis) by induction of ceramid formation or of cytotoxic oligomers of islet amyloid polypeptide formation. By enhancing the generation of superoxide radicals by the respiratory chain, FFAs may also induce the expression of UCP2 in beta cell mitochondria, leading to reduced coupling of oxidative phosphorylation and ATP production, and impaired glucose-stimulated insulin secretion (Lowell *et al.*, 2005). In addition to their role as constituent molecules and sources of energy, FFA can also behave as signaling molecules on PPARs and HNFs, although the potential pathophysiological roles for these interactions remain elusive for the moment. In the context of insulin resistance due to type 2 diabetes and aging, the adipose tissue is subject to an imbalance between fatty acid oxidation in muscle and liver (energy) and lipogenesis *de novo* (lipotoxicity). Thus, by contributing to the impairment of insulin-mediated glucose disposal, enhanced hepatic glucose production, and impaired glucose-stimulated insulin secretion, FFAs may potentially contribute to the development of type 2 diabetes associated with aging.

### GLUCOTOXICITY

Hyperglycemia as a hallmark of diabetes mellitus, in turn, is known to contribute directly to insulin resistance as well as potentially interfering with normal pancreatic cell function, thereby setting the stage for a vicious circle of maladaptive mechanisms. Hyperglycemia, through the deregulation of  $K_{ATP}$ -channel, exerts a toxic effect on insulin secretion via the intracellular  $Ca^{2+}$  oscillation mediated by voltage-gated channels. The exposition of beta cells to chronic hyperglycemia as well as free fatty acids alter the insulin secretion induced by glucose.

### PRODUCTION OF ADVANCED GLYCATION END PRODUCTS (AGES)

One important consequence of IGT and type 2 diabetes is the formation of AGEs. An important role for the production of advanced glycation end products (AGE) and oxidative stress can be evoked not only as a potential mechanism for microvascular and macrovascular complications of diabetes, but also as a contributing factor to insulin resistance. Glucose irreversibly modifies macromolecules with a slow turnover by forming AGEs as a function of glucose concentration and time. Indeed, it has been shown that AGEs are accumulating with aging,

in diabetes and in Alzheimer's disease (Vlassara *et al.*, 2003). AGEs will react with their specific receptors (RAGE) leading to various harmful pathological processes, including endothelial dysfunction and cognitive impairment.

During the formation of AGEs as well as during their interaction with RAGEs, free radicals are produced. Thus, free radicals not only were implicated as a cause and a consequence of the aging process, but also as a consequence of hyperglycemia. AGEs as well as free radicals may directly influence or interfere with the insulin receptor (IR) function and signal transduction by diminishing the tyrosine phosphorylation of IRS1/2, which in turn becomes unable to recruit the p85 $\alpha$  subunit of PI3-kinase. Furthermore, this will result in reduced PKB activity and consequently altered glucose and glycogen metabolism. Moreover, chronic oxidative stress, by chronically oxidizing PTP1B, alters IR activity and signaling. These processes will also interfere with the membrane composition with aging, regulating the localization of IR to lipid rafts. Thus, the aging process, either through oxidative stress or through the development of hyperglycemia, interferes with IR function and signal transduction leading to insulin resistance. We will address this issue further in the chapter.

### GENETICS

There is strong genetic predisposition for type 2 diabetes mellitus. Studies with identical twins showed a high rate of concordance for type 2 diabetes. Recently, the heritability of beta cell dysfunction in type 2 diabetes was found to be 84% in old and 75% in young twins, suggesting a predominant genetic effect that gains more impact with age (Poulsen *et al.*, 2005). In that same study, the heritability of insulin-mediated glucose disposal and insulin-mediated nonoxidative glucose disposal was ~50% and did not change with age, whereas hepatic glucose production appears to be mainly related to environmental factors. Multiple genes are involved in different individuals. So far only calpain 10 has been identified. The HLA DR3 serotype is more common in older adults who require insulin treatment. The exact nature of these genes is still unknown; however, the discovery of the predisposing genes to diabetes via perhaps the sarcopenia susceptibility genes and the central adiposity regulating genes could lead to important therapeutic breakthrough as well as to eventual prevention tools.

## Pathogenesis of Diabetes Mellitus Type 2 in Relation to Aging

### ALTERED INSULIN ACTION: INSULIN RESISTANCE

One factor clearly contributing to this age-related glucose intolerance is a decline with physiologic aging in sensitivity to the metabolic effects of insulin; that is, the

reduction of insulin sensitivity. This means a reduction in the activity of insulin on its target tissues such as muscle, liver, and adipose tissue. In the muscle this results in a decrease of glucose disposal. In the adipocytes this results in the inability of insulin to inhibit the lipolysis leading to the release of free fatty acids in the circulation. These FFAs in turn stimulate hepatic neoglucogenesis and VLDL secretion, reduce muscle glucose uptake, and may alter glucose-stimulated insulin secretion by beta cells. This age-related impairment of insulin action appears to be predominantly due to effects on the insulin signaling mechanism beyond the insulin receptor itself. However, the latter also may be involved to some extent (Fulop *et al.*, 2003). In the liver the resistance results in the inadequate suppression of the endogenous glucose production even in the presence of hyperglycemia. The gold standard technique for measuring the insulin resistance in humans is the hyperinsulinemic glucose clamp; this technique involves a fixed dose of insulin being administered and then normal glucose concentrations being maintained by the infusion of glucose given (the glucose infusion rate or M-value), which reflects insulin sensitivity and is an inverse measure of insulin resistance. Of special note, as already mentioned, is that the insulin resistance alone does not cause the type 2 diabetes; it should be associated with the insulinopenia as occurring in many cases with aging. This is discussed later.

There is still some debate to elucidate whether this altered insulin sensitivity is due to the aging process *per se* or is determined by external, mainly lifestyle, factors such as body composition changes or decrease in physical activity. However, actually it seems that aging *per se* could have a fundamental influence. Euglycaemic clamp studies consistently demonstrate that elderly individuals are insulin resistant and that the dose response curve for insulin is shifted to the right (Moller *et al.*, 2003). This impairment of insulin action affects the mobilization of glucose transporters, which are critical to glucose uptake and metabolism in insulin-dependent tissues such as muscle, liver, and fat.

#### *The insulin receptor signal transduction*

The insulin receptor (IR) and the insulin-like growth factor receptor (IGFR) belong to the receptor tyrosine kinase (RTK) super-family. However, the signal transduction by these receptors mainly occurs via the insulin receptor substrate (IRS) adapter proteins (IRS1 to 4) (Capeau, 2003). IRS proteins seem to present a further important regulatory step in the insulin receptor activation. The degree of serine/threonine (S/T) phosphorylation determines either positively or negatively the signal transmission via IRS proteins. During insulin stimulation, the phosphatidylinositol-3 kinase (PI3K) becomes activated via the IRS association as well as the Ras-MAPK pathway leading to glucose transport activation through GLUT-4 and to other metabolic

actions as well as to mitogenesis and differentiation, respectively. However, this needs the tyrosine phosphorylation of IRS after their binding to the juxtamembrane region of the activated IR.

In contrast, the over-phosphorylation of the S/T could explain that the tyrosine phosphorylation of IRS does not occur in the presence of insulin and leads to insulin resistance (Greene *et al.*, 2002). This over-phosphorylation of S/T also could be induced by tumor necrosis factor (TNF- $\alpha$ ) or chronic increase in the insulin level as may occur during aging. It was also demonstrated that suppressors of cytokine signaling (SOCS), well known for their inhibitory effect on the Jak/STAT pathway, also exert a regulatory action on IRS. Recently, the regulating role of several tyrosine phosphatases such as LAR, SHP-2, PTP-1B in insulin signaling were recognized. Specific actions of insulin are frequently mediated by distinct intracellular signaling pathways. As already mentioned, activated IR through the tyrosine phosphorylation of IRS recruit the PI3K and Akt. This will induce in adipose, muscle, and liver tissues, insulin-stimulated translocation of the glucose transporter GLUT4 from intracellular vesicles to the cell surface, whereas Ras pathways mediate mitogenic effects of insulin. The recently discovered lipid rafts' contribution is just being elucidated in the context of IR signaling.

#### *IR signal transduction changes with aging*

Data obtained concerning insulin receptors (IR) and glucose transporters in aging are contradictory; nevertheless they suggest that neither changes in IR number and affinity nor changes in the glucose transporters could be sufficient to explain the insulin resistance with aging. It is of note that the glucose transporter translocation from vesicles to the membrane in the context of newly discovered lipid rafts has not been investigated in the context of aging. Studies concerning the insulin receptor kinase activity in animal models, resulting in phosphorylation, showed conflicting results with aging. Studies in rats showed that basal and insulin stimulated autophosphorylation of liver insulin receptor and its kinase activity did not change with aging (Kono *et al.*, 1990). On the other hand the rat skeletal insulin receptor kinase activity showed different results, indicating that phosphorylation changed with aging (Kono *et al.*, 1990). Another study has shown that insulin stimulated IR autophosphorylation has been decreased in both liver and muscle of 20-month-old rats (Carvalho *et al.*, 1996). These contradictory results might be explained by the different tissues studied that are not equally sensitive to the aging process or by the different techniques used.

Carvalho *et al.* (1996) also showed that IRS-1 protein levels decreased at a relatively young age (5 months) by 58% and remained at this low level in muscle, though not in liver. Moreover, other signal transduction changes were shown, including decreased IRS-1 phosphorylation, decreased IRS-1 association with the PI3-kinase, and

decreased phosphotyrosine associated PI3-kinase activity upon stimulation by insulin in both muscle and liver tissues of 20-month-old rats. Other studies have also shown that with aging in rats, the insulin receptor and the p85 alpha subunit of PI3-kinase both declined by about 40%, whereas in the meantime these parameters did not change with aging in the skeletal muscle (Martineau *et al.*, 1999). Altogether the bulk of the experimental data suggest that alterations in the early signal transduction events of insulin might have an important role in the insulin resistance observed with aging.

After having described insulin receptor signal transduction changes in cells and in tissue of aging animal models, the question is raised whether identical alterations could be found in humans in view of the increased insulin resistance with human aging. Strangely, only a few studies have examined this question. We have shown with healthy aging in monocytes and neutrophils an alteration in the cAMP and cGMP production under insulin receptor stimulation (Fulop *et al.*, 1987). With aging the cAMP level was increased, whereas that of cGMP did not change. The exact role of this signaling pathway in the insulin effects is mostly unknown, but mainly related to the modulation of the IR tyrosine phosphorylation as shown for adrenergic hormones. A recent study—although not in aged healthy humans, but in insulin-resistant, obese humans—demonstrated that in muscle, insulin signaling by PI3-kinase is impaired, whereas the MEK/MAPK pathway undergoes a normal insulin-dependent stimulation (Cusi *et al.*, 2000). The question concerning the role of these various signaling pathways in various tissues is raised in an insulin-resistance state related to the physiological aging process itself. Altogether, clinical data suggest a marked insulin resistance with aging in humans; however, the biochemical and molecular basis of this insulin resistance level mainly in insulin-sensitive tissues including muscle, adipocytes, and liver is still waiting to be unraveled. Altogether this deterioration of insulin sensitivity with aging, via signaling alterations, contributes to the increased incidence of type 2 diabetes.

#### *How IR signaling changes integrate the general receptor signal alterations found in aging*

There is much experimental evidence that aging is associated with an altered signal transduction in the case of many receptors including dopamine, insulin, adrenergic, and T cell receptors. One ultimate common point of all these receptors is their localization in the membrane that transduces information to the nucleus. Recent studies suggested that the plasma membrane in mammalian cells is not homogeneously organized, but contain specific microdomains in composition and function (Razzaq *et al.*, 2004). These microdomains—also called lipid rafts—are specially enriched in cholesterol and sphingolipids and proteins that are mainly involved in receptor signaling. Thus, these lipid rafts are

involved mainly in signal transduction and membrane trafficking.

It has been well known for a long time that the membrane composition is altered with aging because the membrane fluidity is decreasing. This is mainly due to an enrichment in cholesterol, as well as to the age-related oxidative stress, and ultimately leads to marked functional alterations. One fundamental property of lipid rafts is their ability to move laterally in the membrane; thus, the rigidification of the membrane with aging could interfere with this mobility (Larbi *et al.*, 2004). Also, the signaling alterations found with aging, including that of insulin receptor, could be due to an alteration at the membrane level, as was demonstrated in T lymphocytes. Wherever IR are localized in the membrane (i.e., in caveolae containing cells or in lipid rafts containing cells), aging has been clearly associated with changes in cell membrane properties. This would establish a unifying cause to the altered signal transduction occurring with aging. Moreover, receptor internalization, reexpression, or degradation by proteasome may also be other points where defects or changes could lead to the induction or the chronicity of insulin resistance and its consequences as described earlier.

#### PANCREATIC BETA CELL DYSFUNCTION

The role of impaired insulin secretion due to pancreatic beta cell dysfunction in age-related glucose intolerance and type 2 diabetes has been well known from animal studies. In humans this aspect of type 2 diabetes has remained controversial during a long period (Chang *et al.*, 2003). This was probably due to the earlier failure of taking into account the degree of insulin resistance in the evaluation of beta cell function *in vivo* with techniques such as the OGTT. The relationship between insulin secretion and insulin sensitivity follows a hyperbolic curve so that a reduction in insulin sensitivity normally is associated with an increase in insulin secretion. Thus, similar absolute insulin secretion observed in older vs. younger individuals suggests inappropriate beta cell response in view of the reduced insulin sensitivity in the former group. This only very recently was recognized in IGT and type 2 diabetes of elderly subjects by methods able to assess insulin sensitivity as well as pre-hepatic insulin secretion by deconvolution of the peripheral C-peptide levels with C-peptide kinetics (Chang *et al.*, 2003). The Baltimore Longitudinal Study confirmed, after adjustment of all confounding parameters (e.g., adiposity), that insulin levels were significantly decreased with aging. It was shown in human subjects that the post-hepatic insulin delivery dropped by 25% between the ages of 18 and 85 years when age-related increase in insulin resistance was taken into account. Another recent study has demonstrated that age is independently associated with reduced beta cell function, whereas visceral fat accumulation was associated with both beta cell

dysfunction and reduced insulin sensitivity (Utzschneider *et al.*, 2004).

This reduction of beta cell function occurs in the presence of normal or even higher secretion of gut incretin hormones such as glucose-dependent insulinotropic polypeptide (GIP) and glucagons-like peptide 1 (GLP-1), suggesting beta cell resistance to these hormones in the elderly. Reduced arginine-stimulated insulin secretion has also been observed in older subjects and may indicate a reduction in beta cell mass with aging.

The pancreatic beta cell dysfunction seen with aging is associated with alterations of glucose-stimulated insulin pulse mass, kinetics, and rhythmicity. Normally, insulin is secreted in a pulsatile manner that insures a higher sensitivity at the receptor level and lower needs for secretion. This pulsatile secretion is controlled by the oscillation of the intra-cytoplasmic calcium level. In type 2 diabetes, there is an over-activity of plasma membrane  $K_{ATP}$ -channel due to chronic hyperglycemia altering electrical activity by  $Ca^{2+}$  and consequently the insulin secretion. With aging, calcium metabolism was shown to be altered in various cell types; thus it is plausible that this also occurs in pancreatic cells. Moreover, if intracellular calcium concentration remains high, this could result in the apoptosis of pancreatic cells, potentially contributing to the significant 20 to 40% reduction of beta cell mass associated with type 2 diabetes. Thus, a tight control of calcium metabolism is essential, and its alteration could lead to pancreatic beta cell dysfunction.

Aging is not only characterized by the loss of beta cell mass but also by a progressive loss of beta cell function (Chang *et al.*, 2003; Elahi *et al.*, 2002). How is insulin secretion evaluated? In the case of nondiabetic humans the OGTT was widely used to measure the insulin level at fasting state and after glucose challenge. As mentioned, the OGTT is a complex test to interpret. Thus, an intravenous glucose tolerance test was used with frequent sampling. The results in elderly subjects were not conclusive following these studies. Beta cell function can be better evaluated with the hyperglycemic clamp technique. During this procedure the plasma glucose levels are increased to the same extent above the basal levels in subjects by means of intravenous glucose infusions. The introduction of the insulin resistance factor contributed to the elucidation of the relative decrease of insulin secretion related to insulin resistance. More recently, the use of pulsatile insulin release technique and nonglucose stimuli such as arginine have detected age-related defects in insulin secretion. Thus, the most important alteration seems to be the decrease of the secretion of insulin (both low-amplitude and ultradian pulses), either at the basal status or after glucose and nonglucose challenge. This also could be one component of the type 2 diabetes in aging as the  $\beta$ -cells are not able to adapt their insulin secretion to the insulin resistance status, as was shown in a few studies mainly performed

by Meneilly *et al.* (Meneilly *et al.*, 1997). Finally, the quantity of the secreted insulin is decreasing progressively in time, even if the insulin resistance remains stable as shown in the six-year follow-up data from the UKPDS.

One hypothesis put forward to explain the age-related decline in insulin secretion is the decline in mitochondrial metabolism, which compromises beta cell ATP production. This in turn might lead to reduced closure of the  $K_{ATP}$ -channel, decreased beta-cell depolarization, and lower insulin secretion in response to glucose (Ashcroft *et al.*, 2004). This hypothesis is supported by several lines of evidence. First, accumulation of somatic mutations of the mitochondrial genome is known to occur at an accelerated rate in patients with type 2 diabetes (Nomiya *et al.*, 2002). Second, mitochondrial dysfunction and reduced production of ATP is seen in skeletal muscles in elderly subjects and also very early in the natural history of type 2 diabetes (Nair, 2005; Petersen *et al.*, 2004). Third, mitochondrial function is critical for the coupling of insulin secretion to glucose metabolism in beta cells by controlling the ratio of ATP/ADP. It has been demonstrated that uncoupling the oxidative mitochondrial metabolism and production of ATP leads to the development of impaired insulin secretion (Lowell *et al.*, 2005). Thus, the decline in mitochondrial energy production may contribute to the higher prevalence of type 2 diabetes in the elderly. Altogether, deterioration of beta cell function with advancing age may contribute to the increased incidence and prevalence of type 2 diabetes, although the underlying mechanism remains largely unknown (see Figure 55.1).

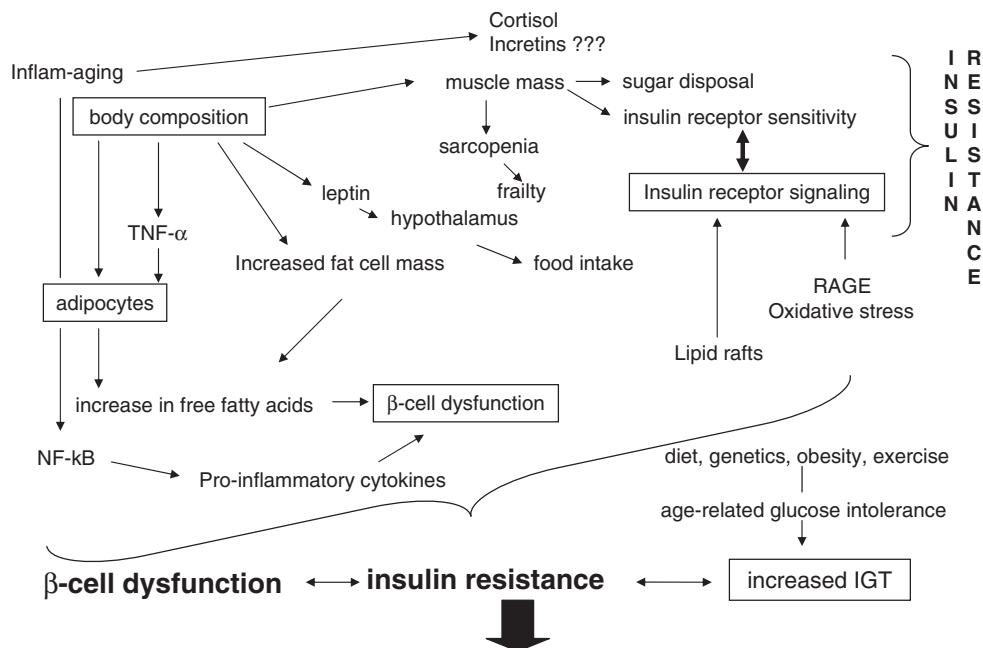

## ROLE OF PRO-INFLAMMATORY MEDIATORS

As described, aging is associated with increased levels of pro-inflammatory cytokines originating from the dysfunction of the immune system and from the altered adipose tissue distribution toward a central predominance. These cytokines are known to enhance adipocyte lipolysis, which further increases the FFA levels, which, as mentioned, exert a negative effect on insulin signaling. Thus exists a vicious cycle, as pro-inflammatory cytokines increase FFA levels, which through the activation of NF $\kappa$ B increases the pro-inflammatory cytokines. In rodent models the neutralization of TNF- $\alpha$  was shown to almost reverse insulin resistance. In humans their contribution is still strongly debated.

## Complications

The increased glucose levels lead to nonenzymatic modification of proteins called glycation (Vlassara *et al.*, 2003). This is initially reversible, but with time this becomes irreversible, leading to functional alterations. Thus, glycation can affect the activities of many proteins with enzymatic properties. Moreover, glycation can

## 55. Diabetes and Aging

Incidence and prevalence of age-related type 2 diabetes mellitus and complications increasing markedly (end-stage renal disease, loss of vision, myocardial infarction, stroke, peripheral vascular diseases and neuropathy)  
Diabetes mellitus affects not only the blood sugar levels, but also the lipid and protein metabolisms

**Figure 55.1** Contribution of the aging process to the development of type 2 diabetes mellitus.

render proteins more susceptible to other attack such as oxidation. One of the best studied examples is LDL. OxLDL plays a pathogenic role in the development of atherosclerosis, by inducing an inflammatory process in the vessel wall.

Furthermore, the glycation can progress and lead to the formation of advanced age products (AGE) that can bind to their specific receptors (RAGE). RAGE are particularly present on endothelial cells, glomeruli, mesangial cells, and monocytes. This interaction leads to the activation of various signaling events intracellularly. The overall effect of AGE products is the production of pro-inflammatory signaling molecules such as TNF- $\alpha$ , IGF-I, and GM-CSF. They induce also the proliferation of the connective tissue including collagen type-IV, laminin, and proteoglycans. This production of connective tissue occurs mainly in the kidney glomeruli, in the retina, and in smooth muscle cells. The AGE products develop a chemotactic activity toward monocytes that will infiltrate various target tissues such as kidney, retina, and arterial wall. The AGE products were involved in the development of glomerulosclerosis, mesangial proliferation, monocyte infiltration, and thrombus formation. By these effects AGE products are recognized to be pro-inflammatory, adding their activities to those already well recognized in aging and type 2 diabetes.

One of the most important complications besides nephropathy is retinopathy. They share many common

features. The diabetic retinopathy is characterized by the loss of pericytes and microaneurysm formation that contribute to the increased capillary permeability. These changes will progress following ischemia to proliferation of endothelial cells and capillaries hemorrhage. The absence of PDGF-B was incriminated to participate in pericyte death and endothelial proliferation. Moreover, some growth factors enriched intraocularly were also found to be contributing to the proliferating activity. IGF-I seems to play a major role in this context. The AGE-inhibitor aminoguanidine confirmed the role of AGEs specifically in the development of retinopathy.

The role of AGEs in diabetic complications was confirmed by the model of diabetic mice, in which the AGEs level was modulated either exogenously by the diet or endogenously by the administration of aminoguanidine. Furthermore, modulation of the AGE-R3 mediated processing and uptake of AGE in nonobese diabetic (NOD) mice confirmed the role of AGEs in the inflammatory process accompanying diabetes and its complications.

### Relationship between Diabetes Mellitus and Aging in the Development of Cardiovascular Diseases

Aging is the single most important risk factor for the development of cardiovascular diseases via the

development of atherosclerosis, as it is also for type 2 diabetes. Aging *per se* could present a state of impaired glucose tolerance due to the physiologic changes described. IGT is known to be a risk factor for progression to type 2 diabetes. Aging associated with the occurrence of type 2 diabetes increases several-fold the risk for development of cardiovascular diseases by approximately six to eight times more than aging alone (Nesto, 2003). This is due mainly to the strong occurrence of the classical, including hypertension, dyslipidemia, and nonclassical, including inflammatory cytokines, homocystein, and CRP risk factors. Altogether, the common pathway could be the insulin resistance and insulinopenia-induced hyperglycemia via the production of AGEs and oxidative stress.

### Experimental Animal Models

Currently there exist several experimental animal models for the study of diabetes (Mathews, 2002). The most currently used are from rodents. All these animal models mainly reproduce by genetic engineering single specific alterations found in type 2 diabetes. These models try to elucidate one particular pathological aspect of the disease. The most widely used are the leptin-deficient *ob/ob*<sup>-/-</sup> mice, *db/db*<sup>+/+</sup> mice,  $K_{ATP}$ -channel mutated, ApoE deficient mice with other deficiencies, several knock-out mice including for RAGE, for specific signaling molecules for IR, for PTP1B.

In this context new models constantly are being developed, such as a transgenic rat model for human islet amyloid polypeptide (IAPP) for studying specifically the loss of beta-cell mass and whether this is occurring by apoptosis (Butler *et al.*, 2004). These rats develop diabetes between 5 and 10 months of age. This model proved very useful to demonstrate certain aspects of the beta-cell toxicity in diabetes mellitus, mainly in the context of glucose toxicity. It is of note that the time of development is very early in life, and perhaps would not be relevant for the age-related effect on diabetes development. Another murine model has been developed to study the role of low birth weight in the development of type 2 diabetes via beta cell dysfunction (Jimenez-Chillaron *et al.*, 2005). This mouse model was developed by undernutrition during pregnancy. These mice developed severe glucose intolerance after six months of age. This is a very useful model; however, the very early development of diabetes renders its application difficult in the context of aging. Nevertheless, this could be a model for some pathophysiological changes occurring as a life-long process in relation to the development of diabetes and perhaps frailty with age. The number of models in development is too many to be enumerated here.

There are only a few models that try to integrate the whole pathophysiological aspects of diabetes like the streptozocine-induced diabetic mice, Zucker fatty rats,

Goto-Kakizaki (GK) rats developed by selective breeding of nondiabetic Wistar rats, or the KK. The KK mouse strain shows inherently glucose-intolerance and insulin-resistance (Ikeda, 1994). These mice become easily obese even by aging itself and show an overt diabetic state. Thus, these mice could be a good model for the study of obesity-related diabetes and also for age-related diabetes. This aspect needs further study.

Recently, the use of nonhuman primates also was advocated as being close to human physiology and pathophysiology (Bruns *et al.*, 2004). Obviously their use is not easy and is very costly. Nevertheless, in some circumstances their use, such as the study of factors related to insulin sensitivity, proved to be very rewarding.

### Experimental Models Linking Diabetes Mellitus to Aging and Longevity

In some species, caloric restriction (CR) is associated with reduction of aging and increased longevity. It was observed that a reduced body size was correlated to an increased life span in mice, dogs, *Caenorhabditis elegans*, or *Drosophila melanogaster*. One very recent study could not find a clear general effect of body size on life span (Hafen, 2004; McCulloch *et al.*, 2003). The question has been asked why smaller individuals would live longer. One explanation that has been put forward, mainly in invertebrates, is the homologous insulin/IGF signaling (IIS). In *C. elegans* it was suggested that the IIS can act to limit the body size. However, in some wild-type strains this correlation was much less clear. Moreover, several mutations in *C. elegans* led to extended longevity phenotype. Among these are the genes involved in the insulin/IGF-signaling pathway, such as *daf-2* and *age-1*, or *clk* mutants related to respiratory metabolism. Similar results were obtained in *Drosophila*. The study in these model organisms of the IIS pathways contributed in various ways to their understanding. Genetic screens identified novel essential components in the pathways. The relation of these pathways to function helped in physiological conditions to make relation to functions such as growth, differentiation, and cell metabolism. They will continue to remain very useful models and should be extended to type 2 diabetes and aging. In mammals, these correlations do not seem to play an essential role. The data ultimately suggest that body size and longevity are linked in very special circumstances as in CR studies, and this could be related to an increased insulin sensitivity, decreased fasting glucose levels, and possibly oxidative stress.

In the context of human aging, an association between the insulin receptor and longevity can be drawn. Hyperinsulinemia is a characteristic of the diabetes mellitus type 2 as a consequence of insulin resistance due to the resistance of IR signaling to the effect of insulin binding. Hyperinsulinemia is part of the so-called metabolic

syndrome characterized by other risk factors such as abdominal obesity, hypertension, and specific dyslipidemia, leading to increased incidence of coronary heart disease. Since atherosclerosis is a disease of later age, it is notable that in euglycemic centenarians insulinemia is low and insulin sensitivity high. This means, as seen in the decreased replicative senescence of cells originated from diabetic subjects, that diabetes type 2 is a model of partial premature aging. Thus, sensitivity, and consequently normal IR signal transduction, are a prerequisite to longevity as shown in caloric restriction studies in rodents and nonhuman primates, as well as in centenarians.

Caloric restriction has been shown to enhance longevity in *Saccharomyces cerevisiae* and *Caenorhabditis elegans* through increased expression of Sir2 (silencing information regulator 2), a NAD<sup>+</sup>-dependent histone deacetylase (Wood *et al.*, 2004; Guarente *et al.*, 2005). Sir2 is a member of a family of proteins called sirtuins, which also includes seven mammalian homologues, among which SIRT1 and SIRT3 have been studied in more details. Caloric restriction by increasing NAD<sup>+</sup> levels enhances longevity in mammalian cells by activating the analog SIRT1 (Cohen *et al.*, 2004). SIRT1 is known to target p53 and forkhead transcription factors, among others, for deacetylation (Luo *et al.*, 2004; Motto *et al.*, 2004). SIRT1 also reduces NF $\kappa$ B transcription by deacetylation of RelA/p65 (Yeung *et al.*, 2004), and also further promotes protection against cellular stress and apoptosis by modulating the FOXO transcription factors. In addition, activation of SIRT1 may reduce adipose tissue differentiation, lipogenesis, and increase fat mobilization by suppressing PPAR- $\gamma$  activation (Picard *et al.*, 2004). SIRT1 appears to link metabolic fasting signals such as increased pyruvate levels in the liver to PGC-1 $\alpha$  activation and induction of gluconeogenesis and hepatic glucose production. SIRT1 may also reduce mitochondrial oxidation and biogenesis by acetylating and deactivating PGC-1 $\alpha$ , whereas activation of SIRT3 in brown adipose tissue enhances UCP1 expression, thermogenesis, and fat oxidation. Recently, the absence of a VNTR polymorphism of the SIRT3 gene that enhances its expression has been associated with reduced longevity in humans. Streptozocin-induced diabetes in mice has also been associated with the suppression of the expression of one of the sirtuin genes (Yechoor *et al.*, 2004). More studies are needed to determine the full impact of these findings for human health and aging, but these studies offer an introduction into new molecular pathways, possibly linking excessive caloric intake, the development of obesity, and diabetes with reduced longevity.

### Recent Advances in Treatment

The recognition that the lipotoxicity link between insulin resistance and beta cell dysfunction has a potential

pathogenic mechanism of diabetes type 2 has provided a strong rationale for the introduction of thiazolidinedione (TZDs), which are PPAR $\gamma$  agonists and which target insulin resistance in part through improvement of postprandial fat storage in adipose tissues (Miles *et al.*, 2003; Boden *et al.*, 2005). Large clinical trials are currently ongoing to test whether these drugs can prevent the progression of beta cell dysfunction in the natural history of diabetes and whether their beneficial effects on cardiovascular function observed in small-scale studies can translate into significant benefits in terms of hard cardiovascular end-points (Kanaya *et al.*, 2003).

AGEs could also be the primary target of treatment of the complications of diabetes. Diet is one target as it is a considerable source of exogenous AGEs participating in the alterations of aging and diabetes. Studies in ApoE deficient streptozocin-diabetic mice showed that specific (Vlassara *et al.*, 2003) diets in these animals were associated with significant reduction in serum AGEs. In humans, low AGE-diets diminished the serum levels of inflammatory markers such as cytokines as well as cell adhesion molecules such as VCAM-1. The development of blockers of AGE receptors (RAGEs) bears hope to diminish, if not suppress, the deleterious effects of these compounds on chronic macro- and microvascular complications associated with aging and diabetes mellitus (Flyvbjerg *et al.*, 2004; Hudson *et al.*, 2004). Inhibition of poly(ADP-ribose) polymerase activity or PKC especially in endothelial cells may provide important therapeutic targets in the future to prevent diabetes and aging-related cardiovascular diseases (Booth *et al.*, 2002; Decker *et al.*, 2002; Pacher *et al.*, 2004).

Metformin is an effective antidiabetic drug known to reduce hepatic glucose production through activation of AMP kinase in the liver, a mechanism of action similar to that of adiponectin. Results from the UKPDS study clearly have shown the beneficial effect on the cardiovascular outcome of obese subjects with type 2 diabetes (UK Prospective Diabetes Study, 1998). With regards to prevention of type 2 diabetes in subjects with glucose intolerance, however, metformin clearly is not as effective as small to moderate weight loss through aggressive lifestyle modification, especially in the elderly (Knowler *et al.*, 2002).

GLP-1 agonists and inhibitors of dipeptidyl-peptidase IV, which have been shown to improve glucose tolerance and glucose effectiveness (noninsulin mediated glucose uptake) in younger patients could also prove to be effective therapeutic tools in elderly patients with diabetes. Reduction of the activity of the inhibiting phosphatases such as PTP1B are potential therapeutic targets for the treatment of insulin resistance. A clinical phase II trial is already under way in this field.

## Future Research Avenues

One of the promising avenues of research is the elucidation of the mechanisms of beta cell dysfunction with aging. Prevention of beta-cell apoptosis by the modulation of intracellular calcium metabolism or by limiting the age-related lipo- and glucotoxicity might also be exploited in the future.

The investigation of the role of lipid rafts composition and function in impaired insulin signaling in the insulin-resistant state may improve our understanding of the age-related alterations in insulin receptor signaling. In this context the modulation IKK may be an important target for new drug development. The understanding of the role of proteasomes and the negative serine phosphorylation in IR functions also will be essential.

The investigation of age-related muscle mitochondrial dysfunction as a contributing factor to insulin resistance as well as to altered beta cell insulin secretion should be further investigated. The sirtuin-PGC-1 $\alpha$  connection merits further intensive investigation.

Although elucidating the molecular mechanisms of diabetes will help identify individuals at highest risk for developing type 2 diabetes and permit the development of new drugs to prevent type 2 diabetes, aggressive lifestyle modification has already been shown to be very effective for the prevention of this disease. The main challenge at this point is to implement the lessons learned in the DPP and the other lifestyle intervention trials in clinical practice, especially with the growing prevalence of diabetes and its complications in an ever-older population. Identifying less labor-intensive and expensive but still effective approaches to help elderly patients with diabetes to lose weight will be important to alleviate the obstacles to implementation of the results of these trials. Better prediction of the risk of developing future complications would allow individually tailored interventions and improve the utilization of therapeutic resources and limit costs. The ultimate goal of all this research is to abolish the untoward impact of type 2 diabetes and promote healthy aging.

## Conclusion

The aging of the population worldwide and the constantly increasing prevalence of type 2 diabetes constitute an important challenge for the next generation of clinicians and scientists. Type 2 diabetes as a model of premature aging may ultimately help us unravel the fundamental keys to the aging process. Although new breakthroughs in basic research will help us identify and design best-fitted interventions for our patients, more advances also are needed in translational research to gain maximal efficiency in implementing these new findings into clinical practice. Applying the lifestyle measures that we already know work best in a more efficient, cost-effective way will remain an important objective for the next decades in

order to reduce the burden of diabetes and aging on humanity.

# Diabetes as a Model of Premature Aging

Arshag D. Mooradian

*There are several genetic or acquired diseases with features that simulate the changes commonly found in aging organisms. One such acquired disease is diabetes mellitus. Phenotypic changes of premature aging in diabetes include decreased life expectancy, increased incidence of cardiovascular disease, osteoporosis, and certain neoplasms, and increased cognitive dysfunction. However, not all the common age-related diseases occur prematurely in diabetes. A case in point is the lack of association between diabetes or glucose intolerance and osteoarthritis. Similarly some changes in diabetes, such as retinopathy and classical diabetic renal lesions, are unique and do not occur in aging.*

*The mechanisms underlying the pathogenesis of diabetes and the age-related changes have common regulatory pathways. These include increased glycation of proteins, increased oxidative stress, and increased activation of protein kinase C. In addition, insulin and insulin-like growth factor 1 (IGF-1) signaling pathways have been implicated in aging of several experimental organisms. Down-regulation of this pathway through caloric restriction is associated with increased life span in mice, worms, flies, and yeast. One of the key transcription factors implicated in aging, namely, FOXO, is regulated by insulin and IGF-1. The FOXO homolog in worms, DAF-16, has a central role in imparting longevity of worms with mutations in the insulin/IGF-1 signaling pathway genes, such as daf-2 and age-1. In this manuscript, mechanisms that may contribute to the premature aging in diabetes will be discussed, and the literature as to the tissue-specific changes of premature aging in diabetes will be reviewed.*

## Introduction

There are several genetic or acquired diseases that have features that simulate the changes commonly found in aging organisms (Mooradian, 1995a). The genetically determined diseases that have features of premature aging include a host of progeroid syndromes; the acquired category of diseases with features of premature aging include diabetes, uremia, hypothyroidism, Cushing's syndrome, and acquired immunodeficiency syndrome (AIDS). In the latter category the most common disease is diabetes.

It is generally accepted that we are currently experiencing an epidemic of diabetes worldwide. The main determinant of this epidemic is the rapidly increasing prevalence of obesity. The prevalence of diabetes increases with age, and it has been estimated that one-fifth of adults over the age of 60 in the United States have diabetes (Harris, 1998). Some predict that by the year 2025 two-thirds of the diabetic population will be elderly. In addition to the human cost, the economic implications of increasing prevalence of diabetes and its complications are enormous. Thus it is essential to understand the major determinants of the pathogenesis of diabetes and its major complications.

The feasibility of preventing diabetes with modest lifestyle changes has been demonstrated. It is important to appreciate that the main interventions that are shown to be effective in diabetes prevention, namely, modest caloric restriction and exercise, are also recognized measures of ameliorating the physiological and pathological changes of aging (Mooradian, 1988a). These observations support the notion that some, if not many, of the mechanisms underlying the pathogenesis of diabetes and the age-related changes have common regulatory pathways.

In this manuscript some of the mechanisms that may contribute to the premature aging in diabetes will be discussed, and the literature as to the tissue-specific changes of premature aging in diabetes will be reviewed.

## Phenotypic Changes of Premature Aging of Diabetes

### LIFE EXPECTANCY

Arguably the ultimate phenotype of premature aging is reduced life expectancy. It is estimated that the onset of diabetes in human subjects reduces the life expectancy by an average of 10 years. The effect of diabetes on life expectancy depends on the age of onset. In general, the older the patient is at the time of diagnosis of diabetes, the lesser its effect is on life expectancy. Nevertheless it appears that diabetes continues to be a major detriment even when the disease onset is in the seventh decade (Songer, 1995).

The epidemiological data from the United Kingdom Diabetes Prospective Study (UKPDS) indicates that mortality in diabetic subjects correlates with the degree

of glycemic control as measured by glycated hemoglobin (HbA1c) levels (Stratton *et al.*, 2000; Mooradian and Chehade, 2000). It is noteworthy that HbA1c appears to be a predictor of mortality even in nondiabetic populations (Khaw, 2001). These latter observations highlight the importance of glycemia and glycation as a predictor of life expectancy. It is also possible that postprandial blood glucose excursions that contribute to the HbA1c measurements to a greater degree when the levels of HbA1c are near normal may have an independent effect on cardiovascular risk and overall mortality (Mooradian and Thurman, 1999a).

### CARDIOVASCULAR DISEASE

The main cause of reduced life expectancy in diabetes is the increased incidence of cardiovascular disease (CVD) (Mooradian, 2003). Although the cause of accelerated atherogenesis in diabetes is mostly the result of increased prevalence of comorbidities such as obesity, hypertension, and dyslipidemia, it appears that hyperglycemia and possibly hyperinsulinemia or relative insulin deficiency have an important role.

Several epidemiological studies have shown a correlation between the glycemic control and risk of having a cardiovascular event. However recently, the independent effect of HbA1c in predicting cardiovascular outcome was questioned (Selvin *et al.*, 2004). In addition, the UKPDS failed to show conclusively that controlling blood glucose levels has significant effects on cardiovascular outcome (Mooradian and Chehade, 2000). In this study the difference in glycemic control of subjects in the tight control arm (HbA1c of 7.0%) was only modestly lower than the HbA1c achieved in the standard care group (HbA1c of 7.9%). This modest difference in HbA1c values was associated with 16% reduction in risk of CVD (UKPDS, 1998a). This difference however, did not reach the statistical significance. In a subgroup of overweight patients, diabetes treatment with metformin was associated with robust and significant reduction in cardiovascular outcomes (UKPDS, 1998b). This favorable effect of metformin on CVD is either a function of its insulin-sparing effect or could be related to the ability of metformin in inhibiting advanced glycation end-product (AGE) formation akin to its congener aminoguanidine.

### NEUROBEHAVIORAL CHANGES

Many of the age-related changes in cognitive capacity are also observed in diabetic subjects (Mooradian, 1988b, 1997a, 1997b). Clinical studies in subjects with type 2 diabetes have shown moderate cognitive impairment, particularly in tasks involving verbal memory and complex information processing, whereas basic attention process, motor reaction time, and short-term memory are relatively unaffected (Mooradian *et al.*, 1988; Strachan *et al.*, 1997).

Some of the cognitive impairment in diabetes is reversible with optimizing blood glucose control. In addition, experiments in diabetic mice also have shown

that insulinization and reducing hyperglycemia ameliorates cognitive deterioration (Flood *et al.*, 1990). Nevertheless, some of the changes in the central nervous system (CNS) function in diabetes are the result of cerebrovascular accidents and as such are not readily reversible with control of blood glucose levels.

The prevalence of Alzheimer's disease (AD) is significantly increased in diabetic subjects compared to nondiabetic controls (Arvanitakis *et al.*, 2004; Janson *et al.*, 2004). Since AD is recognized to be a common feature of aging, it is tempting to suggest that the increased prevalence of AD in diabetes is a reflection of premature aging changes within the CNS. It is noteworthy that changes in Glut-1 content of the cerebral tissue from patients with AD are similar to those found in diabetes (Mooradian *et al.*, 1997). It is possible that the diabetes-related changes in the blood-brain barrier (BBB) contribute to the increased incidence of AD in diabetes (Mooradian, 1997a). The changes in the BBB observed in diabetes are often similar to those found in aging, and disruptions in the BBB have been suspected of being a contributing cause of AD (Shah and Mooradian, 1997). Furthermore, Alzheimer's disease and type 2 diabetes have comparable pathological features in the islet and brain (amyloid derived from amyloid beta protein in the brain in AD, and islet amyloid derived from islet amyloid polypeptide in the pancreas in type 2 diabetes) (Chaney *et al.*, 2003; Galasko, 2003). In the Mayo Clinic Alzheimer Disease Patient Registry (ADPR), pancreas and brain were examined from autopsy specimens obtained for the presence of islet and brain amyloid (Janson *et al.*, 2004). In this study, type 2 diabetes and impaired fasting glucose were more common in patients with AD than in control subjects, as was the pathological hallmark of type 2 diabetes, islet amyloid. However, there was no increase in brain plaque formation in cases of type 2 diabetes, although when it was present, it correlated in extent with duration of diabetes. These data support the hypothesis that the possible linkage between the processes is responsible for loss of brain cells and beta cells in these diseases (Janson *et al.*, 2004).

Another potential pathogenetic process contributing to brain dysfunction in diabetes is related to increased AGE and their receptors (RAGE). It is hypothesized that glycated amyloid beta is taken up via RAGE and is degraded through the lysosomal pathway in astrocytes (Sasaki *et al.*, 2001). The presence of AGE, the process of AGE degradation, and receptor-mediated reactions may contribute to neuronal dysfunction and promote the progression of AD.

It is noteworthy that not all studies have found increased incidence of AD in diabetes. In a historical prospective cohort study of Japanese-American men ( $n=3,774$ ), the expected relationships between impaired glucose tolerance and stroke-related dementia was found, but there was no association of disordered glucose metabolism with AD (Curb *et al.*, 1999).

In addition to cognitive changes in diabetes, affective disorders, notably the incidence of depression, is increased in diabetes (Gavard *et al.*, 1993; Lustman *et al.*, 1986). Major depression has a higher recurrence rate, and depressive episodes may last longer in individuals with type 1 or type 2 diabetes (Lustman *et al.*, 1986; Ryan, 1988). A significant relationship between poor glycemic control and major depression has been reported, although this relationship was not supported by other studies. Insulin resistance has been postulated as the missing link between the affective disorders and AD. However there is no conclusive empirical data to support this hypothesis at this time (Rasgon and Jarvik, 2004). It is not clear whether the high prevalence of depression in diabetes is the result of neurobiochemical changes associated with diabetes, or is secondary to psychological factors related to chronic disease state or its treatment.

### OSTEOPOROSIS

One of the common degenerative diseases of aging is osteoporosis. Bone density is decreased in an age-dependent fashion after it reaches its peak at young adulthood. The prevalence of osteoporosis and fractures increases with age. In women, estrogen withdrawal accompanying menopause plays a major role in the first 10 years. Diabetes also is associated with increased risk of fracture of the hip, proximal humerus, and foot (Inzerillo and Epstein, 2004; Schwartz, 2003). Type 1 diabetes is associated with modest reductions in bone mineral density (BMD), but type 2 diabetes often is characterized by elevated BMD (Inzerillo and Epstein, 2004). The paradoxically increased fracture risk in type 2 diabetes may be explained by a combination of factors, including more frequent falls and poorer bone quality.

The precise cause for the osteopenia or poor bone quality of diabetes is not known. Potential mechanisms contributing to reduced bone mass in diabetes include nutritional deficiencies, alterations in vitamin D metabolism and possibly alterations in the microenvironment of bone as a result of microvascular disease, and increased glycation of key structural proteins such as collagen. In addition, increased cytokine production in diabetes may also contribute to osteopenia. Finally, it has been suggested that decreasing leptin level with peroxisome proliferators-activated receptor (PPAR) gamma agonist treatment is associated with prevention of bone loss in type 2 diabetes (Watanabe *et al.*, 2003). Indeed, leptin-deficient mice have higher bone mass, and the thiazolidinedione drugs have been shown to inhibit the formation of bone-resorbing osteoclasts *in vitro* and to decrease bone resorption markers *in vivo*.

### NEOPLASTIC DISEASE

Neoplastic disease is common in aging. Cancer continues to be the second most common cause of mortality in the older subjects. Insulin and insulin-like growth factors (IGF) are major determinants of proliferation and apoptosis

and thus may influence carcinogenesis (Giovannucci, 2001). Conditions associated with hyperinsulinemia, such as obesity, sedentary lifestyle, or chronic insulin therapy, are also related to high risk (Yang *et al.*, 2004). Hyperinsulinemia can be associated hyperandrogenism and hyperestrogenic conditions, which may play a role in the onset of some malignancies, such as endometrial cancer, breast cancer, and prostate cancer (Guastamacchia *et al.*, 2004).

There are additional hypothetical causes for increased carcinogenesis in diabetes. Type 2 diabetes mellitus may be associated not only with the elevated level of oxidative DNA damage, but also with the increased susceptibility to mutagens and the decreased efficacy of DNA repair (Blasiak *et al.*, 2004). Protein kinase B (PKB) is implicated in glucose metabolism and in the regulation of apoptosis and is activated by insulin, which may partially explain why PKB is over-expressed in some ovarian, breast, and pancreatic carcinomas (Galetic *et al.*, 1999). Inflammatory markers are increased in diabetes. Elevated CRP levels are a strong independent predictor of type 2 diabetes and may mediate associations of TNF-alphaR2 and IL-6 with type 2 diabetes (Hu *et al.*, 2004) (Spranger *et al.*, 2003). Finally, the role of hyperglycemia in carcinogenesis could include pathways related to luminal factors such as fecal bile acid concentrations, stool bulk, and prolonged transit time, or glucose could be the only energy source for neoplastic cells (Chang and Ulrich, 2003). Thus, it is not surprising that the incidence of cancers commonly associated with obesity or aging such as colonic cancer, breast cancer, or uterine cancer is also higher in diabetic patients (Sinagra *et al.*, 2002; Michels *et al.*, 2003). In one study, the increased risk of colon cancer was largely explained by HbA1c concentrations (Khaw *et al.*, 2004).

There are notable exceptions to the increased incidence of age-related cancers in diabetes. The most notable exception is prostate cancer, which is clearly age-related, and yet the incidence in diabetes appears to be less than the nondiabetic controls (Coker *et al.*, 2004; Zhu *et al.*, 2004). Another important point to consider is that although type 1 diabetes is associated with a modest excess cancer risk, specific cancers differ from those associated with type 2 diabetes (Zendeherl *et al.*, 2003).

### Tissue-Specific Biological Changes of Premature Aging in Diabetes

In addition to increased prevalence of diseases typically associated with aging such as CVD, AD, and osteoporosis, there are remarkable similarities in biological changes of tissues in diabetes and those commonly occurring with aging (Mooradian, 1988c, 1990, 1994). This is especially true for tissues that do not have high replicative capacity, such as CNS, skeletal and cardiac muscle, skin and bone (see Table 56.1). The degree of concordance between

diabetes-related changes in the CNS and the changes seen commonly with age is remarkable. On the other hand, tissues with high replicative capacity such as intestinal epithelium and bone marrow do not demonstrate a high level of concordance between the changes in diabetes and those seen with age (see Table 56.2). These tissues do not appear to undergo premature aging in diabetes. It is likely that accelerated aging in diabetes is tissue-specific, and it may be limited to tissues without a high capacity of replication.

## 56. Diabetes as a Model of Premature Aging

**Figure 56.1** Select metabolic pathways contributing to glucotoxicity.

### Mechanisms of Premature Aging in Diabetes

The clinical and phenotypic similarities between aging and diabetes suggest that there may be shared biochemical pathways leading to the tissue changes. Glucose is the principal metabolic fuel for many animal species. In general, with few exceptions, the plasma glucose level in various animals is maintained within a narrow range (60–140 mg/dl). It is possible that the lower limit of blood glucose levels is determined by the minimum tissue requirements of metabolic fuel, and the upper limit defines the threshold beyond which glucotoxicity limits survival of the species (Mooradian and Thurman, 1999b). Avian species, especially owls and parrots, are the exception to this generalization. These animals have high blood glucose levels in the range of 250 to 350 mg/dl and yet have a relatively long life expectancy and show no signs of classical diabetic complications. The overall constancy of blood glucose levels across a wide range of animal species suggests that hyperglycemia, except in rare exceptions, is not compatible with healthy living. However, the lack of correlation between the maximum life span of species and the blood glucose levels raises doubts as to the fundamental role of glucose in the rate of aging. Nevertheless, it can be argued that interspecies comparisons are not necessarily relevant to the role of glucotoxicity. In addition, recent clinical studies indicate that there is a continuum in the relationship between tissue toxicity and serum glucose levels rather than there being a threshold of a glucose level beyond which diabetes complications emerge. Such data underscore the fundamental nature of glucotoxicity in animal biology.

The multiplicity of theories of aging makes it difficult to determine with any degree of certainty, the precise mechanism of premature aging in diabetes. However, several sentinel discoveries within the last three decades have shed light on the potential mechanisms of glucose-related toxicity and its effect on degenerative changes of

aging. There are several biochemical mechanisms of glucotoxicity (Brownlee, 2001) (see Figure 56.1).

These include the polyol pathway, protein kinase C pathway, glycosylation pathway, and the oxidative pathway. These pathways, although conceptually separate, are interlinked biochemically (Brownlee, 2001). It has been suggested that a unifying hypothesis that incorporates these different pathways of glucotoxicity is hinged upon the mitochondrial generation of free radicals (Brownlee, 2001). According to this hypothesis, excess superoxide (oxidation pathway) partially inhibits the glycolytic enzyme GAPDH, thereby diverting upstream metabolites from glycolysis into pathways of glucose over utilization. This increases the flux of dihydroxyacetone phosphate (DHAP) to DAG, an activator of PKC (PKC activation pathway), and of triose phosphates to methylglyoxal, the main intracellular AGE precursor (glycation pathway). Increased flux of fructose-6-phosphate to UDP-N-acetylglucosamine increases modification of proteins by O-linked N-acetylglucosamine (GlcNAc) (hexosamine pathway), and increased glucose flux through the polyol pathway consumes NADPH and depletes GSH, thereby further aggravating the increased oxidative stress (Brownlee, 2001).

Some of the key mechanisms that may contribute to tissue changes in diabetes, and may also be involved in the aging, will be discussed. The relevance of polyol pathway in human disease has been controversial. The hexosamine pathway is an important pathway contributing to the pathogenesis of insulin resistance and diabetes complications. The glycolytic intermediate fructose-6-phosphate (Fru-6-P) is converted to glucosamine-6-phosphate by the enzyme glutamine:fructose-6-phosphate amidotransferase (GFAT). Intracellular glycosylation of key transcription factors, such as Sp1, by the addition of N-acetylglucosamine (GlcNAc) to serine and threonine, is catalyzed by the enzyme O-GlcNAc transferase (OGT). These changes result in profound alterations in the

expression of genes, such as plasminogen activator inhibitor-1 (PAI-1) and transforming growth factor beta-1 (TGF- $\beta$ 1) that are implicated in the emergence of some diabetic complications (Brownlee, 2001). The age-related changes in Sp1 are not concordant with the changes seen in diabetes. Thus, the polyol pathway and hexosamine pathway will not be discussed any further as they appear to be, at the present time, more uniquely related to diabetes rather than to aging.

### GLYCATION PATHWAY

The nonenzymatic glycation of proteins is a common biochemical reaction both in live tissue and in food industry, cooking, and glazing of proteinaceous food with sugar (Brownlee, 1995). Glycation of serum proteins is measured clinically with fructosamine assays, whereas glycation of hemoglobin is clinically monitored as the percent of glycated hemoglobin A1 C. HbA1c has been extensively utilized clinically to monitor the adequacy of glycemic control. According to Diabetes Control Complication Trials, a change of 1% in HbA1c reflects a change in mean plasma glucose of approximately 35 mg/dl (Rohlfing *et al.*, 2002). HbA1c values correlate in a curvilinear fashion with the risk of diabetic complications such that for every point change in HbA1c measurements, the risk of having retinopathy, nephropathy, and neuropathy changes by a fixed percentage point.

The first step in this reaction is the attachment of glucose to an  $\epsilon$ -amino group of a lysine residue of a protein. This labile Schiff base undergoes an Amadori rearrangement into a relatively stable adduct. The latter undergoes additional slow chemical changes to form the AGE. The accumulation of AGE in tissues increases with age as well as in diabetes. Those subjects with established diabetic complications such as retinopathy or nephropathy have higher rates of AGE accumulation compared to those without such complications (Brownlee, 1995). The AGE formation promotes cross-linking of proteins, thereby resulting in stiffening of collagen, increased entrapment of lipoproteins, and immunoglobulins in the blood vessel walls. These changes activate the complement pathway and cause local inflammatory injury of blood vessels. In addition, cross-linking of lipoproteins increases their atherogenic potential. The AGE formed can also cause a host of biological changes through activation of the AGE receptors. This mechanism has been implicated in increased clot formation, increased production of extracellular matrix, and stimulation of cytokine and growth factor production (Brownlee, 1995).

Glucose-induced modification of macromolecules extend beyond the AGE formation to involve adduction and modification of lipids and nucleic acid bases of DNA. These changes may directly alter membrane integrity as well as genetic expression or stability of some genes.

Finally, glycosylation reaction is often coupled with increased production of free radicals. The attendant

increase in oxidative load contributes to the premature aging changes in diabetes.

### OXIDATION PATHWAY

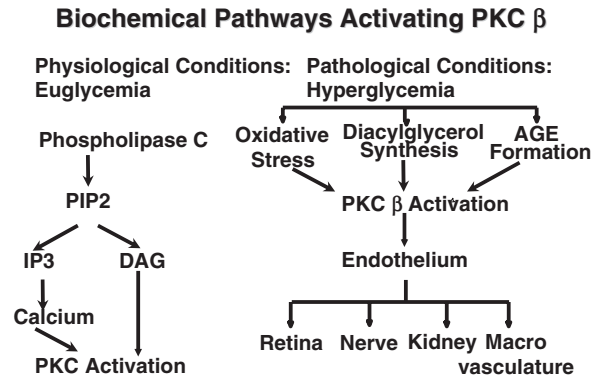

There is some controversy regarding whether uncontrolled hyperglycemia in diabetes causes increased free radical generation or whether the increased presence of oxidized proteins and lipids is the result of defective clearance of these byproducts (Hasanain and Mooradian, 2002; 2004). Nevertheless, there is extensive evidence in human subjects, in various animal models of diabetes, and in cell culture studies that hyperglycemia is associated with reduced antioxidant defense capacity, and increased accumulation of oxidation byproducts. In nuclear and mitochondrial DNA, 8-hydroxydeoxyguanosine (8-OHdG), an oxidized nucleoside of DNA, is the most frequently detected and studied DNA lesion. Elevated urinary 8-OHdG and leukocyte DNA were also detected in diabetic patients with hyperglycemia, and the level of urinary 8-OHdG in diabetes correlates with the severity of diabetic nephropathy and retinopathy (Wu *et al.*, 2004).

The increased superoxide generation is more closely related to hyperglycemic spikes, and cellular adaptive changes reduce the superoxide generation rate during sustained hyperglycemia (Horani *et al.*, 2004). These observations have important clinical implications since epidemiological and some interventional trials have suggested that diabetes complications, notably CVD, correlate better with postprandial excursions of blood glucose level than with preprandial levels (Mooradian and Thurman, 1999a).

The precise mechanism of hyperglycemia-related increase in oxidative load is not entirely clear. Glucose, especially in the presence of copper, has potent pro-oxidant properties (Whemeier and Mooradian, 1994). Glycation of proteins is associated with increased free radical generation, and the proteins become more susceptible to oxidative damage (Mooradian *et al.*, 1996). In addition, alterations in micronutrient stores in the presence of hyperglycemia would reduce the antioxidant defense capacity of the organism (Mooradian, 1995). Similar reductions in antioxidative capacity of tissues are found in aging animals (Mooradian and Uko-Ennin, 1995).

### PROTEIN KINASE C ACTIVATION

In recent years, protein kinase C has emerged as a potential target for therapeutic agents that reduce the risk of complications in diabetes. PKC is a calcium-dependent enzyme involved in signal transduction through changes in the phosphorylation of key cellular proteins. High blood glucose levels increase phospholipase D activity, which in turn, activates the membrane-bound PKC. This activation accounts at least in part for the increased cell permeability and vascular resistance. In pathological state of hyperglycemia, diacylglycerol (DAG) content is increased, which along with the increased oxidative

**Figure 56.2** Biochemical pathways activating protein kinase C  $\beta$  (PKC  $\beta$ ). AGE: advanced glycation end products; DAG: diacyl glycerol; PIP2: phosphoinositol diphosphate; IP3: inositol triphosphate.

stress and glycation process causes the activation of PKC to accelerate (Newton, 1995; Idris *et al.*, 2001; Kawakami, 2002) (see Figure 56.2).

The principal isoforms that are activated are the  $\beta$ - and  $\delta$ -isoforms. Activation of PKC causes a number of pathological consequences, including alterations of endothelial nitric oxide synthase (eNOS), endothelin-1 (ET-1), vascular endothelial growth factor (VEGF), transforming TGF- $\beta$  and PAI-1, as well as activation of NF- $\kappa$ B and NAD(P)H oxidases (Newton, 1995; Idris *et al.*, 2001; Kawakami, 2002).

PKC activation, through phosphorylation of insulin receptor, causes resistance to insulin action. Since changes in insulin receptor signaling have been implicated in aging, the relevance of PKC changes to age-related increases in insulin resistance or to the aging process per se, remains speculative.

## INSULIN RECEPTOR SIGNALING

Insulin and insulin-like growth factor-1 (IGF-1) signaling pathways have been implicated in aging of several experimental organisms (Pardee *et al.*, 2004). This pathway is critical to coordinating the influx of calories with the metabolic rate. Down-regulation of this pathway through caloric restriction is associated with increased life span in mice, worms, flies, and yeast (Barbieri *et al.*, 2003). One of the key transcription factors implicated in aging, namely, FOXO, is regulated by insulin and IGF-1. The FOXO homolog in worms, DAF-16, has a central role in imparting longevity of worms with mutations in the insulin/IGF-1 signaling pathway genes, such as *daf-2* and *age-1* (Kenyon *et al.*, 1993). Over-expression of dFOXO in worms and DAF-16 in flies extends life span through interactions with a host of other nuclear receptors, particularly the PPARs (Giannakou *et al.*, 2004; Henderson and Johnson, 2003). These receptors are up-regulated during caloric restriction, and over-expression of PPAR  $\delta$  in transgenic mice is associated with

increased longevity, whereas PPAR  $\delta$  null mice have reduced life expectancy (Pardee *et al.*, 2004). These observations highlight the central role of PPARs and FOXO in modulating the aging phenomenon.

## Conclusion

There are a host of biological changes attributed to increased blood glucose levels that simulate tissue aging. However, not all the common age-related diseases occur prematurely in diabetes. A case in point is the lack of association between diabetes or glucose intolerance and osteoarthritis, a common degenerative disease of joints in the elderly (Frey *et al.*, 1996). Similarly, despite a large number of similar alterations in tissues, some of the changes in diabetes, such as retinopathy and classic diabetic renal lesions, are unique and do not occur in aging.

Multiple metabolic pathways underlie this apparent toxicity of glucose. Although glucose itself has direct-effects on gene expression (Mooradian and Mariash, 1987) and on oxidation (Whemeier and Mooradian, 1994), many of the changes seen in diabetes are the indirect consequences of increased glycation or activation of PKC. Thus, prevention of diabetes complications should include interruption of PKC signaling and prevention of AGE formation in addition to the traditional approach of emphasizing normalization of blood glucose levels.

It is noteworthy that since the relationship of blood glucose levels and tissue toxicity is a continuum, and there is a biological barrier to reducing blood glucose values below the metabolic needs of cells, inhibition of AGE-related toxicity, or possibly partial interruption of PKC signaling, may extend the life span and prove to be a true fountain of youth.

# Frailty as a Model of Aging

Jeremy D. Walston

*Frailty has been seen by clinicians and investigators as a late-life syndrome of weight loss and declines in strength and vigor. In addition, it has been characterized as a syndrome of extreme vulnerability to external stressors, and one that marks high risk for poor clinical outcomes. Over the past few years, several groups of investigators have attempted to more rigorously define frailty, and to identify physiologic and molecular contributing factors. Many of these definitions involve clinical findings of weight loss, strength decline, and low levels of activity, and are, as such, characterized as physical or musculoskeletal frailty. Other investigators have tried to better identify the cognitive components of frailty. This chapter will describe several recent models of frailty and the validation of these models. In addition, hypotheses related to the biologic underpinnings of frailty, and how these biologic characteristics may be related to the biology of aging, will be presented. Finally, a discussion of the utility of these models in clinical research and the potential relevance for further biologic discovery will be discussed.*

## Introduction

Healthcare providers as well as family members have long noticed and commented on a subset of older adults who appeared to be highly vulnerable to falls, fractures, illnesses, loss of independence, and ultimately mortality (Fried *et al.*, 1998). Although these same healthcare providers and family members often recognize frailty when they observed it, there has been very little consistency in the definition of frailty, and hence few validated clinical models of frailty. This is in part because of the heterogeneity that is inherent in many of the processes that may underlie frailty, including aging processes, the development of chronic diseases, social settings, psychological conditions, and genetic predisposition. In addition, it remains unclear if frailty is in and of itself a biologically distinct entity that could be called a clinical syndrome, or whether it simply represents a cluster of partially related signs and symptoms that are generated by aging or disease related processes (Walston *et al.*, 2005). Over the past several years, many of the following conceptual frameworks and definitions of frailty have been operationalized and validity tested using healthcare

outcomes (Rockwood, 2005). However, there have been few efforts to compare these models with each other for the poor health outcomes that are the hallmark of this most vulnerable subset of older adults.

## A Conceptual Framework: The Cycle of Frailty

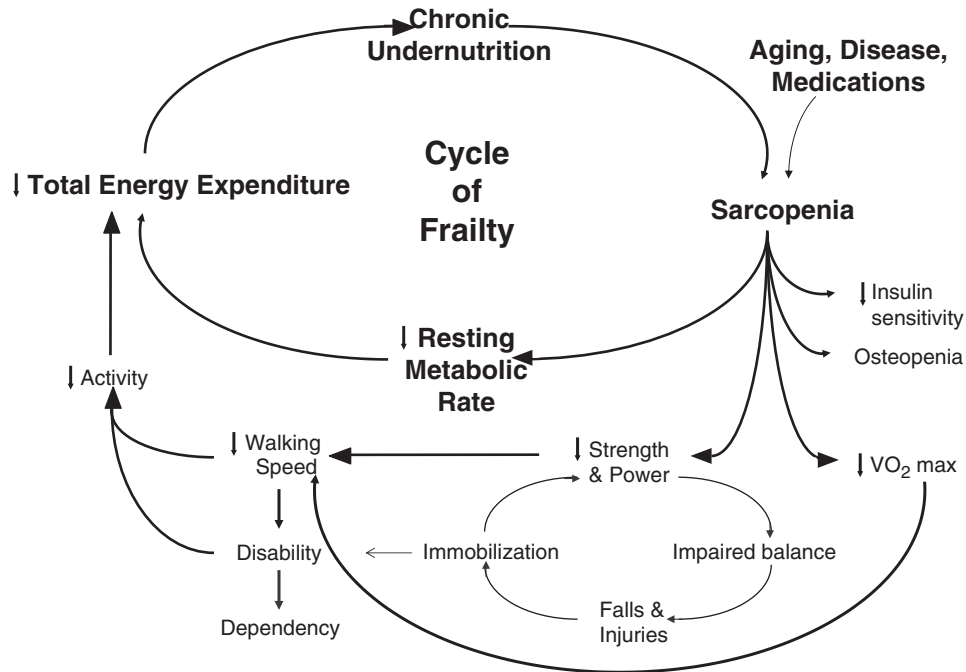

This chapter outlines several conceptual models that provide a state of the art overview of this relatively new field of aging research. A useful conceptual model, entitled the Cycle of Frailty, was developed in order to help conceptualize the multifactorial nature of frailty and to help explain how complex physiologic declines, poor nutrition, chronic illness, social situation, and disability/functional decline influence each other (Fried *et al.*, 2003). This model, shown in Figure 57.1, highlights that individual components of the cycle are associated in a step-wise fashion with other declines, and ultimately provides a conceptual basis for development of vulnerability to poor health outcomes on individual declines.

In the center of this figure, physiologic declines related to aging, including loss of skeletal muscle mass (sarcopenia), declines in resting metabolic rate, energy expenditure, and nutritional status reinforce declines in each system. This in turn influences other physiologic systems, including facilitating declines in insulin sensitivity,  $\dot{V}O_2$  max, strength, and power. These changes then contribute to a subcycle of disability, functional decline, and low levels of activity, which in turn reinforces the physiologic decline. Importantly, this model also provides a model for multiple possible entry points into this cycle of decline, and illustrates how specific illnesses, injuries, or medications can trigger and/or accelerate this cycle of frailty.

## Sign- and Symptom-Driven Definitions: The Syndrome of Frailty

Despite the ongoing debate on the nature of frailty and whether it is an independent clinical entity or syndrome, some investigators have begun to develop syndromic models in order to differentiate frail vs. nonfrail older adults from further study (Walston *et al.*, 2005).

**Figure 57.1** Hypothesized Cycle of Frailty illustrating associated physiologic and functional declines as well as potential entry points into cycle of decline. Adapted from Fried *et al.* (2003).

These syndromic models have been developed using epidemiologic data on characteristics related to weight loss or muscle weakness based on the conceptualization of frailty as a wasting syndrome. For example, Chin *et al.* (1999) previously compared three working definitions of frailty, namely, inactivity combined with (1) low energy intake, (2) weight loss, or (3) low body mass index. The combination of inactivity with weight loss was found to be most associated with lower subjective health and performance measures, as well as more disease and disability. In addition, the three-year relative risk for mortality was substantially higher in this group compared to others in the study cohort (odds ratio (OR) 4.1, 1.8–9.4) (Chin *et al.*, 1999).

Similarly, Fried *et al.* (2001) utilized a syndromic approach and developed and operationalized a hypothetical frailty phenotype based on common physiologic signs and symptoms described by frail, older adults. This tool consists of five items, including muscle strength (lowest quartile as determined by grip strength dynamometer measurement), weight loss (more than 10 pounds of unintended weight loss in the previous year), walking speed (lowest quartile of timed 15 meter walk), low levels of physical activity as measured by the Minnesota Leisure Time Activities questionnaire, and fatigue (measured by questions from a Depression survey asking about energy level). It was operationalized in the Cardiovascular Health Study (CHS), an epidemiologic study of community-dwelling adults over age 65 followed for nine years in

order to better characterize cardiovascular disease and functional decline late in life. If CHS participants met three of five of these criteria, they were deemed frail; if they met one or two of the criteria, they were deemed intermediate; and if they met none of the criteria, they were deemed not frail. Seven percent of CHS participants met the frailty criteria at their baseline exam, and as expected, there was a significant overlap between disability, chronic illness, and frailty (Fried *et al.*, 2001). However, it was also clear that disability and medical illness were not always consistent with frailty, suggesting an etiology independent from disease and disability, and suggesting a separate but perhaps related biology (Fried *et al.*, 2001). Predictive validity analyses were also performed, where the investigators demonstrated that those who were in the frailty category were more likely to fall, enter nursing homes, be hospitalized, and suffer mortality over seven years of follow-up (Fried *et al.*, 2001). These screening criteria were subsequently utilized to identify biologic correlates of frailty as described in more detail later (Walston *et al.*, 2002; Leng *et al.*, 2002; Leng *et al.*, 2004).

The advantage of these models is that the signs and symptoms were chosen because they are consistent with a wasting syndrome, which often appears to have a common biology. A disadvantage may be that by choosing the wasting syndrome signs and symptoms, other important biologic mediators may not be fully explored (Walston *et al.*, 2005).

### Beyond Physical Frailty: Frailty Models that Include Illness, Social and Psychological Status

Because of the likelihood that aging-related changes in physiology, functionality, and disease states may contribute to frailty, some authors have developed models of frailty that include measures of these domains. For example, Rockwood *et al.* (1999) developed and validated a brief clinical instrument to classify frailty in hospitalized patients that included measures of function, cognition, walking, and bladder/bowel function as determining factors. Using Canadian provincial sampling frames from 9008 randomly collected subjects, those who had no abnormalities in these areas were deemed nonfrail, and those with incontinence, dementia, and dependency in activities of daily living were deemed frail (Rockwood *et al.*, 1999). This was further validated by demonstrating a greatly increased risk of nursing home placement in the frail as compared to nonfrail group (Rockwood *et al.*, 1999).

Studenski *et al.* (2004) recently developed and is validating a Clinical Global Impression Measure for Frailty that includes most intrinsic domains represented in the physical frailty models earlier, but also includes extrinsic or consequential domains of healthcare outcomes and complexity, functionality, and psychosocial status (see Table 57.1). An ongoing study of each of these domains in order to determine which if any of these domains best predicts frailty and other poor health outcomes, and in order to be able to measure change in frailty status over time, is important. Once validated, this model could play a potentially important role in measuring responses to interventions. Advantages of these models are that they both can be performed by clinicians rather than trained research technicians (Studenski *et al.*,

2004; Rockwood *et al.*, 1999). In addition, both of these models incorporate components of cognition, health status, and functional domains that may be able to capture additional information about frailty or subtypes of frailty with further study. However, the mixing of outcomes and intrinsic factors in frailty may also make it more difficult to identify common clusters of signs and symptoms that could inform biologic studies (Fried *et al.*, 2005).

### Cognitive Frailty

Investigators and clinicians who care for older adults have also described a late-life syndrome with declines in memory and executive function and increasing social withdrawal, and have termed it mild cognitive impairment (Lopez *et al.*, 2003). They have hypothesized an underlying biology that may be similar to the hypothesized biology that underlies physical or musculoskeletal frailty, including increased levels of inflammatory mediators (Golomb *et al.*, 1995). Although no validated models of purely cognitive frailty have been published, physical frailty models may provide a framework for future development of models in this area, and models such as the Clinical Global Impression of Change that include cognitive and social status markers may provide evidence of an independent cognitive frailty syndrome (Studenski *et al.*, 2004).

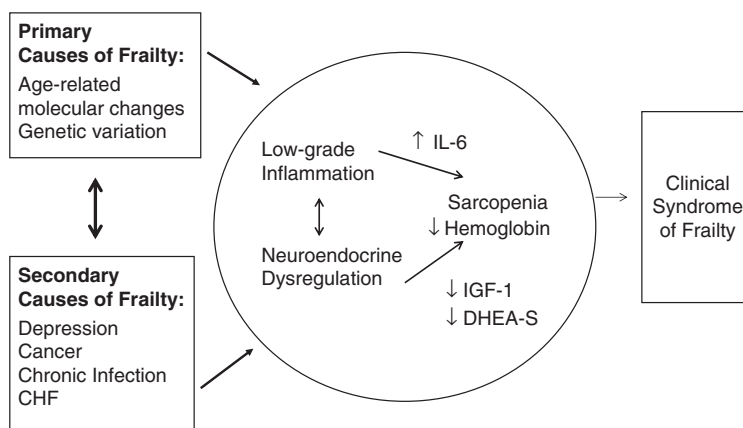

### Physiologic and Biologic Models of Frailty

Building on models of physical frailty mentioned earlier, several investigators have tried to identify additional physiologic characteristics of frail, older adults. Using cross-sectional analyses of data generated in large populations of community-dwelling older adults, these

TABLE 57.1

Extrinsic and intrinsic domains hypothesized to contribute to frailty in older adults. Adapted from Studenski *et al.* (2004)

Intrinsic Domains	Extrinsic Domains
Strength Grip, chair rise	Appearance Grooming, posture, hygiene
Balance Falls, balance exam	Healthcare utilization Hospitalization, MD visits
Nutrition Weight, albumin, cholesterol	Medical complexity Number, severity of conditions
Stamina Self-report fatigue, physical activity	Perceived health Patient/other opinion of health
Neuromotor Speed of movement, attention, coordination	Activities of daily living ADLs, IADLs, travel
Mobility Walking, transfers, stairs	Emotional status Depression, anxiety
	Social status Roles, interactions, life events, living situation

**Figure 57.2** Physiologic Model Pathway illustrating age-related (primary) and disease-related (secondary) triggers for the altered physiology that is hypothesized to underlie frailty. Adapted from Walston *et al.* (2004).

investigators have been able to identify frail and intermediate frail subjects, and then compare inflammatory, endocrinologic, hematologic, and metabolic variables hypothesized to underlie declines in multiple other physiologic systems and ultimately frailty. Figure 57.2 illustrates a hypothesized physiological model of frailty where circulating mediators that are components of inflammatory and endocrine systems influence skeletal muscle, red blood cell production, and ultimately frailty and other poor healthcare outcomes of disability and death.

In this model, the altered physiology is hypothesized to be triggered by both aging conditions and chronic disease (Walston *et al.*, 2003). The development of this hypothesized physiologic model pathway toward frailty was based in part on known interactions between inflammatory cytokines, endocrine systems, CNS/SNS activity, and skeletal muscle observed in both human and animal studies. For example, there is a large body of rheumatoid arthritis and other specific inflammatory disease literature that suggests that circulating inflammatory mediators, such as IL-6, TNF- $\alpha$ , and IL-1 $\beta$ , trigger the loss of total body cell mass in those with inflammatory disease, perhaps via activation of apoptotic pathways (Roubenoff *et al.*, 2003). There are also multiple lines of evidence that demonstrate a biologic link between elevated IL-6 and bone and muscle loss, anemia, insulin resistance, and altered immune system modulation and hypothalamic-pituitary-adrenal (HPA) axis stimulation, making it less likely that IL-6 is simply a benign biologic marker (Ershler *et al.*, 2000). In addition, there is also evidence that inflammatory cytokines such as IL-6 may interfere with anabolic function of sex steroids, growth hormone, and probably IGF-1 (Lazarus *et al.*, 1993; Papanicolaou *et al.*, 1998). Conversely, it is also apparent that loss of estrogen, and perhaps testosterone, leads to the uncovering of important inflammatory gene transcriptional elements, leading to increased production of IL-6 and other inflammatory mediators in several cell types (Ershler *et al.*, 2000).

These relationships have been tested in cross-sectional studies performed in at least three different groups of community-dwelling older adults. Significant positive relationships were identified between frailty and the inflammatory cytokine interleukin-6 (IL-6), C-reactive protein (CRP), and increased numbers of monocytes, and total white blood cells (Leng *et al.*, 2002; Walston *et al.*, 2002; Leng *et al.*, 2005). Higher levels of these same inflammatory mediators correlate with increased vulnerability to disability and mortality in other studies of older adults, further supporting a role for these biologically active molecules and systems in the development of poor health outcomes (Roubenoff *et al.*, 2003). Although none of the mean values of increased inflammatory markers observed in frailty appear to reach the high levels observed in inflammatory diseases such as rheumatoid arthritis or malignancy, they are suggestive of a chronic, low-level activation of inflammatory mechanisms in frail, compared to nonfrail, older adults, and support the need for further study of these pathways in the development of frailty.

Like the inflammatory system, the endocrine and neuroendocrine systems are composed of several separate, but related, organs or tissues that secrete specific hormones and stimulate components of the central and sympathetic nervous system that regulate multiple physiologic processes. The sex steroids and the growth hormone axis have frequently been postulated to contribute to aging-related changes in body composition, and potentially, to frailty (Ershler *et al.*, 2000). The decline of these hormone levels also triggers inflammatory mediator transcription, and interactions between endocrine and inflammatory systems (Ershler *et al.*, 2000). Trajectories in the declines of each of these hormones may prove predictive in the development of frailty, but have yet to be studied.

The adrenal androgen DHEA-S and the growth hormone messenger molecules IGF-1 both decline with age. Importantly, low levels of both DHEA-S and

IGF-1 are associated with at least one frailty definition in older adults (Leng *et al.*, 2005). IGF-1 plays an important role in the development of skeletal muscle cells and is likely an important factor in muscle mass maintenance with increasing age. There is also evidence for interaction between IGF-1 and IL-6, which suggests that inflammation may drive IGF-1 levels down (Cappola *et al.*, 2003). Furthermore, increasing evidence suggests that DHEA-S suppresses NFKB-induced inflammation (Iwasaki *et al.*, 2004). Hence lower levels of DHEA-S observed in frailty may contribute to chronic inflammation and ultimately to frailty.

In addition to these endocrinologic and inflammatory findings, activation of clotting pathways and altered metabolism as represented as increased glucose intolerance have been identified in at least one study of frail older adults (Walston *et al.*, 2002). In this study, those who were frail had significantly higher levels of fasting glucose, and higher levels of insulin and glucose two hours after an oral glucose tolerance test, even after adjustment for multiple potential confounders (Walston *et al.*, 2002). In addition, the frail subset had significantly higher levels of both Factor VIII, fibrinogen, and d-dimers, suggesting a low-grade clotting process (Walston *et al.*, 2002). Although none of these cross-sectional findings can evaluate causality, they support the need for further longitudinal studies and studies of interactions between these important physiologic systems. In addition, they support the need to identify specific aging or disease related triggers that may activate inflammatory pathways and alter endocrinologic systems, and studies of interactions between these pathways (Walston, 2004).

### Theoretical Molecular Models of Frailty

Given the evidence for multisystem decline, and the high likelihood that the development of frailty is a nonlinear process, some authors have used nonlinear dynamics and chaos theory in order to provide new insights into how investigators might detect and quantify changes at the physiological and molecular level. Lipsitz *et al.* (1992) have hypothesized that the decline in complexity of response to stimuli observed in aging and perhaps in frailty in part may be due to loss of complexity in fractal patterns. Fractals are geometric subunits that resemble larger scale units. Many anatomical structures and physiologic processes such as alveoli, neural networks, and bony trabeculae have such repeating subunits and therefore fractal properties. These investigators have theorized that aging and frailty can both, in part, be characterized by a progressive loss of complexity in the fractal architecture of anatomic structures and dynamics of physiologic processes. This loss of structural and functional complexity may impair an organism's ability to communicate within and between systems and to adapt to stress. In addition, most physiologic systems have an ability to undergo reactive tuning, which enables

normalization after periods of physiologic stress. It was hypothesized that this retuning may not be possible with loss of complexity, and this may result in the vulnerability to further decline and poor outcomes seen in frailty. In this hypothesized model, frailty is a continuous, nonlinear process, characterized by a progressive loss of physiologic reserve where those individuals who reach a threshold in the continuum can no longer compensate for a given stress, and enter into a spiral of clinical and functional decline.

### Systems Biology Model Applications

Given the evidence that the clinical presentation of frailty is likely a cumulative outcome of several levels of interrelationships between physiologic systems and probably molecular systems that ultimately impact clinical vulnerability, application of systems biologic approaches may be helpful in elucidating ultimate causes and key biologic processes from within this biologic web. The important interconnections between clinical, physiologic, and biologic levels of organismal functioning, although still hypothetical, may contribute to biological stability of an organism. If these interconnections are lost, then hypothetically, the organism is at high risk for the development of the vulnerability and clinical presentation of frailty (Fried *et al.*, 2005). When intact, this complex, integrated web of systems offers redundancy and the ability to compensate effectively for stressors. The web of interconnectedness between systems suggests that frailty may present a new theoretical model for systems biology approaches. Kitano *et al.* (2002) has proposed that the structure and dynamics of cellular and organismal function must be examined to understand biology at the system level, rather than the characteristics of isolated parts of a cell or organism. Frailty research may benefit from the development of models where robustness in the face of stressors, multiple levels of cellular and organismal function, communication networks, and the relationship of these system properties to the clinical presentation are all entered into the model. In addition, frailty research may benefit from the development of models where feedback between components of clinical presentation and physiologic dysregulation may impact cellular and organism function and molecular characteristics (Csete *et al.*, 2002).

### Conclusion

Over the past decade, significant progress has been made toward refining definitions of frailty, and toward the understanding of the biology that may underlie frailty. Continued refinement of clinical phenotypes and the development of a standardized definition of frailty through contributions of individual domains and through cluster analyses will be critical to compare individuals in large population databases and to better understand the

biology of frailty (Walston *et al.*, 2005). This may be best addressed through studying clusters of signs and symptoms that may be supported by common biology, and utilizing systems biologic methodologies to better incorporate important between-systems interactions (Fried *et al.*, 2005). In addition, development of animal and cellular models, along with the development of large population databases, and the infrastructure to support large-scale analyses, will be helpful in developing the next generation of frailty research and ultimately inform the development of interventions to improve the quality of life in this subset of most vulnerable older adults.

# Osteoporosis and Cardiovascular Disease in the Elderly

Samy I. McFarlane, John Nicasio, and Ranganath Muniyappa

*Osteoporosis and cardiovascular disease are common disorders that increase with aging. Accumulating evidence indicates that both disorders may share common pathophysiologic mechanisms as well as risk factors. Besides age and sedentary lifestyle, diabetes, hypertension, dyslipidemia, estrogen deficiency, and hyperhomocysteinemia are common risk factors for both disorders. Furthermore, therapeutic agents for osteoporosis have antiatherosclerotic properties and agents such as statins that are atheroprotective, and appear to increase bone mass and perhaps protect against fractures.*

*In this chapter, we discuss the basis for a common hypothesis for both osteoporosis and atherosclerosis, highlighting pathophysiologic mechanisms and risk factors common to both disorders, and we discuss therapeutic agents that could potentially be beneficial in the treatment of both disorders.*

## Introduction

Osteoporosis and cardiovascular disease (CVD) are common and serious diseases that affect our aging population, leading to increased morbidity and mortality. Generally viewed as two separate entities, osteoporosis and CVD share common pathophysiologic mechanisms as well as underlying risk factors (Table 58.1). Inflammation, dyslipidemia, and hyperhomocysteinemia are among the possible mechanisms common to both osteoporosis and CVD. Besides advanced age and sedentary lifestyle, menopause, hypertension, diabetes, as well as genetic predisposition increase the risk of both diseases. Furthermore, agents that are known to be atheroprotective also appear to prevent bone loss. For example, nitric oxide (NO) that has known CVD protective effects was shown to stimulate osteoblast function and bone turnover. Clinically, in a randomized controlled trial, nitroglycerine (a donor of NO) was an effective estrogen replacement therapy in preventing bone loss in patients with surgically induced menopause. Additionally, therapeutic agents that reduce atherogenesis such as statins, also have been shown to stimulate bone formation and agents that inhibit bone resorption such as bisphosphonate, and also have

anti-atherogenic effects. This accumulating evidence points to the possibility of common pathophysiologic mechanisms underlying both osteoporosis and CVD, and it remains to be seen if therapeutic agents used for both disorders would develop in the future.

## Association of Osteoporosis and CVD

The association between low bone mineral density (LBMD) and atherosclerosis has been demonstrated in several studies. In the Rotterdam study, a population-based cohort study of 7,983 men and women over the age of 55 years, designed to assess risk factors for progression of atherosclerosis measured at multiple sites (van der Meer *et al.*, 2003), and a cross-sectional analysis examining the association between BMD and peripheral arterial disease (PAD) was performed (van der Klift *et al.*, 2002). Data on BMD and PAD for 5,268 individuals (3,053 women and 2,215 men) were available, and the association between PAD and low BMD at the femoral neck was demonstrated in women, but not in men, suggesting estrogen deficiency as a common denominator between osteoporosis and PAD.

LBMD is also associated with early stages of atherosclerosis as measured by pulse wave velocity (PWV) (Hirose *et al.*, 2003). In a study involving 7,865 Japanese individuals age 50 years or older, PWV, which reflects early atherosclerosis, was associated with osteo-sono assessment index (OSI), a measurement that correlates with BMD (Hirose *et al.*, 2003). OSI was negatively correlated with PWV in both genders, and although this association was much stronger in women, it was independent of age and other risk factors for CVD. This association suggests a link between osteoporosis and CVD, particularly in its early stages (Hirose *et al.*, 2003). In another study of 236 premenopausal women aged 45 to 57 years, followed for nine years, the progression of atherosclerotic calcification of the aorta and metacarpal bone loss was demonstrated (Hak *et al.*, 2000). In this prospective study, a cross-sectional analysis was also performed in postmenopausal women showing a graded inverse relationship between the extent of aortic

calcification and metacarpal bone density (Hak *et al.*, 2000).

LBMD was associated with increased mortality from CVD (Browner *et al.*, 1991; von der Recke *et al.*, 1999). In the study of osteoporotic fractures research group (Browner, 1991), 9704 ambulatory women aged 65 years and older were prospectively followed. LBMD at the proximal radius was strongly associated with increased mortality from stroke (relative risk 1.74; 95% CI 1.12–2.70). This association was not confounded by other risk factors for stroke such as age, hypertension, diabetes, smoking, or previous history of stroke (Browner *et al.*, 1991). Another study involved two populations of healthy women: one group early after menopause with a mean age of 50 years and another later after menopause with a mean age of 70 years. In this study (Von der Recke, 1999), each decrease of one SD in bone mineral content was associated with a 2.3-fold increased risk of dying from CVD within 17 years of menopause. Elderly women (over 70 years of age) had a 1.8-fold increase of such a risk. These data indicate that low bone mineral content at

menopause is a risk factor for CVD risk later in life (van der Recke *et al.*, 1999).

### Common Underlying Mechanisms for Atherosclerosis and Osteoporosis

Like osteogenesis, arterial calcification is a regulated and complex process that involves the interactions of various cells producing matrix vesicles with subsequent mineralization. In fact, cells with osteoblastic potential have been isolated and cloned from bovine aortic media (Watson *et al.*, 1994). These osteoblast-like cells in the vasculature are capable of calcifying vascular cells (Watson *et al.*, 1994) (see Figure 58.1).

Several proteins are involved in both osteoporosis and atherosclerosis, such as osteocalcin (OC), matrix Gla protein (MGP), bone sialoprotein (BSP), bone morphogenetic protein-2 and -4 (BMP-2, BMP-4), osteonectin (ON), osteopontin (OPN), osteoprotegerin (OPG), and receptor-activated nuclear Factor-Kappa B ligand (RANKL) (Dhore *et al.*, 2001). Involvement of these

**Figure 58.1** Common cellular mechanisms underlying both vascular disease and osteoporosis. NO = Nitric oxide; eNOS = Endothelial nitric oxide synthase; iNOS = Inducible nitric oxide synthase; Est = Estrogen; ox-LDL = Oxidized-low-density lipoprotein; HDL = High-density lipoprotein; OPG = osteoprotegerin; RANKL = receptor-activated nuclear factor-kappa B ligand; RANK = Receptor-activated nuclear factor-kappa B; BMP = Bone morphogenetic protein; MGP = Matrix Gla protein; OC = Osteocalcin; IL-6 = Interleukin-6; M-CSF = Macrophage-colony-stimulating factor; IL-1 = Interleukin-1; TNF = Tumor necrosis factor; PGE2 = Prostaglandin E2; TGFβ = Transforming growth factor-beta; OPN = Osteopontin; CVC = Calcifying vascular cell; OLC = Osteoclast-like cell; Cbfa-1 = core-binding factor-α1; TRAIL = Tumor necrosis factor-related ligand.

proteins as well as the inflammatory cytokines in both disease processes suggest a common underlying pathophysiologic mechanism for osteoporosis and atherosclerosis (Dhore *et al.*, 2001). Furthermore, osteoclast-like cells (OLCs) have been found in calcified arteries (Doherty *et al.*, 2002) (see Figure 58.1). These cells may participate in normal mineral homeostasis in the arterial wall or may be recruited for the developing plaque (Doherty *et al.*, 2002). Net calcium deposition occurs as a result of focal imbalance between osteoblast-like cells and OCLs (Doherty *et al.*, 2002). Again this process in the vascular wall maintains similar mechanisms for arterial calcification analogous to those observed in the bone where a delicate balance is kept between osteoblastic and osteoclastic activities (see Figure 58.1).

### The OPG/RANKL/RANK System

The unraveling of the OPG/RANKL/RANK system represented a breakthrough in our understanding of the regulation of osteoclastogenesis by osteoblasts (Khosla *et al.*, 2001). OPG, a potent inhibitor of osteoclast formation, is a soluble, decoy receptor of the superfamily of the tumor necrosis factor (TNF) (Khosla *et al.*, 2001). This cytokine is produced by the stromal cells of the bone marrow, by osteoblasts, vascular smooth muscle cells (VSMCs), as well as by endothelial cells (Khosla *et al.*, 2001). RANKL, soluble, or cell-bound, expressed by osteoblast precursors upon interaction with RANK, initiates a series of reactions that promote osteoclast formation and activation leading to bone resorption (Khosla *et al.*, 2001; Lacey *et al.*, 1998) (see Figure 58.1).

OPG binds to RANKL leading to inhibition of the osteoclastic activation (see Figure 58.1) (Khosla *et al.*, 2001). OPG Knock-out mice develop arterial wall calcification as well as osteoporosis (Min *et al.*, 2000). Reversal of these abnormalities is observed in OPG transgenic restoration (Min *et al.*, 2002). Furthermore, intravenous injection of recombinant OPG protein reverses the osteoporotic phenotype observed in OPG-deficient mice (Min *et al.*, 2000). Also, in a randomized, double-blinded, placebo-controlled study, a single subcutaneous injection of OPG was found to be effective in reducing bone turnover in postmenopausal women, highlighting its potential as a therapeutic agent for osteoporosis (Bekker *et al.*, 2001).

In normal aortas, OPG is expressed by VSMCs where it lines the calcific deposits in advanced atherosclerosis (Dhore *et al.*, 2001). Around these calcium deposits RANK is also found in the extracellular matrix (Dhore *et al.*, 2001). The calcified aortic lesions contain OLC (see Figure 58.1), multinucleated cells positive for osteoclastic markers but negative for macrophage markers (Min *et al.*, 2000; Doherty *et al.*, 2002). These findings indicate the presence of osteoclasts or equivalent cells

(OLCs) that may mediate OPG inhibition of vascular calcification.

In a prospective study involving 490 white women aged 65 years or more, OPG was associated with diabetes and with cardiovascular mortality, raising the possibility that OPG might be a cause/marker for vascular calcification (Browner *et al.*, 2001). These findings highlight the potential role of OPG as a marker for both osteoporosis and atherosclerosis. The exact mechanisms underlying the paradoxical effects of OPG in vascular tissue and bone are largely unknown. However, possible explanation includes site-specific differential expression of RANK/RANKL at these sites (Emery *et al.*, 1998). Apoptosis of the CVC as well as T-lymphocytes may be prevented by the absence of OPG, thus favoring vascular calcification (Emery *et al.*, 1998).

Collectively, these findings indicate that the OPG/RANK/RANKL pathway is a common denominator in both osteoporosis and CVD.

### Gamma-carboxyglutamic Acid (Gla) Proteins

Gla proteins, including matrix Gla protein (MGP) and osteocalcin (OC), are vitamin K-dependent bone proteins that play a key role as mediators and inhibitors of osteoid formation (Price *et al.*, 1982; Pauli *et al.*, 1987). MGP is a secretory protein that is widely expressed in tissues including bone and vasculature (Price *et al.*, 1982). Chronic Warfarin therapy leads to depletion of these vitamin K-dependent Gla proteins, resulting in an excessive mineralization disorder and closure of the growth plate with cessation of longitudinal growth (Price *et al.*, 1982). These features are similar to those observed in the warfarin embryopathy due to exposure of the human fetus to warfarin anticoagulation in early pregnancy (Pauli *et al.*, 1987). Knockout mice lacking MGP develop to term but die within two months due to arterial calcification and blood-vessel rupture (Luo *et al.*, 1997). Additionally, these MGP-deficient mice exhibit inappropriate calcification of the growth plate leading to short stature, osteopenia, and fractures (Luo *et al.*, 1997). MGP are constitutively expressed in human aortas. These proteins are up-regulated in atherosclerosis and plaque formation (Shanahan *et al.*, 2000), suggesting a role for these proteins in limiting vascular osteogenesis. MGP is expressed with high accumulation in bone and cartilage in association with bone morphogenetic protein (BMP) (Bostrom *et al.*, 2001). MGP inhibits BMP-chondrocyte differentiation. Therefore, absence of MGP inhibitory effect leads to osteogenic differentiation and vascular calcification (Bostrom *et al.*, 2001). However, MGP was suggested to prevent nucleation and growth of crystals via binding to hydroxyapatite (Schnike *et al.*, 1999). These two mechanisms are likely operative in prevention of vascular calcification.

## Osteocalcin (OC)

This is the most abundant osteoblast-specific non-collagenous protein (Ducy *et al.*, 1996) (see Figure 58.1). Osteocalcin-deficient mice develop a phenotype characterized by higher bone mass with increased functional quality (Ducy *et al.*, 1996). These mice, however, do not exhibit vascular calcification, indicating that OC is primarily operative in the bone rather than the vascular tissues. The expression of OC and MGP in humans is parallel in normal as well as in atherosclerotic tissues (Dhore *et al.*, 2001).

In women with osteoporosis and atherosclerosis, serum OC is elevated (Bini *et al.*, 1999), suggesting an integral role of Gla protein in both vascular wall and bone.

## Osteopontin (OPN) and Bone Morphogenetic Proteins (BMP)

Osteopontin is a noncollagenous adhesive protein that is found at dysmorphic calcification sites (Wada *et al.*, 1999). This protein is synthesized by macrophages in atherosclerotic plaques and calcified aortic valves representing an adaptive mechanism aimed at prevention of vascular calcification.

In bone tissue, OPN is produced by osteoclasts as well as osteoblasts, and inhibits matrix mineralization (Wada *et al.*, 1999).

OPN is essential in the development of postmenopausal osteoporosis. OPN knockout mice are resistant to ovariectomy-induced bone resorption, compared to wild-type mice (Yoshitake *et al.*, 1999). Furthermore, in the absence of OPN, PTH-induced increase in bone resorption is suppressed, via osteoclastic inhibition (Ihara *et al.*, 2001). In calcified atheromatous tissues, OPN is upregulated (Dhore *et al.*, 2001), probably as a compensatory response to the decrease in the mineralization process. OPN is also likely to play an important role in atherosclerosis (Isoda *et al.*, 2002). Transgenic mice over-expressing the OPN gene develop both medial thickening without injury and vascular remodeling, and restenosis after angioplasty (Isoda *et al.*, 2002).

BMPs are members of the transforming growth factor (TGF- $\beta$ ) super-family of proteins (Wozney *et al.*, 1998). Among the 15 BMPs that are currently identified, BMP-2 and BMP-4 induce differentiation of osteoblast precursor cells into more mature osteoblast-like cells (Yamaguchi *et al.*, 1991). BMPs stimulate the expression of core-binding factor- $\alpha$  1 (Cbfa-1), a key molecule in osteoblast differentiation (Lee *et al.*, 2000). Application of BMPs to mandibular defects in humans stimulated osteogenesis with mineralized bone trabeculae with copious osteoid seams (Ferretti *et al.*, 2002). In human atherosclerotic lesions there is an enhanced BMP-2 and Cbfa-1 (Engelese *et al.*, 2001). These factors are absent in normal arteries, suggesting a role for these molecules in vascular calcification (Engelese *et al.*, 2001).

## Role of Nitric Oxide (NO)

NO is produced by a group of enzymes (NO Synthase, NOS). It is a pleiotrophic signaling molecule that has an important role in vascular tissue as well as in bone (Moncada *et al.*, 1991). Constitutive NOS (cNOS) produces NO in response to calcium. On the other hand, the inducible form of NOS (iNOS) is produced in large amounts independent of calcium (Moncada *et al.*, 1991). Although cNOS is present in the endothelium lining of the blood vessels and osteocytes, iNOS can be induced in the endothelium, VSMC, inflammatory cells, osteocytes, and chondrocytes (Hukkanen *et al.*, 1995). By producing NO, cNOS responds to a variety of physiological stimulation including shear stress, mechanical loading, estrogen, and statins, as well as growth factors (Muniyappa *et al.*, 2000). NO has a protective effect on both bone and vascular tissues (Moncada *et al.*, 1991). Among the atheroprotective effects of NO are the inhibition of VSMC proliferation, platelet aggregation, and cell adhesion. On the other hand, cNOS deficiency in mice leads to hypertension and endothelial dysfunction, reduced bone mineral density (BMD), and osteoblastic number and function. Mice with cNOS deficiency lost bone following ovariectomy, and there was a significantly blunted anabolic response to high-dose exogenous estrogen (Armour *et al.*, 2001). These findings suggest a critical role for NO in regulating bone mass and bone turnover. These findings are also consistent with the results of a clinical trial, where nitroglycerine, a NO donor, was shown to be as effective as estrogen in preventing bone loss associated with surgically induced menopause, when given in a randomized controlled fashion (Wimalawansa *et al.*, 2000). In contrast to these findings in a mouse model of inflammation-induced bone loss, rapid release and high concentration of NO inhibited proliferation and induced apoptosis of osteoblasts (Mancini *et al.*, 2000). Slow and moderate release of NO however, stimulated the replication of primary rat osteoblasts and alkaline phosphatase activity (Mancini *et al.*, 2000). These findings suggest the presence of both stimulatory and apoptosis-inducing effects of NO on primary osteoblasts (see Figure 58.1). Furthermore, in chronic inflammatory conditions such as rheumatoid arthritis, associated with elevated cytokines and high NO levels, inhibition of NO production reversed bone loss (Sakurai *et al.*, 1995). These findings indicate that in bone and in vascular tissues, the biological response to NO is dose-dependent. Deficiency of cNOS accelerates both osteoporosis and atherosclerosis, and iNOS increases bone loss (Mancini *et al.*, 2000; Sakurai *et al.*, 1995).

## Sex Steroids

The effect of sex steroids on skeletal homeostasis is well established, although, the mechanisms mediating those effects are unclear. Estrogen plays a pivotal role in

regulating bone metabolism not only in women but also in men (Khosla *et al.*, 2002). Sex steroids (estrogen and androgens) decrease the genesis of osteoblasts and osteoclasts; however, they stimulate apoptosis in osteoclasts and prolong the life span of osteoblasts (Manolagas, 2000). Sex steroids inhibit bone resorption via effects on the RANKL/RANK/OPG system, as well as by altering cell-mediated release of various cytokines (interleukins, MCSF, TNF- $\alpha$ , TGF $\beta$ , BMP-6), insulin-like growth factor-I (IGF-I), prostaglandins, and NO (Khosla *et al.*, 2002). Overwhelming data, including the Women's Health Initiative study, suggest that HRT reverses bone loss associated during the postmenopausal period (Riggs *et al.*, 2002; Rossouw *et al.*, 2002). Cross-sectional and interventional studies have demonstrated cardioprotective actions of estrogen. However, recent prospective randomized intervention trials have failed to show such beneficial actions (Rossouw *et al.*, 2002). The dose of estrogen, timing of initiating hormone replacement, and presence of prior atherosclerotic vascular disease may have contributed to the apparently contradictory results. Interestingly, coronary artery plaque calcium content and burden have been shown to be associated with estrogen levels in pre- and postmenopausal women (Christian *et al.*, 2002). Estrogen is known to modulate OPG, MGP, RANKL/RANK, and NO, and may mediate some of its actions on arterial calcification.

In contrast to estrogen, well-designed and adequately powered interventional trials examining the effects of testosterone replacement on bone metabolism in elderly men are lacking. Therefore, the effects of androgen supplementation on BMD are largely unknown. Testosterone has been shown to retard atherosclerosis in rodent models; however, prospective or cross-sectional studies have failed to reveal any consistent association of testosterone levels and coronary artery disease (Alexandersen *et al.*, 1999). Similarly, there is no convincing evidence supporting an association of DHEA(S) with atherosclerosis. These studies suggest that estrogen, but not testosterone or DHEA(S), plays a key role in osteoporosis and atherosclerosis.

## Inflammation

Inflammation is an important underlying mechanism in both atherosclerosis and osteoporosis. In atherosclerosis, inflammation correlates with the severity of the disease (Libby, 2002). Inflammatory markers such as C-reactive protein (CRP), TNF-X, IL-6, and MCP-1 have been suggested as nontraditional cardiovascular risk factors (McFarlane *et al.*, 2001). Recent clinical trials indicate that CRP is a stronger predictor for cardiovascular disease events than LDL-cholesterol (Ridker *et al.*, 2002). Inflammatory cytokines are intricately involved in the various processes that culminate in atherosclerosis such as angiogenesis and neointimal thickening (McFarlane *et al.*, 2002). These cytokines are produced by

the vascular endothelial as well as vascular smooth muscle cells (VSMCs) and macrophages, and include IL-1, TNF-X, and IL-6. These cytokines stimulate the transcription of chemoattractant factors genes such as macrophage stimulatory factor, MCP-1, and increase monocyte migration to the vascular wall leading to atherosclerosis and vascular calcification (Tiutut *et al.*, 2001).

Osteogenic differentiation of CVC is stimulated by monocytes and macrophages through the production of inflammatory cytokines such as TNF-alpha (Shioi *et al.*, 2002). These cytokines are also potent stimulators of 1,25 dihydroxy vitamin D in macrophages. Finally, the causal relationship of these cytokines in osteoporosis has been demonstrated in rodent models, where neutralization of IL-1 activity with IL-1ra or of TNF-alpha with binding protein abrogated atherosclerosis. Injection of IL-6 on the hand promoted the process (Huber *et al.*, 1999).

Changes in cytokine profile in atherosclerosis are similar to those in osteoporosis. These cytokines, particularly IL-6, are powerful stimulators of bone resorption (Scheidt-Nave *et al.*, 2001). In a longitudinal study of postmenopausal women, IL-6 was shown to be a predictor of bone loss particularly in the first six years of the postmenopausal period (Scheidt-Nave *et al.*, 2001). Levels of IL-1, IL-6, and TNF-alpha directly correlated with bone resorptive actions of monocytes (Cohen-Solal *et al.*, 1993). These actions were neutralized by the addition of cytokine inhibitors indicating the pivotal role of these cytokines in bone resorption. Therefore, cytokine activities play a major role in both osteoporosis and atherosclerosis, highlighting a common underlying pathophysiologic mechanism for the two diseases. The actions of their cytokines include polymorphic responses in the vessel walls as well as interaction between cells and local micro environment together with a temporal pattern of expression of these cytokines.

## Dyslipidemia

The role of dyslipidemia in atherosclerosis has been clearly established. Both elevated LDL-cholesterol and reduced HDL-C are risk factors for atherosclerosis. This dyslipidemia has been shown to be related to bone mass and bone fragility and might represent a common underlying factor for both osteoporosis and atherosclerotic disease (Yamagushi *et al.*, 2002). In a study of 214 postmenopausal Japanese women, plasma LDL-cholesterol levels were inversely correlated with bone mineral density at the forearm and the lumbar spine (Yamagushi *et al.*, 2002). In this study, plasma HDL-C was positively correlated with BMD at the lumbar spine and at the forearm. Triglyceride (TG) predicted the presence of vertebral fractures in this cohort of postmenopausal women. This indicates that dyslipidemia is common to both atherosclerosis and osteoporosis. Consistent with these findings, the administration of high-fat

diet reduced bone mineralization in mouse models (Parhami *et al.*, 2001), suggesting that an atherogenic diet is also associated with inhibition of bone formation. Furthermore, epidemiologic studies suggest that high intake of specific fatty acids, such as gamma-linoleic acid, is associated with decreased atherosclerosis. These beneficial effects have also been observed in bone (Schlemmer *et al.*, 1999). These beneficial effects of eicosanoids are likely related to their anti-inflammatory action as well as their modulation of prostaglandin metabolism and their effects on NO synthesis. These lipids affect atherosclerosis and bone remodeling in opposite directions, which may help explain the coexistence of both atherosclerosis and osteoporosis in patients with dyslipidemia.

### Homocysteinemia

Elevated plasma homocysteine has been shown to be associated with increased cardiovascular disease (Danesh *et al.*, 1998). Proposed mechanisms underlying this association include reduced NO bioavailability, smooth muscle cell proliferation, endothelial dysfunction and increased thrombosis. Hyperhomocysteinemia has also been associated with osteoporosis (Parrot *et al.*, 2000). However, the exact mechanism underlying this association is largely unknown.

### Hypertension

Hypertension is a well-established risk factor for atherosclerosis. High blood pressure is also associated with abnormalities in calcium homeostasis leading to hypercalciuria (Cappuccio *et al.*, 1999). This negative calcium balance is associated with decreased bone mineral density. In a prospective study involving 3676 white women, after adjusting for age, body weight, smoking, and baseline bone mineral density, higher blood pressure in elderly women was associated with increased bone loss at the femoral neck. Therefore, hypertension appears to be a common denominator in both osteoporosis and atherosclerosis in the elderly.

### Diabetes Mellitus

Diabetes mellitus (DM) is an established risk for atherosclerosis and is associated with both microvascular and macrovascular disease. Accumulating evidence indicates that diabetes also is associated with increased risk of fracture of the hip, proximal humerus, and foot (Schwartz *et al.*, 2003). Although the association of type 1 DM and low bone density is established, in type 2 DM there is a normal or high bone density despite evidence from epidemiologic data of increased fracture (Dominguez *et al.*, 2004). This paradox is explained, in part, by altered bone structure leading to decreased bone strength. Furthermore diabetes is also associated with higher risk

of falls, particularly among elderly women, leading to increased fractures (Schwartz *et al.*, 2001).

In patients with type 1 DM, mechanisms of increased bone loss are largely unknown. These patients also suffer from increased hip fracture at a younger age (Forsen *et al.*, 1999). Poor metabolic control in adolescents with type 1 DM is associated with increased risk for osteoporosis in adult age (Valerio *et al.*, 2002). Studies involving animal models of type 1 DM suggest that advanced glycation end products (AGEs) inhibit osteoblastic function through their interaction with receptors for AGE (RAGE) (Santana *et al.*, 2003). Interestingly, the interaction of AGE with RAGE has been implicated in the vascular complications of diabetes through altered cell signaling, gene expression, release of pro-inflammatory molecules, and free radicals (Ahmed *et al.*, 2005). These findings of inhibition of osteoblastic function as well as altered cell signaling in vascular tissue suggest common pathophysiologic mechanisms of osteoporosis and CVD.

### Pharmacologic Agents

Agents that commonly are used for prevention and treatment of osteoporosis and CVD such as bisphosphonates and statins have beneficial effects on both the bone and the vascular wall. That is not surprising given the common pathway and site of actions for each of these agents (McFarlane *et al.*, 2002). Statins (3-hydroxy-3-methylglutaryl coenzyme-A (HMG-CoA) reductase inhibitors) commonly are used for treatment of dyslipidemia. These agents lower cholesterol by production and enhance LDL clearance. In addition, statins also reduce cellular isoprenoid intermediates, leading to decreased isoprenylation and decreased activity of small GTP binding proteins from the Ras/Rho family (McFarlane *et al.*, 2002).

Bisphosphonates act one step downstream from the site of action of statins on the mevalonate pathway (McFarlane *et al.*, 2002), which is involved in the regulation of Ras/Rho proteins. It is suggested that the inhibition of protein prenylation might be responsible for the antiresorptive actions of bisphosphonates (Fisher *et al.*, 1999).

Accumulating evidence indicate that these two classes of medications, which affect the mevalonate pathway, may modulate both osteoporosis and atherosclerosis (McFarlane *et al.*, 2002). In addition to their pleiotropic effects on the cardiovascular system, statins also stimulate bone formation *in vitro*, and in rodents, an effect that is associated with increase in bone morphogenetic protein-2 (BMP-2) genes in bone cells (Mundy *et al.*, 1999). Lovastatin and simvastatin increased bone formation when injected subcutaneously over the calvaria of mice, and when given orally, these agents increased cancellous bone volume (Mundy *et al.*, 1999). However, the effect of statins on fracture risk is unclear, and although observational studies showed reduced risk of fracture, randomized trials have not been done (Rizzo *et al.*, 2004).

## 58. Osteoporosis and Cardiovascular Disease in the Elderly

TABLE 58.1

Pathophysiologic mechanisms and risk factors common for both cardiovascular disease and Low Bone Mineral Density

Risk factor	Bone	Cardiovascular system
Age	Associated with decreased BMD	Associated with ↑ vascular disease
Sedentary Lifestyle	Associated with low BMD	Associated with increased vascular dysfunction
Smoking	Associated with ↓ BMD Inhibits osteogenic differentiation and osteoblastic growth Increases catabolism of estrogen	Endothelial Dysfunction ↑ oxidative stress, ox-LDL, diminished NO availability, thrombogenicity, VSMC proliferation
Dyslipidemia	Associated with ↓ BMD; ox-LDL Inhibits osteoblastic differentiation	Endothelial dysfunction, diminished NO production, plaque formation, ↑ neointima, ↑ cell adhesion; ox-LDL ↑ CVC activity, HDL ↓ CVC activity and cytokine formation
Homocysteinemia	Associated with low BMD	Endothelial dysfunction, diminished NO-bioavailability, lipid peroxidation, smooth muscle cell proliferation, increased platelet aggregation, enhanced tissue factor activity, reduced von Willebrand factor secretion, inhibition of tissue plasminogen activator
Estrogen Deficiency	↑ Bone resorption, cytokine activity, ↓ TGF-β, ↓ vitamin D	Diminished NO production, ↑ free radical production, ↑ VSMC proliferation, hypercoagulability, ↑ inflammation, ↑ vascular reactivity
Inflammation	↑ Bone loss: ↑ NO production, osteoblast apoptosis, osteoclast activity	Endothelial dysfunction, increased coagulation, plaque instability, ↑ CVC activity, vitamin D production, ↑ vascular calcification

BMD = Bone mineral density; LDL = Low-density lipoprotein; ox-LDL = oxidized-LDL; NO = Nitric oxide; VSMC = Vascular smooth muscle cell; CVC = Calcifying vascular cell; TGFβ = Transforming growth factor- beta; IL-6 = Interleukin-6; LDLRP = Low-density lipoprotein receptor protein.

Bisphosphonates have long been shown to decrease atherosclerosis (Yitalo *et al.*, 1994). These agents prevent the development of atheromatous lesions when used in animal models fed with a high cholesterol diet (Yitalo *et al.*, 1994). Furthermore, bisphosphonates have been shown to reduce the extent of established atherosclerotic lesions and in high doses, a bisphosphonate derivative also has been shown to reduce serum cholesterol by 33% and to exert multiple anti-atherosclerotic effects including suppression of HMG -C0A reductase activity and prevention of lipid oxidation (Jackson *et al.*, 2000). Oral etidronate has been shown to decrease carotid arterial intima-media thickness in type 2 diabetes without changing cardiovascular parameters, suggesting a direct effect of bisphosphonates on the vascular wall (Koshiyama *et al.*, 2000).

In elderly patients with diabetes, the use of alendronate 10 mg/daily for treatment of osteoporosis was associated with a 36% reduction in the daily insulin dosage (Mangeri *et al.*, 2002). This suggests improvement in insulin sensitivity associated with bisphosphonate use.

Thus, bisphosphonates clearly have beneficial effects on both atherosclerosis and osteoporosis.

### Conclusion

Accumulating evidence indicates similar pathophysiologic mechanisms and risk factors underlying both osteoporosis

and CVD, including age, sedentary lifestyle, dyslipidemia, hypertension, and diabetes, among others. Furthermore, therapeutic agents used for treatment of osteoporosis appear to have beneficial effects on atherosclerosis and vice versa. The prospect of newer therapeutic agents that could treat both osteoporosis and atherosclerosis simultaneously is an exciting possibility requiring further investigation.

# Depression in Older Patients

Kiran Rabheru

*Major depressive disorder is frequently undiagnosed and untreated in older patients, and can be associated with high morbidity and mortality in this patient group, who are particularly prone to completed suicide or self-neglect. Grief, pain, sleep issues, concurrent medications, altered physiology, and the presence of comorbid medical and psychiatric conditions can complicate the management of depression in older patients. Comorbid medical conditions, including cardiovascular events, stroke, vascular dementia, and Alzheimer's disease, which are common among older patients, can have a significant impact on depression, and vice versa.*

*Depression is not a natural part of the aging process, and it should be diagnosed and actively treated in the elderly, just as it is in younger patients. Pharmacotherapy can be safe and effective in this population, as long as pharmacokinetic and pharmacodynamic properties, as well as the inherent biological differences in the elderly population are considered when selecting treatments. Psychosocial therapies and antidepressants such as selective serotonin reuptake inhibitors (SSRIs), venlafaxine, and mirtazapine have demonstrated beneficial effects in this population. Although tricyclic antidepressants also have demonstrated efficacy, tolerability can be a problem.*

## Introduction

The prevalence of major depressive disorder (MDD) in older individuals (65 to 100 years) in the community is estimated at 4.4% in women and 2.7% in men (Steffens *et al.*, 2000). The rate of depression is higher among elderly people living alone, those who require assistance with the activities of daily living, and urban vs. rural residents. Several studies have found rates of depression of about 14% among older individuals receiving home care, nursing home residents, and general hospital inpatients. In addition, minor depression (16.8%) and significant depressive symptomatology (44.2%) were very common in a survey of nursing home residents (Teresi *et al.*, 2001).

Although common, depression either is frequently not identified among older patients or is attributed to the normal aging process. In primary care, physicians diagnosed depression in only about 50% of depressed elderly

patients (Volkers *et al.*, 2004). Recognition among nursing home residents was even lower, with staff recognizing only 37 to 45% of cases diagnosed by psychiatrists (Teresi *et al.*, 2001). It appears that the presence of multiple medical problems results in a focus on somatic complaints, with less attention being given to depression. Other factors, such as grief, pain, sleep, and medication use, also contribute not only to the underdetection but also to the undertreatment of depression.

Evidence suggests that only about 10 to 38% of elderly patients with depression receive antidepressants (Steffens *et al.*, 2000; Stek *et al.*, 2004). Antidepressant use was lower among elderly suffering from depression in the community (4.2%), compared to those in institutions (36.0%) in a Canadian study (Newman *et al.*, 1999). In surveys of medication use among older individuals, antidepressants were being used in only 2.2 to 4.1% of those who lived in the community and 3.6 to 16.5% of those in institutions (Riedel-Heller *et al.*, 2001). When antidepressants were used, one-third to two-thirds of older patients received dosages that were lower than those recommended for treatment of depression (Riedel-Heller *et al.*, 2001).

The diagnosis and treatment of depression in the elderly is critical. MDD and depressive symptoms have been reported to increase the risk of mortality among elderly subjects by 1.5 to 2.0 times that of subjects without depression (Blazer *et al.*, 2001; Lavretsky *et al.*, 2002; Schoevers *et al.*, 2000; Schulz *et al.*, 2000).

## Etiology and Pathogenesis

Studies suggest that structural changes of various neuro-anatomic structures including frontostriatal and limbic dysfunction contribute to the pathogenesis of at least some late-life depressive syndromes (Alexopoulos, 2002). Three cortico-striato-pallido-cortical pathways between the frontal lobe and the basal ganglia may be relevant to depression because damage to these pathways leads to behavioral abnormalities that resemble in part the depressive syndrome (Alexopoulos, 2004). In addition, damage to the orbitofrontal circuit may lead to disinhibition, irritability, and diminished sensitivity to social cues; damage to the anterior cingulate may result in apathy and reduced initiative; and damage to the dorsolateral circuit

may result in difficulties in set shifting, learning, and word list generation.

In older patients with depression, studies have described decreases in hippocampal volume (Moffat *et al.*, 2000; Sheline *et al.*, 1999), abnormalities of various frontal lobe structures (Chemerinski *et al.*, 2000; Kumar *et al.*, 2000; Lai *et al.*, 2000), and basal ganglia (Chemerinski *et al.*, 2000), as well as abnormal cerebral blood flow (Alexopoulos, 2004) and metabolic activity (de Asis *et al.*, 2001; Drevets, 2000; Mayberg, 2001) in these structures.

Frontostriatal dysfunction appears to influence the course of geriatric depression. Executive impairment, the neurophysiological expression of striatofrontal dysfunction, was reported to predict poor or delayed antidepressant response, and has been associated with relapse and recurrence, as well as residual depressive symptomatology (Alexopoulos *et al.*, 2002; Alexopoulos *et al.*, 2000; Kalayam *et al.*, 1999). Changes in metabolism in various brain structures have been associated with remission of depression (Drevets, 2000; Mayberg, 2001), risk of relapse, and treatment-resistance (Mayberg, 2001).

Polymorphisms in the promoter region of the serotonin transporter gene (5-HTTLPR) may play a role in the pathogenesis and course of depression and anxiety (Hariri *et al.*, 2003; Sen *et al.*, 2004; Taylor *et al.*, 2005). Geneotype has been related to hippocampal volumes (Taylor *et al.*, 2005) and to amygdala reactivity to environmental stimuli (Hariri *et al.*, 2005). These findings may be related to interactions between the serotonergic system and neurotrophic factors or cortisol response to stresses and may bias an individual's reactivity to stressful life experiences (Hariri *et al.*, 2005; Taylor *et al.*, 2005). Some studies report that genotype significantly predicts the development of depression after stressful life events (Lenze *et al.*, 2005), although others did not find an association (Gillespie *et al.*, 2005). Several studies have suggested that response to antidepressant therapy may be related to serotonin transporter genotype (Murphy *et al.*, 2004). The short (S) allele was associated with a faster response to sertraline (Durham *et al.*, 2004). However, in another study, no relationship with efficacy was seen; rather, the major effect was on SSRI. Results were not consistent with the S allele being associated with more adverse effects with paroxetine therapy, and fewer with mirtazapine, suggesting the effect of this polymorphism on outcome may depend on the mechanism of antidepressant action (Murphy *et al.*, 2004).

Depression in the elderly is common in individuals with vascular neurological diseases, and many of the structural and functional changes identified in patients with depression are associated with a variety of neurologic disorders (i.e., stroke, Parkinson's disease, Alzheimer's disease) (Kanner, 2004). In addition, depression is a risk factor for the development of several neurologic disorders, including dementia (Andersen *et al.*, 2005;

Bartolini *et al.*, 2005; Dal Forno *et al.*, 2005; Modrego *et al.*, 2004; Steffens *et al.*, 2004) and has a negative impact on the course and outcome of most neurologic disorders (Dorenlot *et al.*, 2005; Hughes *et al.*, 2004). Late-life depression is a frequent complication of stroke. Lacunar infarcts in the basal ganglia have the highest comorbidity with depression (Chemerinski *et al.*, 2000), and subcortical atrophy appears to be a predisposing factor.

The relationship between depression and cardiovascular disorders also provides insight into the mechanisms of depression. Abnormalities in neurotransmitters (including serotonin), platelet-activating factor, and nitric oxide, which are involved in atherosclerotic processes, have been implicated in the pathogenesis of depression (Plante, 2005). Moreover, vascular consequences of depression such as heart rate and pulse pressure variations may lead to endothelial dysfunction in critical microcirculation networks (cerebral, myocardial, and renal) and initiate physicochemical alterations in interstitial compartments adjacent to vital organs. Worsening depressive symptoms after a coronary event were associated with impaired autonomic control of the heart, and mortality was almost three times higher among the patients with MDD at the time of the initial event compared to those without depression (de Guevara *et al.*, 2004). The finding of higher rates of relapse of depression among patients taking cholesterol-lowering medications supports the idea of a vascular component to depression (Steffens *et al.*, 2003).

Thus, it appears that both degenerative and vascular processes contribute to the brain abnormalities identified in late-life depression. It is likely that there are bidirectional pathophysiological mechanisms contributing to depression in older patients with comorbid vascular diseases.

## Issues in the Management of Depression in Older Patients

### COURSE

A study of the natural history of late-life depression found that long-term outcomes are poor (Beekman *et al.*, 2002). Over the six years of follow-up, the average symptom severity remained above the 85th percentile of the population average. Symptoms were short-lived in only 14%, remission was achieved in 23%, an unfavorable but fluctuating course in 44%, and a severe chronic course in 32%. Individuals with subthreshold disorders had the best outcome, followed by those with MDD, dysthymic disorder, and double depression. However, the prognosis of subthreshold disorders was unfavorable in most cases (Beekman *et al.*, 2002). Relapse rates without ongoing treatment are high, supporting the importance of long-term maintenance therapy (Flint *et al.*, 1999; Thorpe *et al.*, 2001).

Comorbid anxiety disorders, which are common in this population (23–48%), are associated with a more severe course of depressive illness (Beekman *et al.*, 2000; Lenze *et al.*, 2000).

### COMORBID CONDITIONS

Comorbid medical conditions are the norm in older patients with depression. There appear to be complex bidirectional consequences of depression and comorbid vascular conditions on the pathogenesis, severity, and prognosis of both depression and the comorbidity. Comorbidities complicate the management of depression and vice versa. The relationship between depression and cardiovascular abnormalities, stroke, diabetes, and dementias in terms of prevalence, impact on prognosis, and effects on management strategies is discussed in the later section on management of depression in patients with comorbid illnesses.

### PHARMACOKINETIC AND PHARMACODYNAMIC CONSIDERATIONS

The use of antidepressants in older patients can be complicated by several factors. Older individuals use multiple medications (two or more prescription drugs) three times more frequently than younger persons, increasing the potential for interactions. Age-related alterations in physiology can result in variable plasma drug concentrations, which may increase the number of adverse events, and the elderly may be more sensitive to adverse events (McDonald *et al.*, 2002). Aging is associated with a number of neuroendocrine changes, including alterations in monoamine oxidases, noradrenergic neurons, dopaminergic neurons and concentrations, cholinergic neurons and receptors, adrenocorticotrophic hormone (ACTH) concentration and function, and serotonin receptors and concentrations (Rehman *et al.*, 2001). There is early evidence that some older patients with deficits in executive skills may respond poorly to antidepressant treatment compared with those with intact executive functions (Mohlman, 2005).

Recommended initial doses are lower for the elderly for all antidepressants, and increases should be slow and individualized (De Vane *et al.*, 1999). The pharmacokinetics of some selective serotonin reuptake inhibitors (SSRIs) may be altered in older patients, and it is recommended that doses be adjusted in these patients (De Vane *et al.*, 1999). Lower doses should be used for citalopram and for paroxetine (Muijsers *et al.*, 2002). Medical conditions can affect drug elimination, which is decreased in patients with hepatic (citalopram, fluoxetine, fluvoxamine, sertraline) or renal (paroxetine) impairment (Muijsers *et al.*, 2002).

### SUICIDE RISK

The risk of suicide demonstrates the need for early geriatric psychiatric assessments and vigorous treatment

protocols. Suicidal feelings are high among individuals aged 85 years or over with mental disorders, with 30% believing “life was not worth living” and 10% having thought of taking their own life (Skooog *et al.*, 1996). Among women who felt life was not worth living, the three-year mortality rate was three times that of women without these feelings (43% vs. 14%, respectively). Several studies have shown that recognition of depression among the elderly who attempt or complete suicide is inadequate (Duckworth *et al.*, 1996; Suominen *et al.*, 2004). Only 4% of the elderly who had attempted suicide had been diagnosed with a mood disorder before the attempt, despite having physician contact within the previous year (Suominen *et al.*, 2004). Among elderly depression patients who had committed suicide, 80% of patients had no psychiatric referral, and 87% were untreated (Duckworth *et al.*, 1996). Correlates of suicide include poor perceived health, poor sleep quality, and lack of a confidant (Turvey *et al.*, 2002). There is also a strong association with deliberate self-poisoning using benzodiazepine in the elderly (Ticehurst *et al.*, 2002).

In the Prevention of Suicide in Primary Care Elderly: Collaborative Trial (PROSPECT), use of a multifaceted care management model in primary care was shown to significantly reduce rates of suicidal ideation compared with usual care among elderly patients with depression (Bruce *et al.*, 2004). In addition, a survey of prescribing trends showed a decrease in the rate of suicide associated with prescriptions for antidepressants, antipsychotics, antimanic drugs and analgesics, and an increase with prescriptions for barbiturates, hypnotics, and sedatives (Shah *et al.*, 2001).

## Management of Depression in Older Patients

### TREATMENT GOALS

Like younger patients with depression, older patients should be treated to remission (the virtual elimination of symptoms) rather than simply response (reduction in symptoms). Remission maximizes the impact of treatment on quality of life domains (Doraiswamy *et al.*, 2001). In 100 older patients with recurrent MDD, those who achieved remission with antidepressant treatment showed significantly greater improvement than either partial responders or nonresponders on both emotional and physical quality of life measures.

When treating older patients, a strong doctor–patient relationship is essential, and interventions should include environmental, social, recreational, supportive, and spiritual programs, as well as psychoeducational programs that include the patient’s family. Antidepressant medications at appropriate dosages and durations are the mainstay of therapy as in younger patients, and ECT is recommended for severe cases.

## ANTIDEPRESSANT THERAPY

### *Efficacy for acute and maintenance treatment*

Evidence suggests that older patients will benefit from antidepressant therapy as much as younger adults, but that improvements may occur more slowly (Reynolds *et al.*, 1996). A Cochrane database review of 17 trials of antidepressant use in older patients with depression found similar efficacy for TCAs, SSRIs, and MAOIs (Wilson *et al.*, 2001). At least six weeks of treatment was recommended to achieve optimal therapeutic effect. In a meta-analysis of eight double-blind, randomized controlled trials (RCTs) of venlafaxine, SSRIs, or placebo, no significant age-by-treatment interactions were detected (Entsuah *et al.*, 2001).

The efficacy of bupropion, citalopram, fluoxetine, paroxetine, sertraline, as well as venlafaxine, mirtazapine, and nortriptyline, in treating older patients with depression has been demonstrated in clinical trials (Allard *et al.*, 2004; Bondareff *et al.*, 2000; Cassano *et al.*, 2002; Devanand *et al.*, 2005; Forlenza *et al.*, 2001; Gasto *et al.*, 2003; Navarro *et al.*, 2001; Newhouse *et al.*, 2000; Rocca *et al.*, 2005; Schatzberg *et al.*, 2002; Sheikh *et al.*, 2004; Weihs *et al.*, 2000). There are few statistically significant differences between agents in individual studies, with response rates being about 40 to 75% and remission rates about 30 to 70% (Bondareff *et al.*, 2000; Cassano *et al.*, 2002; Devanand *et al.*, 2005; Forlenza *et al.*, 2001; Gasto *et al.*, 2003; Navarro *et al.*, 2001; Newhouse *et al.*, 2000; Rocca *et al.*, 2005; Schatzberg *et al.*, 2002). There is some evidence that agents with dual mechanism, including the SNRIs, mirtazapine and venlafaxine and the TCA, nortriptyline, may be more effective than agents with a single mode of action such as the SSRIs (Entsuah *et al.*, 2001; Gasto *et al.*, 2003; Navarro *et al.*, 2001; Schatzberg *et al.*, 2002). Therapeutic response to sertraline in older patients with MDD was significantly greater than placebo and comparable in those with or without medical comorbidity (Sheikh *et al.*, 2004).

Few data are available on antidepressant therapy in the very old patient. In a small placebo-controlled trial in very old patients (aged 80 years and over) in long-term care facilities, paroxetine was not significantly better than placebo but was associated with two cases of delirium (Burrows *et al.*, 2002).

Data on the prevention of relapse or recurrence in older patients demonstrates the efficacy of ongoing antidepressant therapy (Bump *et al.*, 2001; Klysner *et al.*, 2002). Results are similar to those in younger patients, with ongoing therapy being associated with reductions in relapse rates of about 30 to 50%. Long-term treatment with citalopram effectively reduced recurrence by about 50% after sustained response in a double-blind, placebo-controlled trial in older patients (Klysner *et al.*, 2002). In a small, open, follow-up study in older patients, paroxetine and nortriptyline demonstrated similar efficacy

in relapse prevention and time to relapse (Bump *et al.*, 2001).

### *Cognitive effects*

Both aging and depression itself have been associated with impairments in cognitive functioning. Older patients with depression have demonstrated impaired executive functioning, compared with younger patients with depression or healthy elderly individuals without depression (Lockwood *et al.*, 2002).

Older individuals with cognitive impairment at baseline do not necessarily reach normal levels of performance, particularly in memory and executive functions after treatment of late-life depression (Butters *et al.*, 2000). However, several studies have demonstrated improvements in various measures of cognitive functioning among older patients treated with SSRI antidepressants. The detrimental effects of TCAs on cognition have been well documented and may reflect the vulnerability of older patients to the central anticholinergic activity of these agents (Peretti *et al.*, 2000). The SSRIs sertraline, paroxetine, and fluoxetine, and the SNRI, venlafaxine have demonstrated significant improvements in cognitive functioning, with sertraline and paroxetine demonstrating some advantages over fluoxetine (Bondareff *et al.*, 2000; Cassano *et al.*, 2002; Doraiswamy *et al.*, 2003; Newhouse *et al.*, 2000; Tsolaki *et al.*, 2000). In contrast, a small study in very old (aged 80 years and over) patients found a risk of adverse cognitive effects with paroxetine: two patients developed delirium, and others were more likely to experience decreases in cognitive scores (Burrows *et al.*, 2002). In patients with MDD and existing cognitive impairment, open treatment with sertraline was associated with minor improvements in cognition among responders and mild deterioration among nonresponders (Devanand *et al.*, 2003).

### *Safety and tolerability*

A meta-analysis of 11 clinical trials in older patients with depression reported an increased withdrawal rate with TCAs compared to SSRIs (Wilson *et al.*, 2004). This was reflected in the higher rate of side effects with TCAs including dry mouth, drowsiness, dizziness, and lethargy. Although there was a relatively low prevalence of side effects associated with SSRIs, a significant minority of older people experienced nausea, vomiting, dizziness, and drowsiness.

In clinical trials, the most common side effects were dry mouth and weight gain with mirtazapine (Schatzberg *et al.*, 2002) and nausea/vomiting with venlafaxine (Allard *et al.*, 2004). Pooled data from eight RCTs in older patients demonstrated the safety of citalopram, with only increased sweating occurring more often than with placebo (Keller, 2000). SSRI and venlafaxine use have been independently associated with

the presence of hyponatremia in elderly patients (Flores *et al.*, 2004; Kirby *et al.*, 2002; Rosner, 2004).

Older patients frequently take multiple medications, which makes the potential for drug interactions with antidepressant medications a concern. The potential for interaction is generally higher with older antidepressant compounds (such as TCAs and MAOIs), which are associated with clinically significant interactions with many medications frequently prescribed to elderly patients (Spina *et al.*, 2002). New antidepressants have a more selective mechanism of action and a lower potential for pharmacodynamic drug interactions.

### PSYCHOTHERAPY

The combination of both antidepressant and psychotherapy has been shown more effective than either therapy alone, in both acute and maintenance treatment (Lenze *et al.*, 2002; Miller *et al.*, 2001; Reynolds *et al.*, 1999; Thompson *et al.*, 2001). In an evaluation of the combination of desipramine and cognitive-behavioral therapy (CBT), compared with either therapy alone, the combination was more effective than the TCA but similar to the CBT alone (Thompson *et al.*, 2001). Maintenance therapy with interpersonal psychotherapy (IPT) alone or in combination with an antidepressant has been shown to protect against recurrence of MDD in elderly patients, with the combination tending to be more effective than IPT or pharmacotherapy alone (Miller *et al.*, 2001; Reynolds *et al.*, 1999). The combination of psychotherapy and medication also has been shown to maintain social adjustment better than either treatment alone and to improve both the duration and quality of wellness (Lenze *et al.*, 2002).

### AUGMENTATION AND NOVEL TREATMENT STRATEGIES

Lithium has demonstrated some benefits when used as augmentation to antidepressants in older patients, with a 50% response acute rate (Zullino *et al.*, 2001). Lithium augmentation significantly reduced relapse rates compared to antidepressants alone over two years (Wilkinson *et al.*, 2002). However, it is recommended that special care be taken when treating elderly patients with lithium, because of a higher risk of adverse effects.

No benefit was seen when total sleep deprivation was added to paroxetine; in fact, the two interventions seem to counteract each other (Reynolds *et al.*, 2005). Light therapy significantly improved depressive symptoms in a study in older depressed patients (Tsai *et al.*, 2004). A small randomized trial comparing repetitive transcranial magnetic stimulation (rTMS) and sham treatment in older patients with treatment-resistant MDD reported antidepressant effects in both groups, with no significant benefits associated with rTMS (Mosimann *et al.*, 2004). St John's Wort has been shown to have antidepressant

effects (Linde *et al.*, 2005). St. John's Wort was shown to be equivalent to fluoxetine, in a randomized trial in elderly patients with mild or moderate depressive episodes (Harrer *et al.*, 1999).

### ELECTROCONVULSIVE THERAPY (ECT)

Although patients who receive ECT tend to be older than those who do not (de Carle *et al.*, 2000), there are few good studies of the use of ECT in the elderly population. ECT has been reported to be effective in elderly patients in several open or retrospective case series (Bosworth *et al.*, 2002; Kujala *et al.*, 2002; Little *et al.*, 2004), with improvement in about 80% and adverse events in about 35% (Kujala *et al.*, 2002; Little *et al.*, 2004). Safety has been generally acceptable, with only minor complications during ECT among older patients with preexisting cardiovascular disease; falls are reported with increasing frequency as the number of treatments increases (de Carle *et al.*, 2000).

In meta-analyses, ECT has been found to be an effective treatment option compared to both placebo and pharmacotherapy (2003; Pagnin *et al.*, 2004). Several open, prospective, follow-up studies have compared one-year outcomes in elderly patients treated with ECT or antidepressants (Huuhka *et al.*, 2004; Navarro *et al.*, 2004a; Navarro *et al.*, 2004b). One study reported a 41% rehospitalization rate, which was similar in both treatment groups (Huuhka *et al.*, 2004). In patients who remained euthymic for one year, there were no brain perfusion abnormalities, and the significant anterior hypofrontality seen at baseline disappeared with sustained remission of depression in both treatment groups (Navarro *et al.*, 2004a; 2004b).

## Managing Depression in Older Patients with Comorbid Conditions

### OVERVIEW

Older patients often have significant medical comorbidity, and evidence suggests a significant association with depressive symptoms (Lee *et al.*, 2001). Comorbid conditions contribute to the underdiagnosis and undertreatment of depression in older patients, with somatic complaints taking precedence over depressive symptoms among both patients and their physicians. However, depression should not be overlooked because it can have an important impact on the outcome of medical conditions and vice versa.

Depression can be safely and effectively treated in patients with comorbid medical illnesses. A Cochrane database review of antidepressants in medically ill patients over age 16 years included 18 studies covering 838 patients with a range of physical diseases (Gill *et al.*, 2000). Patients treated with antidepressants were significantly more likely to improve than those given placebo

with an NNT with antidepressants to produce 1 recovery from depression was 4.2, and the number needed to harm (NNH) to produce 1 dropout for adverse effects was 9.8.

## CARDIOVASCULAR

Depression is common among individuals who suffer acute myocardial infarction (MI) (Akhtar *et al.*, 2004; Rosengren *et al.*, 2004), and the level of depressive symptoms during admission for MI is closely linked to long-term survival (de Guevara *et al.*, 2004; Lesperance *et al.*, 2002; Shiotani *et al.*, 2002). Patients with depression post-MI were at a significantly increased risk of new cardiovascular events (de Jonge *et al.*, 2005; Shiotani *et al.*, 2002; van Melle *et al.*, 2004) and mortality (de Guevara *et al.*, 2004; Pfiffner *et al.*, 2004; van Melle *et al.*, 2004), as well as a poor quality of life, more health complaints, and more disability (de Jonge *et al.*, 2005) compared to those without depression. Similarly, depression was associated with an increased risk of major cardiac events in patients with unstable angina (Lesperance *et al.*, 2000).

Several studies also have demonstrated that depression is independently associated with a substantial increase in the risk of heart failure, particularly among women (Abramson *et al.*, 2001; Powell *et al.*, 2005; Williams *et al.*, 2002). Depression had a significant negative effect on health status, including heart failure symptoms, physical and role function, and quality of life in a six-month prospective cohort study (Sullivan *et al.*, 2004). Higher rates of relapse of depression were reported among patients using cholesterol-lowering medications compared to those who were not (Steffens *et al.*, 2003).

Evidence suggests an association between the use of TCAs and the risk of MI. In a cohort study, there was a doubling of the risk of MI associated with TCA use and no increased risk with SSRIs compared with no antidepressant use (Cohen *et al.*, 2000). However, in a naturalistic study, the abnormalities in conduction and orthostatic hypotension associated with TCA treatment were reported, but cases of first-degree atrioventricular block, prolonged QTc interval, and orthostatic hypotension were also observed in the SSRI-treated patients (Rodriguez de la Torre *et al.*, 2001).

SSRIs have been shown to be relatively safe and effective in patients with a history of cardiovascular disease. Several studies have found sertraline to be effective in patients with MDD after MI and those with hypertension and other cardiovascular morbidity (Krishnan *et al.*, 2001). In a small study, no significant changes in heart rate, blood pressure, cardiac conduction, coagulation measures, or left ventricular ejection fraction were observed. Bleeding time increased in 12 patients, decreased in four patients, and was unchanged in two patients. Paroxetine has also demonstrated good efficacy and tolerability in patients with MDD and documented ischemic heart disease (Nelson *et al.*, 1999; Roose *et al.*, 1998).

Trials to assess impact of treating depression on cardiovascular risk are in their infancy. A recent randomized trial studying the impact of CBT (and SSRIs when indicated) on both major and minor depression post MI was unable to detect an impact on event-free survival (Berkman *et al.*, 2003). However, there is some evidence that SSRIs may reduce the incidence of new cardiovascular events in patients with a history of cardiovascular disease. A case-control study found that antidepressant use was associated with a 15 to 45% decrease in the risk of hospitalization for myocardial infarction among individuals with a history of cardiovascular disease (Monster *et al.*, 2004). Similarly, another case-control study reported significantly reduced odds of MI in individuals taking SSRI antidepressants, with the risk almost halved (Sauer *et al.*, 2003). It has been suggested that reductions in cardiovascular events with SSRIs may be related to their inhibitory effect on platelet aggregation (Maurer-Spurej *et al.*, 2004).

## STROKE

Depressive symptoms are common after stroke (Hackett *et al.*, 2005; Verdelho *et al.*, 2004). MDD has been shown to be an independent predictor of stroke, approximately doubling the risk after other known risk factors are controlled (Jonas *et al.*, 2000; Larson *et al.*, 2001). Depression has been associated with increased mortality and poor long-term functional outcome after stroke (Bozikas *et al.*, 2005; Gillen *et al.*, 2001; Pohjasvaara *et al.*, 2001).

An association between bleeding disorders and the use of SSRIs has been suggested. However, several cohort analyses reported no increased risk in cerebrovascular events with past use of SSRI or TCA antidepressants (Barbui *et al.*, 2005; de Abajo *et al.*, 2000). A review conducted to determine the feasibility and effectiveness of antidepressant treatment for post-stroke depression in elderly patients found that TCAs would be contraindicated in 83% of patients, and SSRIs would be contraindicated in only 11% of patients (Cole *et al.*, 2001). A randomized, placebo-controlled trial demonstrated that reboxetine was safe and effective for use in stroke patients with depression (Rampello *et al.*, 2005). Mirtazapine therapy administered from day 1 post-stroke has been shown to prevent the development of depression compared to placebo (Niedermaier *et al.*, 2004).

There is some evidence to suggest that treatment of depression after stroke can have significant beneficial effects on long-term outcomes. In a study in 104 post-stroke patients with or without depression, nortriptyline produced a significantly higher response rate than fluoxetine or placebo in improving depression, anxiety symptoms, and recovery of activities of daily living (Robinson *et al.*, 2000). A nine-year follow-up of these patients reported that antidepressant therapy significantly improved survival; 70% of patients were alive compared

to 36%, who were treated with placebo (Jorge *et al.*, 2003).

## DIABETES

Diabetes is highly prevalent in older individuals, and significantly increases the risk of cardiovascular events. A meta-analysis found that the rate of depression among individuals with diabetes was twice that of individuals without diabetes (Anderson *et al.*, 2001). In a long-term follow-up of a community cohort, the presence of depressive symptoms at baseline more than doubled the risk of developing type 2 diabetes (Palinkas *et al.*, 2004). In addition, the presence of depression has been associated with poor glycemic control in both patients with type 1 and those with type 2 diabetes (de Groot *et al.*, 2001; Lustman *et al.*, 2000; Palinkas *et al.*, 2004).

Care should be taken to choose antidepressants with no or minimal effects on glucose levels in patients with diabetes. A review of treatment of depression in patients with comorbid diabetes mellitus included six studies of fluoxetine for up to 12 months that demonstrated reductions in weight, in fasting plasma glucose (FPG), and in glycosylated hemoglobin (HbA1c) (Goodnick 2001). Sertraline also has demonstrated beneficial effects on glycemic control, whereas the TCA nortriptyline, which produces increased synaptic catechols, has led to worsening of glucose control. In the United Kingdom Prospective Diabetes Study (UKPDS), every 1% reduction in HbA1c was associated with reductions in risk of 21% for any endpoint related to diabetes, of 21% for diabetes-related deaths, and of 14% for myocardial infarction (Stratton *et al.*, 2000).

## DEMENTIA AND ALZHEIMER'S DISEASE

A higher prevalence of depressive symptoms was seen in patients with vascular dementia (31%) or Alzheimer's disease (AD) (20%) compared to cognitively normal elderly individuals (13.2%) (Li *et al.*, 2001). Depression is also frequent in Parkinson's disease and because of overlapping clinical symptoms, frequently goes unrecognized (Lemke *et al.*, 2004). In numerous cohort studies, depression has been shown to double the risk of Alzheimer's disease and vascular dementia (Andersen *et al.*, 2005; Dal Forno *et al.*, 2005; Modrego *et al.*, 2004; Steffens *et al.*, 2004). The rate of dementias and AD has been shown to increase with increasing depression scores and increasing numbers of depressive episodes (Bartolini *et al.*, 2005; Kessing *et al.*, 2004). Depression has a negative impact on the course and outcome of comorbid neurological disorders, more than doubling the risk of death among patients with Parkinson's disease (Hughes *et al.*, 2004) and significantly increasing the risk of early institutionalization in patients with dementias including AD (Dorenlot *et al.*, 2005).

Response to the SSRIs in patients with dementia or AD has been mixed (Lyketsos *et al.*, 2000; Magai *et al.*,

2000; Petracca *et al.*, 2001). Paroxetine and imipramine demonstrated equivalent efficacy in the treatment of depression in elderly patients with co-existing dementia at eight weeks. There was a trend toward better tolerability with paroxetine, in terms of anticholinergic and serious nonfatal adverse events. In small placebo-controlled trials, there were no significant benefits of sertraline (Magai *et al.*, 2000) or fluoxetine (Petracca *et al.*, 2001) over placebo in the treatment of depression in patients with AD. However, in a study in outpatients with AD, sertraline was superior to placebo for the treatment of major depression, and significantly lessened behavior disturbance and improved activities of daily living, but did not improve cognition (Lyketsos *et al.*, 2000). In a small open trial in patients with Parkinson's disease, reboxetine significantly improved depression with acceptable tolerability, but there were no significant changes in parkinsonian symptoms (Lemke, 2002).

There is some evidence that behavior therapy—pleasant events and behavior therapy—problem solving reduce depression in people with probable AD who are living at home with their primary caregiver (Verkaik *et al.*, 2005).

## CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

Nearly half of all COPD patients experience substantial depressive symptoms (Lacasse *et al.*, 2001; Yohannes *et al.*, 2003), which increase to as much as 90% among patients with end-stage disease (Gore *et al.*, 2000). Depression has an impact on disability (Kim *et al.*, 2000) and may contribute to the progression of COPD through its relationship with early smoking and failure to quit. Patients with COPD rarely receive treatment for mental health problems (Gore *et al.*, 2000; Kim *et al.*, 2000).

Several trials assessing the effects of psychotherapies, such as psychoeducation and CBT, on depression in patients with COPD have demonstrated significant reduction in depression and anxiety symptoms, but generally little or no change in lung or physical function (de Godoy *et al.*, 2003; Kunik *et al.*, 2001). Pulmonary rehabilitation programs have been shown to improve depressive symptom scores.

A randomized, placebo-controlled study of paroxetine demonstrated significant improvements in emotional function and mastery and nonsignificant improvements in dyspnea and fatigue (Lacasse *et al.*, 2004). Drop-out rates were high in this study in frail elderly patients. This is mirrored in an open trial, in which only 25% of depressed patients with COPD agreed to undergo therapy with fluoxetine. Of those who were treated, 57% responded, and the majority of those who refused therapy remained depressed at a six-month follow-up (Yohannes *et al.*, 2001). This underscores the need for effective treatment approaches in this patient group.

## Conclusion

When managing depression in older patients, there are unique concerns that complicate both the diagnosis and the treatment of the disorder. Older patients frequently have comorbid medical conditions, are taking multiple medications, and have altered physiology that can impact the concentrations of antidepressant medications and heighten sensitivity to side effects. However, managing depression in older patients can be done effectively with the antidepressant therapies currently available. Older patients with depression should be treated to remission, just as their younger counterparts are. Residual symptoms of depression are associated with a lower quality of life.

Depression in older patients can have a significant impact on comorbid medical conditions, which are common among the elderly. It is likely that comorbid vascular disorders such as cardiovascular, cerebrovascular, and neurologic disorders play a role in the pathogenesis of depression in older patients. Rates of cardiovascular events and stroke are higher in patients with depression compared to those without. Antidepressant therapy with SSRIs has demonstrated efficacy and tolerability in patients at high risk for cardiovascular events and stroke. Early results suggest that treating depression with SSRIs can significantly reduce the risk of new cardiovascular events in patients with a history of cardiovascular disease, possibly due to their inhibitory effect on platelet aggregation.

MDD has been shown to approximately double the risk of stroke, and has been associated with increased mortality and poor long-term functional outcomes after stroke. SSRIs may be useful in the prevention and treatment of depression after stroke. In addition, the treatment of depression after stroke might significantly improve long-term survival.

Diabetes is also common among older patients, and increases the risk of cardiovascular and other events. Depression has been shown to increase the risk of developing diabetes and the rate of hyperglycemia. Although fluoxetine has more data supporting beneficial effects on glucose levels, other antidepressants may also be useful in patients with diabetes and depression.

Depression has been shown to at least double the risk of developing Alzheimer's disease and vascular dementia, and has a negative impact on the course and outcome of comorbid neurological disorders. Early results in patients with vascular dementia or Alzheimer's disease suggest SSRI therapy may have beneficial effects in the treatment of depression.

Clearly it is essential to identify and treat depression in older patients. Treating depression not only improves quality of life for older patients, but may also have a significant impact on long-term survival. Although early results suggest that SSRIs, venlafaxine, and mirtazapine are relatively safe and effective in older patients with MDD, more work is needed. Based on early results

suggesting improved long-term survival in patients with a history of cardiovascular or cerebrovascular events, priority should be given to studying the role of antidepressants in these patients to confirm the benefits, determine the mechanisms for improved survival, and identify which antidepressant classes or individual agents are beneficial.

# The Aging Human Lung: Age-Associated Changes in Structure and Function

Keith C. Meyer

*The human lung reaches the zenith of its functional capacity in the late second to the third decade of life, but age-associated changes in lung structure and function gradually ensue once this zenith has been reached. Although there is considerable interindividual variation, age-associated decline in lung function of healthy, nonsmoking individuals becomes apparent in the fifth to sixth decade of life when physiologic testing is performed. This decline in lung function coincides with morphologic changes that are associated with alterations in structural proteins that comprise lung matrix, and appears to be caused largely by decreased lung elastic recoil. Other age-related factors associated with declining lung function include diminished chest wall compliance, blunting of ventilatory responses, a decline in respiratory muscle strength, a decline in arterial oxygen tension, an increased prevalence of sleep-disordered breathing, and diminished exercise capacity. Despite these changes, nonsmoking, healthy elderly individuals do not tend to develop clinical symptoms as a consequence of declining lung function. However, certain lung disorders such as chronic obstructive pulmonary disease (COPD) and idiopathic pulmonary fibrosis (IPF) tend to make their appearance in elderly persons and cause significant respiratory system dysfunction, and the elderly display an increased susceptibility to respiratory infection. Animal models have provided some insights into age-associated decline in lung function in humans, but the precise causes of age-associated changes in lung function remain obscure.*

## Introduction

After approximately two decades of postnatal lung maturation, the aging human lung has been estimated to gradually lose up to 50% of its tissue mass over the remaining average lifespan of nonsmoking individuals who appear to be healthy and reside in developed countries. Although environmental factors may play a role in age-associated changes in the lung, loss of lung tissue and elastic recoil, which some have termed *senile emphysema*, appears to be a phenomenon that is linked to the normal aging process (Thurlbeck, 1991; Green and

Pinkerton, 2004). Despite these age-associated changes, there is considerable interindividual variation in the degree and tempo of lung function decline, and these changes are unlikely to reach the point of clinical respiratory dysfunction in healthy elderly persons. However, environmental and genetic factors likely play a significant role in the susceptibility of individuals and populations to age-associated lung function decline, and environmental factors may lead to clinical disease in susceptible individuals, even in nonsmokers. As the life span of humans gradually increases, it is conceivable that “normal” age-associated changes in lung structure and physiology may progress to the point that they cause symptoms associated with respiratory dysfunction and have an impact on quality of life.

One of the most important environmental factors associated with lung disease in the elderly is cigarette smoking. Nearly one in five smokers who have normal  $\alpha_1$ -antitrypsin levels will develop clinically significant chronic obstructive pulmonary disease (COPD) that generally makes its appearance in the sixth decade and beyond (Barnes, 2000). However, exposure to second-hand smoke (Masi *et al.*, 1988) or high levels of air pollution (Gauderman *et al.*, 2005) early in life may significantly affect lung development. Such early exposures may hold consequences for exposed individuals who reach an advanced age and promote an accelerated decline in lung function despite a lack of primary tobacco smoking. Additionally, adaptive responses such as anti-protease or antioxidant defenses may be an important determinant of susceptibility to various environmental factors both in age-associated changes in lung structure and function as well as in the development of clinical lung disease (Taggare *et al.*, 2005; Kelly *et al.*, 2003). Because factors that include even low birth weight can have significant consequences for postnatal lung development (Hoo *et al.*, 2004), environmental influences, respiratory infections, genetic factors, and the bias presented by examining survivors in aged populations (which may not accurately reflect the population as a whole) can blur the separation of the changes in lung structure and function that are due purely to advanced age from

changes that are caused by environmental exposures and genetic susceptibility.

## Age-associated Changes in Lung Structure and Function

### CHANGES ATTRIBUTED TO THE AGING PROCESS

Various aspects of lung function gradually decline with aging in clinically healthy individuals (Rossi *et al.*, 1996; Chan and Welsh, 1998), and these changes affect the lung as well as the respiratory pump (see Table 60.1). Notable changes include alterations in lung matrix that lead to remodeling, and physiologic changes in chest wall dynamics and respiratory muscle function. Elastin, which displays very little turnover in the adult lung (Shapiro *et al.*, 1991), has been reported to decrease gradually in alveolar walls (D'Errico *et al.*, 1989). Additionally, serum elastin peptide levels appear to decrease with advancing age (Frette *et al.*, 1997), suggesting altered mechanisms of lung homeostasis, remodeling, and repair. These changes in lung elastins combined with alterations in another key matrix component, collagen (changes in intermolecular cross-linking plus a shift to insoluble collagens), are a likely cause of progressive decline in lung elastic recoil.

TABLE 60.1  
Changes in structure and function of the aging human respiratory system

Structural changes in the lung	
Structural disruption and possible loss of elastin	
Altered cross-linking of elastin and collagen	
Loss of alveolar surface area	
Enlargement of terminal airspaces	
Decreased number of capillaries per alveolus	
Decreased diameter of small bronchioles	
Increased interalveolar pores (pores of Kohn)	
Other respiratory system changes	
Decreased chest wall compliance	
Decline in respiratory muscle function	
<i>Changes in measures of lung function</i>	
Diminished lung elastic recoil (increased lung compliance)	
Decreased vital capacity (FVC) and forced expiratory flows (FEV <sub>1</sub> , FEF <sub>25-75</sub> )	
Increased residual volume (RV) and functional residual capacity (FRC)	
Decreased inspiratory capacity (IC)	
Decreased diffusion capacity for carbon monoxide (DL <sub>CO</sub> )	
Decreased partial pressure of arterial oxygen (PaO <sub>2</sub> )	
Decreased maximal oxygen consumption during maximal exercise	

However, biochemical analysis of the lung suggests that the total content of elastin and collagen does not change significantly with aging (Lang *et al.*, 1994), and changes in the spatial arrangement or cross-linking of elastic fiber networks rather than measurable elastin loss may be the cause of the observed decline in elastic recoil (Crapo, 1993). The number of capillaries per alveolus also declines and is accompanied by loss of alveolar surface area as terminal airspaces (alveolar ducts and alveoli) increase in volume and the diameter and number of interalveolar pores increase (Thurlbeck, 1991). The causes of age-associated changes in lung matrix remain elusive. Although the loss of elastic recoil and distal airspace enlargement is somewhat similar to smoke-induced emphysema, the airspace enlargement is quite homogeneous, in contrast to the irregular distribution of airspace enlargement in emphysematous lungs that is accompanied by alveolar wall destruction.

Loss of elastic recoil and tethering of airways leads to small airway closure at identical lung volumes in older compared to younger subjects. This causes gradual reduction in forced expiratory flows (FEV<sub>1</sub>, FEF<sub>25-75</sub>), and early airway closure causes more gas to be trapped in the chest such that RV increases while FVC and IC decrease (Janssens *et al.*, 1999). These alterations in measurement of pulmonary function are attributed to diffuse emphysema-like changes in the lung (senile emphysema), which differs in appearance from emphysema induced by tobacco smoke or other environmental exposures (Thurlbeck, 1991; 1999). In addition to altered expiratory flow rates and lung volumes, the loss of alveolar surface area and alveolar capillaries with aging correlates with a gradual reduction of DL<sub>CO</sub>.

The ability of the lung to facilitate gas exchange also declines with advancing age. The PaO<sub>2</sub> begins to decline in the third decade of life, and the average PaO<sub>2</sub> may approach 70 mm Hg in the eighth decade but then tends to stabilize (Sorbini *et al.*, 1968; Cerveri *et al.*, 1995). The gradually widening alveolar to arterial oxygen gradient that is associated with advancing age is considered to be a consequence of ventilation-perfusion mismatching due to closure of small airways as lung matrix tissue is lost or disrupted and elastic recoil declines. The elderly tend to breathe with a greater frequency but with smaller tidal volume compared to young normal subjects while maintaining a similar minute ventilation (Krumpe *et al.*, 1985), but resting ventilatory responses to both hypoxia and hypercapnea become blunted (Peterson *et al.*, 1981). In contrast to the decline in arterial oxygen tension, PaCO<sub>2</sub> is maintained at approximately 40 mm Hg despite the blunted response to hypercapnea.

Other age-associated phenomena that affect respiratory function include changes in the chest wall, impaired respiratory muscle function, and altered breathing patterns during sleep. Chest wall compliance progressively decreases and is presumed to be due to diminished mobility of the costovertebral joints, calcification of intercostal

cartilage, narrowing of intervertebral disc spaces, and the appearance of varying degrees of kyphoscoliosis (Peterson and Fishman, 1982). Maximal inspiratory and expiratory pressures in the elderly appear to correlate quite well with peripheral muscle strength (Enright *et al.*, 1994). With advancing age the contribution of thoracic muscles (intercostals) to ventilation declines as the chest cage becomes less compliant (Mizuno, 1991). Diaphragmatic muscle mass tends to be preserved, but intercostal muscles display a decline in mean cross-sectional area after the fifth decade. Although diaphragmatic mass is preserved, respiratory muscle performance is reduced by the increase in RV and FRC, and the ability of the diaphragm to develop maximal force becomes impaired (Polkey *et al.*, 1997). Other factors such as poor nutritional status and low body mass index have a deleterious effect on respiratory muscle strength and can confound the age-associated changes in respiratory muscle function (Arora and Rochester, 1982). Respiratory muscle function is also linked to cardiac performance, as reflected by cardiac index or maximal oxygen consumption, and maximal inspiratory pressures can fall as a consequence of cardiac dysfunction (Nishimura *et al.*, 1994; Mancini *et al.*, 1992).

Changes in the control of breathing in both the awake and sleep state are associated with aging. Blunted ventilatory and cardiac responses to both hypoxia and hypercapnia have been observed in the wakeful state (Peterson *et al.*, 1981; Kronenberg and Drage, 1973), and attenuated responses to these stimuli when measured by mouth occlusion pressure (Peterson *et al.*, 1981) suggest that this decline in respiratory drive may be caused by diminished ability to process information from mechanoreceptors and chemoreceptors. Indeed, responses to resistive loads are also diminished in the elderly (Tack *et al.*, 1982). When compared to middle-aged individuals, ventilatory dysfunction during sleep is quite prevalent in the elderly. Significant upper airway obstruction during sleep affects up to 75% of elderly individuals, and the prevalence of sleep apnea has been reported to approach 50% (Ancoli-Israel and Coy, 1994). Additionally, ventilatory responses to upper airway occlusion is attenuated in elderly subjects compared to younger control subjects (Krieger *et al.*, 1997). Despite these changes in the control of breathing in the resting state, ventilatory responses to CO<sub>2</sub> are maintained or even increased in the elderly during exercise (Poulin *et al.*, 1994).

#### PULMONARY DISEASE STATES ASSOCIATED WITH ADVANCED AGE

Some disorders that involve remodeling of airways and distal lung parenchyma tend to appear with advanced age and become quite prevalent in elderly populations. These disorders include COPD and idiopathic pulmonary fibrosis (IPF). The prevalence of obstructive lung disease is increased in the elderly and may be greatly underestimated in certain elderly populations (Malik *et al.*, 2004; Lundback *et al.*, 2003). Both asthma and COPD

may be considerably underdiagnosed in the elderly (Lebowitz *et al.*, 1975; Janssens *et al.*, 2001), perhaps, in part, due to a decreased ability to perceive an added resistive load such as that caused by bronchoconstriction (Tack *et al.*, 1982).

Airflow obstruction is generally quite reversible in asthmatics with appropriate treatment, which stands in contrast to patients with COPD for whom obstruction is not generally reversible despite therapy. Asthma prevalence in elderly populations may range as high as 8% (Burrows *et al.*, 1991; Parameswaran *et al.*, 1998), and it can be difficult to differentiate from COPD. Older asthmatics with long-standing asthma may have considerable airway remodeling with a prominent component of irreversible airflow obstruction (Finucane *et al.*, 1985), and these individuals often have relatively severe and difficult-to-treat asthma. Some investigators view asthma and COPD as different expressions of one disease entity, a concept that has been named the *Dutch hypothesis*, because it was first proposed in Groningen in 1961 (Postma and Boezen, 2004). This hypothesis suggests that asthma, chronic bronchitis, and emphysema have various genetic (atopy and airway hyperresponsiveness) and endogenous factors (sex and age) that interact with various exogenous factors (allergens, smoking, pollutants, viral infections) to cause obstructive lung disease (Postma and Boezen, 2004; Bleecker, 2004). However, there are distinct clinical, physiologic, and pathologic characteristics that appear to differentiate asthma from COPD (Fabbri *et al.*, 2003), and patients with fixed airflow obstruction due to asthma tend to have a better response to therapy and better prognosis than patients with COPD (Burrows *et al.*, 1987; Kerstjens *et al.*, 1992).

Chronic obstructive pulmonary disease is the fourth leading cause of death in the United States, and poses a huge economic burden for society (Michaud *et al.*, 2001). Tobacco smoking is the cause of at least 90% of all COPD cases, but other exposures have also been associated with COPD (Barnes, 2000; Fishman, 2005).  $\alpha_1$ -Antitrypsin deficiency accounts for a about 2% of cases of emphysema (nearly all patients are smokers), and emphysema associated with  $\alpha_1$ -antitrypsin deficiency is usually diagnosed in the fourth to fifth decade of life (Needham and Stockley, 2004). In contrast, patients with normal  $\alpha_1$ -antitrypsin levels usually do not develop clinically significant emphysema until they have reached their sixth decade of life. The prevalence of COPD in adults recently was found to be 8.6% in a large survey, and the prevalence in disadvantaged elderly (Malik *et al.*, 2004) or elderly smokers (Lundback *et al.*, 2003) may be considerably higher. A recently published case-control autopsy study showed a prevalence of emphysema or chronic bronchitis of 26.6% for 3,685 patients age 65 or older that were autopsied between 1972 and 1996 (Janssens *et al.*, 2001).

One additional disorder that tends to make its appearance in the elderly is idiopathic pulmonary fibrosis (IPF)

(Coultas *et al.*, 1994). Idiopathic pulmonary fibrosis is characterized by progressive lung remodeling with excess matrix deposition and distortion of lung architecture, which causes a restrictive physiology and impaired gas exchange (Noble and Homer, 2004; Selman and Pardo, 2003). Fortunately, the incidence and prevalence of this progressive disorder, which has a median survival of approximately three years, is much lower than that for asthma and COPD (Coultas *et al.*, 1994; Demedts *et al.*, 2001). Nonetheless, it is estimated that at least 50,000 patients in the United States have this disease, and there are currently no effective therapies that prevent progression to respiratory failure and death (Meyer, 2003).

#### IMMUNE SURVEILLANCE AND SUSCEPTIBILITY TO INFECTION

Respiratory infections are recognized as the fifth leading cause of death for individuals over age 65 (National Vital Statistics, 2001). There are many factors that make the elderly more susceptible to lung infections. These include declining immune function, impaired oral and mucociliary clearance, neurologic disorders, malnutrition, chronic organ dysfunction syndromes, and the presence of parenchymal lung disease (Meyer, 2004). Although various aspects of systemic immunity decline with advancing age, there is considerable variation among individuals. Fairly robust immune responses can be identified in centenarians (Franceschi *et al.*, 1995), and many other factors such as the presence of a swallowing disorder and aspiration can cause pneumonia in the elderly despite intact immune responses.

Both T and B lymphocyte responses tend to gradually wane with advancing age, and antibody responses to vaccines are less robust in the elderly than in younger individuals (Meyer, 2001). Although the effect of advancing age on acquired immune responses has been studied fairly extensively, relatively little is known about the effect of age on compartmentalized innate immune responses in the lung. Important components of innate immunity that may play a critical role in defense against infection include the ability of epithelia or other resident lung cell populations to produce antibacterial peptides such as the defensins (Huttner and Bevins, 1999) or collectins (Sano and Kuroki, 2005). Because the innate immune system is a key component of respiratory host defense that provides constant surveillance and immediate protection against invading pathogens (Meyer, 2001), age-associated decline in various components of innate immunity may play a key role in susceptibility to pulmonary infections.

One host defense mechanism that has been shown to decline gradually with advancing age in both animal models and human subjects is mucociliary clearance. Tracheal mucus velocity gradually declines in beagle dogs beginning at approximately age four (Mauderly and Hahn, 1982), and aged rats have diminished clearance of bacteria compared to young animals (Antonini *et al.*, 2001). Mucociliary clearance has been shown to decline

in humans with advancing age (Puchelle *et al.*, 1979), and microtubular abnormalities in cilia have been associated with depressed nasociliary clearance time and lower ciliary beat frequency (Ho *et al.*, 2001). Although not proven, age-associated ciliary dysfunction may significantly increase susceptibility to respiratory infection for elderly individuals and may also increase susceptibility to irritation and damage to airway mucosae by inhaled particulates that are deposited on airspace surfaces and not rapidly cleared.

#### Animal Models and Insights into Mechanisms of Lung Senescence

Changes that are similar to those in the aging human lung have been observed in both rodents and dogs (Pinkerton *et al.*, 2004). The mouse makes an attractive model for mechanisms of lung senescence because of its relatively short lifespan, which is approximately 30 months for the strains used most commonly for research. A special strain, the senescence-accelerated mouse (SAM), has been established and has a median lifespan as low as 12 months (Takeda *et al.*, 1981). An increase in total alveolar surface area combined with an increase in interalveolar pore size and number and in volumes of airspaces distal to the respiratory bronchioles suggest that lung hyperinflation occurs in aged mice, and decreased elastic recoil has been associated with an age-associated decline in elastic fibers in BALB/c mice (Kawakami *et al.*, 1984). Lung hyperinflation appears to be accelerated in SAM mice and mimics changes in older mice from other strains (Kurozumi *et al.*, 1994), making the SAM mouse an attractive model for examining altered matrix and cell populations associated with advancing age. In contrast to the mouse, the aging rat lung does not seem to show altered lung compliance or a decline in alveolar surface area (Pinkerton and Green, 2004), and Lewis and Fischer 344 rats show an increase in cross-linked collagen in the lung parenchyma (Mays *et al.*, 1988; Sahebajami, 1991). However, this increase of interstitial collagen in rats does not seem to alter lung compliance (Pinkerton *et al.*, 1982).

Age-associated changes in the dog lung, which has greater morphological similarity to the human lung than rodent lungs, have been studied fairly extensively. Changes in airways and in distal parenchyma show considerable similarity to changes observed for the human lung and include enlargement of submucosal glands (Robinson and Gillespie, 1973), progressive calcification of bronchial cartilage (Robinson and Gillespie, 1973), a decline in mucus velocity (Mauderly and Hahn, 1982), and a decrease in alveolar tissue density with altered alveolar size and enlargement of respiratory bronchioles and alveolar ducts (Robinson and Gillespie, 1973). Focal accumulations of macrophages have also been observed in respiratory bronchioles and the junction

of alveolar ducts and alveoli (Robinson and Gillespie, 1973).

When observations that are currently available from animal models of lung aging are merged with observations of altered structure and physiology of the aging human lung, it becomes clear that the most prominent feature of lung aging is loss or altered composition of matrix tissue accompanied by rearrangement of distal airspace structure such that elastic recoil declines and ventilation to perfusion relationships are altered. These changes show many similarities to emphysema, although important differences separate the emphysematous lung from an aged lung. Emphysema is characterized by airway inflammation and expanded populations of inflammatory cells (macrophages, neutrophils, and lymphocytes) in distal airspaces or airway walls (Barnes, 2000; Sassetta *et al.*, 2001), and proteolytic and oxidative stress associated with the influx of inflammatory cells is thought to play a key role in the pathogenesis of emphysema. It is interesting that bronchoalveolar lavage (BAL) in aged C57BL/6 mice (Higashimoto *et al.*, 1991) show a modestly increased number of lymphocytes and neutrophils on differential cell counts. Studies in normal human volunteers have also shown an increase in BAL neutrophil and lymphocyte populations for elderly subjects compared to younger individuals (Meyer *et al.*, 1996; Meyer *et al.*, 1998; Meyer and Soergel, 1999), and it is tempting to speculate that a mild increase in inflammatory cell traffic and/or activation states in the aging human lung may gradually damage and alter elastin, collagen, and other matrix proteins over long periods of time. The causes of altered BAL cell and proinflammatory mediator patterns in apparently healthy, elderly subjects are not clear, but may represent a failure to regulate inflammatory responses, a response to subclinical aspiration, or heightened responses to inhaled agents such as fine particulates in ambient air.

Another important factor important in lung aging may be the ability of homeostatic mechanisms to maintain the integrity of the lung microvasculature and alveolar wall capillary bed. Vascular endothelial cell growth factor (VEGF) appears to be an extremely important gene product for the development and maintenance of the lung vasculature (Berse *et al.*, 1992; Monacci *et al.*, 1993; Zeng *et al.*, 1998), and recent studies have shown that emphysema in smokers is associated with a reduction in VEGF expression (Kasahara *et al.*, 2001; Koyama *et al.*, 2002; Kanazawa *et al.*, 2003a; Kanazawa *et al.*, 2003b). Blockade of VEGF receptors in a rat model has been shown to correlate with induction of epithelial cell apoptosis and cause distal airspace enlargement (Kasahara *et al.*, 2000). However, this change was prevented by the administration of a caspase inhibitor, which suggests that if VEGF production by epithelial cells and VEGF signaling is not disrupted, emphysematous changes do not occur. These investigators have also shown a link between oxidative stress and alveolar septal cell apoptosis induced by VEGF receptor blockade

(Tuder *et al.*, 2003), and targeted VEGF inhibition in mice via intratracheal instillation of a viral vector that ablated the VEGF gene, causing alveolar septal wall damage and a reduction in lung elastic recoil (Tang *et al.*, 2004). Although VEGF gene expression in the lung has not been studied in animal models of lung senescence, VEGF levels gradually decline in BAL fluid with advancing age in normal volunteer subjects (Meyer *et al.*, 2000). Indeed, a diffuse, age-associated decline in VEGF expression or VEGF receptor function in the aging lung may explain many of the structural changes that affect the distal airspaces of the aged human lung. Alterations in VEGF homeostasis may be induced or accentuated by increased numbers of inflammatory cells coupled with altered antioxidant defenses that have been described for aged lungs in both mice and humans (Chen *et al.*, 1990; Teramoto *et al.*, 1995; Bottje *et al.*, 1998; Higashimoto *et al.*, 1991; Meyer *et al.*, 1996; Meyer *et al.*, 1998).

## Conclusion

Although it is somewhat difficult to differentiate age-associated changes in the structure and function of the aging human lung from environmentally induced lung disorders and genetic susceptibility to lung disease, changes in the lung matrix that alter airway and parenchymal structure, which some investigators have termed “senile emphysema” or ductasia, appear to be a generalized phenomenon that occurs in the absence of environmental risk factors. These changes lead to a decline in elastic recoil and altered ventilation to perfusion relationships that affect pulmonary function testing values and gas exchange. The precise cause of these changes is not clear, but similar changes have been shown in the lungs of aged mice or dogs. The investigation of cellular compartment turnover, matrix alterations, and the role of cytokines such as VEGF, which can have a profound effect on the microvasculature, in these animal models may provide additional insights into the age-associated processes that alter the structure and function of the aging human lung. Models that seem particularly attractive for such investigations are aged C57/Bl mice, the SAM mouse, and Beagle dogs. Animal models may also help to identify age-associated factors that put the elderly at an increased risk for acute events such as pneumonia. Relatively little is known about innate immune mechanisms in the aged human lung, for one, and such models could facilitate the study of age-associated changes in innate immunity that may increase the risk of lower respiratory tract infection in the elderly and provide strategies to prevent pneumonia.

# Iceland as a Model for Human Aging

Adalsteinn Gudmundsson and Pálmi V. Jónsson

*Iceland may be viewed as a small but prototypic Western society, strategically located between mainland Europe and North America. Its ethnically and socioeconomically homogeneous population is served by an advanced healthcare system through a national health and social insurance. Interdisciplinary geriatric care is well established, and Iceland was one of the first countries to adapt, from the United States, the resident assessment instrument (RAI), which makes a cross-country comparison of long-term care feasible. Among a number of biotech companies recently established in Iceland are leading companies in the field of linking genetic variation to diseases. Historically, the population of Iceland has been exceptionally supportive and willing to participate in both transectional and cohort studies. The Icelandic Heart Association launched a major population study on interactions between age, genes, and environment (AGES) in 2002 in collaboration with the U.S. National Institute of Aging (NIA). Ultimately, we may expect that a cutting edge aging research in Iceland will contribute to our understanding of how to maintain better health, independence, and active participation in later life, and how to best care for those who become frail and in need of formal care.*

## Introduction

Facing the global phenomenon of population aging, many countries are sharing their interest in collaborative research projects relating to aging. Although most countries are seeing declines in mortality rates, Western societies, in addition, have experienced secular declines in fertility rates, which continues to sustain a steady increase in the ratio of older to younger generation (Kinsella, 2005).

New approaches and frameworks of longitudinal databases are needed, which take into account both differences and similarities in aging-related processes across ethnic and national boundaries (the National Academy of Sciences, 2001). Fortunately, this occurs at a time when travel and use of long-distance communication through the Internet make long-distance collaboration and cross-national research easier and more sophisticated than ever before.

In the context of cross-national research, Iceland has unique potential for contribution. The purpose of this chapter is to give the reader some background information on the aging population in Iceland. How and why the rugged terrain of this island of 103,000 km<sup>2</sup> (43 thousand square miles) surfacing the North Atlantic in a strategic location between North America and mainland Europe has become a fertile ground for both current and future research on aging will be described.

## History

Iceland was first settled between 870 and 930 A.D. by Norwegian Vikings. Recent research has shown that 20 to 25% of the founding males had Gaelic ancestry. The majority of the females are thought to have come from the British Isles during the time of settlement. At the end of the initial settlement period, the population is estimated to have numbered approximately 30,000 (Halldorsson, 2003). A period of favorable climate conditions sustained a local population growth through the twelfth century, when the estimated population may have plateaued at 80,000. This era was followed by centuries of colder climate, and several periods of substantial population reduction occurred. Two epidemics, of plague in the fifteenth century and several smallpox epidemics in the sixteenth to early eighteenth century, reduced the population of the entire island to as low as 30,000 on more than one occasion. The fallout from a volcanic eruption in 1875 devastated the Icelandic economy and caused widespread famine. During the last quarter of the nineteenth century, approximately 20% of Iceland's population emigrated, mostly to Canada and the United States (Jonsson, 1998). This explains why the population of Iceland, which has remained in relative genetic isolation through 1100 years, is quite homogeneous, with many residents sharing common ancestors. Screening for individual mutations in the population is facilitated by the Icelanders' fascination with genealogy. Details of births, marriages, and deaths have been kept in church records for more than three centuries. Extensive computerized genealogy databases have been created, which allow the pedigree of most Icelanders to be traced back to the seventeenth century, and for many further back to the settlement of the island. Islingabok is the only

genealogy database in the world, which covers a whole nation. It includes information on more than 95% of all Icelanders from 1703 onward. It includes information on about 700,000 Icelanders, which is about half of all Icelanders who have lived on the island since its settlement (Islendingabok, 2003). These facts of history lead to a strong founder effect and the genealogy database greatly facilitates genetic research.

Iceland's founder population provides advantages for researchers studying complex disorders such as many of the age-associated diseases. This has been repeatedly demonstrated in recent years with the discovery of genes and biomarkers associated with cardiovascular disease, central nervous system diseases, osteoporosis, obesity, and cancer (Jonsson *et al.*, 2004).

Although Iceland only recently (1944) has become a sovereign state after many centuries of colonialism, it has since World War II transformed from being one of Europe's poorest into being among the richest countries in the world by per capita measures. Its culture and social structure resembles other Scandinavian countries and strong market ties remain to the European market without being a member of the European Union.

Still, in more than just geographic sense, Iceland is closer to North America than most of Europe. It has grown into and benefited from being an "in between" country with cultural and strong economic and trading ties to the United States over the last 50 years. Cooperation in health sciences has been steadily growing between Iceland and the United States. A first milestone in this regard was the establishment of the laboratory at Keldur lead by Dr. Bjorn Sigurdsson in 1946 through the Rockefeller Foundation. Dr. Sigurdsson's work resulted in the original concept of slow viral infections (Palsson, 1994).

## Figures and Facts

Iceland is one of the least densely populated countries in the world, with a total population of 290,500 people in 2003, averaging 2.9 inhabitants per square kilometer (Statistical Yearbook of Iceland, 2004). About two-thirds of the population live in and around the capital of Reykjavik, which is located on the southwest corner of the island. Mainly due to effects of the Gulf Stream, Icelanders enjoy a warmer climate than its subarctic location would indicate. The average July temperatures have passed 12° C in recent years from being 10.5° C in previous decades (Statistical Yearbook of Iceland, 2004). Unconfirmed, this has been viewed by many as one of the strongest indicators of global warming. The average temperature in January remains around the freezing point.

Both by ethnic and socioeconomic measures, the population is homogeneous. Still, its society and people offer a prototype of a western society with an advanced but small infrastructure. The past decade with rapid

economic growth and low unemployment figures has stimulated immigration of workers from a variety of countries. During 2000 to 2004, the Icelandic Directorate of immigration has issued 5000 to 6500 residence permits of all categories annually (The Icelandic Directorate of Immigration, 2005). Hence, the historic advantage of a homogeneous population is about to disappear due to globalization. Instead, we will gain valuable prospective information on how a western society adapts to an influx of immigrants of all ages, and its effect on care and caregiving for the elderly.

In the year 2000, the costs of healthcare, including long-term care, were 7.7% of the gross domestic product. The healthcare system is nationalized, with 85% of total cost paid for through taxes (Highlights on health in Iceland. WHO Regional Office for Europe, 2000). By conventional measures and indicators through health statistics, Icelanders enjoy good health status. Strong economy, favorable social situations, and good access to healthcare have brought Iceland into a leading position as having one of the world's highest life expectancies at birth. Life expectancy at birth has increased from 61.0 years for women in 1921 to 1930, to 82.5 years in 2001 to 2003. During the same period, the life expectancy for men has increased from 56.2 to 78.7 years, the highest in the world (Statistical Yearbook of Iceland, 2004). This gender difference in life expectancy of less than four years in Iceland is smaller than in most industrialized countries, where it is usually five to seven years. Although the group of older citizens in Iceland has increased remarkably by absolute numbers in recent years, the proportion of older than 65 years remains less than 12% mostly due to relatively high fertility rate with 1.98 births/woman (Statistical Yearbook of Iceland, 2004).

Eighty-seven percent of Icelanders over the age of 65 live independently in the community. The remainder live in facilities for assisted living or nursing homes. A major disadvantage of the health care system in Iceland is its waiting lists. This is particularly true in Reykjavik, where long lists remain for both assisted living and nursing homes and where there is congestion of elderly awaiting discharges from acute hospitals (Ingimarsson *et al.*, 2004).

## Lifestyle

The nutritional value of diet in Iceland improved significantly during the last century, and it now comes closer in most respects to the targets set by the Icelandic Nutrition Council. Surveys in 1990 and 2002 show a decrease in the daily intake of fat, mainly due to less consumption of margarine and nonskimmed milk, and an increase in consumption of fruits (39%) and vegetables (15%). There is a clear social gradient, with those who have better education or higher incomes eating more vegetables. On the negative side, the country's consumption of fish per capita has diminished by 43% during this

period and is now only slightly above many other European countries (Halldorsson, 2003).

Obesity is an increasing problem in Iceland, especially among children. In a recent study, body mass index was found to have increased considerably between 1938 and 1998 among nine-year-olds. The proportion of overweight children has increased from a few percent in 1938 to around 20% in 1998, and the proportion of obese children has increased from less than 1% to approximately 6% (Briem, 1999).

There has been a similar development among adults. In 1994, approximately 60% of women and 70% of men aged 45 to 64 years were either overweight or obese, which is comparable to that observed in many Western countries (Thorgeirsdottir, 2001).

One recent study of adult Icelanders concluded that one of four Icelandic men and one of five women do not participate in regular physical activity. More than half of adult Icelanders are overweight or obese, but the risk is halved among those who exercise at least five days per week, compared to those who exercise less frequently. Sedentary lifestyle has become even more common among Icelanders than in the neighboring countries (Gudmundsdottir, 2004).

Follow-up surveys on the number of daily smokers in Iceland have shown favorable results in recent decades. In 1985, approximately 43% of men and 37% of women smoked on a daily basis, but in 2001 the figures were 26.5% and 24.6%, respectively. Daily smoking among tenth-graders has declined steadily according to surveys, from 23% in 1998 to 14% in 2002. Although consumption of alcohol in liters per capita is lower than in most of Europe, the consumption has been increasing steadily and had reached 6.3 liters per person 15 years and older in 2002 (Halldorsson, 2003).

## Geriatric Care

The importance of geriatric care has been recognized, and geriatric evaluation and management units and interdisciplinary teamwork are well established in Iceland (Jonsson, 1998). Interest among physicians in formal geriatric training has increased rapidly during the past 10 years, and in 2002, 15 fellowship-trained geriatricians had appointments at academic hospitals. Iceland was one of the first countries to adopt the comprehensive Resident Assessment Instrument (RAI) in nursing homes from the United States by a mandate in 1996. A crucial consequence of the international adoption of the RAI is that comparison of long-term care between countries has become feasible (Jonsson and Palsson, 2003). More interRAI assessment tools currently are being adopted in Iceland such as home care, post-acute care, and mental health, all paving the way toward a seamless information system in elderly care and formation of a longitudinal database.

Icelandic law mandates use of the Nursing Home Preadmission Assessment (NHPA); no one can enter a nursing home without undergoing this certified need assessment. A multidisciplinary team performs the NHPA; the team consists of a physician, nurse, and social worker. The assessment is in standard form and content. It remains valid for up to 18 months and is expected to be revised if the applicant's condition or situation changes during this time (Johannesdóttir and Jonsson, 1994).

The NHPA system generates national and regional waiting lists for the currently 3,700 nursing home beds available. Based on analysis of the NHPA database for the period 1992 to 2001 in the Reykjavík metropolitan area, the average enrollment age of men in nursing homes in Reykjavík was 82.7 years, and for women, 84.4 years. Men were about one-third of residents in nursing homes. The mean survival in nursing homes in Reykjavík was 2.5 years for men and 3.1 years for women (Ingimarsson, 2004).

The structure of care for the elderly is similar in the five Nordic countries (Sweden, Finland, Denmark, Norway, and Iceland). A close collaboration exists between the Nordic professors in geriatric medicine. This collaboration has already produced strategic documents relating to geriatric assessment and geriatric rehabilitation (Jonsson *et al.*, 2002; Sletvold *et al.*, 1996).

In 1999, an Institute on Gerontological Research (IGR) was established by the University of Iceland and Landspítali University Hospital. As an umbrella-like organization its main goals are to coordinate and facilitate broad research and collaboration in gerontology at the University of Iceland and the University Hospital. Researchers from the IGR are involved with, to mention but few, research at DeCODE company (Alzheimer's and longevity studies), the AGES study, and European and Nordic collaboration (Jonsson *et al.*, 2003; Fialova *et al.*, 2005).

## Research Environment

During the past decade, there has been a remarkable increase in expenditure on research and development work. Icelanders spent 3% of their gross domestic product on research and development undertakings in 2001, compared to 1.1% in 1990, thereby reaching the goal that the European Union has set for itself to achieve by 2010. The benefits of this investment may be measured, for instance, by the favorable outcome of Icelandic scientists in international cooperation and through added innovation, which has led to growth in employment and in the export of goods and services based mainly on knowledge (the Icelandic Centre for Research, 2005). In 2005, Iceland ranked second in the world by measuring the degree of preparation of a nation or community to participate in and benefit from information and communication technologies (the Global Information Technology Report, 2004–2005).

Because of Iceland's small size and scale of resources, the majority of Icelandic physicians and many other disciplines seek their postgraduate training abroad, either in Europe or North America. This has benefited healthcare and research in Iceland as the majority repatriates, bringing back the connections, ambitions, and initiative, that allow them to achieve success on an international scale. Although the smallness of the country limits resources, it is balanced by advantages of short routes of communication among individuals, institutions, and businesses.

Through health registries, which may date back a century or more, Iceland offers rich resources for health-related research, which cover the entire population, including cancer prevalence, cardiovascular health, and mortality. Linking the Icelandic health registries to the extensive genealogy database is beginning to underscore the importance of genetic predisposition for an entire population (Jonsson *et al.*, 2004).

A national cancer registry was started in 1954. It contains information on around 30,000 individual cases of cancer diagnosed since then. It is one of few such registries in the world containing information on an entire nation. Currently, about 1000 cases of cancer are diagnosed annually in Iceland. The most commonly affected organs are the prostate for men and the breast for women, closely followed by the lung for both sexes. Research in cancer epidemiology has been one of the main functions of the Icelandic Cancer Society since the cancer registry was started (the Icelandic Cancer Society). Data from the Icelandic population was also important in identifying both the BRCA1 and BRCA2 genes for breast cancer, but a founder mutation in each gene is present in the Icelandic population (Bergthorsson *et al.*, 1998; Thorlacius *et al.*, 1998).

The public is generally supportive of medical research, and the high public participation rate is a distinctive advantage of locating such research in Iceland (see Table 61.1). Furthermore, the population has lived through and been exposed to relatively similar

environmental conditions (climate, altitude, diet, pollutants, infectious agents) in comparison to larger nations. It is interesting to note that the total population of individuals older than 65 is only 33,500 (15,000 men and 18,500 women). This is a manageable size on its own, and harbors unique opportunities for research on health and disease pertinent in an entire population (Gudmundsson, 2004).

Research into the social aspects of aging has been limited until now, but with an established teaching and research position in social gerontology at the University of Iceland, that is about to change.

### Biomedical Research in Iceland

Favorable situations have paved the way for the local establishment of a number of biotech companies in recent years. One of them is Decode Genetics, a recognized world leader in its field (Breithaupt, 2002). Among its goals is to link genetic variation to longevity and to many age-associated diseases, including dementia, osteoporosis, stroke, Parkinson disease, and osteoarthritis. By using a computerized genealogy database, the genetic component of longevity has been demonstrated, as well as lower age-specific death rates in offspring of long-lived parents (Gudmundsson *et al.*, 2000).

Several other genomic-based biotechnology companies are operating in Iceland. One of them, the Iceland Genomics Corporation (IGS), focuses on cancer biology through agreements with clinicians, the main national hospitals, and the National Cancer Registry. The project aims to increase the value of the data obtained from the IGS collection of biological samples, including patient DNA and tumor biopsies, by using family information supplied by the Genealogical Committee of the University of Iceland and clinical information supplied by the National Cancer Registry and collaborating clinicians, in order to obtain the world's first comprehensive survey of cancer across an entire nation. This will allow an unprecedented depth of analysis, where the relationship between genotype, disease, and clinical outcome can be probed. The company currently is taking advantage of this unique resource by searching for novel cancer genes using both association studies and linkage analysis (the Iceland Genomics Corporation, 2005).

One of the largest and longest lasting epidemiological studies available involving a representative unselected population is the Reykjavik study, which the Icelandic Heart Association (IHA) launched in 1967 around an initiative to battle against increases in cardiovascular diseases in Iceland. The study invited 25,000 men and women born between 1907 and 1934. The response rate was high (76%) for clinic visits, and participants were followed from one to six times for up to 30 years by thorough questionnaires, medical examinations, and biochemical measurements that accumulated vast resources of information (Hardarsson *et al.*, 2000).

TABLE 61.1  
Iceland: Advantages for health-related research in the twenty-first century

- 
- A small prototypic Western society with advanced infrastructure
  - Official health registries
  - Universal access to healthcare
  - Advanced training abroad common
  - Founder population and extensive genealogy databases
  - Environmental similarity
  - The general public supports and participates in research
  - High-tech biomedical research companies
  - The Reykjavik-AGES study
-

The quality and depth of the data collected in the Reykjavík study has been widely recognized and has led to over 300 publications. The IHA has participated in the international WHO coordinated project on heart disease (MONICA) and maintains a detailed record of heart attacks and coronary artery interventions for the entire Icelandic population. In 2001, the National Institute on Aging (USA) and the Icelandic Heart Association announced their collaboration on a new study of the original cohort from the Reykjavík Study. In this new study on the interactions of age, genes, and environment (AGES), which started in 2002, the prior participants in the Reykjavík study are offered the opportunity to participate again. This well-established cohort and the current AGES will focus on establishing phenotypes and definitions of quantitative traits related to diseases and conditions of old age, and will collect genetic and other biologic specimens. The 7,000 to 8,000 remaining participants will contribute to the project through questionnaires, physical examinations, and state of the art measurements of the health of their bones, muscles, and metabolic and nervous systems (NIH News Release, April 23, 2001).

Important steps in improving the current concept of genetic association studies will include better measures of quantitative traits as phenotypes. The mid-life data available from the participants in the Reykjavík study such as cardiovascular measures (blood pressure, ECG, and cholesterol) is an important contribution. More importantly, now decades later, are state of the art imaging techniques and molecular markers, which better define the present phenotypes. The Reykjavík-AGES study uses new technology for the measurement of quantitative traits, for instance, calcium scoring of the coronary arteries by computerized tomography (CT) and post-processing of magnetic resonance imaging (MRI) of the brain; in addition to standard phenotypic measurements. Furthermore, this enhanced understanding of genetic and environmental contributions could create novel opportunities to prevent disease and limit disability associated with aging (Gudnason *et al.*, 2005).

## Conclusion

Through private and public funding, Iceland is being established as a model for opportunities in research on aging. Iceland entered the twentieth century as an isolated founder population of poor sheep farmers and small-scale fishermen, but at the turn of the twenty-first century Iceland has been transformed into a knowledge-based high-tech society whose still interrelated and aging population will deliver important lessons on the interactions between age-associated diseases, the environment, and genetic components. Ultimately, cutting-edge aging research in Iceland can contribute to our understanding of how to maintain better health, independence, and active participation in later life.

# Behavior and Personality in the Study of Successful Aging

Judith Corr and Loraine Tarou

*Although science has greatly extended human longevity, efforts to improve the quality of life experience for older people must be increased if we are to avoid creating a generation of long-lived, but isolated, lonely, and inactive elders. Ultimately, the goal in any investigation of human aging should be to both extend and improve the quality of life for increasing numbers of elderly. It is argued here that it is essential to expand aging research designs to include both biological and behavioral variables whenever possible, so that a more complete understanding of growing older as the culmination of multiple processes can be achieved. The search for a general, theoretical framework of human aging has been largely unsuccessful, perhaps because all primates, human and nonhuman, become aged within a complex network of varying environments and social structures. Also, individuals react differently to the same conditions, making differences among members of the same species critical in the understanding of the individual aging experience. Along with predictable biomarkers of aging, there may be a set of identifiable behavioral traits that cross-culturally influence successful human aging. Behavioral traits that are consistent over time are termed personality. Use of personality testing in humans and nonhuman primates, using the Big Five, is reviewed, and new directions for aging investigations are suggested.*

## The Importance of Behavior

Most of us want to become old, but we worry about being old.

Baltes and Baltes (1998)

The ultimate goal in the investigation of human aging is to extend and improve the quality of life for increasing numbers of elderly. Worldwide fertility rates have declined, coincident with increases in life expectancy, creating a large and expanding bulge at the top of the global population pyramid. In the United States, for instance, more than one in five Americans will be

65 years or older by 2030 (U.S. Census Bureau, 2004), a trend that is fast becoming global and carries immense implications for all world cultures and economies. Moreover, in addition to aging of the general population, demographics within the aged group itself are also shifting as the category of *oldest old* (80+ years) is growing faster than any other segment of elderly. Now, along with increased longevity provided by scientific achievements, science should also work to increase life satisfaction and happiness for growing numbers of aged. Extended years should be years lived well, if possible. It is our view that aging research should be collaborative across disciplines; as an understanding of the biological bases of aging without consideration of behavior or individual differences, or vice versa, is an incomplete understanding.

Although science has greatly extended human longevity, efforts to improve the quality of life experience for older people must increase if we are to avoid creating a generation of isolated, lonely, and inactive elders, a trend that is already a sad reality in industrialized Japan, where birthrates have fallen to 1.29 children per female and numbers of elderly are growing rapidly. This means that, within the next few years, Japan will have more elderly people than they have children (U.S. Census Bureau, 2004). Traditionally, Japanese culture places adult children in extended natal homes that provide for the inclusion of elders. However, current demographic pressures and economic realities are removing that option while elder care facilities are either inadequate or completely lacking in many parts of Japan. Therefore, an increasing number of Japanese elders are living solitary lives. In an attempt to compensate for increasing elder isolation and loneliness, healing partner dolls are currently being marketed to Japanese families of the isolated aged. These interactive dolls are personalized, capable of using up to 1200 different spoken phrases, and can be programmed in accordance with the owners' sleep-wake schedule (Suzuki, 2005). Demand for these companion dolls is high in Japan, and many elders who have them report not feeling alone any more and say they are raising the dolls "as they did their own children."

## An Evolutionary Framework of Aging

The search for a general, theoretical framework of aging has long been of interest to both geriatrics and gerontology. Before 1900, Weismann proposed the first evolutionary theory of aging and argued that biological aging and death are adaptations that ensure species renewal and are programmed within the organism itself (1889). Mutation Accumulation Theory later explained aging as a process that, due to lessening effects of natural selection on post-reproductive individuals, mutations continue to accumulate over time, increasing mortality in later life (Medawar, 1946). Finally, Antagonistic Pleiotropy describes natural selection as having a bias toward youth that selects against longevity when genes that have pleiotropic effects are advantageous in the young but disadvantageous in the aged organism (Williams, 1957). For an expanded review of these and other proposed evolutionary theories of aging, see Gavrilov and Gavrilova (2002) or Crews (2003).

Why organisms have a short or a long life and why they grow old and die remain questions that are best addressed within an evolutionary framework (Gavrilov and Gavrilova, 2002). While the search for an evolutionary, universal theory of biological aging continues, current directions focusing on physiological aging, in addition to asking why organisms age and die, are also continuing to identify factors that act to further extend life (i.e., via caloric restriction, maintenance of cortical function, and tissue rejuvenation, etc.). Additionally, however, some contemporary investigators are adjusting the focus of their aging investigations to describe biological senescence as part of a general, life history model of inquiry. Although in our view, this methodological approach to aging investigation is a step in the right direction, it can also be limiting unless it addresses individual, behavioral variation (personality) and its effect on successful aging.

All biological organisms develop, mature, and age over the life span. Although the processes of human development, maturation, and reproduction have been broadly researched, aging studies have, for the most part, limited their focus to longevity and biological senescence (i.e., on geriatrics). Aging, however, is a complex interaction of factors that go beyond clinical aging and biological senescence, and should be investigated from a broader, multidimensional perspective if we hope to enhance our expanded longevity. In contrast to geriatrics, gerontology is interested in understanding the processes of normal, undiseased aging, and draws on collaborations from diverse disciplines, both biological and behavioral (Crews, 2003). It is argued here that it is essential to expand aging research designs to include both biology and behavior whenever possible, so that a better understanding of growing older as the culmination of multiple processes can be achieved.

## Successful Aging

The concept of successful aging has no consistent definition. Some use it to describe simple survival, whereas others define its parameters through self-perceived quality of life measures: that is, an individual's report of their physical health, psychosocial health, vigor, contentment, and so on (Baltes and Baltes, 1990). Over the past decade, the results of several longitudinal human aging studies have been widely reported, all of which suggest that the role of individual differences in life experience and basic personality are key to understanding how one experiences being elderly (Corr, 2004).

Valliant (2002), in reporting on the Harvard Study of Adult Development, concluded that successful aging in the individual requires resilience and the selection of positive individual lifestyle choices. The MacArthur Foundation Study of Successful Aging (Rowe and Kahn, 1998) reported similar observations and added that individual lifestyle and attitude may even contribute more to successful aging than genes in many cases. Finally, Snowdon (2001), in the well-known Nun's Study, showed that positive behavior and personality in the individual can even overrule the often devastating biology of aging, including the pathology of Alzheimer's. These intriguing reports require further investigation of aged human behavioral variation, both within and between populations. Along with predictable biomarkers of aging (presmyopia, arthritis, increased susceptibility to disease, etc.), there may be a set of identifiable behavioral traits that cross-culturally influence successful human aging.

In a 1945 compendium, the American anthropologist George Murdock (1945) outlined 67 characteristics, or cultural *universals*, found across all human societies: family, religion, rites of passage, marriage, and so on. Since then, behavioral and psychological universals also have been explored and debated across disciplines, in anthropology, sociology, and psychology, for instance (Norenzayan and Heine, 2005). The search for behavioral universals specific to the aged, however, has a relatively short history.

The long-accepted perception that behavior, activity levels, and social interactions change with increasing age stimulated interest in aging and resulted in the advent of human gerontology as a discipline in the 1940s. Several theories of universal behavioral or psychosocial aging have since been proposed to explain perceived aged behavior. Of these, the following are of particular interest: The first formal theory proposed to explain the process of growing older was the Theory of Social Disengagement proposed by Cumming and Henry (1961). Social disengagement argues that, with increasing age, mutual withdrawal between the individual and society is a natural, inevitable phenomenon that finally culminates in death. Activity Theory of psychosocial aging argues that, if individuals are to age successfully, they must maintain their ongoing roles and activities into their later years

(Lemon *et al.*, 1972). Similarly, Continuity Theory states that successful aged adults use strategies that maintain their individual activity and interaction patterns into old age. In this view, successful adults react to the physical restrictions of aging in an adaptive way (Neugarten *et al.*, 1968). Finally, in the Selective Theory of Aging, Carstensen (1987) and Carstensen *et al.* (2003) describe the process of aging as including a selective pruning of social relationships in later years, and the retention of only the most important relationships. Of these proposed theories, both disengagement and activity theories find no consistent empirical support, but continuity and selectivity theories do enjoy some empirical support.

The most recent theoretical contribution to an understanding of aging as adaptation comes from Ronald Lee (2003). Lee counters the argument that the force of natural selection against aging is too weak to be effective in postreproductive individuals, and reemphasizes the selective importance of behavioral contributions an elder makes to the survival of future generations. Lee argues that this view offers a fresh look at the forces favoring longevity.

### The Nonhuman Primate (NHP) Model of Aging

The use of nonhuman primates as a model for the mechanisms of biological aging is well known (Corr, 2000). Crews (2003) correctly notes that, because of the shared evolutionary history of human and nonhuman primates, greater insight into the complex processes of aging and senescence can be gained through comparisons of phylogenetically similar organisms that have the most parallels to aging humans. Both human and nonhuman primates experience similar morphological and physiological decline with increasing age, including chronic degenerative conditions and an increased risk of disease, making nonhuman primates invaluable as a model of human aging (Crews and Garruto, 1994). Investigations of the associations of age with social behavior in nonhuman primates, however, have not proven as informative.

Primatologists have tested most of the proposed gerontological theories of human social or behavioral aging across various species of nonhuman primates. Primate gerontology, however, is a relatively new field that is based on very few studies, many of which present conflicting evidence (Corr, 2002). In tests of the social disengagement theory, for instance, Pavelka (1991), using Japanese macaques (*Macaca fuscata*), found no support for social disengagement in older monkeys, but Nakamichi (1984), also working with Japanese macaques, found the opposite and reported evidence that sociality did decrease with increasing age. Additionally, Corr (2000), in a comparison between rhesus macaque (*Macaca mulatta*) age groups, reported finding decreased

sociality of aged rhesus macaque females, but increased levels of sociality in aged rhesus males in the same population. Moreover, two studies focusing on social behavior in aging lemurs (Picq, 1992; Taylor, 1998) also reported conflicting levels of social withdrawal. In apes, Bloomsmith *et al.* (2000) reported that their observations of Yerkes chimpanzees and gorillas showed significant behavioral differences in some categories between younger and older animals, but no significant differences between age groups in rates of social behavior.

Clearly, the search for aged behavioral universals in primates has not provided consistent insights into the social behavior of aged individuals. One reason may be that the relationship between social behavior and physical aging is greatly impacted by a number of factors, both cultural and ecological. All primates, human and nonhuman, become aged within a complex network of varying environments and social structures. If we are to clarify and broaden our understanding of becoming old, these variations must be fully considered. Such a broadened horizon, for instance, could explain the differences found in aged sociality between the described two, free-ranging populations of Japanese macaques living in different environments: one in mountainous Japan and one in the desert of Texas. Also, considerations of species-specific sex-based roles and life histories could explain why males and females of the same rhesus population would differ in their social behavior with increasing age as each sex lives very different lives. Primate aging occurs within a multiplicity of factors: basic biology, species-level behavioral repertoires, varying adaptations to environmental pressures, widely varying social structures, and so on. One of the hallmarks of the Order Primates is plasticity of behavior and diet, which allows primates to adjust and adapt to varying environmental pressures. It would seem, therefore, that consideration of individual and population-level differences in aging must be investigated within that context.

Although nonhuman primates make an excellent biological model for human aging, there are several important impediments to their use in aging research that should be noted. First, nonhuman primates do not have a comparable life span to humans, preventing direct comparison. Second, due to predation pressures and lack of long-term field studies that follow identified individuals over the life span, known aged primates are rare in wild populations. Third, though established colonies offer higher numbers of aged primates, they are semi-free ranging, provisioned populations, which could confound results. Finally, the use of aged nonhuman primates under laboratory conditions has become increasingly difficult due to the lack of elders that have known histories and that are not compromised from participation in past projects. Moreover, funding limitations and ethical considerations place additional limitations on the scope of aging research. Still, the use of nonhuman primates as a human aging model is

predicted to increase, particularly in rhesus monkeys (Roth *et al.*, 2004).

### Limitations, Benefits, and Methods in Testing Individual Differences

As discussed earlier, the results of behavioral studies of aging in nonhuman primates suggest that establishing a universal description of the aging process may be difficult using cross-sectional research designs. One complication of this type of research is that there are often large individual differences between individuals within the same age group (Tarou *et al.*, 2002). For example, in a study of aging chimpanzees at the Yerkes Primate Research Center, one 43-year-old chimpanzee showed severe signs of senescence, spending large amounts of time inactive, likely as the result of arthritis and glaucoma, whereas another chimpanzee of the same age, living in the same environment, spent more time engaged in active behavior and appeared to be unaffected by senescent changes (Tarou, unpublished data). These individual differences could be the result of heritable or environmental differences in disease susceptibility and transmission. However, they could also indicate individual behavioral traits that are consistent across the life span.

In humans, individual differences that are relatively stable across the life span of an individual are referred to as personality traits. In nonhuman primates, Suomi *et al.* (1996) found consistent individual differences in rhesus monkeys that could be described as personality across the life span. There were common age-related changes in 10 of 31 measured behaviors within individuals; however, across individuals, there were large individual differences. These results are similar to the stability and change in personality with age found in adult humans (Pedersen and Reynolds, 1998). Given such commonalities in aging research across divergent species, it is likely that the underlying mechanism may represent common evolutionary history.

The quantitative measurement of human personality traits began in the 1940s by distilling and categorizing all descriptive English words that seemed to cluster and that could be associated with a specific personality trait. Using factor analysis, descriptors were then established that could be used to identify and measure self-reported behavioral traits in the individual. Since then, further work has resulted in the reduction of the original factors into what are now known as the *Big Five*: extroversion, neuroticism, agreeableness, conscientiousness, and openness to experience. They are described as follows (www.psychcentral.com):

- Extroversion: a tendency to seek stimulation and the company of others
- Neuroticism: a tendency to easily experience unpleasant emotions

- Agreeableness: a tendency to be compassionate rather than antagonistic
- Conscientiousness: a tendency to show self-discipline, act dutifully, achieve
- Openness to experience: a tendency to enjoy art and new intellectual ideas

Having an optimistic or positive attitude has been found to be strongly associated with longevity in humans. As part of the Nun Study, the autobiographies of 180 Catholic nuns were read and analyzed on the basis of the level of positive emotional content contained in their writings (Danner *et al.*, 2001). Results showed that the emotional content of work written early in life predicted longevity 60 years later such that those sisters who wrote fewer sentences and words containing positive emotion also had a higher risk of earlier mortality than those who wrote more positively about their lives. Optimism is believed to facilitate subjective well-being (happiness) and good health (Wrosch and Scheier, 2003). Happiness has been strongly linked with the Big Five personality factors (Schmutte and Ryff, 1997), particularly extroversion and neuroticism. Specifically, neuroticism correlates negatively and extroversion correlates positively with subjective reports of well-being in humans (Sackett, 1991).

Several personality traits also have been linked to physical disease and longevity in humans. Specifically, hostility and neuroticism have been found to be negatively associated with coronary heart disease and longevity, whereas optimism has a positive influence on longevity (Smith and Spiro, 2002). These personality traits are presumed to affect not only risk, but the reporting of symptoms of illness and illness behavior (Feldman *et al.*, 1999). According to a review of the literature on personality, health, and aging (Smith and Spiro, 2002), one of the causal ways that personality can influence disease is through an individual's response to stress. For example, an individual who scores high on a measure of hostility reacts to stressful situations with larger increases in blood pressure, heart rate, and stress-related hormones. Furthermore, these increases do not return to baseline levels in such an individual as quickly as they do for people who score high on agreeableness, thereby affecting recovery. Hostility is negatively associated with agreeableness and positively associated with neuroticism. The personality trait neuroticism is associated with depression and anxiety, which, in turn, are associated with an increased risk of heart disease, stroke, cancer, reduced immune functioning, recurrence of disease, and reduced longevity. It is believed that an optimistic personality allows people to more readily adapt to change and cope better with stress.

Interest in the study of animal personality has increased dramatically in the last 15 years (Gosling, 2001). Once considered anthropomorphic and taboo, the systematic study of individual differences among members of the same species is being recognized as important

both from evolutionary and ontological points of view. Most studies designed to investigate animal personality involve having zookeepers or animal caretakers who are highly familiar with the animals fill out questionnaires similar to those used in human studies of personality (Itoh, 2002). Individual animals are rated on several adjectives or descriptions using a scaling system. Data then are analyzed using either principal component or factor analysis to determine which of the adjectives load positively or negatively with each other. Though personality factors that have emerged in animal studies often are labeled differently across studies, a recent review of the literature found that distinct personality factors have been reliably described in a variety of species (Gosling and John, 1999). A neurotic animal, for example, would be one that engages in abnormal or stereotypic behavior and is highly reactive in novel situations or environments. Additionally, extroversion and neuroticism have been found to be reliable factors for describing the personality of individual chimpanzees, gorillas, rhesus monkeys, dogs, cats, pigs, donkeys, guppies, and octopuses (Gosling and John, 1999).

Some traits have not been found across all species tested, which could be due to differences in methodology. For example, agreeableness is a factor that appears to be shared by humans, some species of nonhuman primates, and other mammals (Gosling and John, 1999). A person scoring high on the factor agreeableness can be described as trusting, sympathetic, helpful, soft-hearted, good-natured, flexible, cheerful, lenient, and forgiving (McCrae and Costa, 1987). Though many of these terms are not readily applicable to (nonhuman) animals, those individuals considered high in agreeableness show lower levels of aggression and hostility toward others. In both animals and humans, openness can best be described as the curiosity level of the individual. Openness in humans refers to creativity, curiosity, independence, and complexity (McCrae and Costa, 1987). Openness was found to be a personality factor in 7 of 12 species of animals examined (Gosling and John, 1999).

Of the species tested, chimpanzee personality seems to be the most similar to humans. The fifth personality factor in the Big Five is conscientiousness, and has been found only in humans and chimpanzees. Conscientiousness in humans is described by adjectives such as dependability, dutifulness, order or neatness, and self-discipline, all of which are difficult to attribute to nonhuman species. Chimpanzee conscientiousness is best described by adjectives describing a lack of behavior that is erratic, unpredictable, and disorganized (King and Figueredo, 1997). In chimpanzees, the five personality factors have been found to be heritable and to be relatively independent of differences in housing environment, which are also findings similar to studies of personality in humans (Weiss *et al.*, 2000).

Of the Big Five, not all studies have found that optimism or cheerfulness is necessarily good for health

and aging. Interestingly, one study has found that cheerfulness in children may be inversely related to longevity and that conscientiousness is a stronger predictor of long-term survival (Friedman *et al.*, 1993). Conscientiousness can be described by the level of control or lack of impulsivity that an individual possesses. Conscientiousness could influence longevity through self-protective behaviors such as the maintenance of good eating habits, avoidance of dangerous situations, and adherence to health regimens. However, a follow-up study showed that conscientiousness was not a reliable predictor of cause of death (Friedman *et al.*, 1995). Although conscientiousness did predict rates of variables such as smoking and drinking, which are related to health and mortality, these variables accounted for little variance in the relationship between conscientiousness and longevity. Friedman and colleagues (1995) hypothesize that this relationship may be the result of an underlying psychobiological process that is associated with both conscientiousness and long life. However, they suggest that a more likely explanation for the results is that conscientiousness allows a person to better cope with stress and maintain social relationships. As stated previously, chimpanzees are the only nonhuman species studied to date for which a personality trait that is analogous to conscientiousness in humans has been described (Gosling and John, 1999). The term used to describe this personality trait in chimpanzees is dependability (King and Figueredo, 1997; Weiss *et al.*, 2000).

Given the association between physiology and personality in humans, an animal model of personality, aging, and longevity may not only be appropriate, but also pragmatic. Disease susceptibility and recovery in humans often is confounded by a variety of social, cognitive, and environmental factors. Identifying stable personality traits in nonhuman primates, measuring them, and correlating them with risk of disease, recovery, and survival, could provide insight into human successful aging. There appears to be great consistency with regard to major personality descriptors in nonhuman primates despite differences in raters, species, and how the traits are labeled (Gosling, 2001; Gosling and John, 1999), indicating that these consistencies in personality traits may represent homologous traits passed down through evolutionary history. Furthermore, similar to human personality traits, these traits are consistent in individuals over time (Capitanio, 1999; Suomi, *et al.*, 1996).

## Personality and the NHP Model

Many of the methods and constructs used to measure human well-being are not directly applicable to nonhuman primates. However, psychological well-being is a topic that has become of great concern for the ethical care of captive nonhuman primates. In captive populations, animals are said to have psychological well-being when they show few physiological and behavioral signs of stress

(Moberg, 1985). Recently, this also has been found to be an indicator, or by-product, of psychological well-being in humans in that higher levels of psychological well-being have also been associated with lower levels of cortisol release (Lindfors and Lundberg, 2002). Environmental enrichment is often used to alleviate stress and promote psychological well-being in captive nonhuman primates. This is particularly important as stress has been clearly associated with a variety of undesirable physiological effects, mostly as the result of compromised immune system functioning (Kelly, 1985; Shapiro *et al.*, 1998).

Typically, psychological well-being in nonhuman primates is measured through behavioral observations and/or hormonal analyses. However, at least one recent study has shown that well-being or “happiness” can be reliably estimated by human raters who are familiar with the individual (King and Landau, 2003). In these studies, zookeepers or researchers with extensive experience working with or observing individual chimpanzees were asked to rank them on overall mood, quality of social relationships, extent to which they were successful in achieving goals, and how much they would like to “be” a particular chimpanzee. Results showed that reliability across raters was as consistent as have been found in human studies of subjective well-being. Furthermore, this construct appears to be heritable and generically correlated with dominance (Weiss, King, and Enns, 2002). There was a strong correlation between personality and subjective well-being in chimpanzees, and many aspects of well-being in chimpanzees are surprisingly similar to those observed in humans (King and Landau, 2003).

There are, however, methodological issues associated with personality testing in nonhuman primates (Itoh, 2002). Personality in animals is often measured using subjective assessment methods such as questionnaires, which may have problems with construct validity. Most principal component analyses have not been tested for reliability across research groups. As deWaal (2002) has cautioned, subjective human ratings of animal personality traits may reflect anthropomorphic projections of human traits onto animal behavior. For a complete understanding of both the physiological and behavioral changes associated with aging, objective tests in which behaviors are systematically recorded coupled with subjective assessments from animal care providers may be the most useful methodological approach.

## New Directions in Aging Research

Investigations into the role of individual differences in behavior, or personality, in the aged are largely the result of a paradigm shift away from old age as an independent category of life, to a focus on old age as part of a lifelong developmental continuum. Diener and Suh (1997) showed that, although there is an unavoidable, universal physical decline and loss of function with increasing age, an individual’s personal sense of feeling “happy and well”

can increase concurrently with physiological decline or disability. Specifically, two recently proposed theoretical views of aging, Selection, Optimization, and Compensation Theory (SOC) and Socio-emotional Selectivity Theory (SST), are redirecting social aging research by considering growth and decline as a process that impacts all age categories. In SOC, Baltes and Baltes (1998) use the interaction of three universal regulatory processes to define adaptive development, or successful aging: an individual’s selection from available options, optimal use and acquisition of resources, and ability to compensate to adjust for physical or resource loss. In this view, by setting goals and working toward them through appropriate resource use and compensation for loss, an individual’s sense of positive well-being can be maintained throughout both adulthood and old age. Lockenhoff and Carstensen (2004), in describing SST, add that the knowledge a successful individual has of coming toward the end of life and of having limited time may serve as a motivator in their determination to achieve well-being and emotional meaning in old age. Both researchers agree that a theoretical shift toward life history thinking and a focus on individual differences in goals and preferences should guide future aging research.

Currently, comparative, transcultural studies of human aging are being conducted that offer a global perspective on human aging and reveal “a wondrous array of social responses to the physical imperatives of growing old” (Sokolovsky, 1997). Sokolovsky (1997) describes this growing, multidisciplinary trend as “qualitative gerontology,” and being comprised of investigations from widely divergent fields (anthropology, biology, psychology, demography, medicine, etc.). Also, as the information age continues to globalize access to resources, those that focus specifically on aging are helping to unify research designs, including cross-discipline collaborations, new professional organizations, journals, other print resources, web-linked sites, academic gerontology programs, and so on. In addition to the described qualitative movement, there is also an important effort being made by investigators to achieve consistency in research methods used in quantitative cross-cultural studies of human aging. Such consistency of methods is imperative if we are to maximize the usefulness of these comparative studies and tease out the meaningful differences, similarities, individual variations, and even universals of human aging within a variety of social contexts.

In an example of an inclusive aging research design, considering both biology and behavior, the investigation of the molecular biology of social behavior is another emerging field that is certain to contribute a great deal to our understanding of aging. This area of interest looks at neural, molecular, and endocrine mechanisms that influence behavior in social species. Additionally, new programs of advanced study in the area of interface between biology, ecology, and behavior are rapidly being

established in American universities. These programs will address cross-species behaviors such as predation, violence, addictions, and so forth from both biological and behavioral perspectives. Such a focus requires an interdisciplinary approach that will cut across the traditional structure of university departments.

Finally, a new and unique opportunity to extend the use of nonhuman primates as a model for behavioral aging is provided by the recent establishment of sanctuaries designed to accommodate retired chimpanzees (*Pan troglodytes*). In 2000, the CHIMP Act (Chimpanzee Health Improvement, Maintenance, and Protection Act) was signed into law and implemented the chimpanzee sanctuary system in the United States. The first of these, Chimp Haven, Inc. in Shreveport, Louisiana, is now receiving chimpanzees, many of which are aged. Each of these individual animals has given its life to biomedical research, the entertainment industry, or has lived as a pet. Now, instead of being euthanized or languishing away singly caged in a lab for years, more than 600 individuals will have a permanent home where they will live out their lives in an enriched, social environment appropriate for chimpanzees. Such sanctuaries, in addition to paying an ethical debt to our phylogenetically closest relatives, provide a unique opportunity for behavioral studies of all kinds, including investigations of individual personality and its impact on aging. Additionally, use of personality assessment in nonhuman primates, already shown to be a helpful management tool in chimpanzees (Dutton *et al.*, 1996), gorillas (Gold and Maple, 1994), and rhesus monkeys (Capitanio and Widaman, 2005), should prove to be an excellent management tool to guide chimpanzee caretakers in easing an individual's adjustment into the sanctuary, and also in the formation of successful social groups. Since nonhuman primate traits, particularly those of the chimpanzee, evolutionarily underlie human traits, a greater understanding of individual behavioral differences among them, particularly with regard to social behavior and aging, cannot help but inform our own experience of being old. We look forward to the coming new wave of aging research and to all the benefits it will provide.

# Andropause

Rabih Hijazi and Glenn R. Cunningham

*This chapter seeks to provide you with an overview of the potential effects of testosterone (T) deficiency in aging men. Although we acknowledge the age-related reduction in serum levels of the adrenal androgens, dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEA-S), the chapter focuses on the much more potent testicular androgen, T and its metabolites, dihydrotestosterone (DHT) and estradiol (E<sub>2</sub>). Many of the symptoms and signs of aging and testosterone deficiency are shared. Although investigators frequently administer T to aging men in an effort to differentiate symptoms and signs related to aging from those caused by T deficiency, a large definitive study assessing efficacy and risk is lacking. Thus, we seek to provide you with our current understanding of the effects of T deficiency in aging men, using insights from small, nondefinitive clinical trials.*

## Introduction

Symptoms of T deficiency are similar to many of those associated with aging. They include loss of stamina, depressed mood, decreased libido, erectile dysfunction, decreased muscle mass and strength, increased fat mass, frailty, osteopenia, and osteoporosis. It may be difficult to distinguish the changes that are age-related from those that are caused by T deficiency.

## T and Aging

### T LEVELS AND AGING

Multiple cross-sectional and a few longitudinal studies have shown that serum T levels in men decrease with age (Deslypere *et al.*, 1984; Harman *et al.*, 2001; Morley *et al.*, 2000). Age-related changes in total T underestimate changes in T available to target tissues. Several cross-sectional studies have shown that an increase of sex hormone binding globulin (SHBG) with aging and a decrease in T and free T (fT) levels are independent of changes in body mass index (Deslypere *et al.*, 1984; Morley *et al.*, 2000). Approximately 40 to 50% of circulating T in men is bound with high affinity to SHBG. This portion of the circulating total T is not readily available to target tissues, whereas T bound to albumin and fT (1–3%) are available to target tissues (Pardridge 1981). The albumin

bound and the fT are referred to as the bioavailable or weakly bound T (bT). Thus, serum concentrations of T and, to a greater extent, fT and bT, are decreased in aging men.

Serum SHBG levels are affected by several conditions. SHBG levels are inversely correlated with increased total body fat, subcutaneous and visceral adiposity (Couillard *et al.*, 2000). Levels also vary inversely with hyperinsulinism in nondiabetic subjects. They seem to be an indicator of general adiposity rather than an index of altered insulin/glucose homeostasis in morbidly obese subjects. Hyperinsulinism decreases SHBG synthesis by cultured hepatic cells. These observations have been interpreted to show that obesity causes insulin resistance and hyperinsulinism, and hyperinsulinism decreases SHBG levels. Hypothyroidism and the nephrotic syndrome also reduce SHBG levels. Estrogen, hyperthyroidism, some anticonvulsants, a high phytoestrogen diet, hepatic cirrhosis, and aging increase SHBG levels (Anderson, 1974; Kley *et al.*, 1975).

We recently reported that SHBG levels are increased in some patients with cancer, and the elevated SHBG may maintain total T levels within the normal range even though the calculated fT and bT levels are low. Thus, SHBG levels are variable in older, obese men, and this limits the value of total T levels in this age group.

Approximately 20% of men 60 to 70 years of age and 30% of men 70 to 80 years of age have T levels below that of 97.5% of healthy 20- to 45-year-old men (Harman *et al.*, 2001). Longitudinal studies have confirmed these findings (Feldman *et al.*, 2000; Harman *et al.*, 2001; Morley *et al.*, 1997). Feldman and coworkers found total T levels decreased at 0.8% per year, bT fell at 2% per year, and SHBG levels increased 1.6% per year (Feldman *et al.*, 2000). This is due in part to a reduction in the number of Leydig cells in the testes that produce T.

The decline in T levels with aging when associated with symptoms and signs of androgen deficiency has been called *andropause*. This association also has been referred to as androgen deficiency in the aging male (ADAM), partial androgen deficiency in the aging male (PADAM), aging-associated androgen deficiency (AAAD) or late-onset hypogonadism. The term *andropause* is inaccurate because men do not have menses and because androgen secretion gradually decreases, and usually is

TABLE 63.1

Immune System

continued at some, albeit reduced, level when compared with younger, healthy men. However, andropause is widely used by the lay press and laypersons as well as clinicians.

**LH LEVELS AND AGING**

LH levels increase slightly with aging (Baker *et al.*, 1976; Morley *et al.*, 1997). Tenover and coworkers studied older men and noted that pituitary secretion of LH was intact, but testicular secretion of T was impaired in some older men (Tenover *et al.*, 1987). They noted that the normal diurnal variation in T levels is blunted in aging men (Tenover *et al.*, 1988). However, the majority of hypogonadal men over age 60 have low or inappropriately normal LH levels (Korenman *et al.*, 1990). Older men with low T levels typically have abnormal LH pulse frequency and reduced pulse amplitude, suggesting hypothalamic dysfunction (Deslypere *et al.*, 1987). Less pulsatile T and more LH were secreted in healthy middle-aged men at night compared to healthy young men. The association between T rhythm and REM sleep also was disrupted. Most investigators have concluded that the decline in T observed with aging results from combined testicular and hypothalamic abnormalities.

**ANDROGEN ACTION AND METABOLISM OF T**

Androgen action appears to be mostly maintained with aging, but this has not been studied extensively. Androgen binding sites in the hippocampus, penile tissues, and genital skin are decreased in aging men and animals (Roehrborn *et al.*, 1987; Tohgi *et al.*, 1995). It is recognized that shortening of the CAG repeat in the androgen receptor increases androgen action, but it is not likely that this, per se, changes with aging (Lamb *et al.*, 2001). It will be important to determine if there are age-related changes in coactivators and corepressors that are important in mediating androgen action at the cellular level.

T is metabolized to dihydrotestosterone (DHT) and to estradiol (E<sub>2</sub>) in tissues that have 5 $\alpha$ -reductase activity

and/or aromatase activity. DHT is a very potent androgen at the tissue level. It contributes most of the androgenic effects in genital tissues, accessory sex organs, and hair follicles. Five-alpha-reductase activity also is present in some areas of the brain and in bone (Russell *et al.*, 1994). Aromatase activity is primarily present in adipose tissue, so most of the circulating estradiol and estrone in males comes from peripheral conversion of T and androstenedione (Simpson *et al.*, 1997). T production rates in young adult males range between 4 and 10 mg/24 hours with an average of 6.6 mg/24 hours (Vermeulen, 1976). In men over age 65, the mean production rate decreases to approximately 4 mg/24 hours. Plasma levels of T reflect an age-related decrease in both secretion and the metabolic clearance rate.

**ORGAN SYSTEMS AFFECTED BY LOW T LEVELS**

*Brain*

**Cognitive function.** Cognitive function decreases with aging. Most of the age-related changes in cognition are associated with vascular and/or degenerative diseases that cause anatomic changes in the central nervous system. The possibility that an age-related fall in T causes functional changes in cognition is of great interest. In a study involving 407 men aged 50 to 91 years at baseline and followed for an average of 10 years, Moffat and colleagues showed that higher free T indices were associated with better scores on visual and verbal memory, visuospatial functioning, and visuomotor scanning, and a reduced rate of decline in visual memory (Moffat *et al.*, 2002). On the other hand, men classified as hypogonadal had significantly lower scores on measures of memory and visuospatial performance and a faster decline in visual memory. Of course, changes in the CNS could cause hypogonadism rather than be caused by hypogonadism. In another study by Barrett-Conner and associates, low estradiol and high total and bioavailable T levels predicted better performance on several tests of cognitive function in older men (Barrett-Connor *et al.*, 1999). T could exert its actions through androgen receptors that could modulate serotonin, dopamine, calcium, and acetylcholine signaling pathways. Androgen also increases neurite arborization facilitating intercellular communication. T can be aromatized in the brain to estrogen, and thus some of the effects of T may be mediated through its conversion to estradiol. Most of the effects of androgen on cognitive function are thought to be domain-specific. For example, observations that men outperform women in a variety of visuospatial skills suggest that androgens might enhance these skills. Some, but not all, of the trials found better verbal memory and spatial cognition in the T-treated men compared with placebo-treated men, but no better scores on other cognitive domains (Cunningham *et al.*, 1990; Janowsky *et al.*, 2000; Kenny *et al.*, 2002).

## 63. Andropause

**Mood and depression.** It is estimated that two million older Americans are depressed (NIMH, 2003). Depression increases with aging, in part due to diseases associated with aging. Although depression is not a part of the aging process, medical diseases associated with aging such as stroke, diabetes, and heart disease reduce physical activity and contribute to depression. It is estimated that 80% of older adults with depression improve when they receive therapy with an antidepressant medication, psychotherapy, or both (NIMH, 2003). T may have a beneficial effect on mood and depression, as it is known to modulate the serotonin and dopamine pathways.

Androgens appear to improve positive aspects of mood and reduce negative aspects of mood such as irritability in young, hypogonadal men, and some improvements in mood usually are observed in clinical trials involving mostly middle-aged men (Wang *et al.*, 1996).

**Libido.** T also appears to be essential for development and maintenance of libido or sexual desire. Males with congenital hypogonadotropic hypogonadism have minimal libido. This is increased by therapy that increases their T levels. Reduced libido also is observed in men with acquired hypogonadism, and clinical trials with replacement doses of T in young and middle-aged men usually show improved libido.

### Bone

Bone strength decreases with aging. Men undergo a gradual loss in bone mass beginning in their 30s. It is estimated that two million men in the United States have osteoporosis and that one in eight men over age 50 will have an osteoporosis-related fracture (NIAMS, 2003). Risk factors for osteoporosis include family history of osteoporosis, smoking, excessive alcohol intake, physical inactivity, poor nutrition, vitamin D deficiency,

inadequate calcium intake, hypogonadism, and use of some medications (e.g., glucocorticoids, anti-convulsants).

Osteopenia and osteoporosis are common in males with congenital causes of hypogonadism, and severe T deficiency occurring later in life also results in bone loss. For example, androgen deprivation therapy for prostate cancer has been shown to result in rapid bone loss, osteopenia, and osteoporosis (Smith, 2003). Although less severe T deficiency in aging men appears to increase osteopenia and osteoporosis, population-based studies suggest that estrogen levels are better correlated with loss of BMD in men (Greendale *et al.*, 1997; van den Beld *et al.*, 2000). Estrogen is very important in bone development in males as illustrated by individuals with aromatase deficiency (Maffei *et al.*, 2004). Males with inactivating mutations of the aromatase gene develop osteopenia and osteoporosis that improve with estradiol therapy. Estrogen also plays a major role in bone metabolism of older males (Khosia *et al.*, 1998).

**Figure 63.1** Prevalence of hypogonadism based upon low levels of total testosterone, free testosterone index (T/SHBG), and bioavailable testosterone. The black bars represent the percentage of the population with total testosterone levels <325 ng per deciliter, bars with diagonal lines represent the percentage of the population with free T index <0.153 nmol/nmol, and the white bars represent the percentage of the population with bioavailable testosterone levels <70 ng per deciliter. Bioavailable testosterone was not measured in some age groups. (25, 44)

In aging men treated with a GnRH agonist (a model of severe hypogonadism), estrogen treatment decreases markers of bone resorption and increases markers of bone formation. The investigators in these studies have estimated that two-thirds of the effect of testosterone replacement therapy (TRT) is due to an estrogen effect (Khosia *et al.*, 1998). Most of the estrogen in men is derived from the aromatization of T to estradiol and androstenedione to estrone. Estradiol is more potent, but accurate measurement in males is difficult because levels are low and assay sensitivity and accuracy are marginal in many reports. Total E<sub>2</sub> levels also are affected by SHBG levels, so accurate measurement of free estradiol or bioavailable estradiol are most informative.

Males have larger bones and greater bone mass than women, so androgen as well as estrogen is critical for the development of a normal male skeletal mass. T and estrogen also may act directly through receptors in bone cells or indirectly by modulating the action of cytokines or growth factor metabolism. In summary, both androgens and estrogens affect bone metabolism in men, and both may be reduced with aging and hypogonadism.

#### *Muscle*

Aging is associated with a decrease in lean body mass and strength, even if total body weight is maintained at a level achieved in the early 20s. It is estimated that skeletal muscle mass decreases 35% between the ages of 20 and 80. This sarcopenia associated with loss of strength leads to impairment of physical function such as impaired ability to rise from a chair, climb stairs, maintain balance, and generate gait speed. This can result in loss of mobility, falls and fractures, loss of independence, and depression (Roubenoff *et al.*, 2000).

The cellular and molecular mechanisms by which androgens affect changes in fat-free mass, muscle mass, and strength are only partially understood. Androgen administration to sexually immature boys increases nitrogen retention. Other studies have observed increased protein synthesis and muscle hypertrophy (Sinha-Hakim *et al.*, 2002). Multiple placebo-controlled trials in both younger and aging men with T deficiency have assessed changes in muscle strength and body composition measures in response to exogenous T. They usually have noted increases in fat-free mass and decreases in fat mass. Some, but not all, have found significant improvements in leg and arm strength (Amory *et al.*, 2004; Snyder *et al.*, 1999; Urban *et al.*, 1995). Bhasin and coworkers clearly demonstrated dose-related increases in skeletal muscle mass in young males (Bhasin *et al.*, 1996). In other studies, the Bhasin group also has demonstrated a dose-dependent increase in muscle mass and strength in younger men made hypogonadal with a GnRH agonist (Sinha-Hakim *et al.*, 2002; Storer *et al.*, 2003). More recent studies have demonstrated that T caused dose-dependent increases in skeletal muscle mass in aging men (Bhasin *et al.*, 2005). The Bhasin group has observed that supraphysiological

doses of testosterone increase satellite cell and myonuclear cell number (Sinha-Hakim *et al.*, 2003). They have postulated that in addition to stimulating muscle protein synthesis, decreasing muscle protein degradation, and improving reutilization of amino acids, testosterone promotes the commitment of pluripotent stem cells into the myogenic lineage and inhibits their differentiation into the adipogenic lineage (Bhasin *et al.*, 2003). They suggest that this increases myonuclear number and satellite cell number.

#### *Adipose tissue*

Adipose tissue increases with aging, and many aging and obese men meet criteria for the metabolic syndrome. The ATPIII criteria for making the diagnosis of metabolic syndrome require that an individual have at least three of the following: waist circumference >40 inches, serum triglycerides  $\geq 150$  mg/dL, HDL cholesterol <40 mg/dL, blood pressure  $\geq 130/\geq 85$ , or fasting glucose  $\geq 110$  mg/dL. These individuals are at increased risk for developing cardiovascular disease. Obesity decreases SHBG levels and total T levels, and fT levels are decreased with more severe obesity. Obesity and serum leptin, an adipokine, are positively correlated. Endogenous T levels vary inversely with serum leptin levels (Thomas *et al.*, 2000), and testosterone administration suppresses leptin levels. Serum adiponectin (another cytokine) levels correlate inversely with obesity, and TRT reduces adiponectin levels (Lanfranco *et al.*, 2004).

TRT in middle-aged and older men typically causes some reduction in adipose tissue (Mayes *et al.*, 2004). Whether changes in visceral fat are greater than the percent changes in subcutaneous fat is of interest because visceral fat is metabolically more active (Dicker *et al.*, 2004). T can increase lipoprotein lipase, which can increase lipolysis. As noted previously, Bhasin and colleagues postulate that T inhibits differentiation of pluripotent stem cells into adipose cells (Bhasin *et al.*, 2003). Because the studies suggesting this effect were conducted using pharmacological doses of T, it remains to be demonstrated that this is a mechanism for the reduction in adipose tissue noted with physiological replacement doses of T.

#### *External genitalia*

T and its metabolite, DHT, are critical for development of the external genitalia. They probably have a direct effect on penile erections. Jain and associates conducted a meta-analysis evaluating the effects of T supplementation on erectile dysfunction (Jain *et al.*, 2000). Some of the men were not hypogonadal, but they found an overall response rate of 57%. TRT affects nocturnal erections and penile rigidity in hypogonadal males (Cunningham *et al.*, 1990). Although erections can be induced in hypogonadal men in response to sexually explicit visual stimuli, TRT improves penile rigidity (Carani *et al.*, 1995). These clinical observations are consistent with findings

in lower animal models (Mills *et al.*, 1999). TRT normalizes cavernous nerve-stimulated erections in castrated rats. This effect is reduced by concomitant treatment with a 5 $\alpha$ -reductase inhibitor, indicating it is mediated by DHT. T or DHT increased neuronal and endothelial nitric oxide synthase activity, and this is thought to increase nitric oxide, the most potent relaxor of corpora cavernosal smooth muscle. In the rat, neurons responsible for penile vascular smooth muscle relaxation possess both androgen receptors and nitric oxide synthase. In a recent study by Aversa and colleagues, T appears to have a direct vascular effect in the human corpora cavernosa, mediating the ability of nitric oxide to relax corporal tissue and allow increased penile blood flow (Aversa *et al.*, 2003). Combination treatment with a physiological dose of T plus a phosphodiesterase inhibitor may cause greater rigidity than either agent alone in awake and sleep-related erections. The T concentrations needed to maintain normal sexual activity appear to be in the low normal range, or possibly somewhat less than 300 ng/dL in healthy young men.

#### *Testes*

Seminiferous tubule function declines with aging. Older men have decreased sperm motility, increased number of abnormal sperm, and lower ejaculate volume. There is a negative correlation between age and sperm production, and this finding does not appear to be caused only by a loss in the number of Leydig cells (Neaves *et al.*, 1984). Serum inhibin levels also are decreased in older men indicating a decline in the hormonal function of the seminiferous tubules (Tenover *et al.*, 1988).

#### *Prostate and accessory sexual organs*

The prostate, seminal vesicles, and vas deferens are androgen-dependent tissues, and they also have high levels of 5 $\alpha$ -reductase activity. Individuals with 5 $\alpha$ -reductase type 2 deficiency have rudimentary prostates. The prostate is the sex organ that is most affected by diseases associated with aging.

**Prostate cancer.** Prostate cancer is the most common nonskin cancer in males. The greatest risk factor is age, with more than 75 percent of new diagnoses occurring in men over 65. The autopsy prevalence of microscopic or occult prostate cancers is rare in men who were in their 40s, but approximately 40 to 50% of men 60 to 70 years of age have occult prostate cancer and 80% by age 80 (Sakr *et al.*, 1994). The prevalence of prostate cancer has been reported for the 2,950 men (age range, 62–91 years) who were assigned to the placebo group in the Prostate Cancer Prevention Trial. Men who never had a PSA level of >4.0 ng/mL or an abnormal digital rectal examination after being in the study for seven years underwent a prostate biopsy (Thompson *et al.*, 2004). Prostate cancer was diagnosed in 15.2% of the men, and 14.9% had a Gleason score of 7 or higher. The prevalence

of prostate cancer for men with PSA levels <0.5 ng/mL was 6.6%, 10.1% for values of 0.6 to 1.0 ng/mL; 17% for values of 1.1 to 2.0 ng/mL; 23.9% for values 2.1 to 3.0 ng/mL; and 26.9% for values of 3.1 to 4.0 ng/mL. High-grade cancers (7 or greater) increased from 12.5% with the lowest PSA levels to 25% in the group with PSA of 3.1 to 4.0 ng/mL. Most of the occult cancers never become clinical cancers. However, it is not known whether TRT will increase this risk.

Two prospective cohort studies and 10 nested case-control studies have correlated T levels with future development of prostate cancer (Rhoden *et al.*, 2004). None of these studies found a positive correlation between total T or bioavailable T (four studies) levels and future prostate cancer; however, the nested case-control study reported by Gann and colleagues found a positive relationship after T was adjusted for the SHBG level. Although it is reasonable to adjust for SHBG, this study found that high total T levels and low SHBG levels were correlated with future prostate cancer. Total T levels usually increase with increasing SHBG. As suggested by Hsing, it is desirable to correlate prostate cancer with measures of androgen action, rather than a single blood level at some point in the past, but such studies are lacking.

The influence of T on prostate carcinogenesis and other prostate outcomes remains poorly defined. Some animal studies suggest that T may be a weak carcinogen in susceptible animals. Most studies indicate that T can act as tumor promoter at normal physiologic levels (Bosland, 2000; Stanbrough *et al.*, 2001). The direct relevance of these studies to humans is uncertain. Despite the lack of evidence implicating androgens in carcinogenesis, it is clear that prostate cancer rarely, if ever, develops in an environment devoid of androgens, and the majority of prostate carcinomas require androgens for growth. Androgen ablation causes regression of metastatic prostate carcinoma; however, cancer cells that survive androgen deprivation ultimately proliferate, causing relapse and androgen-independent disease.

**Benign prostatic hyperplasia.** Benign prostatic hyperplasia (BPH) is a noncancerous enlargement of prostate that can obstruct urine flow. Around 90 percent of males 70 and older have some symptoms of lower urinary tract obstruction; but nonprostatic factors commonly contribute to lower urinary tract symptoms in men and women. Although treatment of men with large prostates with a 5 $\alpha$ -reductase inhibitor will cause a 15 to 20% reduction in prostate volume, longer studies indicate that finasteride significantly reduced progression of BPH, urinary retention, and need for invasive treatment (McConnell *et al.*, 2003). It may be that combining TRT with a 5 $\alpha$ -reductase inhibitor will reduce risk of progression of BPH and need for invasive treatment of BPH. Long-term use of a 5 $\alpha$ -reductase inhibitor for prevention of BPH progression or prevention of prostate cancer is not routinely advised at this time, but this could change

as we learn more about the long-term effects of these inhibitors on development of prostate cancer and progression of BPH.

#### *Cardiovascular*

Cardiovascular disease remains the number one killer for men in the United States. The prevalence of cardiovascular disease is approximately twice as common in men as in women at any age during the reproductive years (Wu *et al.*, 2003). Whether this is due to protective effects of estrogen, harmful effects of T, or to other factors has been the subject of many studies. Estrogen therapy of men with cardiovascular disease increased cardiovascular events. Furthermore, estrogen therapy of postmenopausal women also appears to cause some increase in cardiovascular events (Anderson *et al.*, 2004; Grady *et al.*, 2002). Epidemiological studies in men show a neutral or a negative correlation between T levels and cardiovascular disease (Wu *et al.*, 2003).

Most studies have examined the effects of T on individual factors that contribute to cardiovascular disease such as lipids, apoproteins, insulin sensitivity, endothelin levels, platelet function, clotting parameters, vascular reactivity, arterial intimal thickening, and hematocrit. The correlations vary depending upon the specific endpoint. These trials were mostly of short duration (4 weeks to 36 months) and involved only a relatively small number of men. Physiologic T treatment of older men recently was reported to improve cardiac function in men with low ejection fraction and reduced exercise capacity. Confirmatory studies are needed before this observation is incorporated into routine practice. Because T is anabolic, it may cause some sodium retention.

#### *Bone marrow*

Boys and girls have similar red blood cell counts prior to puberty; however, puberty in males is accompanied by an increase in red blood count. This causes a significant rise in the hematocrit and hemoglobin in postpubertal boys and adult males. T increases red blood cells by stimulating erythropoietin synthesis and secretion by the kidney and by a direct effect on red blood cell precursors. In the absence of hypoxia, T deficient men usually have a mild anemia. The In-Chianti Study evaluated 586 men 65 years of age and older. Men with hemoglobin levels <13 grams/dl had lower circulating levels of calculated fT and bT. No significant association was noted between erythropoietin and total fT or bT levels. This suggests that the anemia is due to less stimulation of red blood cell precursors and not to less stimulation of erythropoietin. Typically, T replacement in androgen deficient men is accompanied by a significant increase in hemoglobin and hematocrit. In older men, T replacement can cause erythrocytosis in some men, especially when T is given as intramuscular injections. If the hematocrit increases above 54 or 55%, it can increase blood viscosity and

decrease blood flow. This is a concern in older men with cerebral vascular disease who are at risk for stroke. Therefore, the hematocrit and hemoglobin must be monitored carefully in hypoxic and older hypogonadal men who are treated with T.

#### *Liver*

The liver is an important target tissue for T. Much of the circulating T is metabolized and cleared by the liver. The metabolic clearance rate for T decreases as men age. It is thought that this is due in part to the increase in SHBG levels and the reduction in fT levels (Want *et al.*, 2004). The metabolic clearance rate for T also can be reduced by drugs such as anti-convulsants, which increase SHBG and decrease fT. The arterial and hepatic vein blood concentrations of T and DHT do not indicate that T is converted by the liver to DHT; however, there is a significant increase in hepatic vein DHT glucuronide (Ishimaru *et al.*, 1978). This is true in younger and older men, and it indicates that the conversion of T to DHT occurs in extrasplanchnic tissue. Fatty liver disease and cirrhosis usually are accompanied by an increase in serum levels of estrone and to a lesser degree in estradiol. SHBG levels are increased, and fT levels are reduced (Kley *et al.*, 1975). Basal luteinizing hormone (LH) levels are increased in patients with less severe liver disease, and they are reduced in the presence of more severe liver disease when compared with controls.

T and its metabolite, estradiol, are recognized to affect liver production of proteins such as SHBG, cortisol binding globulin (CBG), thyroid binding globulin (TBG), apoproteins, lipids, and factors that affect blood clotting and clot lysis. Estrogens increase and androgens have some suppressive effect on SHBG, CBG, and TBG levels.

Serum T and fT in epidemiological studies are positively correlated with HDL-cholesterol and ApoA1 levels, and fT was positively correlated with ApoB levels (Van Pottelbergh *et al.*, 2003). However, high doses of T can increase hepatic lipase and reduce HDL, HDL(2), and HDL(3)-cholesterol and increase LDL particle size (Herbst *et al.*, 2003). Inhibition of T secretion in normal men will increase these parameters. A meta-analysis reviewing 19 studies with intramuscular T esters given in near physiological doses found small, dose-dependent decreases in HDL-cholesterol, LDL-cholesterol, and total cholesterol (Whitsel *et al.*, 2001). A three-year study comparing T patch vs. placebo patch in men  $\geq 65$  years of age and a total T level <475 ng/dl at baseline failed to detect significant changes in HDL-cholesterol, LDL-cholesterol, or total cholesterol, apolipoprotein A-I, or apolipoprotein B (61).

Estrogen is recognized to adversely affect coagulation parameters in women, and this, along with a greater prevalence of coronary heart disease in men prior to age 50, has raised concerns about the effect of T on coagulation parameters in men. A Belgian epidemiological study

(715 healthy middle-aged men) did not find any correlation between endogenous T,  $E_2$ , calculated fT, or calculated f $E_2$  and the mean serum fibrinogen level. The relationship of endogenous T to basal fibrinolytic activity was evaluated in 55 hyperlipidemic men (Glueck *et al.*, 1993). T levels correlated positively with tPA activity and inversely with PAI-1 and fibrinogen. The Paris Prospective Study II evaluated 251 healthy, middle-aged men for correlations between T and hemostatic factors (Bonithon-Kopp *et al.*, 1988). T levels were negatively correlated with factor VII activity and alpha 2-antiplasmin. No association was observed between T levels and fibrinogen or antithrombin III levels. These authors concluded that low circulating T levels might be associated with a hypercoagulable state. Hypogonadism in men has been associated with enhanced fibrinolytic inhibition caused by increased synthesis of PAI-1. Smith and colleagues (2005) conducted a double-blind, randomized, placebo trial with physiological replacement doses of T in 46 men with stable angina. Although there was a significant increase in bT level in the treated group, there were no changes in fibrinogen, tissue plasminogen activator (tPA) activity, or plasminogen activator inhibitor-1 (PAI-1) activity. Thus, the effects on the coagulation system of physiological replacement doses of T in men with T deficiency are uncertain.

#### *Immune system and inflammatory cytokines*

Aging is associated with increased susceptibility to infection, cancer, and an increase in inflammatory cytokines, which are associated with cardiovascular disease. The possibility that age-associated changes in the immune system are affected by changes in circulating levels of estrogen and T are suggested by observations that estrogen and androgen receptors are expressed in primary lymphoid organs and peripheral immune cells, and the female predominance of autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, Hashimoto's thyroiditis, and Graves' disease. Furthermore, females have higher levels of immunoglobulins and greater antibody response to antigens. Castration in male and female mice causes enhanced adrenal and immune responses to endotoxin, which are prevented by treatment with T (Gaillard *et al.*, 1998). T treatment decreases IL-6 production by monocytes and reduces IgG production (Kanda *et al.*, 1996). Gabriel and colleagues (2002) used lipopolysaccharide (LPS) from *salmonella abortus equi* and *Escherichia coli* to stimulate peripheral blood mononuclear cells (PBMCs) *in vitro*. Older patients had excessive secretion of IL-1 $\beta$ , IL-6, and IL-8 by PBMCs. Other investigators have reported that T reduced IL-1 secretion stimulated by LPS. *In vivo* studies also have shown that T replacement in androgen-deficient men with coronary artery disease suppresses IL-1 $\beta$  and TNF $\alpha$  and increases IL-10 (Malkin *et al.*, 2004). It is suggested that this could reduce cytokine mediated atheromatous plaque development and complications. Whether some of the altered immune responses observed with aging

are related to T deficiency and whether T replacement will prove to have a net benefit in suppression of excessive immune and cytokine responses will require much more research; however, the possibility that T may be beneficial should encourage studies of the hormonal-immunological interactions in aging men and women.

## Conclusion

Serum total T concentrations fall with aging, and this may have adverse consequences for energy, sexual function, muscle mass and function, and bone. There also are unconfirmed reports that low total T levels are associated with increased risk of mortality due to cancer. Although increasing the serum T concentrations of elderly men to those of young men might prevent or reverse some of these changes, we do not know if TRT might increase several T-dependent diseases to which elderly men are prone. Thus, the benefit:risk ratio of TRT in aging men is not known.

# Aging and the Perceptual Organization of Sounds: A Change of Scene?

Claude Alain, Benjamin J. Dyson, and Joel S. Snyder

*The peripheral and central auditory systems undergo tremendous changes with normal aging. In this review, we focus on the effects of age on processing complex acoustic signals (such as speech and music) amid other sounds, which requires a set of computations known as auditory scene analysis. Auditory scene analysis is the process whereby the brain assigns parts of the acoustic wave derived from an amalgamation of physical sound sources into perceptual objects (such as words or notes) or streams (such as ongoing speech or music). Solving the scene analysis problem, therefore, depends on listeners' ability to perceptually organize sounds that occur simultaneously and sequentially. The perceptual organization of sounds is thought to involve low-level automatic processes that group sounds that are similar in physical attributes such as frequency, intensity, and location, as well as higher-level schema-driven processes that reflect listeners' experience and knowledge of the auditory environment. In this chapter, we review prior research that has examined the effects of age on concurrent and sequential stream segregation. We will present evidence supporting the existence of an age-related change in auditory scene analysis that appears to be limited to concurrent sound segregation. Evidence also suggests that older adults may rely more on schema-driven processes than young adults to solve the scene analysis problem. The usefulness of auditory scene analysis as a conceptual framework for interpreting and studying age-related changes in sound perception is discussed.*

## Introduction

Normally, our brains do a masterful job of filtering and sorting the information that flows through our ears such that we are able to function in our acoustic world, be it conversing with a particularly charming individual at a social gathering, or immersing ourselves in a joyful piece of music. Unfortunately, as we get older, our sound world becomes impoverished as a result of the normal changes in peripheral auditory structures, which represent a significant challenge for hearing science and medicine because of their prevalence, significant impact on quality

of life, and lack of mechanism-based treatments. Moreover, as average life expectancy continues to increase, auditory problems will apply to an ever-greater number of individuals. Older adults experience a general deterioration in auditory processing, the most common form of which is age-related peripheral change in hearing sensitivity or presbycusis, characterized by impaired thresholds particularly for high frequencies, which become increasingly prominent after the fourth decade of life (Morrell, Gordon-Salant, Pearson, Brant, and Fozard, 1996). Presumably, these losses in peripheral sensitivity result in impoverished and noisy signals being delivered to the central nervous system. This initial distortion of the acoustic waveform may lead to further reductions in fidelity as the incoming acoustic signals are submitted to increasingly detailed analyses, resulting in the eventual disruption of higher-order processes such as speech comprehension.

Age-related change in auditory perception varies substantially between individuals and may include: (1) impaired frequency and duration discrimination (Abel, Krever, and Alberti, 1990); (2) impaired sound localization (Abel, Giguere, Consoli, and Papsin 2000); (3) difficulties in determining the sequential order of stimuli (Trainor and Trehub, 1989); (4) difficulties in processing novel (Lynch and Steffens, 1994) or transposed melodies (Halpern, Bartlett, and Dowling, 1995); and (5) difficulties in understanding speech, especially when the competing signal is speech rather than homogeneous background noise (Duquesnoy, 1983), or when speech occurs in a reverberant environment (Gordon-Salant and Fitzgibbons, 1993). Although sensorineural hearing loss is highly correlated with speech perception deficits (Abel, Sass-Kortsak, and Naugler, 2000; Humes and Lisa, 1990) and accounts for some of the difficulties in identifying novel melodies (Lynch and Steffens, 1994), there is increasing evidence that age-related changes in the peripheral auditory system (e.g., cochlea) alone cannot adequately account for the wide range of auditory problems that accompany aging. For instance, some of the auditory deficits experienced by older adults remain even after controlling for differences in audiometric thresholds (Divenyi and Haupt, 1997). In addition, some older

individuals with near-normal sensitivity exhibit problems in speech discrimination (Middelweerd, Festen, and Plomp, 1990), whereas others with hearing loss receive little benefit from hearing aids despite the restoration of hearing thresholds to normal levels (Chmiel and Jerger, 1996). Moreover, hearing status does not always interact with age, suggesting that hearing impairment and age are independent sources contributing to many older listeners' difficulties with understanding speech (Gordon-Salant and Fitzgibbons, 2004).

Since reductions in hearing sensitivity fail to account completely for speech perception deficits, it is necessary to consider the additional possibility that the elderly may also suffer from impairment at one or more levels of the central auditory processing pathways. That is, the difficulties commonly observed in older individuals may in fact be related to age-related changes in the neural mechanisms critical for the perceptual separation of the incoming acoustic information to form accurate representations of our acoustic world, rather than simply the reception of a weak and noisy signal from the ear. Auditory scene analysis is one framework that guides our theorizing with respect to the putative mechanisms involved in age-related changes in auditory perception, providing novel insights about how our perception of the auditory world breaks down as a result of normal aging.

### Auditory Scene Analysis

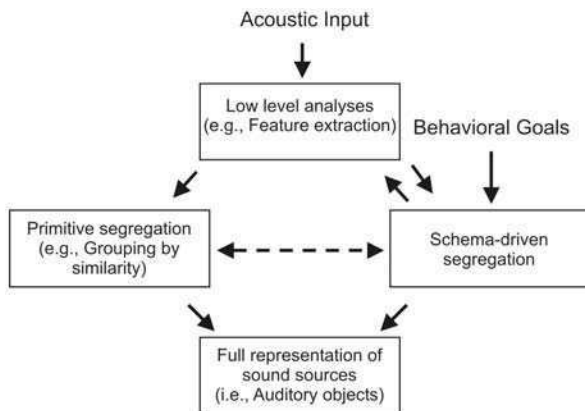

The root of the auditory scene analysis problem is derived from the inherent complexity of our everyday acoustic environment. At any given moment, we may be surrounded by multiple sound-generating elements such as a radio playing music, or a group of people speaking, with several of these elements producing acoustic energy simultaneously. In order to make sense of the environment, we must parse the incoming acoustic waveform into separate mental representations called auditory objects or, if they persist over time, auditory streams. The problem is compounded by the fact that each ear has access to only a single pressure wave that comprises acoustic energy coming from all active sound sources. The cocktail party problem, which is a classic example of speech perception in an adverse listening situation, can therefore be viewed as a real-world auditory scene analysis problem in which individuals must attempt to separate the various, simultaneously active sound sources while trying to integrate and follow a particular ongoing conversation over time. It should come as no surprise, therefore, that auditory perceptual organization is commonly described across two axes: organization along the frequency axis (i.e., simultaneous organization) involves the moment-to-moment parsing of acoustic elements according to their different frequency and harmonic relations; organization along the time axis (sequential organization) entails the grouping of successive auditory

events that occur over several seconds into one or more streams. Understanding how speech and other complex sounds are translated from the single pressure waves arriving at the ears to internal sound object representations may have important implications for the design of more effective therapeutic interventions. Moreover, it becomes essential to understand the effects of normal aging on listeners' abilities to function in complex listening situations where multiple sound sources are producing energy simultaneously (e.g., cocktail party or music concert) if we hope to provide treatments through which individuals can better cope with these changes and continue to have fulfilling auditory experiences.

Auditory scene analysis is particularly useful for thinking about complex acoustic environments because it acknowledges both that the physical world acts upon us as our perception is influenced by the structure of sound (i.e., bottom-up contributions), just as we are able to modulate how we process the incoming signals by focusing attention on certain aspects of an auditory scene according to our goals (i.e., top-down contributions). As for the inherent properties of the acoustic world that influence our perception, sounds emanating from the same physical object are likely to begin and end at the same time, share the same location, have similar intensity and fundamental frequency, and have smooth transitions and "predictable" auditory trajectories. Consequently, it has been proposed that acoustic, like visual, information can be perceptually grouped according to Gestalt principles of perceptual organization, such as grouping by similarity and good continuation (Bregman, 1990). Figure 64.1 shows a schematic diagram of these basic components of auditory scene analysis.

Many of the grouping processes are considered automatic or *primitive* because they can occur irrespective of a listener's expectancy and attention. Therefore, an initial stage of auditory scene analysis following basic feature extraction involves low-level processes in which fine spectral and temporal analyses of the acoustic waveform are employed so that distinct perceptual objects can be formed. However, the perception of our auditory world is not always imposed upon us. Our knowledge from previous experiences with various listening situations can influence how we process and interpret complex auditory scenes. These higher-level schema-driven processes involve the selection and comparison between current auditory stimulation and prototypical representations of sounds held in long-term memory. It is thought that both primitive and schema-driven processes are important for the formation of auditory objects, and these two types of mechanisms might interact with each other to constrain perceptual organization.

The auditory scene analysis framework allows for the act of listening to be dynamic, since previously heard sounds may lead us to anticipate subsequent auditory events. This is well illustrated by phenomena in which the

**Figure 64.1** Schematic representation of a working model of auditory scene analysis. This model postulates low-level analyses where basic sound features are processed such as frequency, duration, intensity, and location. Scene analysis can be divided into at least two modes: primitive (bottom-up) and schema-driven (top-down). Primitive processes, the subject of most auditory scene analysis research, rely on cues immediately provided by the acoustic structure of the sensory input. These processes take advantage of regularities in how sounds are produced in virtually all natural environments (e.g., unrelated sounds rarely start at precisely the same time). Schema-driven processes, on the other hand, are those involving attention, or are based on experience with certain classes of sounds—for example, the processes employed by a listener in singling out a familiar melody interleaved with distracting tones. Our behavioral goals may further bias our attention toward certain sound attributes or the activation of particular schemas depending on the context. In everyday listening situations, it is likely that both primitive and schema-driven modes are at play in solving scene analysis problems.

brain “completes” acoustic information masked by another sound, as in the continuity illusion (see Figure 64.2A).

In this illusion, discontinuous tone glides are heard as continuous when the silences are filled by noise bursts. In another example, missing phonemes can be perceptually restored when replaced by extraneous noise, and these effects occur primarily in contexts that promote the perception of the phoneme, suggesting that phonemic restoration may be guided by schema-driven processes (Repp, 1992).

With respect to speech and music, schemata are acquired through exposure to auditory stimuli; they are consequently dependent on a listener’s specific experiences. For instance, in speech processing, the use of prior context helps listeners to identify the final word of a sentence embedded in noise (Pichora-Fuller, Schneider, and Daneman, 1995). Similarly, it is easier to identify a familiar melody interleaved with distractor sounds if the listener knows in advance the title of the melody (Dowling, Lung, and Herrbold, 1987) or if they have been presented with the same melody beforehand (Bey and McAdams, 2002).

Even though the role of both bottom-up and top-down processes are acknowledged in auditory scene analysis, the

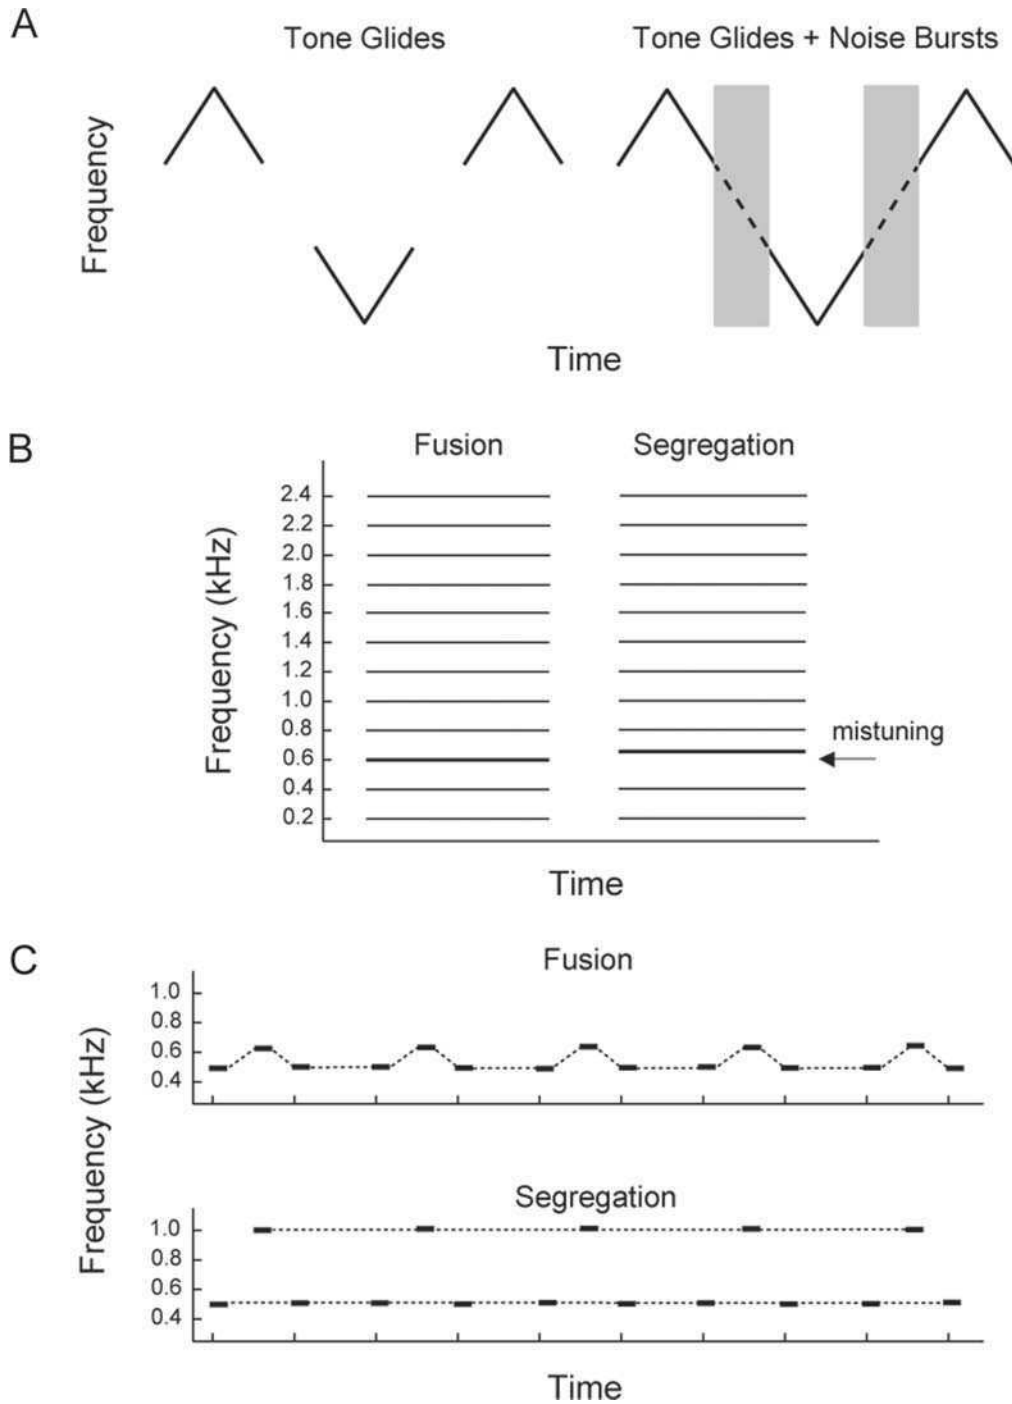

effects of age on these collective processes are not well defined. Yet, it is clear that deficits in both simultaneous and sequential sound organization would have dramatic consequences for everyday acoustic computations such as speech perception. For example, deficits in concurrent sound organization may result in the perceiver being unable to adequately separate the spectral components of the critical speech event from the background noise. A failure to segregate overlapping stimuli may also result in false recognition based on the properties of the two different sounds. For example, in dichotic listening procedures, which involve simultaneous presentation of auditory materials to the two ears, individuals presented with “back” in one ear and “lack” in the other ear often report hearing “black,” suggesting that acoustic components from two different sources may be “miscombined” into one percept (Handel, 1989). Moreover, difficulties in integrating acoustic information over time and maintaining the focus of auditory attention may further limit the richness of acoustic phenomenology, leading to problems in social interaction and an eventual retreat from interpersonal relations.

Although auditory scene analysis has been investigated extensively for almost 30 years, and there have been several attempts to characterize central auditory deficits in older adults, major gaps between psychoacoustics and aging research remain. The goal of this chapter is to assess the scene analysis framework as a potential account for age-related declines in processing complex acoustic signals such as speech and music. This review may assist in the development of more effective ways to assess and rehabilitate older adults who suffer from common types of hearing difficulty by evaluating the role of bottom-up and top-down processes in solving scene analysis problems. We now consider auditory scene analysis with respect to the initial parsing of the acoustic signal, before going on to discuss more schema-driven and attention-based mechanisms in audition. With respect to primitive grouping, this may be performed by segregating and grouping concurrently or sequentially presented sounds.

## Concurrent Sound Segregation

A powerful way to organize incoming acoustic energy involves an analysis of the harmonic relations between frequency peaks. Typically, an examination of the spectra for single sound sources in the real world reveals consistencies in the spacing of frequency peaks. For example, complex sounds with a distinct pitch (e.g., a voice or a chord) corresponding to a low fundamental frequency ( $f_0$ ) are accompanied by other higher frequencies that are multiples of the  $f_0$ . This is because frequencies emanating from the same source tend to be harmonically related to one another; that is, frequency peaks are approximately integer multiples of the  $f_0$ . If acoustic energy contains frequency elements that are not related to the dominant  $f_0$ , then it is likely that this portion of

**Figure 64.2 A.** Continuity illusion. Schematic representation of a repeated ascending and descending glide pattern interrupted by a brief gap (left panel). When the gaps are replaced by loud broadband noise (right panel), listeners reported hearing an ascending and descending glide pattern without interruption. That is, the brain appears to offer a good guess of what might be happening “behind” the noise. **B.** An example of concurrent sound segregation. Schematic representation of harmonic series comprised of 12 pure tones with a fundamental frequency at 200 Hz. When all the harmonics are integer multiples of the fundamental, observers report hearing one buzz-like sound (left panel). However, if one of the harmonics is mistuned by 4% or more of its original value, then listeners report hearing two sounds simultaneously, a buzz plus another sound with a pure tone quality. The arrow indicates the mistuned harmonic. **C.** An example of sequential sound segregation. The top and bottom sequences show five cycles of a three-tone pattern. When the frequency separation between the adjacent tones is small, most observers report hearing one stream of sound with alternating pitch and a galloping rhythm (indicated by the dashed line in the top panel). However, when the frequency separation is large, the three-tone pattern splits into two separate streams of sounds with constant pitch and an even rhythm. Each bar represents a pure-tone in the three-tone pattern.

acoustic energy belongs to a separate, secondary source. Hence, one way of investigating the effects of age on concurrent sound segregation is by means of the mistuned harmonic paradigm. Here, the listener typically is presented with two successive stimuli, one comprised entirely of harmonic components, and the other containing a mistuned harmonic (see Figure 64.2B). The task of the listener is to indicate which of the two stimuli contains the mistuned component. Several factors influence the perception of the mistuned harmonic, including the harmonic number in relation to the fundamental, and sound duration (Moore, Peters, and Glasberg, 1985). For example, thresholds for detecting inharmonicity are lower for long- than short-duration sounds.

In a different version of the mistuned harmonic paradigm, listeners are presented with complex sounds with either all tuned or one mistuned harmonic and indicate on each trial whether they hear a single complex sound with one pitch or a complex sound plus a pure tone, which did not “belong” to the complex. Using this more subjective assessment of listeners’ perception, it was found that when a low harmonic is mistuned to a certain degree (4% or more of its original value), listeners often report hearing two concurrent sounds (Alain, Arnott, and Picton, 2001; Moore, Glasberg, and Peters, 1986). The listeners’ likelihood of hearing two concurrent objects increases with the degree of inharmonicity and is greater for long- rather than short-duration (e.g., 100 ms or less) sounds. In terms of phenomenology, the tuned stimulus often sounds like a buzz with a pitch corresponding to the  $f_0$ , whereas the complex sound containing a low partial mistuned by 4% (or more) contains the buzz element plus a separate sound with a pure-tone quality at the frequency of the mistuned harmonic. Therefore, within the same burst of acoustic energy, two concurrent sounds can be perceived when one component of a complex sound is mistuned such that it is not an integer multiple of the  $f_0$ . In this regard, a sound that has a different fundamental from other concurrent sounds (i.e., the mistuned harmonic) might signal the presence of another object within the auditory scene such as a smoke alarm or a telephone ring. The auditory system is thought to achieve this type of perceptual organization by means of a pattern-matching process in which predictions regarding a potential harmonic series are made on the basis of the  $f_0$  (Lin and Hartmann, 1998). Acoustic energy is then filtered through this harmonic sieve or template, essentially separating out the tuned components from mistuned components. When a portion of acoustic energy is mistuned to a sufficient degree, a discrepancy occurs between the perceived frequency and that expected on the basis of the template, signaling to higher auditory centers that multiple auditory objects may be present within the environment. This early registration of inharmonicity appears to be independent of attention (Alain and Izenberg, 2003) and occurs in primary auditory cortex, the earliest stage of sound processing in the cerebral cortex (Dyson and Alain, 2004).

Difficulties in resolving harmonic relations may contribute to some of the speech perception problems experienced by older adults since the perception of a mistuned harmonic, like speech embedded in babble or noise, depends on the ability to parse auditory events based on their spectral pattern. Older listeners may have difficulty in detecting mistuning because auditory filters tend to broaden with age (Patterson, Nimmo-Smith, Weber, and Milroy, 1982). In terms of the harmonic template account, this would mean that inharmonic partials would have to be mistuned to a greater degree in order for segregation from the tuned components to occur, given that the harmonic filters in older adults allow for more frequencies to pass through the sieve as tuned components. Therefore, one prediction that the auditory scene analysis account makes is that older adults should exhibit higher thresholds in detecting a mistuned harmonic. Alain *et al.* (2001) tested this hypothesis using a two-interval, two-alternative forced-choice procedure in young, middle-aged, and older adults. Stimuli consisted of short (100 ms) or long (400 ms) duration sounds with either the second, fifth, or eighth harmonic tuned or mistuned. They found that older adults had higher thresholds for detecting a mistuned harmonic than young or middle-aged adults. This age-related increase in mistuning thresholds was comparable for the second, fifth, and eighth harmonic, but was greater for short- than long-duration sounds (see Figure 64.3) and remained significant even after statistically controlling for differences in audiometric threshold between age groups.

This indicates that age-related problems in detecting multiple objects as defined by inharmonicity do not solely depend on peripheral factors and must involve an age-related decline in central auditory functioning. In each group, a subset of participants also completed the

**Figure 64.3** Thresholds for detecting inharmonicity for 100 ms and 400 ms sounds in young (YNG), middle-aged (MA), and older (OLD) adults. The threshold for inharmonicity detection is expressed as percent mistuning. The error bars indicate standard error of the mean. Adapted and reprinted with permission from Alain, C. *et al.* (2001). Copyright 2001, Acoustical Society of America.

Speech In Noise (SPIN) test, which requires identifying the last word of a sentence embedded in multitalker babble. The SPIN threshold, estimated by calculating the signal-to-noise ratio at which participants correctly identify 50% of words, was higher in older adults than in young adults. The increased SPIN threshold in individuals who also showed deficits in detecting a mistuned harmonic is consistent with the hypothesis that age-related changes in processes critical for primitive sound segregation may contribute to the speech perception problems found in older adults.

We propose one possible explanation for the effect of concurrent sound segregation on eventual speech identification. Listeners who find it difficult to detect mistuning may assimilate one or more frequency components coming from secondary sound sources into the target signal. The inclusion of extraneous frequency components into the target signal would lead to subsequent errors in perception, given the blend of acoustic energy incorrectly conjoined at an earlier stage of processing. However, since previous investigations used a task that did not require participants to identify the frequency of the mistuned harmonic, it remains an empirical question whether the age-related increase in thresholds for detecting a mistuned harmonic contributes to speech identification problems. Furthermore, it is worth exhibiting caution when generalizing from relatively artificial sounds such as pure-tone complexes to over-learned stimuli such as speech sounds. For instance, perception of ecologically valid or over-learned stimuli may be less sensitive to aging because they are more likely to activate schema-based representations or allow the use of multiple redundant cues.

Another example of concurrent sound segregation that to some extent overcomes the artificiality of the mistuned harmonic paradigm is the double-vowel task. The additional benefits of this task are that it provides a more direct assessment of the effects of age on speech separation, and also evokes the processes involved in acoustic identification as opposed to detection. Here, listeners are presented with a mixture of two phonetically different synthetic vowels either having the same or different  $f_0$ , and are required to indicate which vowels were presented. Psychophysical studies have shown that the identification rate improves with increasing separation between the  $f_0$  of the two vowels (Assmann and Summerfield, 1994). In addition to this basic finding, Summers and Leek (1998) also reported an age effect, in that older individuals failed to take advantage of the difference in  $f_0$  between the two vowels and that age accounted for most of the variance in vowel identification performance. This effect of age was observed in both normal and hearing-impaired listeners, once again emphasizing the need to consider both deficits in peripheral and central auditory systems.

More recently, Snyder and Alain (2005) found that normal-hearing older adults had greater difficulty than

young adults in identifying two concurrently presented vowels and that older adults took more time to identify the nondominant vowel, especially when the difference between vowel  $f_0$  was small. However, it is unlikely that the age effects on accuracy during the task were due to general perceptual and cognitive decline because the young and older adults did not differ in identifying the dominant vowel within the acoustic blend. Rather, age effects on performance manifested themselves only when attempting to extract the nondominant vowel. Hence, it appears that age impairs listeners' ability to parse and identify concurrent speech signals. This effect of age on concurrent sound segregation suggests an impairment in performing a detailed analysis of the acoustic waveform and is consistent with previous research showing age-related declines in spectral (Peters and Moore, 1992) and in temporal (Schneider and Hamstra, 1999) acuity.

In everyday situations, it is fairly unusual to have concurrent sound objects emanating from the same physical location, as was the case in the vowel segregation study. Sounds that radiate from different physical sources are also likely to be coming from different directions, and the auditory system must decide whether several sound sources are active or whether there is only one sound source with the second source being generated by the first's reflection from nearby surfaces. Hence, in addition to spectral cues, directional cues alone or in conjunction with spectral and temporal cues can also be used to break apart the incoming acoustic wave into separate concurrent auditory objects. For example, early and now classical work has shown that increasing the spatial separation between two concurrent messages improves performance in identifying the task-relevant message (Cherry, 1953; Treisman, 1964). Another task that has been helpful in investigating a binaural advantage in sound segregation is the masking level difference paradigm, where a masking noise and a target signal are presented either at the same or at different locations. Typically, thresholds for detecting the signal decrease when it is presented at a different location than the masking noise, and the magnitude of this threshold reduction is termed the masking level difference (MLD). Pichora-Fuller and Schneider (1991) measured the MLD in young and older adults and showed that thresholds for detecting the signal (e.g., 500 Hz tone) was comparable in both groups when the target and the masking noise were presented at the same location. When binaural cues were introduced, both groups' thresholds decreased, although the magnitude of this threshold reduction was smaller in older than in young adults. Similar age-related differences have also been observed using speech sounds (Grose, Poth, and Peters, 1994). Hence, it appears that normal aging impairs the binaural processing necessary to effectively separate a target signal from masking noise (Grose, 1996; Warren, Wagener, and Herman, 1978). However, other studies using whole sentences embedded in noise rather than single brief targets failed to replicate

the age-related decline in MLD (Helfer, 1992), suggesting that environmental support provided by whole sentences may alleviate age differences in binaural processing. In other words, older adults may compensate for deficits in binaural processing by calling upon schema-driven processes in order to solve the scene analysis problem.

The findings reviewed in this section indicate that the aging brain exhibits difficulty in parsing and identifying concurrent auditory events. This age-related decline in concurrent sound segregation remains even after controlling for age difference in hearing sensitivity. Older adults appear to have difficulty in using both spectral and directional cues in solving the scene analysis problem, indicating general rather than specific deficits in concurrent sound segregation. Further research is needed to clarify the link between spectral and temporal acuity and the age-related decline in concurrent sound segregation. We now turn to the effects of age on sequential sound organization.

### Sequential Sound Segregation

A second form of primitive grouping takes place along the time axis, and auditory streaming acts as a striking psychophysical demonstration of how sequential sound segregation works (see Figure 64.2C). In a typical experiment, participants are presented with ABA—ABA—sequences in which A and B are sinusoidal tones of different frequencies and — is a silent interval. The frequency separation between the A and B tones is manipulated to promote either the perception of a single gallop-like rhythm (ABA— ABA—) or the perception of two distinct perceptual streams (A—A—A—A— and B—B—). Listeners are required to indicate when they can no longer hear the two tones as separate streams, but instead hear a single galloping rhythm. The fusion or coherence boundary refers to the frequency separation where individuals perceive a single stream of sounds with a galloping rhythm, whereas the fission or segregation boundary refers to the point where listeners can no longer hear the galloping rhythm and report hearing the sounds as coming from two separate sources. The area between the fusion and fission boundaries is typically ambiguous and leads to a bistable percept in which listeners' perception alternates between hearing the sounds with a galloping rhythm or hearing two concurrent streams. Using such a paradigm, Mackersie, Prida, and Stiles (2001) observed only a tendency for older listeners to have increased threshold at which the single stream became two streams. This weak relationship between fission threshold and age may be related to a lack of power given that only five participants with normal hearing formed the sample. However, Mackersie *et al.* also reported a strong relationship between fusion threshold and simultaneous sentence perception, suggesting that sequential sound segregation does play an important role in higher auditory and cognitive functions. Rose and Moore (1997) showed that

bilaterally hearing-impaired listeners required greater frequency separation than normal hearing listeners for stream segregation to occur. Moreover, the impact of hearing loss on sequential stream segregation has been observed in a number of other studies using a similar paradigm to that of Rose and Moore (Grimault, Michey, Carlyon, Arthaud, and Collet, 2001; Mackersie, Prida, and Stiles, 2001). These changes in sequential stream segregation for hearing-impaired listeners and older adults with normal hearing may once again be related to a broadening of auditory filters, in that wider frequency regions are processed in the same frequency channels (i.e., grouped together) in the older individuals. However, Mackersie *et al.* (2001) and Rose and Moore (1997) did not find a significant relationship between stream segregation and frequency selectivity. Furthermore, Stainsby, Moore, and Glasberg (2004) showed that older hearing-impaired listeners could segregate sounds using temporal cues and suggested that stream segregation does not depend solely on the frequency resolution of the peripheral auditory system. Thus, it appears that both place and temporal coding of acoustic information contribute to sound segregation and that although older adults with either normal or impaired hearing can segregate sequential acoustic information, they nevertheless show a tendency to report hearing only one perceptual stream.

One limitation of these studies, however, was that the effects of age on sequential stream segregation were assessed using subjective reports only. Other studies using more objective measures of auditory streaming suggest that aging per se may have little impact on sequential stream segregation. For example, Alain, Ogawa, and Woods (1996) used a selective attention task to examine the effects of age on auditory streaming. Young and older adults with normal hearing were presented with four-tone patterns presented repetitively at a high rate for several minutes. Participants were asked to focus their attention on either the lowest or highest frequency in order to detect infrequent changes in pitch (i.e., targets). In one condition, the frequencies composing the pattern were equally spaced at three semitone intervals along the musical scale (e.g., 1000, 1189, 1414, and 1682 Hz). In another condition, the two middle frequency sounds were clustered with the lowest and highest frequency, respectively (1000, 1059, 1587, and 1682 Hz). Frequency clustering was expected to favor auditory streaming because sounds that are near one another in frequency tend to be perceptually grouped with one another. Alain *et al.* found that accuracy as well as response time to targets improved in situations that promoted auditory stream segregation. Although older adults were overall slower than young adults, the effects of streaming on accuracy and response time were comparable in both age groups, suggesting that aging has little impact on sequential sound segregation when assessed by objective measures such as reaction time and accuracy.

Additional aspects of sequential sound segregation in older adults were explored by Trainor and Trehub (1989). Here, temporal order judgments were measured across age groups for sequences of tones presented at various speeds and in various contexts designed to encourage or discourage stream segregation. Participants were exposed to alternating frequency patterns and asked either to identify the order of the stimuli or to make same/different judgments. They found that older adults were less able than young adults in distinguishing between tone sequences with contrasting order, regardless of the speed of presentation, nature of the task (identification vs. same/different), amount of practice, or the frequency separation of the tones. Therefore, these findings are consistent with a temporal sequencing impairment in older listeners, but do not suggest age differences in streaming processes.

Although the putative central acoustic deficits associated with aging do not appear to have an effect on sequential sound segregation per se, sensory hearing loss does appear to impair listeners' ability to separate out sequentially occurring stimuli. These findings should be interpreted with caution, however, as the sample size in each age group tends to be relatively small in the case of the gallop paradigm, whereas the other tasks used (i.e., the selective attention task and judgment order task) may not have been optimal to assess auditory streaming. Moreover, a direct link between these age-related changes and the speech perception problems of older adults has yet to be established since the relation between task performance and speech perception has not been fully explored. The Trainor and Trehub, (1989) study reminds us that although older adults appear to show no deficit in segregating multiple acoustic streams, the integration of any one particular stream over time may be a problem for the elderly.

### **Schema-Driven and Attention-Dependent Processes**

Current models of auditory scene analysis postulate both low-level automatic processes and higher-level controlled or schema-based processes (Alain and Arnott, 2000; Bregman, 1990) in forming an accurate representation of the incoming acoustic wave. Whereas automatic processes use basic stimulus properties such as frequency, location, and time to segregate the incoming sounds, controlled processes use previously learned criteria to group the acoustic input into meaningful sources and hence require interaction with long-term memory. Therefore, in addition to bottom-up mechanisms, it is also important to assess how aging affects top-down mechanisms of auditory scene analysis.

The use of prior knowledge is particularly evident in adverse listening situations such as a cocktail party scenario. For example, a person could still laugh in all the

right places at the boss's "humorous" golfing anecdote as a result of having heard the tale numerous times before, even though only intermittent segregation of the speech is possible (indeed, the adverse listening condition in this example may be a blessing in disguise). In an analogous laboratory situation, a sentence's final word embedded in noise is more easily detected when it is contextually predictable (Pichora-Fuller, Schneider, and Daneman, 1995), and older adults appear to benefit more than young adults from contextual cues in identifying the sentence's final word (Pichora-Fuller, Schneider, and Daneman, 1995). Since words cannot be reliably identified on the basis of the signal cue alone (i.e., without context), stored knowledge must be applied to succeed. That is to say that the context provides environmental support, which narrows the number of possible alternatives to choose from, thereby increasing the likelihood of having a positive match between the incoming sound and stored representations in working and/or longer-term memory. There is also evidence that older adults benefit more than young adults from having words spoken by a familiar than unfamiliar voice (Yonan and Sommers, 2000), suggesting that older individuals are able to use learned voice information to overcome age-related declines in spoken word identification. Although familiarity with the speaker's voice can occur incidentally in young adults, older adults need to focus attention on the stimuli in order to benefit from voice familiarity in subsequent word identification tasks (Church and Schacter, 1994; Pilotti, Beyer, and Yasunami, 2001). Thus, schema-driven processes provide a way to resolve perceptual ambiguity in complex listening situations, and, consequently, older adults appear to rely more heavily on controlled processing in order to solve the scene analysis problem.

Musical processing provides another real-world example that invokes both working memory representations of current acoustic patterns and long-term memory representations of previous auditory structures. Evidence suggests that young and older adults perform equally well in processing melodic patterns that are presented in a culturally familiar musical scale, whereas older adults perform worse than young adults when the patterns are presented in culturally unfamiliar scales (Lynch and Steffens, 1994). The age difference in processing melodic patterns from unfamiliar cultural contexts again suggests that older adults may rely more heavily on long-term knowledge of musical grammar than young adults. This age effect may be related to impairment either in the processing of ongoing melodic patterns and/or working memory given that a long-term representation of the unfamiliar melodic structure is unavailable. Other studies have shown that aging impairs listeners' ability to recognize melodies (Andrews, Dowling, Bartlett, and Halpern, 1998), and this age-related decline is similar for musicians and nonmusicians (Andrews, Dowling, Bartlett, and Halpern, 1998), suggesting that musical training does not necessarily alleviate age-related decline

in melodic recognition. The use of musical stimuli in aging research offers a promising avenue for exploring the role of long-term representation and its relation with schema-driven processes involved in solving the scene analysis problem. Moreover, tasks involving musical stimuli are likely to be more engaging for participants than tasks using typical laboratory stimuli (e.g., white noise, pure tones, harmonic series) that may be less pleasant to listen to for extended periods of time. Furthermore, the results possess a higher degree of ecological validity in terms of everyday, meaningful acoustic processing.

### Methodological Issues

In reviewing the preceding literature, a number of methodological procedures suggest themselves for future research on aging and auditory scene analysis. First, and somewhat obvious, it is essential that participants be screened for hearing impairment in both ears. In particular, the integrity of the cochlea should be assessed in a more comprehensive way than just measuring pure tone thresholds in an effort to dissociate nonthreshold-changing peripheral deficits from true central deficits in auditory processing. One test that could provide some information is a distortion-product otoacoustic emission (OAE). Although outer hair cells must be functioning to some degree in order to measure normal thresholds, OAEs are a more sensitive measure of outer hair cell health than pure-tone audiometry and may prove useful in assessing cochlear damage in general. Another potentially useful test would be fine-scale audiometry, which consists of obtaining thresholds with a greater degree of frequency resolution. This method can provide evidence for hearing changes that are not reflected in octave-wide measurements. There are obviously a number of deficits that cannot be easily accounted for by any peripheral problems, but the age-related problems in a wide range of auditory tasks might be accounted (at least partly) by peripheral degradation. Distortion-product OAE assessment might be useful in addressing this issue since it is readily available (and fast), and because it is generally accepted as a sensitive measure of cochlear integrity.

Whenever possible, speech discrimination scores should also be obtained for each ear. Given that the nature of auditory scene analysis research can often rely upon somewhat artificial stimuli, the acquisition of SPIN test scores (or another comparable test) becomes critical. This allows the researcher to establish a correlation between performance in experimental tasks thought to tap into the operation of low-level acoustic mechanisms and speech comprehension in noise, which is an important end product of auditory scene analysis. Also, since musical expertise is likely to influence auditory scene analysis, participants should be asked about the duration of any musical training, and groups should be matched for musical training and listening habits. All of this should be in addition to using standard exclusion screening

criteria such as neurological or psychiatric illness and drug or alcohol abuse.

It is well recognized that hearing sensitivity diminishes with age, especially in the high frequency range. Despite screening for hearing impairment, it is not uncommon to find residual differences in hearing thresholds between young and old adults. Hence, several steps should be taken to dissociate the contribution of age-related changes in peripheral processing from those in central auditory processing. First, stimuli should be presented at a suprathreshold level (e.g., 80 dB sound pressure level) rather than at a given intensity increment above hearing threshold. This approach controls for loudness recruitment associated with sensorineural hearing loss (Moore, 1995). Second, stimuli generated using the lower frequency range should be used wherever possible as presbycusis affects primarily higher frequency signals. Third, analyses of covariance should be performed using participants' audiometric levels (pure tone and speech reception thresholds) as covariates to adjust for the contribution of age-related changes in hearing thresholds on behavioral measurements. Whenever possible, three or more age groups should be tested, thereby enabling the examination of when specific maturation processes begin, as well as observing differences in the rate of changes across the various age groups. Such experimental design considerations provide information that goes beyond merely identifying areas where older people perform worse than young people. Taken as a whole, the proposed research strategy provides a means to assess central auditory processing while taking into account differences in hearing thresholds.

### Conclusion

Our auditory environment is inherently complex. Hence, it should not come as a surprise that successful identification of simultaneous and sequentially occurring acoustic events depends on listeners' ability to adequately parse sound elements emanating from different physical sounds, and at the same time, combine those arising from a particular source of interest across time. Solving this problem involves low-level mechanisms that take advantage of physical properties in the acoustic environment as well as high-level mechanisms that take advantage of our knowledge about the auditory world. The evidence reviewed in this chapter indicates that aging impairs listeners' ability to parse concurrent sounds based on both spectral and directional cues. Further research is nevertheless needed to clarify the link between age-related decline in low-level sound segregation and higher-level processes such as the perception of speech in noise. It is also unclear whether extended training could be used to alleviate some of the age effects on simultaneous sound and speech separation.

The robust and reliable age-related decline in concurrent sound segregation contrasts with the more subtle

age effects observed in sequential sound segregation. An important difference between concurrent and sequential sound segregation is that the former relies on a more precise temporal and frequency representation. The studies reviewed in this chapter suggest that the likelihood of deficits in auditory stream segregation increases with hearing loss, in that the greater the hearing loss the less likely the individual perceptually segregates the incoming stimuli into two distinct streams of sounds. This suggests that sequential sound segregation involves a relatively coarse temporal and frequency representation, which may be more resilient to the aging process than concurrent sound segregation.

We propose that speech and music perception can be viewed as complex auditory scene analysis problems that engage both low-level and schema-driven processes. It is likely to be the interaction between low-level and high-level mechanisms that lead to successful speech identification in adverse listening situations since primitive grouping mechanisms alone are not sufficient to fully account for perceptual organization of speech (Remez, Rubin, Berns, Pardo, and Lang, 1994). In solving the scene analysis problem, older adults appear to rely more on schema-driven than on low-level processes. Although knowing what to listen for helps both young and older adults, older adults appear to benefit the most from prior learning in understanding their acoustic environment. Once again, these results leave many questions unanswered, and therefore further research is needed to understand the extent to which schema-driven processes are affected by age. Nevertheless, by using the scene analysis framework scientists can bridge various areas of aging and hearing research that encompass signal detection and the formation of more abstract representations of our auditory environment. Only by considering both bottom-up and top-down influences, as the current framework allows us to do, may we arrive at a complete picture as to how the auditory scene changes as a function of aging.

# Models of Immune Function in Aging

Christopher A. Jolly and Zhun Xu

*The most prevalent rodent models used in aging research are relatively healthy long-lived rats and mice and short-lived mice. The short-lived mice typically spontaneously develop a particular disease or are genetically altered. This review focuses on the most prevalent disease model, the autoimmune-prone mouse, to study the impact of diet on aging. The benefit of these mice is that their life span is half that of the long-lived strains, allowing for data to be generated faster. Specifically, evidence showing the beneficial effects of feeding calorie restriction, omega-3 fatty acids, and combining calorie restriction with omega-3 fatty acid feeding is discussed. Overall, the published data support the observation that the combination of calorie restriction and omega-3 fatty acid feeding is the most beneficial at delaying the onset of autoimmune disease in mice. In order to properly extrapolate this data to humans, the differences in T and B cell immunology between humans and rodents are examined. The most common effect of aging seen in both humans and rodents is thymic involution and reduced peripheral T cell proliferation ex vivo. However, significant differences do exist between humans and rodents in lymphocyte development and plasma membrane receptor expression. Finally, the potential use of these autoimmune-prone mice as a model of chronic inflammation to study the impact of diet on heart disease is discussed.*

## Introduction

One of the most prevalent questions that people ask is whether disease causes aging, or aging causes disease. Disease does not cause aging because even the healthiest people will ultimately die. However, diseases can dramatically shorten life span. Aging, on the other hand, can increase the prevalence or likelihood of developing disease because there has simply been more time in older animals for cellular and molecular changes to occur. Thus, understanding both the biological process of aging and diseases that are more prevalent in the elderly are important areas of research in the aging field. The predominant model used to study aging historically has been rodents (rat and mice), especially those referred to as long-lived. These rodents live approximately 24 months and oftentimes do succumb to disease, but

death occurs much closer to their natural maximal life span. Alternatively, short-lived strains of mice are becoming more popular primarily because they live for a year or less, and biological elements that are thought to impact aging can be tested faster. There are primarily two types of mice used as short-lived mice in aging research: genetically altered mice, which have a defect in the expression of a specific gene thought to be important in aging; and mouse strains that spontaneously develop autoimmune diseases that dramatically reduce their life span. This review will focus on discussing the current uses and findings of short-lived autoimmune-prone mice. The two most prevalent autoimmune-prone mouse strains that have been examined are the (NZBxNZW)<sub>F1</sub> and MRL/Lpr mice. These mice serve as excellent models for examining human autoimmune diseases like Sjogren's Syndrome and Systemic Lupus Erythematosis (Fernandes and Jolly, 1998). As we also will discuss, these mice serve as models of chronic inflammation, making them a valuable model to the study of inflammation-linked diseases like heart disease.

## Compare/Contrast Rodent Versus Human Immune Function

### LYMPHOID TISSUES

The human and mouse diverged over 50 million years ago; however, the major components of the lymphoid tissues are almost identical. The primary or central lymphoid organs include the bone marrow and thymus where B cells and T cells are generated, respectively. The secondary or peripheral lymphoid organs include the lymph nodes (LN), spleen, and lymphoid tissues associated with mucosa where B cells and T cells are activated to generate the adaptive immune response. Although the overall structure of the LNs are similar between humans and mice, humans have significantly larger numbers of LNs than the mouse (Haley, 2003). This is most likely due to the fact that a human is physically larger than a mouse; therefore more LNs are required in the human. In contrast to LNs, the mouse spleen has some anatomical and structural differences when compared to the human spleen. For example, the periarteriolar lymphocyte sheath and the marginal zone can be found only in the rodent (Sternberg, 1997), and the endothelial cells in human spleen

that surrounds the vascular sinuses are missing in the mouse (Haley, 2003). A major difference between the human and mouse spleen is that mouse spleen has hematopoietic activity, whereas the healthy human spleen does not (Cotterell *et al.*, 2000). However it should be kept in mind that the mouse spleen is not the main source of hematopoiesis. The rat, on the other hand, has a much lower amount of hematopoietic activity in the spleen than the mouse, and thus more closely models the human spleen (Fujitani *et al.*, 2004). The rodent and human also differ significantly in the bronchus-associated lymphoid tissue (BALT), which is not discernible in humans but is readily identifiable in the mouse and rat (Pabst and Gehrke, 1990). Peripheral blood immune cell composition also differs between humans and mice. Human blood contains more neutrophils (50–70%) than lymphocytes (20–40%), whereas mouse blood has a higher percentage of lymphocytes (50–70%) relative to neutrophils (15–20%) (Pabst and Gehrke, 1990).

## B CELLS

Overall, early B cell development is similar in humans and mice (Burrows and Cooper, 1997). Defined by the rearrangement of the immunoglobulin (Ig) genes, a hematopoietic stem cell in bone marrow undergoes the early pro-B cell stage, late pro-B cell stage, pre-B cell stage, and finally becomes an immature B cell (Burrows and Cooper, 1997). The most striking difference occurs at the molecular level in the signaling control of the pre-B cell receptor (pre-BCR) stage (Conley *et al.*, 2000). For example, more than 75% of the human genetic disorders in B cell development are due to the mutation in Bruton's tyrosine kinase (Btk) (Conley *et al.*, 1998) with clinical manifestations such as repeated bacterial infections, hypogammaglobulinemia, and less than 1% of normal B-cell numbers in the periphery. Molecular research of this disease, named X-linked agammaglobulinemia (XLA) (Campana *et al.*, 1990) is characterized by the inability to produce immunoglobulins (Igs) of all isotypes. In contrast, the mouse model of Btk mutation, Xid mouse (X-linked immunodeficiency) is still semi-competent in antibody (Ab) production and has almost half the normal B cell numbers and only low concentrations of IgM and IgG3 (Wicker and Scher, 1986). This difference appears to be due to the observation that Btk in humans controls B cell development at the point of transition from pro-B cell to pre-B cell (Campana *et al.*, 1990), whereas in mice it seems that Btk plays a role only after the immature B cell stage is reached (Kerner *et al.*, 1995). Interleukins (IL) -2, IL-4, IL-7, IL-9, and IL-15 receptors share a common signal transducing chain— $\gamma_c$  (Cao *et al.*, 1995). Mutation in the  $\gamma_c$  chain blocks both T and B cell development in mice. In contrast, patients with X-linked severe combined immunodeficiency (XSCID) disease caused by a  $\gamma_c$  mutation have normal B cell development and are deficient in T cell development (Cao *et al.*, 1995). Thus, humans and mice show a

different requirement for IL-7 in B cell differentiation (Prieyl and LeBien, 1996).

Mature B cells are heterogeneous, and distinct B cell populations have unique receptor expression profiles and functional repertoire. For example, the CD5 receptor, an antigen (Ag) receptor adaptor protein, is critical in the regulation of autoimmunity in B-1 cells (Hayakawa and Hardy, 2000). Studies in humans suggested that (1) CD5 and CD23 are exclusively expressed on murine B cells, whereas co-expression of CD5 and CD23 on human cord blood B cells is normal (Gagro *et al.*, 2000); (2) in humans, CD5<sup>+</sup> and CD5<sup>-</sup> B cells have an indistinguishable response to *in vivo/in vitro* stimulation in regard to the expressional change of CD5 and CD23 (Gagro *et al.*, 2000); and (3) CD40, together with BCR co-stimulation, can increase CD5 expression and at the same time down-regulate CD23 expression in humans. However, in mice, CD40 will decrease CD5 expression but enhance CD23 expression, and surface IgM cross-linking can induce the CD5 expression (Gagro *et al.*, 2000; Wortis *et al.*, 1995). The plasma cell is the terminal differentiation stage in B cell development. One of the characteristics of human plasma cells is high CD38 receptor expression. Lower levels of CD38 are also found on B cells located in germinal centers so CD38 expression is used as marker of B cell activation and differentiation (Mainou-Fowler *et al.*, 2004). This criterion is not applicable to the mouse model since CD38 expression remains high until the B cell is activated and moves into the germinal center where CD38 expression is totally absent in plasma cells (Oliver *et al.*, 1997). Humans and mice also differ in the isotypes of Abs produced (Haley, 2003). Most notably, rats do not produce IgA, and there are additional differences in the organization and regulation of IgG subclasses. Structurally, no homologues of human IgG subisotypes can be found in mouse or rat. Functionally, an important role of human IgG is opsonization, whereas in the rat IgG<sub>1</sub> can mediate the uptake of pathogens by binding to complement, and mouse IgG<sub>1</sub> is involved in hypersensitivity reactions (Haley, 2003).

## T CELLS

Similar to B cell development, T cell development undergoes several stages and can be followed by the combined expression of specific cell-surface receptors. Certain cell-surface markers have different expression patterns in humans and mice. For example, Thy-1, an Ig-like glycoprotein, is present on both thymocytes and peripheral T cells in mice but only on rat thymocytes (Tokugawa *et al.*, 1997). In humans, Thy-1 expression is found only on stem cells and disappears from thymic progenitors. Thus, Thy-1 is used as a stem cell marker in humans, but as a T-cell marker in mice (Spits *et al.*, 1998). With the exception of some species-specific cell-surface receptors (CD44 and CD25) to indicate T cell differentiation stages in the mouse, the major features of T cell development are similar in humans and mice. One striking

difference between human and mouse T-cells is the expression of the CD8 $\alpha$  and CD8 $\beta$  isoforms (Spits *et al.*, 1998). These CD8 receptor isoforms can appear as homodimers or heterodimers on T cells. Furthermore, interaction with the CD8 receptor and MHC I on thymic cortical epithelial cells is important for T cell development in the thymus. The double positive (DP) (i.e., expressing both CD4 and CD8 receptors) T cells in the thymus are positively selected based on functionality of CD4 and/or CD8. In mice, 60% of CD8 $\alpha$  is normal, being able to bind to p56<sup>LCK</sup>, whereas the other 40% is an isoform (CD8 $\alpha'$ ) resulting from alternative splicing. CD8 $\alpha'$  has a short cytoplasmic domain preventing interaction with p56<sup>LCK</sup> (Zamoyska and Parnes, 1988). This truncated CD8 $\alpha'$  isoform is not generated in humans or rats; thus, the balance of CD4<sup>+</sup> and CD8<sup>+</sup> mature T cell populations in the periphery may be different between humans, rats, and mice (Barber *et al.*, 1989; Zamoyska and Parnes, 1988). The integrated work of other genes that activate specific transcription factors at different stages is essential to T cell development. Zap-70, a protein tyrosine kinase (PTK), is critical in signaling pathways initiated by T cell receptor (TCR) engagement. In Zap-70 knockout mice, T cell differentiation is stopped at CD4<sup>+</sup> CD8<sup>+</sup> DP stage; in humans, Zap-70 defects lead to SCID. Patients with SCID express CD4<sup>+</sup> T cells with defective function. These studies indicate that Zap-70 is a key element for both CD8<sup>+</sup> and CD4<sup>+</sup> T cell development in mice but is required only for CD8<sup>+</sup> T cell development in humans. This difference in humans may be due to the PTK, Syk, which can partially compensate for Zap-70 function in human T cell development. Syk expression is higher in human T cells when compared to mouse T cells (Chu *et al.*, 1999; Elder *et al.*, 2001).

Optimal activation of mature T cells requires two signals. The first (mandatory) signal involves stimulation of the Ag-specific TCR/CD3 complex. The second costimulatory signal is derived from various other receptors on the T cell. To date, the CD28 receptor is the best studied costimulatory signal. The CD28 receptor on T cells is activated by interacting with B7-1 receptors on antigen presenting cells, and there are several differences in the B7-CD28 family's expression and function in humans and mice. First, CD28 is expressed on almost all mouse CD4<sup>+</sup> and CD8<sup>+</sup> T cells, but only 80% on human CD4<sup>+</sup> and 50% on human CD8<sup>+</sup> T cells (Lenschow *et al.*, 1996). Second, ICOS deficiency in mice causes deficient B cell reactivity and Ig isotype switching, which can be reversed by CD40 stimulation (Wang and Chen, 2004). In humans, the ICOS mutation alters B cell development resulting in decreased B cell numbers and no memory B cells (Wang and Chen, 2004). Since ICOS has proven to be required for proper T helper cell function (Wang and Chen, 2004), ICOS may have different effects on T helper cell function to regulate B cell differentiation, Ig isotype switching, and generation of memory B cells. The biggest difference of the B7-CD28 family between humans and

mice exists in the function of the B7-H3 receptor. In humans, it functions to enhance the T cell response, but in mice, it inhibits T cell activation and subsequent cytokine generation (Prasad *et al.*, 2004). Since the members of the B7-CD28 family have multiple functional consequences on T cell function, homeostatic T cell function can be maintained by altering the expression levels of these receptors in response to various stresses and stimuli.

Another interesting difference between human and mouse T cells is the expression of MHC-II. Normally, MHC-II molecules are expressed on professional Ag presenting cells (APCs) and function to present Ag peptide to CD4<sup>+</sup> T helper cells initiating an Ag-specific immune response. MHC-II is also expressed on human T cells following T cell activation and its synthesis is regulated by the class II transactivator (CIITA) using the CIITA promoter III (CIITA-PIII). In contrast, MHC-II receptors are not found on activated mouse T cells most likely because CIITA-PIII is methylated, preventing CIITA transcription (Holling *et al.*, 2004). It is currently thought that MHC-II bearing T cells can work like APCs to process and present exogenous Ag to other T cells. It is not clear whether the antigen presenting function of human T cells results in increased T cell activation, clonal anergy, or apoptosis (Holling *et al.*, 2004).

Once the TCR is engaged, TCR $\xi$  and CD3 chains are phosphorylated immediately, which consequently activates the Src and Syk PTK family kinases and a cascade of adaptor and effector proteins, ultimately resulting in cytokine production and cell proliferation. One of the key pathways involved in human T cell activation is the PKC-dependent activation of the phosphatidylinositol (PI) pathway, which can increase the Ca<sup>2+</sup> concentration by releasing Ca<sup>2+</sup> from intracellular stores, and increase the transmembrane influx of Ca<sup>2+</sup> from outside the cell at the expense of K<sup>+</sup> efflux, which is regulated by K<sup>+</sup> channels. In contrast, these K<sup>+</sup> channels are not present in mouse T cells (Koo *et al.*, 1997), suggesting that their ionic concentrations are regulated differently.

Stimulation of CD4 helper T cells results in their differentiation into either Th1 or Th2 cells, which are phenotypically identified based upon their cytokine production profile. This differentiation process is controlled by the strength of Ag stimulation, the cytokine micro-environment, and B-7 receptor family costimulation. IFN- $\alpha$  can induce CD4<sup>+</sup> T cell differentiation toward a Th1 phenotype as well as the activation of STAT4 cascade in humans, but fails to do so in mice. This is mainly because an adaptor protein involved in the IFN- $\alpha$  receptor complex, STAT2, has a different C-terminal in the human and mouse, resulting in mice not being able to transduce the stimulatory signal to STAT-4 (Farrar *et al.*, 2000). In contrast, TCR stimulation plus IL-10 is sufficient to induce Th1 differentiation in the mouse CD4<sup>+</sup> T cells, but has little effect on human CD4<sup>+</sup> T cells

(Battaglia *et al.*, 2004). The immunosuppressive cytokine IL-10 is secreted by mouse Th2 cells, but it is secreted by both Th1 and Th2 T cells in humans (Del Prete *et al.*, 1993). This indicates that, in humans, the Th1/Th2 classification based on their cytokine production is less clear and exclusive.

Recently, data has emerged showing that a new type of regulatory T cell exists in addition to the Th-1/Th-2 subsets. The CD4<sup>+</sup>CD25<sup>+</sup> regulatory T cell (T-reg) is a T cell subset expressing both CD4 and IL-2R $\alpha$  on its surface, and requires only low levels of TCR and IL-2 signals to respond robustly. The function of T-reg cells is unique and important to T cell activation. It can suppress the activation of CD4<sup>+</sup>CD25<sup>-</sup> T cells, CD8<sup>+</sup> T cells, natural killer (NK) cells, and negatively regulate cytokine production by target cells. The amount and surface phenotype of T-reg cells are different between humans and mice. In mice, CD25 expression is relatively high and about 10% of CD4<sup>+</sup> T cells are T-reg cells, whereas in humans, CD4<sup>+</sup>CD25<sup>high</sup> occupies only 2 to 4% of CD4<sup>+</sup> T cells. Some other cell surface receptors expressed on mouse T-reg cells like CD62L and CD38 are absent in human T-reg cells as well. The activity of T-reg cells is important in autoimmune disease; thus, differences in CD25 expression in humans and mice may result in quantitative differences in stopping the activity of T cells bearing self-Ag (Baecher-Allan *et al.*, 2004).

### Comparison of Rodent Aging and Human Aging

A hallmark of aging in both humans and rodents is thymic involution or decrease in thymic mass. Although this suggests that the ability of the thymus to produce new naïve T-cells decreases in combination with decreased progenitor production in the bone marrow, it would be predicted that peripheral T-cell numbers should decline with age. However, the impact on peripheral T-cell number appears to be minimal. This may be due to clonal expansion of mature memory and naïve T-cells in the periphery. The spleen is one of the major secondary lymphoid tissues, and aging appears to reduce germinal center (GC) size by as much as 90%, as determined based on size and cellularity. The decrease in GC size, which may result in decreased B cell activation and subsequent proliferation, may be responsible for the decrease in plasma B cells. Recent evidence demonstrated that the decline in proliferation in the GC is due to the lack of costimulatory signals provided by T cells located in the surrounding tissue (Zheng *et al.*, 1997).

Aging also results in dysregulated humoral immunity, which may be due to defects in B cells directly and T cell help indirectly. Two problems in B cell development have been found in aged mice. First, the generation of pre-B cells from pro-B cells is two-fold less in aged mice (Klinman and Kline, 1997), which may be due to decreased RAG gene expression in B cell precursors

(Ben-Yehuda *et al.*, 1994). Second, the generation of sIgM<sup>+</sup> B cells from sIgM<sup>-</sup> B cells is reduced by aging. The net result is an accumulation of sIgM<sup>-</sup> B cells and subsequent reduction in mature B cell formation. Altogether, the rate of mature B cell generation is only 20% in old mice as compared to young mice (Klinman and Kline, 1997). However, the total peripheral B cell number is normal in aged mice, which may be due to a slower turnover rate (i.e., longer lifespan) of mature B cells in the aged (Klinman and Kline, 1997). B cells that do reach maturity in aged mice also have defects. For example, some aged B cells have defects in Ig gene rearrangement, specifically V gene repertoire formation, which has been shown to result in hyper B cell reactivity to phosphorylcholine (Riley *et al.*, 1989). The net result of these age-associated defects in B cell development is a decreased response to foreign antigen and a shift from IgG to IgM predominance (LeMaoult *et al.*, 1997). Paradoxically, autoantibody production increases in old mice and humans. This may be due to the indirect actions of the help B cells receive from autoreactive T cells that may be increased with age (Klinman and Kline, 1997; LeMaoult *et al.*, 1997).

Although in both humans and mice, the total number of peripheral T cells doesn't change significantly with age, a decrease in T cell subpopulations does occur. Commonly, a decrease in naïve T cell numbers and a concomitant rise in memory T cells are seen in aged rodents and humans. The increase in memory T cell proportions correlates with reduced polyclonal T cell proliferation *ex vivo* in response to a wide variety of mitogens like anti-CD3 and concanavalin A in humans and rodents. Two major changes in aged T cells have been found in humans, which may explain the reduced proliferation. First, CD28 receptor expression is decreased on human, but not rodent, T cells. Approximately 99% of the T cells from newborn humans express CD28, which decreased to 85% in adults and further decreases with age to 50 to 70% in the elderly (Effros, 1996). Second, CD95 receptor expression also declines. In young T cells, CD95 expression will increase upon stimulation, preventing T cells from proliferating out of control by inducing apoptosis (Aspinall *et al.*, 1998). In aged T cells, the increase in CD95 expression and subsequent induction of apoptosis do not occur in response to stimulation *ex vivo*, suggesting that there is a defect in T cell deletion following a normal immune response (Herndon *et al.*, 1997).

As mentioned before, anti-TCR or anti-CD3 mAb treatment on resting T cell could initiate a series of activation of protein kinases and an increase of Ca<sup>2+</sup> concentration, which contribute to the activation of transcription factors, secretion of cytokines, and cell proliferation. In old mice, CD4<sup>+</sup> T cells lose the ability to robustly increase intracellular Ca<sup>2+</sup> concentrations in response to stimulation. It seems that this phenomenon is independent of IP<sub>3</sub> production and function, but related to high levels of Ca<sup>2+</sup> extrusion and a low level of Ca<sup>2+</sup>

release from the intracellular pool (Miller *et al.*, 1997). Similar to the calcium signal, phosphorylation signals in T cell activation are different in old mice. More specifically, the extent of CD3 $\gamma$  chain phosphorylation is much weaker in old T cells. This decreased phosphorylation of CD3 $\gamma$  chain reflects a combination of decreased kinase activity, increased phosphatase activity, and increased difficulty to access the TCR/CD3 complex (Miller *et al.*, 1997). Downstream, other protein kinases such as Raf-1, MEK, and ERK show age-associated decline in activity upon stimulation (Miller *et al.*, 1997). Recently, the function of negative regulators in T cell signal transduction pathways and its effects on aging are beginning to be examined. For instance, Cbl-b, an E3-ubiquitin ligase, can bind with both CD3 and CD28 upon cell stimulation and consequently associate with various proteins that are essential to signal transduction (Bachmaier *et al.*, 2000). In contrast to the positive regulator that enhances the stimulatory signals, Cbl-b can catalyze the ubiquitination of the associated signaling proteins and down-regulate protein function by either sending them to the proteasome for degradation or blocking the association of substrate proteins with other effector protein in a proteasome-independent mechanism (Xu *et al.*, 2004). Thus, Cbl-b can set the threshold of T cell activation. Cbl-b itself can be down-regulated upon T cell stimulation in young T cells, and such proteasome-mediated degradation is missing in old T cells. Thus, in old T cells, a stronger negative regulation from Cbl-b persists upon stimulation, and T cell activation is diminished in old T cells (Xu *et al.*, 2004). As a result of reduced T cell activation, IL-2 production is reduced, and a dysregulation of T helper cell function results, which may impact B cell, CD8<sup>+</sup> T cell, and other accessory cells in old rodents.

A significant proportion of aging immune research has focused on the CD4<sup>+</sup> T helper cells because of its functional importance in regulating both humoral and cell-mediated immunity. Recently, changes in CD8<sup>+</sup> T cytotoxic cells have also been found to occur in aging, and examination of both T cell subsets will be important in understanding immune senescence. For example, up to 70% of CD8<sup>+</sup> T cells in aged rodents express an identical TCR gene, indicating they are derived from same-parent CD8<sup>+</sup> T cells. These types of CD8<sup>+</sup> T cells are called large CD8 T cell clones and have a poor proliferate capacity in both human and mouse (Ku *et al.*, 1997). The reason for the large CD8<sup>+</sup> T cell clones is most likely due to frequent exposure to the same antigen, which is most likely to occur on old rodents and humans (Ku *et al.*, 1997).

### Testing Dietary Interventions in Autoimmune Prone Mice to Delay Aging and Age-Associated Diseases

Typically, calorie restriction (CR) refers to a 30 to 40% reduction in food intake. CR feeding is important in aging

research because CR is the only known experimental regimen to increase life span in all experimental models tested including yeast, nematodes, flies, and rodents (Jolly, 2004). The models examined are not malnourished because the CR diets have enriched vitamin and mineral content to compensate for the decreased food intake. CR is also potent at delaying the onset of diseases like autoimmune disease and certain types of cancer. Therefore, it appears that CR may be a dietary regimen that not only increases life span by altering the biological process of aging, but also improves the quality of life by decreasing the severity of age-related diseases.

The primary immune cell studied examining the impact of CR feeding on immune function in aging and age-associated disease has focused on the T cell. The main reason for this is that the T cell is critical in determining both the type and extent of an immune response. Two of the most consistent effects of CR on aged T cell function in rodents are maintenance of T cell IL-2 production and subsequent proliferation while maintaining a naïve T cell phenotype (Pahlavani, 2000). Maintaining an optimal immune response in aging is especially critical because the leading causes of death in geriatric hospitals are infectious diseases (Hirokawa and Utsuyama, 2002). An important feature of CR feeding is that its most dramatic impact on aging is observed when the dietary regimen is started in young rodents and maintained throughout life. This is not completely surprising because dietary regimens are normally the most beneficial when used as a prophylactic treatment as opposed to a therapeutic one.

The most well-studied autoimmune-prone model examining the impact of CR on immune function is the autoimmune-prone (NZB $\times$ NZW)<sub>F1</sub> (B/W) mouse. This model is especially valuable since multiple organs have been examined, such as spleen, kidney, mesenteric lymph nodes, peripheral blood, and submandibular glands. The B/W mouse is a good model to study the human disease Systemic Lupus Erythematosus. As in humans, autoantibodies can be found in young adult B/W mice prior to the detection of clinical disease. The B/W mice die from autoimmune renal disease (i.e., nephritis), which can be monitored by measuring proteinuria, at approximately 10 to 12 months of age. Feeding the B/W mouse a 40% CR diet beginning at six weeks of age delayed autoimmune kidney disease by 30% (Jolly, 2004). The life span of the B/W mice could be doubled when the corn oil (CO) based CR diet was substituted with fish oil (FO) (Jolly *et al.*, 2001). It is equally important to note that CR typically does not impact T cell function in young mice even though they have been on the CR diet for a significant amount of time (Jolly, 2004). This is significant because it suggests that CR feeding alone may not cause the T cell to be immunocompromised.

In the kidney, CR prevented the disease-associated rises in the proinflammatory cytokines IFN- $\gamma$ , IL-12, IL-10, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and the

proinflammatory transcription factor nuclear factor kappa B (NF- $\kappa$ B) activation (Jolly, 2004). In peripheral blood, CR blunted the disease-induced increases in IL-2 and IFN- $\gamma$  production by both CD4 and CD8 T cell subsets as well as IL-5 production in CD4 T cells (Jolly, 2004). In contrast, CR reduced the disease-associated increase in IFN- $\gamma$  and IL-10 production in splenic CD4 T cells and increased the loss of IL-2 and IFN- $\gamma$  production in CD8 T cells (Jolly, 2004). Clearly the effect of CR on immune function is dependent on the immune compartment examined, but the consistent effect is that CR appears to normalize the immune alterations caused by autoimmune disease. The majority of the rodent studies have focused on the splenic T cell since the spleen is the largest source of easily accessible T cells in rodents. It has been shown that CR feeding in B/W mice delays the disease-associated rise in memory T cells, similar to that seen in long-lived strains, and increased expression of the CD69 receptor activation marker *in vivo*. Autoimmune disease caused an increase in T cell activation induced cell death, decreased proliferation, also as seen in long-lived aged mice, and increased Fas expression following *ex vivo* stimulation of splenic lymphocytes in B/W mice. The CR dietary regimen prevented the disease-associated increase in activation-induced cell death and restored NF- $\kappa$ B activation to predisease levels (Jolly, 2004). These results are similar to those seen for CR's effects in aged long-lived mice. Furthermore, CR prevented disease-associated decreases in splenic lymphocyte proliferation and blunted the rise in Fas-induced apoptosis and Fas ligand expression (Jolly, 2004). Both CO- and FO-based CR diets were equally effective in the peripheral blood and splenic T cells at restoring CD4 and CD8 T cell populations to predisease levels (Jolly, 2004). Overall, the FO CR diet appeared to be the most effective in mesenteric lymph nodes at restoring CD4 and CD8 T cell populations to predisease levels and blunting disease-associated increases in cytokine (IFN- $\gamma$ , IL-4, IL-5, IL-10) and immunoglobulin (IgM and IgG) production<sub>3</sub> (Jolly, 2004). It remains to be determined whether the beneficial influence of CR on immunoglobulin secretion was due indirectly to altered T cell cytokine production or to direct modulation of B cell function. Similar results were seen in submandibular gland cultures from B/W mice where it was found that CR decreased disease-associated increases in IL-12, IL-10, and IFN- $\gamma$  messenger RNA levels (Muthukumar *et al.*, 2000). Also notable was the reduction of IgA, IgM, and IgG<sub>2a</sub> production by CR since the B/W mice also have active autoimmune disease in their salivary glands (Muthukumar *et al.*, 2000). It is important to note that the autoimmune disease in the salivary glands is normally not life threatening. The results in B/W salivary glands are supported by observations in long-lived mice fed a CR diet in that the age-dependent increase in both IgA and IgM secretion was associated with reduced polymeric immunoglobulin receptor gene expression (Jolly, 2004).

The impact of CR feeding on T cell function in the B/W mouse is clearly unique to different anatomical sites; however, the common feature of CR is that it maintains a predisease T cell phenotype.

A major potential mechanism that may explain the beneficial effects of CR feeding in autoimmune-prone mice is change in oxidative status. First, CR may increase the protection of T cells from oxidative damage by increasing antioxidant enzyme activity. This is supported by data showing that CR increased renal superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GSH-Px) activity. Interestingly, the FO-based CR diet was more effective than the CO-based CR diet, which may protect the kidney from oxidative damage. CR also blocked the disease-associated increase in cellular peroxide levels in splenic lymphocytes (Jolly, 2004). This data is similar to observations made in long-lived mice where CR prevented age-associated increases in cellular peroxides in splenic lymphocytes and age-associated susceptibility of lymphocytes to hydrogen peroxide-induced apoptosis was blunted (Avula and Fernandes, 2002). In summary, these observations suggest that CR may improve T cell function (i.e., increase proliferation *ex vivo*) by reducing the increased susceptibility to age-dependent increases in apoptosis and decreasing free radical damage.

In addition to delaying the onset of autoimmune disease, CR or FO CR may also alter the development of other diseases like atherosclerosis in autoimmune-prone mice. Autoimmune disease in these mice increases the expression of key adhesion receptors like intercellular adhesion molecule-1 (ICAM-1), CD28, CD80, and Mac-1, autoantibody production and LDL-cholesterol, which are known to be reduced by CR feeding (Muthukumar *et al.*, 2004) (Muthukumar *et al.*, 2004). Their importance in heart disease may be in recruiting and activating immune cells in the coronary arteries since chronic inflammation is now considered to be an important risk factor in the etiology of heart disease. It is important to note that the beneficial effects of the FO CR diet on lipid profiles were seen early in the initiation of the dietary regimen, which was prior to the onset of active disease (Muthukumar *et al.*, 2003). Once again the beneficial effects of the combination of FO CR feeding may be due to decreases in free radical damage and increased antioxidant enzyme activity, which has been shown in response to the induction of oxidative stress by cyclophosphamide injection (Bhattacharya *et al.*, 2003). Overall, these data suggest that combining two different dietary regimens known to delay the onset of inflammatory diseases may have additive benefit and relevance to multiple diseases.

The concern with the CR dietary regimen is that it may not be realistic for the human population at large. The majority of the studies discussed administer CR at a 40 to 60% reduction in food intake, and this would be quite dramatic for most people. However, simply eating

the recommended daily allowances could have similar beneficial effects. The National Institute on Aging/NIH started a study in 2002 called CALERIE (Comprehensive Assessment of Long-term Effects of Reducing Intake of Energy) in humans. It will be interesting to see how well, and how long, this population of people follows this dietary regimen and what types of results are obtained from this long-term study in humans. The true benefit of these studies may be in identifying immune-associated biomarkers, which could then be targeted in dietary supplementation and pharmacologic studies to prevent or treat various immune-mediated diseases. This would be of enormous importance to overall human health because the immune system is involved in the etiology of multiple diseases and most of the major diseases in humans.

### Autoimmune-Prone Mice as a Model of Chronic Inflammation and Heart Disease

Inflammation is a key component in the development of heart disease (Ross, 1999). The inflammatory process is propagated by immune cells like the T cell, which migrate to the site of inflammation. This is significant because the T cell plays a critical role in determining both the type and extent of immune response via the production of cytokines. Specifically, T cells have been shown to drive the inflammation found in atherosclerotic lesions (Benagiano *et al.*, 2003). The inflammation in arterial walls is propagated by both the expression of adhesion molecules like ICAM-1 and VCAM-1, which recruit immune cells to the site of inflammation, and the production of cytokines by both nonimmune and immune cells. The autoimmune prone MRL-lpr has been used as an experimental system to examine chronic inflammation and heart disease (Qiao *et al.*, 1993) primarily because many of the adhesion molecules and cytokines thought to be important in human atherosclerosis are up-regulated in this animal model.

Nutrients serve as an excellent means to delay the onset of heart disease (Osiecki, 2004). The omega-3 fatty acids found in fish oil are well-established anti-inflammatory nutrients (Fernandes and Jolly, 1998). Important in heart disease, dietary omega-3 fatty acids have been shown to suppress the expression of both ICAM-1 (De Caterina *et al.*, 2000) and VCAM-1 (De Caterina *et al.*, 1995) in endothelial cells. Proinflammatory cytokines like TNF- $\alpha$  and IFN- $\gamma$  are also found at sites of inflammation, and their levels can be reduced by dietary omega-3 fatty acid feeding in MRL-lpr mice (Venkatraman and Chu, 1999). We have specifically found that dietary omega-3 fatty acids can decrease IFN- $\gamma$  and TNF- $\alpha$  levels associated with nephritis in the kidneys of (NZBxNZW)<sub>F1</sub> (B/W) mice. Furthermore, dietary omega-3 fatty acids have been shown to reduce IFN- $\gamma$  production in T-lymphocytes found in the

peripheral blood, mesenteric lymph nodes, and spleens (Jolly, 2004) of B/W mice.

Omega-3 fatty acids can be derived from many food sources. Flaxseed oil, enriched in linolenic acid, and fish oil, enriched in eicosapentaenoic acid and docosahexaenoic acid, are the two sources of omega-3 fatty acids that have been commonly used to examine the anti-inflammatory properties of omega-3 fatty acids. However, direct comparisons of the two oils are limiting in the literature. Recent evidence suggests that both flaxseed and fish oil could decrease T-lymphocyte proliferation *ex vivo* in rats, but fish oil was the most potent. Whether this translates into fish oil being the most effective at delaying the onset of heart disease and/or autoimmune disease needs to be directly addressed.

### Conclusion

The autoimmune disease-prone mouse has proven to be an excellent short-lived mouse model to examine autoimmune disease and the impact of dietary interventions. One of the limitations of most rodent models is that they do not perfectly mimic immune function in humans. However, since many of the age-dependent immune phenomena seen in humans are also seen in rodents, the mouse serves as a good surrogate. The biggest drawback to the B/W model, and most other autoimmune disease models for that matter, is that the etiology of the disease is not known. Thus this mouse model would be difficult to use in assessing dietary interventions on the cause of autoimmune disease. The most fascinating fact regarding the B/W mouse and others like it is that its real contribution to research in the future may be as a model of chronic inflammation to study other major diseases afflicting the human population and not actually in studying autoimmune disease *per se*.

# Human T Cell Clones in Long-Term Culture as Models for the Impact of Chronic Antigenic Stress in Aging

Graham Pawelec, Erminia Mariani, Rafael Solana, Rosalyn Forsey, Anis Larbi, Simona Neri, Olga Dela Rosa, Yvonne Barnett, Jon Tolson, and Tamas Fülöp

*Monoclonal human T lymphocytes can be maintained untransformed in tissue culture by intermittent antigen restimulation in the presence of growth factors for only a finite period (which, however, varies greatly from clone to clone). This tissue culture model can be employed to examine many aspects of clonal expansion and contraction under conditions of chronic antigenic stress, such as that which occurs in vivo in the elderly (where herpes viruses represent an important chronic stressor), as well as in cancer. In this context, the model can be used for biomarker discovery at the genomic, proteomic, and functional levels, and to test remedial interventions of possible utility in vivo. Furthermore, the clonal characteristics of cells from donors of different ages and states can be compared using this model (cloning efficiency, mean longevity, maximum longevity, aging behavior, etc.). This chapter briefly describes techniques for the production and maintenance of human T cell clones, their growth characteristics and longevity in vitro, culture age-associated changes of parameters such as telomere lengths, DNA damage, surface molecules and so on, and the application of proteomic analyses to study this model of immunosenescence in detail.*

## Introduction

T cells from young or old donors can be cloned and cultured *in vitro*, provided that they are supplied with growth factors and intermittently stimulated via their surface receptors for antigen and costimuli. The critical advantage of using monoclonal populations is that the changes observed over time are not due to age-associated alterations in the proportions of different T cell subsets, a confounding factor plaguing innumerable studies. Mostly, peripheral blood lymphocytes are the starting material for cloning, but other sources of T cells, such as lymph node, behave in the same manner. On initial stimulation, T cells upregulate growth factor receptors, which are soon down-regulated again regardless of the presence of growth

factors unless restimulation via the antigen receptor (or under certain circumstances, other surface receptors) takes place. Restimulation is required for re-upregulation of growth factor receptors and continued growth. Restimulation too soon after antigen exposure, on the other hand, may lead to activation-induced cell death by apoptosis (activation-induced cell death, or AICD), whereby the definition of “too soon” changes according to circumstances, importantly, including the age of the clone, and is also different from clone to clone. Thus, T cell clones (TCC) must be maintained in careful balance between too much antigen (apoptosis) and too little (growth termination). Under appropriate culture conditions, all major subsets of T cells can be cloned (i.e., CD4<sup>+</sup> TCR2, CD8<sup>+</sup> TCR2, CD4, 8-negative TCR1, and NKT cells). However, the latter two types are more difficult to maintain. Clonal longevity studies are rare because of the time-consuming nature of the experiments, but some data are available on the behavior of human T cell clones from different sources.

## Generation and Growth Characteristics of Human TCC

Early data from McCarron *et al.* (1987) suggested that clonal longevity was influenced by age of the donor: clones derived from neonates averaged 52 population doublings (PD), those derived from young adults (20–30 yr) managed 40 PD, but those from the elderly (70–90 yr) only 32 PD, as calculated from the data given in that publication. Our own more extensive results are somewhat different: although individual T cell clones do have very varied life spans, the overall patterns for T cells of quite different origins and donors of different ages are remarkably similar. Table 66.1 provides a cumulative update of our experience with CD4<sup>+</sup> TCC, following previously published work (Pawelec *et al.*, 2002).

Cloning peripheral T cells from young healthy donors can be performed with a high cloning efficiency

TABLE 66.1  
Longevity of human CD4<sup>+</sup> T cell clones

Clones/Origin	%CE	Expts	Percentage of clones reaching:			Longest lived clone
			20 PD	30 PD	40 PD	
CD3 (young)	47	1355/15	47	24	15	90 PD
CD3 (old)	52	298/7	48	26	16	77
CD3 (cent)	38	52/3	41	23	17	80
CD3 (CML)	49	35/1	60	35	14	51
CD34 (periph)	55	533/6	31	17	6	60
CD34 (cord)	43	94/2	29	15	5	57

CE, cloning efficiency (calculated from percentage of wells positive in cloning plates). Longevity is expressed as a percentage of established clones (i.e., those counted as positive in calculating the CE) that survive to 20, 30, or 40 population doublings (PD) ( $10^6$ ,  $10^9$ ,  $10^{12}$  cells, respectively). Origins: CD3, mature peripheral T cells from: (young)—apparently healthy donors under 30 yr.; (old)—perfectly healthy SENIEUR-compliant donors over 80 yr.; (cent)—centenarian donors >100 yr.; (CML)—middle-aged donor with chronic myelogenous leukemia in chronic phase treated with interferon- $\alpha$ ; CD34, positively selected lineage-negative hematopoietic progenitor cells from peripheral (periph) or umbilical cord (cord) blood (Pawelec *et al.*, 1998).

(CE) of >50%, suggesting that these particular cloning conditions are favorable for outgrowth of a majority of T cells. However, cloning mixtures of T cells result in most of the TCC obtained being CD4<sup>+</sup>. To obtain CD8 (or TCR1 and especially NKT) cells, it is necessary to presort or otherwise remove CD4 cells. Cloning from a mixture of CD4 and CD8 cells with a CE of >50% implies that almost all CD4<sup>+</sup> cells are initially clonable (defined as accumulation of ca. 1000 cells from one original cell). The CD4 T cell repertoire of the starting population is therefore present more or less in its entirety. However, after 20 PD, when the clone size has increased from  $10^3$  to  $10^6$ , about half of the clones have been lost (mean of 47% for cloning of young donor CD3 cells; see Table 66.1). By 30 PD, about another half is lost, so that only one quarter of the originally clonable cells is still present. However, at 40 PD (which theoretically represents a very large clone size of  $10^{12}$  cells), although more clones have been lost, 15% of the original starting clonal population does still remain. These results indicate constant attrition of the T cell population at the clonal level, but with retention of something like 5% of the original CD4 repertoire up to 40 PD and with retention of very rare clones for considerably longer. Although difficult to establish, similar clonal attrition probably occurs *in vivo* as well, at least in infectious mononucleosis, perhaps with quite similar distributions of clonal longevity (Maini *et al.*, 1999).

Comparisons of T cell CE from young or old donors, or other sources, may be informative. Our hypothesis was that T cells generated *in situ* from CD34<sup>+</sup> hematopoietic progenitors would have greater longevity due to their lack of a previous T cell proliferative history (Pawelec *et al.*, 1998). Reciprocally, we anticipated that CE of cells from the elderly would be reduced as would their clonal longevity, and that this would be more prevalent in less healthy donors than in those rigorously selected for good

health. Finally, we predicted that T cells from younger donors but in situations of chronic *in vivo* antigenic stress, such as in cancer, also would have lower CE and longevity. However, none of these expectations was fulfilled (see Table 66.1). CE was not lower in the elderly than in the young, and neither was the state of health of the donor critical. The CE was equally high when the cells derived from a patient with chronic myelogenous leukemia, a donor putatively subjected to a high level of antigenic stress. CE was also similar in the extra-thymic T cell differentiation cultures employed. It has to be concluded that CEs of the T cells from these markedly different sources are nonetheless similar. Is this true for average and maximum longevity also? It seems so: very similar proportions of TCC achieve 20, 30, and 40 PD regardless of their origin. In addition, the maximum longevity of the longest-lived clone is also similar and very close to the Hayflick Limit of 50–60 PD. Overall, it seems that CE and longevity of T cells in culture are essentially identical regardless of whether the cells to be cloned are derived from progenitors, young or old donors, healthy or sick.

#### PROTOCOL FOR CLONING BY LIMITING DILUTION

1. Dilute the cells for cloning in culture medium (e.g., RPMI 1640 + 15% prescreened FCS or human serum; or serum-free medium such as X-Vivo 15) to which 40 U/ml of IL-2 is added. Set the concentration so that 10  $\mu$ l contain 45, 4.5, or 0.45 cells. Then plate 10  $\mu$ l of the 0.45 suspension into 60  $\times$  1 mm-diameter wells of culture trays (Terasaki plates) and leave in a vibration-free area for an hour. Check the distribution of cells in the wells visually using an inverted microscope, being careful to look around the edges of the wells. According to

the Poisson distribution, only a maximum of 37% of the wells should contain cells. Readjust dilutions if necessary, and recheck.

2. Plate at least five trays with the 0.45 cells/10  $\mu$ l, suspension, one with 4.5 and one with 45, and add a constant number of feeder cells to each well. Irradiated PBMC commonly are used as feeder cells at  $1 \times 10^4$ /well. Use autologous PBMC, a mixture of autologous PBMC and autologous B-lymphoblastoid line cells, or other appropriate APC, in the presence of specific antigen. Alternatively, use an antigen-nonspecific stimulus such as 50 ng/ml of the anti-CD3 monoclonal antibody OKT3 or 2  $\mu$ g/ml of the mitogen PHA, together with the same number of allogeneic or autologous PBMC.
3. Stack plates and wrap in aluminum foil for ease of handling and as a precaution against contamination. Incubate for about a week and then examine the plates using an inverted microscope. Transfer contents of positive wells (> one-third full, ca. 1000 cells) to 7 mm-diameter flat-bottom microtiter plate wells with fresh medium and  $1 \times 10^5$  of the same feeder cells as before. Check Terasaki plates again at intervals of a few days up to two to three weeks of age to identify late developers and transfer these also. Check microtiter plates every few days, and identify wells becoming crowded within a week post-transfer. These must be split 1:1 into new culture wells and re-fed with medium (but not feeder cells). After one week in microtiter plates, contents of wells with growing cells are transferred to 16 mm-diameter cluster plate wells with two  $5 \times 10^5$  of the same feeder cells, and fresh medium. Observe after three to four days and establish which wells are already full or nearly full. The former should be divided into four, the latter into two, with fresh media, but no more feeders. After a total of one week in cluster plates, count the number of cells in each clone and split to  $2 \times 10^5$ /well, again with two  $5 \times 10^5$  feeders/well and fresh medium. Feed after three to four days with fresh medium, and split again if necessary. Clones successfully propagated in cluster plate wells for this second week are taken to be established. At this point, some (or all) can be cryopreserved and the remainder cultured under different conditions to establish optimal parameters for each particular clone. Having a frozen stock enables one to test different culture conditions in order to optimize growth, without the fear of losing the whole clone.
4. Test whether established clones can be propagated with the most convenient feeder cells (80 Gy-irradiated B-lymphoblastoid cell lines) instead of PBMC feeders. Most TCC flourish on B-LCL alone, but some appear for unknown reasons to benefit from the presence of PBMC as

well (this is especially true during cloning). Propagation of the TCC on PBMC feeders can also be continued, but it may be found preferable to prepare standardizable batches of B-LCL rather than having to repeatedly isolate PBMC. Furthermore, PBMC from the autologous donor may not be freely available in sufficient amounts for large-scale propagation of numerous clones. The international availability of well-characterized MHC homozygous B-LCL makes it possible to match the feeder cell to the specificity of the TCC being propagated and enhance the antigen-presentation function of the feeders.

5. As a matter of convenience, it is easier to grow TCC in scaled-up culture vessels than in cluster plates, but not all clones can be adapted to growth in flasks. This must also be tested for each clone, using  $1 \times 10^5$  and  $5 \times 10^5$ /ml TCC with an equal number of feeders in tissue culture flasks. Those clones not growing under these conditions rarely can be adapted to flask growth by altering the amounts or concentrations of TCC or feeders seeded or by increasing or decreasing the frequency of stimulation and/or feeding. It remains unknown why some TCC fail to flourish in flasks.
6. Establish restimulation parameters for each clone. T cells require periodic reactivation through the T cell antigen receptor in order to retain responsiveness to growth factors. This can be accomplished specifically or nonspecifically. All clones can be propagated with weekly restimulation; some but not all can be propagated with restimulation only every two weeks. Human T cell clones can be readily cryopreserved using the same protocols as are suitable for freezing resting T cells. Clones developing with different kinetics can thus be collected and conveniently tested for cytotoxicity in the same experiment.

## Age-Associated Alterations to the Cells During Culture

### SURFACE PHENOTYPE AND FUNCTION

This *in vitro* clonal culture model may also be informative for longitudinal studies of age-related changes in TCC under chronic antigenic stress. Because of the constraints of the cloning procedure, young cells already have accomplished at least 22 or 23 PD, but at this stage, we still have a good representation of the starting repertoire (as discussed earlier). One of the simplest analytical techniques to study these cells over time is to use flow cytometry with monoclonal antibodies detecting molecules expressed on the cell surface. We have examined a large range of different surface markers and found relatively few that change with age (where aging is defined as increasing PD). The most common pattern of age-associated alterations involves a reduction of the

level of expression of the costimulatory receptor CD28, and sometimes the putative costimulatory receptors CD134 and CD154 (Pawelec *et al.*, 1997), whereas despite increased susceptibility to AICD, surface CD95 expression remains constant (Pawelec *et al.*, 1996). The cells have a memory effector phenotype (CD45RA-negative, CCR7-negative, CD45RO<sup>+</sup>) as would be expected from chronically stimulated T cells. The level of the TCR also remains stable, suggesting that these cells retain the ability to recognize and respond to antigen. Major functional changes may follow from the decreased level of expression of costimulatory receptors, both CD28 and in all likelihood others yet to be investigated. The most dramatic changes are in the patterns of cytokines secreted, commonly resulting in decreased levels of IL 2 and increased levels of IL 10 (Pawelec *et al.*, 1997). Because the expression of the TCR is maintained and antigen-specific signaling still occurs, it is likely that these differences are caused by differences in the delivery of costimuli to the T cells.

### TCC RECEPTORS AND SIGNAL TRANSDUCTION

T cell functions are mediated by intracellular signaling via surface receptors such as the antigen receptor and the costimulator CD28, as discussed earlier, from the membrane (early events) through the cytoplasm (intermediate events) to the nucleus (late events). Age-related immune alterations can be partially explained by defects in receptor signal transduction. For instance, decreased calcium mobilization, MAPKinase phosphorylation, PKC $\theta$  recruitment to the membrane, NF- $\kappa$ B translocation to the nucleus and ultimately IL-2 production are hallmarks of T cell senescence. TCR ligation induces its phosphorylation at specific sites and its redistribution to specific membrane microdomains, called lipid rafts. This redistribution, also known as polarization, allows the formation of the signalosome, a large signaling platform composed of key signaling molecules that must be properly configured within the lipid raft. The signaling cascade involving tyrosine kinase activation (p56<sup>Lck</sup>, ZAP-70), adaptor proteins (linker of activated T cells), and second messenger generation including calcium mobilization will take place only if these conditions are fulfilled. Cholesterol is a major constituent of lipid rafts, conferring on them their specific characteristics and permitting their stability. It has been shown that polyunsaturated fatty acid content will determine the association of signaling molecules in lipid rafts. All these parameters would influence membrane fluidity and ultimately cell signaling/activation. Alterations to lipid rafting with age could represent an important aspect of senescence (Larbi *et al.*, 2004b).

#### *Lipid raft isolation protocol*

Lipid rafts are insoluble in nonionic detergents such as Triton X-100, and application of a sucrose gradient (45% to 5% sucrose) allows them to be separated from

the other membrane domains. For this purpose, cell lysates in Triton X-100 1% are overlaid with sucrose and ultra-centrifuged for 16 h at 100,000 rpm at 4°C. Fractions from the top are collected and analyzed for lipid raft markers, among the best of which are gangliosides (GM1 and GM3). However, recent data indicate heterogeneity in lipid raft composition in each cell type. In this connection, flotillin can be used, even for functionally different rafts. Once the lipid raft fractions are identified, several experiments including protein localization/phosphorylation (Western-blotting), kinase activity, and immunoprecipitation can be performed to assess composition. Lipid raft fluidity can be assessed using diphenylhexatriene as a probe for fluorescence anisotropy.

#### *How to visualize lipid rafts*

To analyze membrane organization, and protein-protein interaction in the resting state, as well as following receptor ligation, microscopy procedures are available. Lipid rafts can be stained using Alexa-conjugated cholera toxin  $\beta$ -subunit (Molecular Probes) and lipid rafting in T cells monitored in a time- and stimulus-dependent manner. Colocalization studies can be performed to have direct imaging of signal transduction changes during immune senescence.

Lipid raft composition (lipids, signaling molecules) will determine TCC activation. A change in lipid raft properties has already been described in T cells from SLE patients. With the tools described in the previous section it is possible to determine even slight changes in lipid raft properties, which may, in turn, have critical effects as seen in immune senescence. One way of examining this is to use fluorescence anisotropy (inverse value of fluidity) on TCC from donors of different ages at different PD. As shown in Table 66.2, anisotropy in TCC decreases as the PD increases. This indicates an increased fluidity with cell expansion, which may result from a loss of membrane cholesterol. These data corroborate findings in primary T cells concerning fluidity during TCR- and CD28-induced proliferation.

TABLE 66.2  
Anisotropy (*r*) measured in T cell clones originated from individuals of various ages at different population doublings (PD)

TCC from: PD	Anisotropy ( <i>r</i> )			
	Progenitors	Young	Elderly	Centenarians
Low	0.283	0.286	0.270	0.263
Medium	0.266	0.275	0.260	0.252
High	0.294	0.268	0.253	0.245

Anisotropy (*r*) is the inverse value of fluidity: (*f*) = 1 / (*r*)  
Cells were incubated 30 min at 37°C with diphenylhexatriene (DPH) at 2  $\mu$ M. Anisotropy is directly measured using a spectrofluorimeter coupled to a polarizer (Larbi *et al.*, 2004a).

The lowest membrane fluidity was observed at any doubling in TCC derived from centenarians, indicating a high degree of functionality and adaptability. The progressive change in membrane fluidity is part of the immune senescence of TCC and may help to explain age-associated TCC behavior.

#### TELOMERE LENGTH AND GENOME INTEGRITY

Telomeres are specialized structures consisting of characteristic DNA repeat sequences and a complex of associated proteins, which cap and protect chromosome ends and serve to preserve genome integrity. In most somatic cells, progressive rounds of cell division are associated with telomere shortening. The length, structure, and function of telomeres have been proposed to contribute to cellular and organism phenotypes associated with cancer and aging (Kim *et al.*, 2000). In order to protect the germline and the subpopulation of stem cells from senescence, mechanisms have evolved to prevent telomere attrition in these cellular compartments. The most common and best-studied mechanism involves the activation of a ribonucleoprotein enzyme complex known as telomerase (Granger *et al.*, 2002). Nonetheless, the analysis of telomere length in a particular cell type can be a biomarker of its replicative history and cellular senescence.

The measurement of telomere length in the TCC is an important method to determine whether these cells reach replicative senescence in culture as they do *ex vivo*. The flow-FISH technique (Rufer *et al.*, 1998) in which a fluorescein isothiocyanate (FITV)-labeled telomere-specific peptide nucleic acid (PNA) probe is hybridized in a quantitative way to telomere repeats, followed by telomere fluorescence measurements on individual cells by flow cytometry, is in common use for this purpose. The advantages of looking at the telomere fluorescence in different types of cells in the same sample (lymphocytes and P815 cells), and the requirement for relatively low numbers of cells ( $10^5$ ), are an important reason for using this method instead of Southern blotting (Baerlocher *et al.*, 2002). It is necessary to use an internal control for telomere length; for this purpose, the P815 cell line is mixed with the TCC.

#### *Telomere protocol*

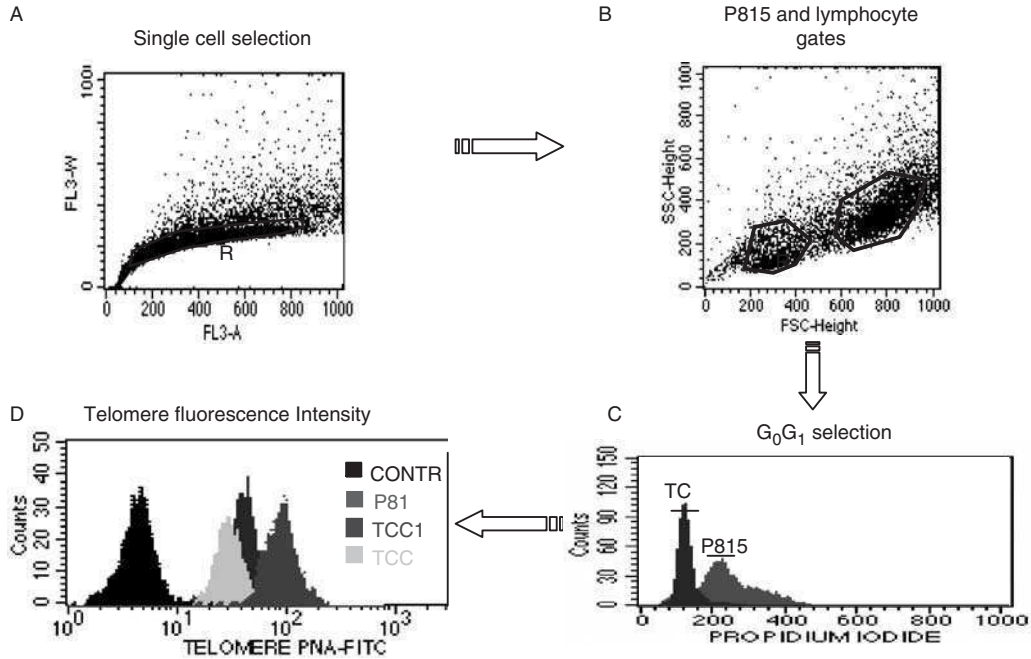

1. Wash TCC in phosphate-buffered saline (PBS), centrifuge at 400 g for 5 min, and resuspend in 1 ml PBS. After washing, mix TCC 1:1 with P815 cells and collect a total of  $1 \times 10^6$  mixed cells in 1.5 ml tubes. Hybridize cells with or without the FITC-labeled  $(C_3TA_2)_3$  peptide nucleic acid probe and incubate 10 minutes at 82°C to separate double-stranded DNA. Then incubate at room temperature overnight.
2. Remove the hybridization solution by incubating with wash solution at 40°C for 10 minutes and

remove after spinning down. After two washes, stain with propidium iodide (PI) and RNase A solution in order to stain DA for  $G_0/G_1$  selection. After three hours of incubation at 4°C, the cells are maintained at 4°C until data acquisition.

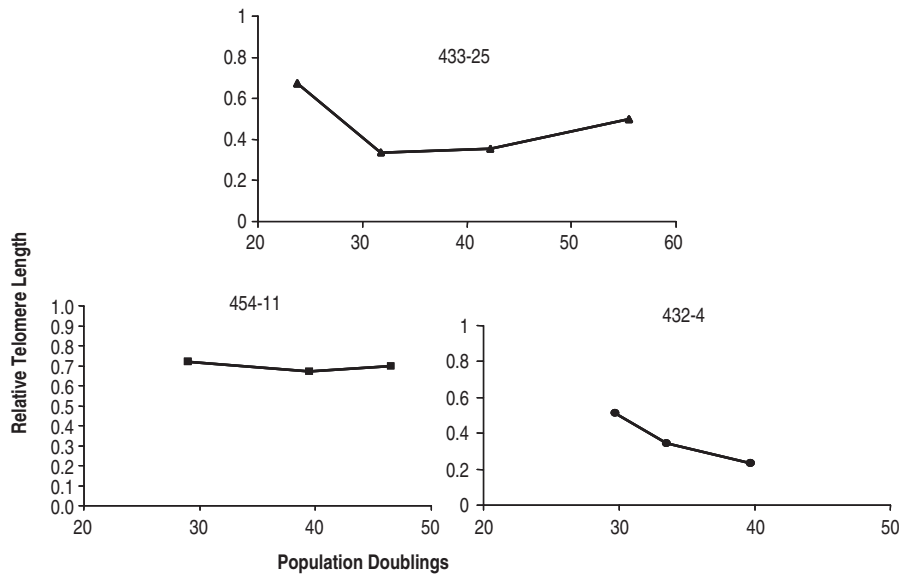

3. To correct for daily shifts in the linearity of the flow cytometer, FITC-labeled fluorescent calibration beads (Dako FluoroSpheres, Denmark) each having a fluorescence corresponding to different known amounts of molecular equivalents of soluble fluorochrome (MESF), have to be run in each experiment. The FL1 channel is used for detection of the fluorescein signal and the FL3 channel for PI. Collect  $10^4$  cells in each experiment.
4. The telomere fluorescence signal is defined as the mean fluorescence signal in  $G_0/G_1$  cells after subtraction of the background fluorescence signal (i.e., FISH procedure without probe). The relative telomere length value is calculated as the ratio between the telomere signal of each sample and the control cell line (P815) with compensation for the DNA index of  $G_0/G_1$  cells. This compensation is performed in order to normalize the number of telomere ends per cell. As seen in Figure 66.1A, the single-cell population is selected in the FL3-width versus FL3-area dot plot. The gated cells are then displayed in the FSC and SSC dot plot to separate the P815 cells from the TCC (see Figure 66.1B, gates R2 and R3), which are validated in experiments with purified suspensions. As the number of chromosomes and thus telomere ends is strongly correlated with the DNA index calculated from DNA histogram analyses, select the  $G_0/G_1$  phase of the cell cycle, because at this stage the cell has one copy of its genome. This is achieved by setting the correct gates (see Figure 66.1C, gates R4 and R5). The cell cycle phases from the DNA histograms need to have a variation coefficient lower than 7% of cells out of the  $G_0/G_1$  phase (Rapi *et al.*, 1996).
5. The telomere fluorescence intensity is then analyzed in the FITC histogram using the previously selected gates with the P815 cell line as a positive control. For each TCC, the specific telomere fluorescence is calculated by subtracting the mean fluorescence of the background control (no probe) from the mean fluorescence obtained from cells hybridized with the telomere probe. The concept of Relative Telomere Length (RTL) is used to assess differences between TCC, with P815 defined as 100%.

Figure 66.2 shows an example of the kind of data obtained with TCC using this technique. In the majority, there is a decrease of the RTL at the first 40 PD. Thereafter, clones exceeding this life span may show stabilization or even increased RTL on further culture.

**Figure 66.1** Flow Fish analysis of T cell clones. T cell clones were mixed with the P815 cell line, and the mixed sample was analyzed after hybridisation with or without FITC-labeled  $(C_3TA_2)_3$  peptide nucleic acid. Cells were gated on region 1 (R1) on the basis of FL3-A and FL3-W to select single cells as shown in **A**. Different regions were selected within R1 from forward (FSC) versus side scatter (SSC) dot plots for P815 and TCC, as is shown in **B**. Results within TCC and P815 were depicted for cell cycle on histogram **C** to select the  $G_0/G_1$  cells. Histogram **D** represents the analysis of the PNA fluorescence intensity of two different T cell clones, and the highest peak shows the P815 positive control cells.

**Figure 66.2** Relative telomere length of different TCC. The y axis represents the RTL of TCC versus the time of culture in terms of Population Doublings. Three different TCC are shown (Clones 433-25, 454-11, and 432-4).

### MICROSATELLITE INSTABILITY (MSI)

The influence of DNA repair capacity on genomic integrity is suggested by the positive correlation between

life span and DNA repair capacity and evidenced by progeroid syndromes in which DNA repair defects can cause phenotypes resembling premature aging (Lombard *et al.*, 2005). The accurate maintenance of

nuclear DNA is critical to cell and organism functions, and therefore numerous DNA repair pathways have evolved for the different types of DNA lesions. Among these pathways, the nucleotide excision repair mechanism (because of its role in repair of UV-induced damage) and the nonhomologous end joining pathway (the predominant double-strand break repair system) are the most intensely studied, and together with the base excision repair pathway do appear to be altered with age (Lombard *et al.*, 2005). The function of the mismatch repair (MMR) system during aging is to scan newly replicated DNA and to deal with replicative and recombinational errors leading to mispaired bases (mismatches) by excising the mutated strand in either direction to the mismatch, thus contributing to genomic protection against replication-induced mutations (Loeb, 1994). This would be most important in rapidly replicating cells, such as TCC.

An experimental approach to the study of defects in this pathway is the evaluation of microsatellite instability (MSI), evidenced by expansions or contractions of microsatellites, highly polymorphic tandemly-repeated sequences from one to six bases, interspersed in the genome and particularly prone to replication slippages that change strand lengths, either by insertion or deletion of repeated units.

Mutations occur both in repeated sequences and randomly throughout the genome. Therefore, MSI indicates a higher susceptibility to mutations. Despite the trend to errors occurring in all dividing cells, microsatellite lengths remain stable due to the intrinsic activity and fidelity of the MMR system. Hence, MSI serves as a marker for a malfunctioning MMR system. There is an increased instability both in the mucosa of aged patients with gastric lymphomas (Starostik *et al.*, 2000) and also in microsatellite sequences from total peripheral blood DNA of old subjects obtained at a 10-year interval (Ben Yehuda *et al.*, 2000; Krichevsky *et al.*, 2004; Neri *et al.*, 2005).

One possible cause of MMR deficiency could be the inactivation or the altered expression of MMR genes due to epigenetic mutations, as suggested by the finding of hypermethylation-mediated MMR gene inactivation in sporadic cancers showing microsatellite instability and by the age-related inactivation of hMLH1 by promoter methylation found in normal colon cells. Data on *in vitro* aging of TCC suggest that the MMR system could differently change its efficiency during *in vitro* proliferation, depending upon the cell type and/or that repeated doublings could contribute to the accumulation of genetic alterations not repaired by the MMR system (Neri *et al.*, 2004).

#### Protocol for MSI analysis

1. Extract genomic DNA from cell pellets using the QIAamp DNA Mini Kit (Qiagen GmbH, Germany) following the manufacturer's

instructions; quantify DNA by spectrophotometric determination at 260 nm.

2. For MSI analysis, at least five repeated sequences should be tested; for example, the following loci containing tetra- and pentanucleotide polymorphic tandem repeat sequences: CD4 (12p13), a (TTTTC) repeat located in the 5' nontranscribed region of the T cell surface antigen gene; VWA31 (12p12-pter), an (AGAT) repeat in intron 40 of the von Willebrand factor gene; Fes/FPS (15q25-qter), an (ATTT) repeat in intron 5 of the c-fes proto-oncogene; TPOX (2p23-pter), an (AATG) repeat in intron 10 of the thyroid peroxidase gene; p53 (17p13), an (AAAAT) repeat in the first intron of the TP53 gene.

Carry out the PCR amplifications using the following specific primers:

CD4-pF: 5'-TTGGAGTCGCAAGCTGAAC-TAGC-3',

CD4-pR: 5'-GCCTGAGTGACAGAGTGA-GAACC-3';

VWA31-pF: 5'-CCCTAGTGGATGATAAGAA-TAATCAGTATG-3',

VWA31-pR: 5'-GGACAGATGATAAATACA-TAGGATGGATGG-3';

Fes-pF: 5'-GGGATTTCCCTATGGATTGG-3',

Fes-pR: 5'-GCGAAAGAATGAGACTACAT-3';

TPOX-pF: 5'-ACTGGCACAGAACAGGCACT-TAGG-3',

TPOX-pR: 5'-GGAGGAACTGGGAACACA-CAGGT-3';

p53-pF: 5'-ACTCCAGCCTGGGCAATAA-GAGCT-3',

p53-pR: 5'-ACAAAACATCCCCTACAACAGC-3'.

Combine template DNA (50 ng), 1  $\mu$ M each primer, 200  $\mu$ M each deoxynucleotide triphosphate, 1.5 mM (for CD4, Fes/TPOX and p53) or 2.5 mM (for VWA31) MgCl<sub>2</sub>, 1X PCR buffer II (50 mM KCl, 10 mM Tris-HCl, pH 8.3) and 1.25 U AmpliTaq DNA Polymerase (Perkin Elmer, Roche Molecular Systems, USA) in 25- $\mu$ l reactions. Amplification profiles are, respectively: 10 cycles (1' 94°C, 45'' 62°C) followed by 20 cycles (1' 90°C, 45'' 62°C) for CD4; 30 cycles (1' 94°C, 1' 57°C, 1' 72°C) for VWA31; 30 cycles (1' 94°C, 1' 54°C, 1' 72°C) for Fes; 30 cycles (1' 94°C, 1' 64°C, 1' 72°C) for TPOX; and 30 cycles (1' 94°C, 45'' 65°C, 45'' 72°C) for p53. Include in all reactions a negative control (sample without template).

3. Analyze 10  $\mu$ l of each PCR product on 2% agarose gels in order to verify amplification and then perform electrophoresis with product-adjusted amounts on 10% nondenaturing polyacrylamide vertical gels (20 cm long, 0.75 mm thick) containing 5% glycerol, in TBE buffer, for 16 to 18 hrs at 100 to 150 V, together with the DNA Molecular Weight

Marker VIII (Roche Molecular Systems, Branchburg, USA) and allelic ladders prepared by mixing known alleles.

4. Silver stain gels at room temperature with continuous shaking. After 10' fixation in 10% EtOH and 2' oxidation in 1% nitric acid, stain the gels for 20' in 0.02% AgNO<sub>2</sub>, rinse in distilled water, and then reduce in developing solution (3% sodium carbonate and 0.1% formaldehyde) until an optimal band intensity is observed. Stop the development by adding 5% acetic acid for 3' and finally place the gels in distilled water.
5. Conclude genotyping by side-by-side comparison with allelic ladders. Results showing allele modifications in DNA samples derived from the same donor must be confirmed by repeating the analysis.

#### DNA DAMAGE ACCUMULATION IN T CELLS AS A FUNCTION OF AGE

A more general approach to DNA damage and repair can also be informative in clonal models and *ex vivo* studies, several of which have shown that T cells *in vivo* accumulate DNA damage and mutations (point and chromosomal), for example, in free-living healthy humans aged 35 to 69 years. However, when the same genetic damage endpoints were examined in a group of healthy, older than average (75–80 years) humans, genetic damage levels similar to the levels present in subjects aged 35 to 39 years were found, and significantly less than in subjects aged 65 to 69 years (King *et al.*, 1997). These and many other data support the importance of maintenance of genomic stability, as a determinant factor promoting health and longevity. This hypothesis is supported by the results of work from others in premature aging conditions or in groups of successfully aged humans (centenarians) (Franceschi *et al.*, 1995).

Extensive use has been made of the *in vitro* human peripheral blood-derived CD4+ T cell clone model of immunosenescence described in this chapter in order to examine DNA damage accumulation under chronic antigenic stress (Hyland *et al.*, 2001). Alkaline comet assays revealed low levels of DNA damage as the clones progressed through their *in vitro* life span, with a significant increase in DNA damage in the majority of the clones immediately prior to the end of their life spans. The results of modified comet assays for the detection of oxidized purines and pyrimidines revealed an age-related increase in oxidative DNA damage in the TCC as they aged in culture. Figure 66.3 illustrates levels of oxidative purine damage in 11 peripheral blood-derived CD4+ T cell clones as a function of their age *in vitro*. Similar results have been found for levels of oxidative pyrimidine damage.

It is interesting to speculate what the biological consequences of genetic damage in T lymphocytes might

be. There is much evidence that above a threshold level, genetic damage can cause cell cycle arrest in dividing cells, this effect being mediated via cyclin-dependent kinases and their inhibitors, or indeed induce apoptosis. Since T cells are required to undergo numerous rounds of replication following stimulation by a specific antigen prior to mounting an immune response, the impact of an age-related increase in genetic damage in T cells could be to reduce proliferative capacity of the T cells or inhibit capacity altogether, or indeed result in T cell death by apoptosis. It is interesting to note here that in studies with the CD4+ TCC model, approximately three to six days after the oldest weekly samplings of the T cells for analysis, and therefore when DNA damage levels were highest, the T cells die by apoptosis. It is not yet known if the age-related increase in genetic damage within T cells *in vivo* is sufficient to result in T cell replicative arrest or apoptosis. However, the results of previous studies have suggested that T cells containing mutations in genes coding for normal cellular metabolism may be selected against *in vivo*. T cells containing such mutations might have a reduced proliferative capacity, lowered response to proliferative stimuli, or may become nonviable. For example, Podlutzky *et al.* (1996) demonstrated that human T lymphocytes containing mutations in the HPRT gene have reduced proliferation rates *in vitro*. The work of Dempsey *et al.* (1983) to quantify the number of lymphocytes containing HPRT gene mutations in carriers of the Lesch–Nyhan mutation, found that only 1 to 9% of lymphocytes carried a mutation. This percentage is much lower than would be predicted (50%) for such carriers, suggesting that HPRT-negative mutant lymphocytes are selected against *in vivo*.

#### *Protocol for the measurement of DNA damage by the comet assay*

A suitable technique to examine levels of DNA damage (DNA single-strand breaks and alkali-labile lesions) in TCC is the alkaline comet assay, originally developed by Singh *et al.* (1988) and modified by Collins *et al.* (1993). In the latter, T cells embedded on slides are treated with either formamidopyrimidine glycosylase (FPG), which recognizes oxidatively modified purines, or with endonuclease III (ENDO III), which recognizes oxidatively modified pyrimidines. These enzymes nick DNA at the sites of oxidatively damaged nucleotides, creating single-strand breaks that can be detected with the alkaline comet assay.

1. Comet assays are performed at 4°C to minimize the repair of existing basal levels of DNA damage present in the T cells.
2. Cells are embedded in a 1% agarose gel on frosted microscope slides (2 × 10<sup>4</sup> cells/gel), and lysed for at least one hour in a high salt alkaline buffer (2.5 M NaCl, 0.1 M EDTA, 0.01 M Tris, 1%(v/v) Triton X-100, pH 10).

## 66. Human T Cell Clones in Long-term Culture as Models

**Figure 66.3** Levels of oxidative purine damage in 11 different TCC as a function of their *in vitro* life span, determined using a modified alkaline comet assay. Values represent the Mean  $\pm$  SEM for each assay, counting 50 cells/slide.

3. For the modified comet assay, to determine levels of oxidative purine or pyrimidine damage, the following additional steps are performed:

- FPG treatment:

Slides must be equilibrated in enzyme buffer (0.04 M HEPES, 0.1 M KCl, 0.5 mM EDTA, 0.2 mg/ml BSA, pH 8.0) and then treated with the enzyme at 37°C in a humid, dark chamber for 45 minutes, which nicks oxidatively damaged purines, creating single strand breaks.

- EndoIII treatment:

Slides are equilibrated in enzyme buffer (0.04 M HEPES, 0.1 M KCl, 0.5 mM EDTA, 0.2 mg/ml BSA, pH 8.0) three times for five-minute washes and then treated with the enzyme at 37°C in

a humid, dark chamber for 45 minutes, in this case nicking oxidatively damaged pyrimidines, creating single strand breaks.

4. Slides treated with the lesion-specific enzymes are then incubated at 37°C in a humid dark chamber for 45 minutes.

5. T cells treated with 150  $\mu$ M hydrogen peroxide for five minutes at 4°C (to induce oxidative DNA damage) should be used as internal positive controls in the modified alkaline comet assay to verify enzyme activity.

6. Following enzyme treatment (or directly after alkaline lysis in the case of the alkaline comet assay) the slides are placed in an electrophoresis buffer (0.3 M NaOH, 1 mM EDTA, pH 13) for

40 minutes to allow alkaline unwinding of the DNA, and then electrophoresed at 25 V, 300 mA, for 30 minutes.

7. Following electrophoresis, the slides are neutralized using 0.4 M Tris pH 7.5 and stained with 50  $\mu\text{g}/\text{ml}$  ethidium bromide. Stained slides can then be digitally analyzed, for example, using UV microscopy and Komet 3.0 analysis software (Kinetic Imaging, UK), counting 50 cells per slide. DNA damage results are expressed as percentage DNA in the comet tail.

## PROTEOMICS

Today the common application of genomic analysis cannot reveal changes in proteins present in cells as they age, but it is a useful screening approach to focus on certain candidates that may change and can be specifically studied (as described elsewhere in this book). Alternatively, direct proteomic analyses using traditional 2-D-gels with or without antibody (Pawelec *et al.*, 1988) or more modern techniques can be applied. Here, we describe an example of a more recently introduced technique using SELDI ProteinChip<sup>®</sup> technology from Ciphergen (Freemont, CA). This approach combines the retention of proteins to an array surface by chemical or physical interaction followed by analysis by Laser Desorption/Ionisation Time of Flight mass spectrometry. A reproducible “protein profile” is achieved according to mass and has been applied successfully to the study of biological samples for the definition of candidate biomarkers of disease. Increasingly, the technology has been combined with powerful software analogues to distinguish ions that hold predictive significance of disease state, either individually or in combination with other ions. This marriage of analytical chemistry and bioinformatics has proved to be a very sensitive and novel proteomic technology, defining a paradigm in the way proteins can be analyzed in complex mixtures.

### *Proteomics protocol*

TCC are lysed in 200  $\mu\text{l}$  lysis buffer on ice (50 mM Tris HCl, 5 mM EDTA [pH 6.0], 2 mM PMSF, 1% Triton X-100), followed by five short bursts with a sonic finger before centrifugation at  $150 \times g$  for 20 minutes to pellet cell debris. Lysates are diluted 1:4 in pH 9.0 binding buffer (100 mM Tris Base) and applied to SAX2 (anion exchange) arrays (Ciphergen) in duplicate. Arrays are read in a ProteinChip Reader (Ciphergen) after the application of  $2 \times 0.6 \mu\text{l}$  sinapinic acid matrix. Generated spectra of masses in the range of 2000–16000 Daltons (Da) are calibrated externally by a mixture of known calibrants. Finally, profiles are aligned and normalized to a common mass occurring in all spectra at a consistent intensity. Using a multilayer perceptron Artificial Neural Network (ANN) (Neuroshell 2) with a back propagation algorithm, models can be generated to sort significant ions consistently predictive of known-age clones by stage,

using raw data (mass to charge [m/z] value versus intensity) from mass ranges 2–5, 5–10, 10–16 (see Figure 66.4).

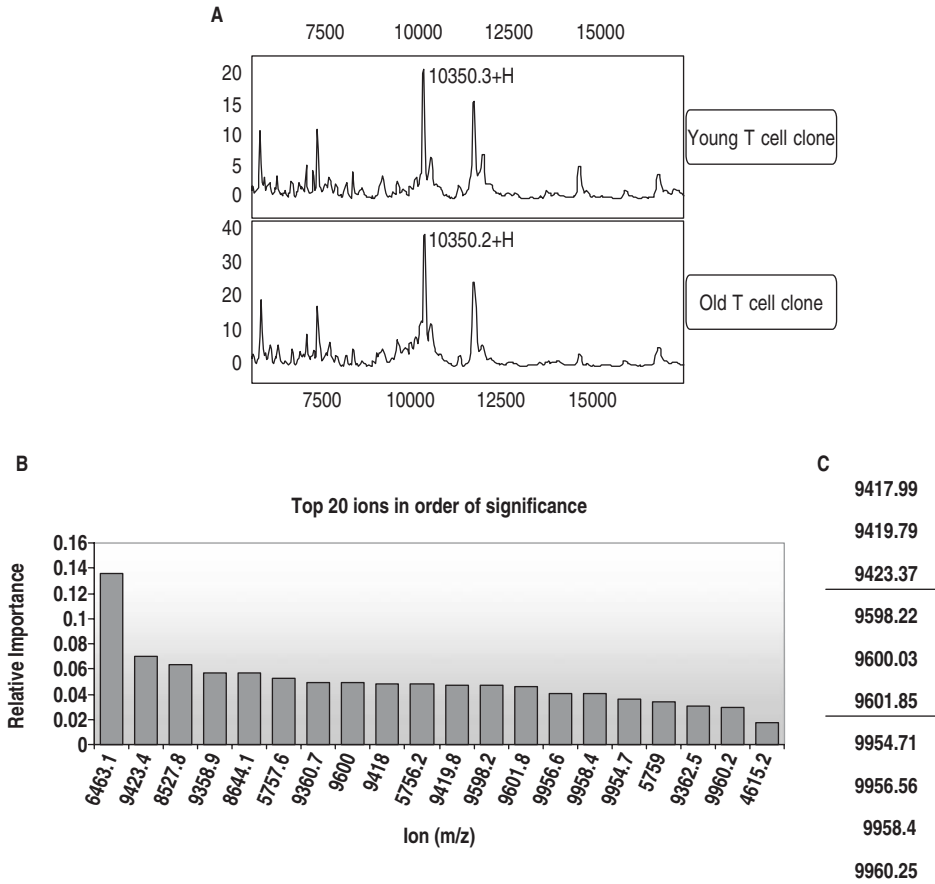

The top 100 ions of predictive value are selected from each and put forward to further analysis to rank a top 50. Ions with high predictive value that do not correlate with protein peak/part of peak signals on the original SELDI data are filtered out. In the example using 77 TCC samples shown here, the resulting ion list contained three ion-clusters at 9417-23 Da (cluster A), 9598-601 Da (B), and 9954-60 Da (C). Each cluster was tested individually and in conjunction with the other two for predictive ability. Though each cluster held little predictive value individually, in combination A+C and A+B+C were able to correctly predict the age of the test clones with greater than 70% accuracy. The model was then tested on seven unseen, validation clones. Again, both the top 50 and top 20 ions yielded >80% accuracy, though each cluster proved individually poor. The success of combining A+C could not be repeated on the unseen data, but of note is the ability of the model to predict with greater than 70% accuracy the combination of A+B+C, reflecting the result of the test data.

The selection of ion clusters around a certain mass and then cross-referencing with the SELDI data for the presence of a peak is an important step to eliminate artifacts from the data processing. For example, the ion with by far the most predictive power is a single ion found at 6463.08 Da but is very much within the noise of the SELDI data. This cannot be a protein or peptide. However, clustered ions in the top 20 could be correlated to peaks on the SELDI, and their predictive power established on seen and unseen data with some degree of success. Potentially, these proteins can be identified by biochemical methods and characterized to establish their true value within the aging model system studied here. This example illustrates the potency but also the potential pitfalls of this powerful combined proteomic/bioinformatic approach and the degree to which caution must be exercised in interpreting protein pattern data.

## Conclusion

In this chapter, we have detailed a method for the production and maintenance of human monoclonal T cell populations in long-term culture, and we have provided selected examples of protocols for analytic techniques with which to seek age-associated changes therein (biomarkers of aging). The model represents a situation of chronic antigenic stress, where TCC are constantly reexposed to stimulating antigen. There are reasons to believe that this model does reflect common challenges to the immune system *in vivo*, particularly in the elderly where the chronic stressor may be Herpes virus, particularly Cytomegalovirus (CMV) (Pawelec *et al.*, 2004), but also in younger individuals carrying large antigenic loads that cannot be cleared (cancer patients, patients infected with persistent parasites, etc.). This chronic antigenic

**Figure 66.4** SELDI proteomic analysis of TCC. **A:** Example of SELDI mass spectra of young and old clones. **B:** Top 20 ions listed in order of predictive significance within ANN test data. **C:** Ion clusters from Top 20 list.

stress in the elderly leads to clonal exhaustion and shrinkage of the T cell repertoire, which increases susceptibility to novel pathogens, as sketched in Figure 66.5.

A cluster of age-associated immune alterations, including CMV status, designated the Immune Risk Phenotype (IRP) can be distinguished, which is predictive

of mortality in longitudinal studies of the very elderly (Wikby *et al.*, 2005). Refinement of this concept and its extension to younger individuals, using lessons learned from culture models and tests of intervention carried out in those models, may contribute to improved immunity, better health, and decreased mortality due to immunosenescence.

### Recommended Resources

The SAGE Web site is a useful resource (<http://sageke.sciencemag.org/>). Specialist journals or sites on immunosenescence are still rare. The new Open-Access journal *Immunity & Aging* aims to fill this gap (<http://www.immunityageing.com/home/>).

# Age-Related Changes in the Human Retina

Carlo Cavallotti and Nicola Pescosolido

*An increasing number of elderly give a good cause for investigations on age-related changes in the human retina. Samples of fresh retinal tissue obtained from young and old humans were studied by means of traditional histological methods and by scanning electron microscopy. Particular attention was paid to morphometrical data. In fact, with the aid of the quantitative analysis of images, a large amount of morphometrical data were collected. Moreover, the amount of protein content in retinal tissues was determined. Particular care was taken in order to clarify the changes occurring in the human retina with aging. Retinal thickness significantly decreases with age. The ganglion cells seem to be more vulnerable to age-related loss than other retinal cells. The number of retinal capillaries was diminished with age. The intercellular connections between photoreceptors, the number of cellular processes, and the number of synaptic bodies of the bipolar cells also decreased significantly with age. Biochemical dosage of proteins demonstrates that the amount of proteins in retinal tissues decrease with age. In conclusion, all morphological, morphometrical, ultra-structural, and biochemical data agree in demonstrating that the human retina undergoes specific changes with age. Scanning electron microscopy performed on human retina in young and old subjects confirms the age-related changes of photoreceptor cells as well as of bipolar and ganglion cells, and provides new morphometrical findings. These results can be considered as a model and as normal values for other changes that may occur in the human retina in pathological conditions.*

## Introduction

The majority of elderly people suffer from deficiencies in both photopic (Owsley and Burton, 1991) and scotopic (Sturr and Hannon, 1991) vision, not related to any organic pathology, but rather as part of the general decline in all the functions of the body. Based on the theory of physical deterioration, it is believed that the body is placed under stress and injury, both extrinsic (dependent on the environment) and intrinsic (dependent

on biological processes). This damage derives from small, highly reactive molecules known as free radicals (Armstrong, 1984), which are produced during normal metabolic processes and are associated with important cellular functions (Brizee and Ordy, 1981). Of these damaging agents, we shall consider reactive oxygen intermediates, capable of inducing oxidative stress. In addition, peroxy-nitrites, endogenous alkylating agents, and aldehyde products, resulting from the oxidation of lipids, also have the capacity to damage macromolecules (protein and lipid complexes, DNA, etc.) (Dykens, 1999). Macromolecular damage results in cellular dysfunction manifested by nuclear instability, inappropriate cell differentiation, and consequent cell death (necrosis or apoptosis) (Handelman and Dratz, 1986). These age-related changes of the retina primarily cause a loss of visual acuity and impairment of color discrimination as well as reduction of the visual field. Impairment of visual functions in aged subjects has long been considered the consequence of opacity of the dioptric media, whereas little attention has been paid to the retinal age-related changes. In light of our present findings, we can hypothesize that the fall in visual acuity occurring in old age is influenced, at least in part, by the age-related changes observed in human retinal tissues (Cavallotti *et al.*, 2004). In fact, our group studied the Scanning Electron Microscopic (SEM) features of the human retina. For a detailed evaluation of the effects of aging on retinal morphology, a quantitative analysis of images was performed for obtaining morphometrical data. Our findings underlined that the human retina can be considered an optimal model for studies on neuronal maturation and/or neuronal aging, being particularly sensitive to age-related changes and to senile decay.

This chapter discusses the following:

- Morphological and functional organization of the human retina
- Choroid-retinal complex (choroid, Bruch's membrane, basal membrane, retinal pigmented epithelium)
- Neuronal cells of the retina
- Glial cells of the retina
- Retinal vessels

- Aging of the whole retina (experimental results)
- Aging of the choroid-retinal complex
- Aging of neuronal cells of the retina
- Aging of glial cells of the retina
- Aging of retinal vessels
- Age-related diseases of the human retina

## Morphological and Functional Organization of the Human Retina

The retina is the most internal of the three sheets that coat the posterior wall of the eye. This sheet extends from the optical nerve to the pupil-iris border, and it can be divided into an optical part, dedicated to the function of vision, and a blind part, in conjunction with the border of the pupil. The two parts are separated by the ora serrata. The retina is structurally divided into two shares: one outer and one inner.

The outer share of the retina consists of the retinal pigment epithelium (RPE), which lies on the basal membrane and the Bruch's membrane. The RPE with the basal membrane, Bruch's membrane, and the inner choroid form a single functional complex named the choroid/Bruch's membrane/basal membrane/RPE complex, or chorio-retina (Streiff and Faggioni, 1971). The integrity of this complex maintains the integrity of the retinal photoreceptors, and therefore the integrity of the whole retina.

The inner share of the retina or neurosensory retina represents the real nervous part of the eye bulb. It is of encephalic derivation and, therefore, derives directly from the central nervous system. It consists of three consecutive neurons, identifiable as the rods and cones (first neurons), bipolar cells (second neurons), and the ganglion cells (third neurons). In reality, the retinal cells and their processes are assigned into 10 layers (see Figure 67.1–67.6):

- Retinal pigmented epithelium (RPE)
- Layer of the acromeres of the photoreceptors
- Outer limiting membrane (OLM), which is not a real membrane but a small zone with numerous zonulae adherens between the Müller cells and the photoreceptors
- Outer nuclear layer (ONL), formed by the bodies of the photoreceptor cells
- Outer plexiform layer (OPL), formed by the synapses between the photoreceptors, the bipolar cells, and the horizontal cells
- Inner nuclear layer (INL), which includes the cell bodies of five cell types: horizontal, bipolar, amacrin, interplexiform, and the Müller cells
- Inner plexiform layer (IPL), formed by the synapses between the bipolar cells, the amacrin cells, and the ganglion cells
- Ganglion cell layer (CGL), which also contains some amacrin cells

**Figure 67.1** Light microscopic image of a normal human retina. The RPE is detached from the other retinal layers (it is not contained in this image on the left side). P = photoreceptors; B = bipolar cells; G = ganglion cells (magnification 1600x).

- Nervous fiber layer (NFL), which contains the axons of the ganglion cells
- Inner limiting membrane (ILM), formed by the terminal processes of the Müller cells

The neurosensory retina, therefore, is formed by a large variety of cells described in the next sections.

## Choroid-Retinal Complex

The choroid-retinal complex is formed by choroid, Bruch's membrane, basal membrane, and retinal pigmented epithelium (named also chorio-retina).

### CHOROID

The choroid is the intermediate layer of the three sheets of the posterior wall of the eye. It is vascular in nature. The inner part of the choroid lies in close contact with the retina, and takes part in common with the choroid/Bruch's membrane/basement membrane/RPE complex, and therefore is named chorio-retina (Streiff and Faggioni, 1971).

### BRUCH'S MEMBRANE

The Bruch's membrane extends from the optic disk to the ora serrata. Its thickness varies in different parts of the eye; it is thickest close to the optic disk (2–4  $\mu\text{m}$ ) and thinner at the periphery (1–2  $\mu\text{m}$ ). It is formed by the following five layers: (1) The basal membranes of the RPE cells form the inner layer of the Bruch's membrane; followed by (2) the internal collagen layer; (3) the elastic layer; (4) the external collagen layer; and (5) the basal membrane of the choriocapillaries. Collagen and elastane are the principal structural proteins of the Bruch's membrane. Certain types of collagen (type I, II, III, V, and IX) aggregate in long fibrils. Other types (IX and XIII) are found on the surface of the fibrils and are linked to other components of the matrix. Type IV collagen forms a soft net. The elastane fibers give elasticity

to the membrane. Fibronectin and laminin are large glycoproteins, which, through their multiple bonds, help the cells to join to the membrane (Feeney-Burns and Ellersiek, 1985).

#### BASAL MEMBRANE

The basal side of the RPE lies on a basement membrane that is uniform in thickness throughout the retina. The basal cell membrane shows only a few in-folding. The cell membrane on the apical side is like that in the nonpigmented epithelium; there are numerous cell junctions. The lateral surfaces show interdigitations (Hogan *et al.*, 1971). The basal membrane is made up of collagen connective tissue and contains some specific proteins named membrane bound protein (MBP) and proteoglycans (PG).

#### RETINAL PIGMENTED EPITHELIUM

The cells of the RPE are postmitotic cells with a hexagonal shape that form a single layer of cuboidal epithelial cells that separate the external portion of the photoreceptors from the choroid. The RPE provides metabolic and functional support for the external portion of the photoreceptors. Each human eye contains between 4 and 6 million RPE cells. In the central part of the retina, the shape and dimensions of the RPE cells are uniform. They are circa 14  $\mu\text{m}$  in diameter and 12  $\mu\text{m}$  in height. At the equator the cells are taller and larger and at the extreme periphery lose the uniformity of size and shape. Some cells may contain more than one nucleus, and at the ora serrata the RPE cells may measure up to 60  $\mu\text{m}$  in diameter (Panda Jonas *et al.*, 1996).

These cells are formed of a basal portion, an apical portion, and six lateral faces. The basal portion has a cell membrane with numerous invaginations, which can sink up to 1  $\mu\text{m}$  into the cytoplasm, in order to increase the absorbent surface. The basal membrane of these cells is adjacent to the basal lamina, which forms the proximal layer of the Bruch's membrane. The basal invaginations increase the surface area of the cellular membrane, as this is involved in transport functions. The apical portion of the RPE cells, which sits in front of the acromere of the photoreceptors, is folded to form microvilli of 5 to 7  $\mu\text{m}$  length, that surround the third terminal of the acromere of the photoreceptors. As the acromeres of the rods and the cones are of different dimensions, the villi that surround the external portion of the rods are smaller (3  $\mu\text{m}$ ) than those that surround the cones. From a functional point of view there are two different types of microvilli—one softer, which is dedicated to transepithelial transport, and the other connected to the distal lamina of the photoreceptors.

The lateral portions of the RPE are linked (zonula occludens and adherens) to create the external haemato-retinal barrier and at the same time are interconnected through intercellular junctions. The cells have a round basal nucleus, and the cytoplasm is rich in lysosomes,

smooth endoplasmic reticulum, mitochondria at the basal level, round pigmented granules, and oval ones containing melanin. The majority of the melanin granules are found in the apical portion or in the villi. The granules measure up to 1  $\mu\text{m}$  in diameter and from 2 to 3  $\mu\text{m}$  in length. The pigment granules adsorb light, preventing diffusion and also act as free radical "scavengers." The RPE cells in the macular and equatorial regions contain the major quantity of pigment (Katz and Robison, 1984).

#### FUNCTIONAL ROLE OF RPE

The RPE plays a fundamental role in the transport and storage of the retinoids, essential for maintaining the visual cycle. Another function of the RPE is to eliminate components of the acromeres of the photoreceptors through phagocytosis activity mediated by cathepsin D and by the integrins that act as membrane receptors that mediate the phagocytosis. The phagosomes are linked to lysosomes to form phagolysosomes, where they are digested by the intracellular digestive enzymes located at the basal surface of the cell. The final metabolism products are expelled into the choroidal circulation by exocytosis through the Bruch's membrane. If they are not completely digested, they accumulate inside the cells as *granules of lipofuscin*. These granules increase with age (Iwasaki and Inomata, 1988), especially in the macular area. The constant exposure of the RPE to light, at elevated concentrations of oxygen, together with the high metabolic activity of these cells, creates an environment favorable, especially in the macular area, to the formation of toxic reactive oxygen radicals. In defense against oxidative stress, the RPE cells contain antioxidants such as superoxide dismutase, catalases, reduced glutathione, melanin, and carotenoids. In reality, the quantity of these reduces with age, as the antioxidant defenses decrease.

#### Neuronal Cells of the Retina

The first category of retinal cells are neurons: photoreceptors, bipolar cells, and ganglion cells. The intra-retinal nervous optic pathway consists of three consecutive neurons: rods and cones (first neuron), bipolar cells (second neuron), and ganglion cells (third neuron). These cells in human retina are: first neuron about 125 million; bipolar cells about 12.5 million; and ganglion cells about 1.25 million in the ratio 100:10:1.

The neuronal cells of the retina (Radnot, 1978), the inner and outer segments of photoreceptors (Antal, 1977), and the pigment epithelium and its relationships with the photo-receptors were well studied and well described (Leuenberger, 1971). Retinal thickness is known to vary between its central and peripheral regions (Follman and Radnot, 1979) as well as between temporal and nasal zones (Lewis *et al.*, 1969). Moreover, large individual variations have been described in the numbers of neuronal cells localized in the different layers of the human retina

(Osterberger, 1935). Consequently, all retinal quantifications must be performed precisely considering the same topographical location for each sample of investigated retinas.

## Glial Cells of the Retina

The second category of retinal cells are glia cells: macroglia and microglia.

### MACROGLIA CELLS

Macroglia are cells that regulate the retinal metabolism and modulate neuron function and blood vessels. There are two cell types as part of the macroglia: Müller cells and astrocytes. The Müller cells cross the thickness of the retina from the RPE to the inner limiting membrane. The bodies of the cells are located in the inner nuclear layer, and they are the principal regulatory cells for the metabolism of glutamate, the ion balance, and neuron function. The Müller fibers form an extended net that sustains and surrounds all the nervous cells. In addition, their axons and dendrites help to form the inner and outer limiting membranes.

The astrocytes, on the contrary, are limited to the nervous fiber layer and envelope the blood vessels and ganglion cells with their cellular protrusions. The branched protrusions of these cells occur at right angles with respect to the Müller fibers, and the two structures are not linked. The astrocytes are star-shaped, with round nuclei and numerous thin protrusions. They are horizontally placed and surround the blood vessels with a dense net of fibers. They form an arched, honeycomb structure, which surrounds and sustains the axons of the ganglion cells. They are firmly anchored to the walls of the blood vessels (Vernadakis, 1986).

### MICROGLIA

The microglial cells are similar to the tissue macrophages (Chen *et al.*, 2002). These cells are normally resting, but are sensitive to alterations in the homeostasis of the retina; when the retina is altered, the microglial cells rapidly change into phagocytes. Finally, in the retina we also find endothelial cells and pericytes, which flank the nerve cells and glia cells or arrange themselves around the blood vessel walls. Pericytes are modified smooth muscle cells that regulate the vascular flow through dilation and contraction of the vessels. The endothelial cells regulate the homeostatic function and form the haemato-retinal barrier.

## Retinal Vessels

The retina and the optic nerve head are the only parts of the central nervous system that can be inspected during life with an ophthalmoscopic examination. Moreover, the ophthalmoscope allow us to inspect the superficial retinal vessels.

The vascular supply of the retina comes from the ophthalmic branch of the internal carotid artery, which in turn gives origin to the central retina artery. The latter, upon issuing from the optic disk, divides into four arterioles, which supply the four quadrants of the retina (see Figure 67.1–67.7).

The ganglion cells and bipolar cells receive their blood supply from these arterioles and their capillaries, whereas photoreceptor elements receive nourishment from the underlying choroidal vascular bed. These small vessels react in diseases like vessels of corresponding sizes in the brain. Since the walls of the retinal arterioles are transparent to the ophthalmoscope, what is seen is a column of blood cells. In hypertension and/or arteriosclerosis (usually coexistent with hypertension), the lumens of the vessels are narrowed because of fibrous tissue replacement of the media and thickening of the basement membrane. The light reflection from the vessel then has a different refractive index than the adjacent retinal tissue. Spreading of vessels, decrease of the size of the lumen, and arteriole-venous compressions are other signs of hypertension and arteriosclerosis (see Figure 67.1–67.8).

Capillary-venular aneurysms may develop, most often in diabetes mellitus (see Figure 67.9).

Since the central retina vein and artery share a common adventitial sheath, atheromatous plaques in the artery may result in thrombosis of the vein. Round or oval hemorrhages always lie in the outer plexiform layer and linear or flame-shaped ones in the superficial layer of the retina, as occurs in conditions with extremely high intracranial pressure.

## Aging of the Whole Retina (Experimental Results)

In our experiments, only samples of the retinas coming from living humans and not from autopsies were used because post-mortem phenomena may bring about early modifications in the morphometric data obtained from the retinas. Our studies were approved by the local Ethical Committee, and patients or their relatives gave their informed written consent. The investigations were performed according to the guidelines of the Declaration of Helsinki. After removal, the eye-bulb was dissected with a razor blade and samples of intact retinal tissue (located precisely in the same site, equatorially in the nasal region) were harvested. The whole thickness of the retina was measured by a micrometric gauge. Small fragments of the retina were then placed in ice-cold fixative (for morphological staining) or submersed in ice-cold buffer (for estimation of protein content).

### LIGHT MICROSCOPY

Samples of the human retina were immediately prefixed in 2% osmium tetroxide at pH 7.4 in veronal-acetate buffer

## 67. Age-Related Changes in the Human Retina

for five minutes at 4°C. After fixation, the specimens were washed with veronal-acetate buffer (pH 7.4), dehydrated in a graded ethanol series and embedded in paraffin. Thin sections (about 4  $\mu$ m) were made for morphological staining with toluidine blue (0.05% for 1 minute). Lipids were stained by means of special histo-chemical techniques for light microscopic analysis. In order to determine the composition and distribution of the lipids, three different stains were used: the bromine–Sudan black B stain, which stains all classes of lipids; bromine–acetone–Sudan black B, which stains only phospho-lipids; and Oil red O, which stains neutral lipids (especially esters of saturated and unsaturated fatty acids).

### SCANNING ELECTRON MICROSCOPY

Other samples of human retina were used for scanning electron microscopy. Prefixation tissue samples were oriented, and the exposed surface coated with gold-carbon vapor and examined in a JEM 100 B electron microscope with the EM Asid High Resolution Scanning Device (University of Pecs, Hungary). Photographs were taken using ORWO NR 5R NP 20 films. Microphotographs were printed in black and white.

### QUANTITATIVE ANALYSIS OF IMAGES

For a detailed evaluation of the effects of aging on retinal morphology a QAI was performed on slides and on microphotographs using a Quantimet Analyzer (Leica®) equipped with specific software. This software made it possible to determine (see Table 67.1):

- The thickness of the retina
- The number of ganglion cells/mm<sup>2</sup> of retina
- The number of capillaries/mm<sup>2</sup> of retina
- The number of synaptic bodies/area
- The number of cellular processes/observed area
- The number of intercellular connections in the matrix between the photoreceptors

Final values must be submitted to statistical analysis of data. The values reported in this chapter represent the “values” of staining for each age group and are expressed in conventional units (C.U.)  $\pm$  S.E.M. C.U. are arbitrary units furnished and printed directly by the Quantimet system (Leica, 1997).

### ESTIMATION OF PROTEIN CONTENT

Samples of human retina were weighed and homogenized 1/10 w/v into an ice-cold homogenization buffer (veronal acetate pH 7.4). Tissue protein concentrations were determined, using bovine serum albumin (BSA) as standard and Folin phenol as reagent (Lowry *et al.*, 1951).

### STATISTICAL ANALYSIS OF DATA

The statistical methods used throughout this study must be interpreted as an accurate description of the data rather than a statistical inference of such data. The preliminary studies of each value were performed with the aid of basic sample statistics. Mean values, maximum and minimum limits, variations, standard deviation (S.D.), standard error of the means (S.E.M.), and correlation coefficients were calculated. Correlation coefficients denote a significant level less than 0.001 ( $P < 0.001$ ), but is not significant when  $P > 0.05$  (n.s.) (Castino and Roletto, 1992).

### EXPERIMENTAL RESULTS

Comparing the images obtained from younger subjects with those obtained from older ones (see Figure 67.2) and observing the quantitative data reported in Table 67.1, we can find:

1. A lower number of capillaries
2. A marked decrease of the synaptic buttons
3. A marked reduction of the cellular processes
4. An increase of the intercellular spaces.

TABLE 67.1  
Age-related changes in human retinas harvested from patients of different ages: Values of quantitative analysis of images and biochemical values of protein amount

Age-related Changes	Young (n=7)	Old (n=5)
Thickness of the retina $^{\circ}\mu\text{m} \pm \text{SEM}$	426 $\pm$ 34.2	261 $\pm$ 18.9*
$\wedge$ Ganglion cells number mm <sup>2</sup> $\pm \text{SEM}$	413.5 $\pm$ 32.3	256.2 $\pm$ 26.8*
Capillaries number mm <sup>2</sup> $\pm \text{SEM}$	3.6 $\pm$ 1.4	1.8 $\pm$ 1.2*
Synaptic bodies area C.U. $\pm \text{SEM}$	122.4 $\pm$ 4.9	38.5 $\pm$ 1.6*
Cellular processes area C.U. $\pm \text{SEM}$	82.3 $\pm$ 3.1	13.1 $\pm$ 1.5*
Intercellular gaps area C.U. $\pm \text{SEM}$	36.4 $\pm$ 2.5	14.3 $\pm$ 1.4*
Protein $\gamma/\text{mg}$ of fresh tissue $\pm \text{SEM}$	92.1 $\pm$ 1.8	78.3 $\pm$ 1.3*

$^{\circ}$ without the pigmented epithelium that is detectable from all remaining layers

\* $P < 0.001$  old versus young

n= number of retinas

C.U.= Conventional Units furnished and printed directly by analyzer (Leica 1997).

$\wedge$  Number of ganglion cells corresponds to the number of the optic nerve fibers.

**Figure 67.2** Micro-anatomical details of the human retina harvested from a young donor (18 years) observed by scanning electron microscopy. The ganglion cell layer (G), bipolar cell layer (B) and photoreceptor cell layer (P) may be seen (magnification 1600x). Reproduced by permission of the Canadian Ophthalmological Society.

**Figure 67.3** Scanning electron photomicrograph showing the outer as well as the inner segments of photoreceptors. Moreover, the external limiting membrane, the bipolar cell layer, and numerous capillaries can be distinguished. Samples of the human retina were harvested from an old donor (68 years old) (magnification 8000x). Reproduced by permission of Canadian Ophthalmological Society.

In the human retina, all layers can be clearly discerned and easily defined on the basis of well-known observations using light microscopy (see Figure 67.1).

Moreover, aging induces a strong decrease of the whole thickness of the retina from  $426 \pm 34,2 \mu\text{m}$  in younger to  $261 \pm 18,9 \mu\text{m}$  in older (i.e., a decrease of about 40%) as reported in line 1 of Table 67.1. Line 2 shows a strong decrease of the ganglion cells. These cells are  $413.5 \pm 32.3/\text{mm}^2$  in the retinas of young humans and go down to  $256.2 \pm 26.8/\text{mm}^2$  in the retinas of old humans, a decrease of about 38%. At line 3 a strong decrease of the number of the capillaries is reported. The latter are  $3.6 \pm 1.4 \text{ C.U.}$  in adult patients, and go down to  $1.8 \pm 1.2 \text{ C.U.}$  in the old age-group, a decrease of about 50%. The synaptic bodies (Table 67.1, line 4) go down from  $122.4 \pm 4.9$  to about  $38.5 \pm 1.6 \text{ C.U.}$  (old) for each microscopic area observed. The cellular processes (Table 67.1, line 5) also show a reduction from  $82.3 \pm 3.1$  to  $13.1 \pm 1.5 \text{ C.U.}$  for each microscopic area observed. The intercellular connections decrease from  $36.4 + 2.5 \text{ C.U.}$  to  $14.3 + 1.4 \text{ C.U.}$  The protein content is slightly reduced:  $92.1 \pm 1.8 \mu\text{g}/\text{mg}$  of fresh tissue in younger subjects in comparison to  $78.7 \pm 1.3$  in older ones.

### Aging of the Choroid-Retinal Complex

As stated earlier, the choroid-retinal complex includes many structures, the most important of which are the pigmented epithelial cells.

#### RPE CELLS

As previously stated, postmitotic cells perform numerous metabolic functions throughout our lives, not only for themselves, but also for the photoreceptors. From about 20 years of age, the RPE cells show alteration as a result of their constant activity in the course of the years.

**Figure 67.4** Scanning electron photomicrograph showing photoreceptor cells' outer segments. Samples of the human retina were harvested from a young donor (21 years old). The cellular matrix is sometimes crossed by intercellular connections. These structures are due to a collapsed inter-photo-receptor matrix, which normally fills the sub-retinal spaces. The apex of many photoreceptors can be observed (magnification 16.000x). Reproduced by permission of Canadian Ophthalmological Society.

Each single RPE cell metabolically supports around 30 photoreceptors (Dryja *et al.*, 1998).

Everyday, 10 to 15% of the acromeres of each rod are phagocytosed by the RPE cells and replaced. The highest turnover of acromeres of retinal photoreceptors involves the parafoveal rods and the first signs of retinal aging appear in the macula. The subfoveal RPE maintains its function for the longest period, due to its high density of cones. A decrease in the functionality of the RPE occurs with aging, which manifests itself through various morphologic signs (Weiter *et al.*, 1986). The signs of RPE aging consist of the reduction of the granules

## 67. Age-Related Changes in the Human Retina

**Figure 67.5** The intercellular spaces of the outer layers of a retina harvested from a young man (19 years old). Numerous cellular processes and synaptic buttons can be seen. Finally, a presumed interplexiform cell may be identified (magnification 9600x). Reproduced by permission of the Canadian Ophthalmological Society.

**Figure 67.6** Scanning electron photomicrograph showing the bulges of the outer nuclear layer appear tightly attached to one another, with only very narrow bridges of cellular matrix between them. The ganglion cells appear as large, spherical bodies, arranged in a fibrous network. Most of the cell bodies are smooth, but some of them were seen to have a villous surface. This retina was harvested from a young man (19 years old). Numerous synaptic bodies, cellular processes, and intercellular spaces may be observed (magnification 16000x). Reproduced by permission of Canadian Ophthalmological Society.

of melanin (depigmentation) and the migration of the pigment granules to the basal portion of the cells, the loss of hexagonal shape of the foveal cells, the reduction on the cell density (atrophy, hyperplasia, hypertrophy, cellular migration), and the intracytoplasmic accumulation of abnormal molecules due to incomplete degradation of the metabolic products in the form of intracytoplasmic granules (lipofuscin, melanolipofuscin) (Young, 1982). These granules are partially the result of a phagocytosis process of the acromeres of the rods and cones and their elimination by the phagosomes. Inside these latter, the gradual digestion of the discs of the acromeres, with the formation of residual bodies, occurs.

Many incompletely digested discs and some phagosomes are eliminated in the basal lamina of the Bruch's membrane. Large quantities of residual bodies are seen often in the eyes of individuals aged between 40 and 60, with a strong increase after the 80th year. The accumulation of this cellular detritus inevitably leads to the suffering of the RPE. These changes are more noted in the macula than in the equatorial and peripheral areas (Burns and Fenev Burns, 1980). Now we shall examine, in greater detail, the typical signs of RPE aging.

### VARIATION IN THE TYPE, QUANTITY, AND STRUCTURE OF THE GRANULES OF LIPOFUSCIN

With advancing years, inside the cells of the RPE, granules of lipofuscin appear, which represent the lysosomal accumulation of residual bodies including the nondegradable final products of metabolism and the phagocytosed acromeres of the photoreceptor, as already stated (Burns and Fenev Burns, 1980).

Each cell of the retinal pigment epithelium (RPE) is in a continuous process of intracellular renewal. Sometimes this process of molecular degradation is not complete and results in the accumulation of metabolic debris and interference with other metabolic activity in these cells. The residual materials are "useless" molecular aggregations, normally called *lipofuscin granules*, that contain damaged RPE cells and membranes of rod and cone phagocytes (i.e., incompletely degraded cellular debris) (Armstrong, 1984). The incomplete molecular degradation seems to be due to altered substrates, which therefore are not recognized by the enzymatic systems. These molecular alterations result from the harmful effects that free radicals have on the RPE cells and their photoreceptors, rich in polyunsaturated fatty acids that become peroxidised. The damaged molecules are phagocytosed by the RPE cells and accumulate in their cytoplasm, thus compromising their metabolism and inducing cell death. The acromeres of the retinal photoreceptors can be abnormal due to oxidative damage prior to phagocytosis, or the abnormality can be hereditary. The reason why the acromeres of the photoreceptors are sensitive to oxidative stress is their richness in polyunsaturated fats. Exposure to light, and particularly short wavelength radiation, increases the production of free radicals and accumulation of lipofuscin in the macular RPE. In addition, environmental factors such as cigarette smoke reduce the level of antioxidants and promote the formation of free radicals, contributing to the accumulation of cellular debris (Lerman, 1988).

Lipofuscin exists inside the RPE cells in the form of granules that appear yellow-green under UV light excitation. Topographically, the majority of the granules of lipofuscin accumulate in the posterior pole of the eye bulb, whereas the quantity reduces in the fovea. This distribution of lipofuscin with respect to the location remains constant during the entire life and correlates with the density of photoreceptors. The lipofuscin granules

contain lipids and proteins. The cytoplasmic volume of the RPE occupied by lipofuscin increases with age, from 8% at age 40 to 29% at age 80. Furthermore, the cytoplasmic volume occupied by lipofuscin in the macula is greater than that in the periphery: 19% in the macula versus 13% in the periphery. The excessive accumulation of lipofuscin in the RPE cells slows the metabolic activity of the cells and predisposes them to age-related macular degeneration (AMD) (Bird, 1997).

Lipofuscin is the generic name given to a heterogenic group of lipid-protein aggregates that are found in aging cells in all human tissues. Different from the other tissues, in the retina the lipofuscin does not derive from the degradation of intracytoplasmic organelles, but from the incomplete degradation of the products deriving from the phagocytosis of the outer portions of the photoreceptors following the peroxidation of the unsaturated fatty acids. Once accumulated, the lipofuscin causes the death of the RPE cells because it acts as a true generator of free radicals (Boulton *et al.*, 1993); lipofuscin can release lysosomotropic amines. Finally, other authors consider lipofuscin to be an inert substance that acts directly through the congestion of the cytoplasm (in some tissues lipofuscin can occupy up to 30% of the cell volume) (Elderly and Lasky, 1993).

#### MELANIN GRANULES

Melanin has a double role in the retina: to reduce the chromatic aberration, increasing the visual acuteness, and to protect against oxidative stress by acting as a cellular antioxidant. Its concentration increases from the equator to the posterior pole reaching a peak in the macula. The increased concentration of melanosomes in the macula is due to the fact that the RPE cells here are larger and concentrated into a smaller area with respect to the smaller extra-macular RPE cells dispersed in a much larger area (Handelman and Dratz, 1986). The differential distribution of melanosomes is maintained during the first 40 years of life, but afterward a significant reduction in the melanin granules is seen in all regions of the retina (Weiter *et al.*, 1986). To make a comparison, consider three age groups: 10–20; 21–60; and 61–100. The reduction in the quantity of melanosomes between the first and the third class is 35%. Talking in terms of cell volume, therefore, around 8% is occupied by melanin in the first two decades of life, which reduces to 6% in the second age group, and finally further diminishes, arriving at 3.5% in the third age group (Feney Burns, 1984).

Melanin is a complex heterogenic biopolymer, containing free radicals, which can be identified using electron spin resonance spectroscopy (ESR). Using this technique a 40% reduction in melanin content is observed with aging (Sarna *et al.*, 2003). Three possible mechanisms may explain the loss of melanin from RPE cells: expulsion of the granules, lysosomal degradation, and chemical damage. The expulsion of the granules may be a

possibility, notwithstanding the fact that the granules are not found in the Bruch's membrane or in the interphotoreceptor space. Lysosomal degradation is highly elevated due to its function of degrading the acromeres of the photoreceptors (Boulton and Wassel, 1998). With aging comes an increase in the number of melano-lysosomes, accompanied by a change in the appearance of the melanin granules. Notwithstanding that the morphology of the melanosomes changes following an interaction with the lysosomes, it is likely that the melanin is not degraded and that the changes derive from the degradation of the proteins of the matrix on which the melanin is deposited. The third mechanism is that of chemical degradation. The irradiation of human eyes with intense blue light induces a nonuniform photobleaching of the melanosomes. The lack of uniformity of the bleaching seems to be due to the fact that lipofuscin is also found in the complex granules of aged RPE cells and this is more photoreactive than melanin, or even may act as photosensitizers. Blue light therefore would induce oxidative photo-degradation of melanin by the formation of superoxide anion and hydrogen peroxide. On the one hand the photo-degradation of melanin (oxidation or irreversible bleaching) does not have any biological significance in tissues with high turnover (such as hair and skin); on the other hand, this event gains a high importance when it occurs in those tissues with low turnover such as in the RPE cells, which are postmitotic cells (Boulton *et al.*, 1998).

#### COMPLEX GRANULES

With the increasing of age, melanin, lipofuscin, and lysosomes can join together to form complex structures (melanolipofuscin and melanolysosomes) inside the RPE. These granules have a regional distribution similar to that of lipofuscin; i.e., the highest concentration is in the macula, and it decreases in the periphery and in the fovea. Concerning the percentage of the cellular volume occupied by complex granules, this varies from 3.3% in the first decade of life and reaches to 8 to 10% in the sixth decade. The association of lysosomes with pigment granules (for example, melanosomes, lipofuscin granules, and complex pigments) explains their age-dependant variation observed in the lysosomal enzyme levels and the activity of the RPE cells. The increase in pigment granules with age causes an increase in lysosomes and in the activity of various enzymes such as acid phosphatase and Cathepsin D, in order to maintain the normal degradation cycle, which follows the ingestion of the acromeres of the photoreceptors by the RPE cells (Boulton *et al.*, 1998).

#### CHANGES IN THE CELLULAR DENSITY

It has been observed that with aging, a physiological decline in the number of RPE cells occurs, especially in the macula. In the peripheral retina, however, the number of RPE cells can increase, diminish, or remain the same

## 67. Age-Related Changes in the Human Retina

with aging, whereas in the central retina the density of RPE cells decreases with age (Dorey *et al.*, 1989). More precisely, Panda-Jonas *et al.* (1996) observed an average annual loss of 17 RPE cells/mm<sup>2</sup> per year with respect to an original RPE cell population of 5,232 cells/mm<sup>2</sup>. These authors estimated that in the course of a life of 100 years, around 30% of RPE cells are lost. These values are associated with an age-related loss of 3000 to 5000 optic nerve fibers, around 0.3% per year, in a population of 1.4 million fibers at birth and a diminution in the density of cones and rods of 0.3 to 0.5% per year with respect to the photoreceptor density at birth. These observations indicate a reduced reserve capacity in elderly patients with respect to younger individuals. This fact may be the cause of the decline in vision function even in the absence of active pathologic processes. Given that the RPE cells do not have the capacity to reproduce, the cells adjacent to those lost increase their cell volume, restoring the normal continuity of the RPE cells/photoreceptors. Dorey *et al.* (1989) have found that the average ratio of photoreceptors/RPE cells is higher in the macula with respect to the paramacular and equatorial areas, and that this ratio increases with age. The retina is one of the most reactive tissues of the eye and can undergo atrophic, hypertrophic, and hyperplastic modifications as well as migration processes.

### AGING OF THE BRUCH'S MEMBRANE

The human Bruch's membrane ages in a manner similar to the inner tunic of the arteries and other connective tissues, in which the plasmatic lipoproteins represent the known source of extracellular cholesterol. Morphologic and biochemical studies have shown that with aging the Bruch's membrane undergoes profound changes, such as the thickening and progressive accumulation of deposits in the internal layers. The changes to the Bruch's membrane progressively reduce the efflux of fluids from the retina to the choroids and the metabolic exchange between the choriocapillaries and the RPE cells. Moore and Clover (2001) have shown that there is an age-related reduction in the permeability (hydraulic conductivity) of the Bruch's membrane in the retinal periphery and the macula. Furthermore, it has been shown that the presence of lipid deposits plays a statistically important role in the reduction of permeability of the Bruch's membrane. Lipids are one of the components of the Bruch's membrane. The other components are collagen, adhesion molecules, lipoproteins, and advanced glycosylation end products (the last of which may inhibit the activity of the lysosomal enzymes). The effect of aging on the passage of metabolites across the Bruch's membrane needs to be better ascertained. However, two groups of studies have demonstrated that the flux of macromolecules reduces with age. The first group, using fluorangiography, showed that in the ocular fundus (Figures 67.7–67.9) of elderly patients with good acute vision, there are areas that show reduced choroidal perfusion. In fact, the deposition of lipids in the Bruch's

**Figure 67.7** Retinal fundus in a young (25 years of age) and healthy subject. In correspondence of the head of the optic nerve the ophthalmic artery is branched in four divisions for each quadrant of the retina. In this image the nasal superior and inferior branches are evident (field 40° corresponding to a magnification of about 5x).

**Figure 67.8** Retinal fundus in an old (70 years of age) subject. The retinal vessels show a decreased calibre. We can see a dystrophic zone in RPE (field 25° corresponding to a magnification of about 8x).

membrane leads to the degeneration of the elastic fibers and collagen, causing rigidity of these structures with consequent reduction of their compliance. These reductions in turn cause resistance of the choroidal vessels, edema, and reduction of blood flow. These events lead to a worsening of all the functions of the RPE, including the ability to transport the catabolites resulting from the phagocytosis of the photoreceptors.

**Figure 67.9** Retinal fundus in a subject of 60 years affected by nonproliferating diabetic retinal pathology. The white spots are wax exudates, while the black ones are blood stains (field 40° corresponding to a magnification of about 5x).

#### AGING OF THE FUNCTIONAL MORPHOLOGY OF THE BRUCH'S MEMBRANE

Investigations have shown that the areas of reduced perfusion have an elevated threshold of adaptation to the dark and a pattern of changes similar to those observed in cases of Vitamin A deficiency. The second group of studies arrived at the same conclusions by demonstrating that Sorsby's dystrophy, an illness that causes loss of central vision at a young age, is characterized by the presence of rich deposits of lipids in the Bruch's membrane. The conclusion of these studies is that the loss of vision function results from the accumulation of deposits in the Bruch's membrane, which acts as a barrier to the elimination of catabolites as well as the arrival of nutrients to the retina.

Pauleikoff *et al.* (1990) examined the immunohistochemical and ultrastructural properties of the Bruch's membrane of 30 human eyes of ages 1 to 95 years. The results of the three age groups from 0 to 30, from 31 to 60, and from 60 onward show that there is an age-related progressive increase in the lipid content of the Bruch's membrane. In the young age group, none of the stains caused any coloration. In the second age group, 8 out of 10 samples, and in the over-60 age group all the samples, were colored with Bromine-Sudan Black B, with and without acetone; only a few samples from the second and third age groups showed strong coloration, whereas only samples from the third age group showed coloration with Oil Red O (see Figure 67.10).

Moore and Clover (2001) were the first to measure the permeability of the Bruch's membrane to

**Figure 67.10** Light microscopy of the Bruch's membrane belonging to donors aged 18 (top), 47 (middle), and 75 (bottom). The three figures on the left are stained with Bromine-Acetone-Sudan Black B, those on the right are stained with Oil Red O. It can be seen that the intensity of staining with both systems increases with age, which shows the progressive age-related accumulation of lipids (magnification 400x; calibration bar 10  $\mu$ m).

macromolecules, the first to determine the maximum dimensions of molecules that can cross the Bruch's membrane, and the first to ascertain the effects of age on the barrier that the Bruch's membrane represents against the flow of substances other than water. Age has three effects on the permeability of macromolecules across the Bruch's membrane. First, the exclusion based on molecular mass reduces gradually; second, in the eighth decade of life the membrane selectively impedes the passage of specific macromolecules, not on the basis of their molecular weight, but on other criteria. Finally, in the ninth decade, the membrane becomes an impermeable barrier to any molecule.

#### AGING OF THE BASAL MEMBRANE

The basement membrane of the RPF in young eyes is thin and uniform in thickness. With increasing age there is a significant alteration of the RPE cells and the basement membrane. In the aged eye most of the RPE cells show deep infoldings of the basal cell membranes. In the young eye the basement membrane of the RPE appears as an ordinary basement membrane. With increasing age this basement membrane becomes thicker and forms a reticular pattern. Within the reticular meshwork there is a granular material consisting of many deeply osmiophilic coarse and fine granules, and groups of membrane-bound vesicles. The apical cell membrane that faces the pigmented epithelium is fairly straight. The pigmented epithelial cells face each other at their apical surface, joined by the zonula adherens and/or occludens. Interdigitations along the lateral cell membrane are found mainly in the basal or inner third of the cells.

The lateral cell membranes exhibit junctions that are mostly desmosomal and are located along the apical

third of the cells. Both MBP and proteo-glycans show substantial age-related changes (Cavallotti *et al.*, 2005).

### **Aging of the Retinal Neurons (Photoreceptors, Bipolar Cells, Ganglion Cells)**

The majority of elderly people suffer from deficiencies in vision not related to any manifested pathology. The normal function of vision depends on the integrity of numerous factors, including the transparency of the dioptric media, the photoreceptor mosaic, the integrity of the intraretinal pathways, and the nervous connection between the brain and the vision-related structures. All these elements may show age-related changes. The constriction of the pupil and the opacity of the dioptric media together reduce the quantity of light shining on the retina. One of the most important questions in the study of the aging of the visual system is to determine which contributions are related to optical factors, and which are related to nervous factors. Both these factors reduce the photopic and scotopic vision (Owsley and Burton, 1991; Sturr *et al.*, 1991). The spatial density and the dimensions of the cones and rods in the human retina changes with age. Furthermore, previous studies of the aging of the neurosensorial retina have described the degeneration and loss of a large number of photoreceptors (Cavallotti *et al.*, 2004).

### **CONES AND RODS**

The acromeres of the cones and the rods become disorganized, and the internal segments fill with refractant bodies, presumably lipofuscin. The dislocation and partial loss of photoreceptor nuclei happens without significant modifications to the RPE, the Bruch's membrane, and the choriocapillaries (Curcio *et al.*, 1993). Gao and Hollyfield (1992) suggest that the loss of rods begins early in adult life, and the density of cones diminishes gradually in the extreme retinal periphery. On the contrary, Curcio *et al.* (1993) affirm that there is no evidence of a reduction in the density of the foveal cone peaks, although the interperson variability is high. The loss of foveal photoreceptors begins to manifest itself in persons over 90 years old. As previous studies haven't precisely specified the anatomic location of the observed zones of the retina, it was difficult to confront the changes in retinal anatomy with age-related changes in visual function. Curcio *et al.* (1993) have examined, using digital computer imaging, the topography of the retina of healthy eyes of people divided into four groups by age: Group 1 (27–37 years), group 2 (44–58 years), group 3 (61–75 years), and group 4 (82–90 years) in order to distinguish paraphysiological changes resulting from aging and/or from pathological changes. It was seen that in the central 43° of the ocular retina studied, rods but not cones are lost during the course of the life.

### **QUALITATIVE ASPECT OF THE PHOTORECEPTOR MOSAIC**

The photoreceptor mosaic of aged retinas, without pathologic changes, is similar to that of young retinas. However, the aged retinas show two typical cytological aspects. The first is the presence of refractive particles (of around 1  $\mu\text{m}$  in diameter) located at the ellipsoid-mioid junction of the cones. These refractive particles appear like refractive bodies or granules of lipofuscin that are found in the internal segments that begin to be observed after 30 to 40 years. The second aspect is the dislocation of the nuclei, which are occasionally found situated in the internal segment layer rather than in the external nuclear layer.

### **AGE-RELATED CHANGES OF THE EXTRA-FOVEAL CONES**

The cone density of the fovea in all age groups is high and reduces rapidly with the eccentricity and in a small amount in an area that extends around the optic disk and in the nasal retina. The density of cones is variable in the different groups of age (coefficient of variability from 15 to 30%) around the optic disk; it is nonetheless lower (<15%) over 1 mm of eccentricity. In the map (personal unpublished results) the average difference between the older age groups and the younger group is significant; cold colors indicate a density lower than that of the younger group, and warm colors indicate that the average density is higher than that of the younger group. The map, which is yellow-green, indicates that the difference between the groups is minimal.

The map indicates that the group from 44 to 58 years has the smallest cone density difference (88% of the younger group), but small differences were also seen in older groups. The mapped retinal region in all the eyes was of 8 mm diameter; that is, 5% of the whole retinal area of the eye contains 10% of the cones that are found in the central 28.5°. The average number of cones over all the eyes in this region was 488,600.

### **AGE-RELATED CHANGES OF THE FOVEAL CONES**

The cone density range between age 56 and 90 is quite limited (116,600 to 210,000 cones/mm<sup>2</sup>), with the oldest overlapping the lower limit of the younger donors. An area of 0.8 mm diameter centered on the fovea is the only part of the retina where there are more cones than rods. This region contains 31,200 cones/mm<sup>2</sup> with a variability coefficient of only 12%, and the gradient of the linear regression with respect to age is not significantly different from zero. This data supplies evidence that the cone population in the central 2.8° remains stable during adult life; furthermore the topography of the cones does not show any relevant evidence, as already said, of age-related loss of cones in the central 28°. The extrafoveal cones are not more vulnerable to aging than foveal cones according to the hypothesis that the macular pigment, highly concentrated in the central 2°, is an antioxidant

that improves the light-induced peroxidation of lipids, and also because a small quantity of this carotenoid is detectable outside the fovea. However, the overall stability of the total number of cones does not exclude the loss of a small number of these. As there is no evidence for a loss of cones of this magnitude, the increase in the distance between foveal cones does not significantly contribute to the age-related decline in visual resolution. The loss of acuity, therefore, may be explained by other changes in the visual system, including an age-related reduction of 25% in the number of ganglion cells that reside over the central 11° of the vision field. Also, recent evidence has shown that in the majority of cases, optical rather than retinal factors contribute to deficiencies in scotopic function, and therefore a reduction in sensitivity to spatial contrast at medium and high frequencies can be explained by a lower transfer modulation of the ocular medium in healthy elderly eyes. However, neuronal factors may play a role in other photopic functions, such as the sensitivity to differences in luminosity (across the visual field) or spatial vision (for example, contrast sensitivity and visual acuity) considered at the mesopic or high scotopic level.

#### AGE-RELATED CHANGES IN THE TOPOGRAPHY OF THE RODS

The rods are absent from the center of the retina and increase in number with retinal eccentricity to form a high-density ( $>150,000$  rods/mm<sup>2</sup>) elliptical ring from 2 to 5 mm of retinal eccentricity, with the peak at 4 to 5 mm wider than the fovea. The interpersonal variability in the rod density for all age groups is very high (variation coefficient  $>45\%$ ) at the border of the rod deprived zone, high within 1 mm of the fovea and around the optic disk, and low ( $<15\%$ ) elsewhere. With aging, the rod density reduces in both the foveal and extrafoveal retina. The loss is higher in the high rod density ring. The number of rods within the central 8 mm in all retinas changes from  $7.40 \times 10^6$  at age 45 to  $3.60 \times 10^6$  at 82 years of age.

The gradient of the linear regression suggests an average loss of 648 rods/mm<sup>2</sup>/year in the central 28.5° of vision such that at age 90 the total number of rods is reduced to 69% of that at 34 years of age.

#### EXTREME RETINAL PERIPHERY

Curcio *et al.* (1993) show the stability of the central cones and the reduction in the rods between the fiftieth and sixtieth year. This data contrasts with the results of Gao and Hollyfield (1992). In fact, these authors affirmed that at the temporal equator, the rod density reduces by 15% between the second and fourth decade, with a total loss of 32% by the ninth decade, and the cone density significantly reduces by 23% during the same period. These results indicate, together, that the peripheral retina ages in a different way in relationships with the central brain area of the vision (areas 17,18,19 of Brodmann, near the calcarina scissura).

#### AGE-RELATED CHANGES IN THE DIAMETER OF THE ACROMERES AND THE COVERAGE OF THE PHOTORECEPTORS

The area of selective rod loss is located 3 mm from the fovea. The spaces left empty by the cell loss are occupied by larger rods. The diameter of the rod acromeres ranges from 2.2 to 2.8  $\mu\text{m}$  in young retinas, and those of surviving rods in older retinas are 13.5% larger in the same eccentricity range. One of the most significant results of Curcio *et al.* (1993) is that the spatial density of rods reduces by around 30% in the central 28.5° during the period from 34 to 90 years in apparently healthy eyes. This loss is less in the fovea between 45 and 61 years and from the ninth decade is larger in a parafoveal ring from 0.5 to 3 mm eccentricity. Notwithstanding the diffuse loss of rods in the central retina, the appearance of the photoreceptor mosaic is qualitatively normal, as only around 2 rods/mm<sup>2</sup> are lost per day. Furthermore, the retina does not show either gaps or the insertion of other types of cells (glia), such that the extension of the acromeres of the remaining rods is equal to that of younger retinas. There is no evidence of an age-related decrease in the quantity of rhodopsin as might be expected with the loss of photoreceptors. The remaining photoreceptors are sufficient to perform their function.

Using densitometry, it has been shown that there is a small but significant increase in the density of the pigment of the rods between 12 and 78 years up to the temporal 16°. As the number of rods in this area diminishes with age, the acromeres of the remaining rods should contain more pigment in older retinas than in younger ones. This increase may be at least partly due to the twisting that effectively increases the total length of the acromeres by around 40% without varying the distance between the outer limiting membrane and the RPE. It is calculated that this process affects from 10 to 20% of the total rod population from the seventh decade, whereas in the central retina it is from 2% in both young and old donors, suggesting that the increase in rhodopsin can be due to the fact that the acromeres of elderly eyes are larger than those of younger eyes but morphologically similar. For example, if the diameter of the acromeres increases in proportion with the inner segments, the membrane of the disk would contain 29% more pigment in older eyes than in younger. The compensatory hypertrophy of the acromeres of the rods is in agreement with the proof of the plasticity of the rod system in adults after its partial loss.

At this point we ask ourselves if the age-related loss of rods contributes to the reduced scotopic function. Since the extension of the rods is the same in young and old retinas, it is thought that other factors such as changes in the sensitivity of the photo-pigments, regeneration, response, neuro-transmitters, and the membrane charge weaken the sensitivity of the rods.

### WHY DO ONLY RODS DIE WITH AGE?

One possible mechanism is the selective vulnerability of rods. One explanation for the higher vulnerability of rods with respect to cones is the fact that the acromere disks of the rods have a higher rate of renewal. This requires a notable energy expense by the rods for the renewal of the disks and by the RPE for the disposal of the old ones (Owsley *et al.*, 2000). The RPE are responsible for the integrity of the photoreceptors, and it has been seen that the age-related changes of the photoreceptors independent of those of the RPE are slight. For example, an RPE dysfunction causes a slowdown of the rate of renewal of the photopigments in both the cones and the rods, and an increase in the convolution of the acromeres of the rods.

The principal age-related changes to the RPE are the accumulation of lipofuscin and the reduction of the granules of melanin, which is concomitant with the thickening and the accumulation of deposits in the Bruch's membranes. It has been observed that the accumulation of intracellular lipofuscin significantly reduces the function of the photoreceptors. High levels of lipofuscin have been correlated with a low number of photoreceptors in the retina. As lipofuscin is tightly related with the rods, the loss of rods should be highest in the ring with the highest density of rods, 3 to 5 mm from the center of the fovea. On the contrary, the results of Curcio *et al.* (1993) placed the rod loss closer to the fovea, at 0.5 to 3 mm, contradicting the correlation between the accumulation of lipofuscin and the loss of photoreceptors.

### Aging of the Macroglia (Müller Cells and Astrocytes)

The functional weakening of the CNS that occurs with aging and age-related neurodegenerative disorders has been partially attributed to a decline in mitochondrial function. In particular, it has been demonstrated that oxidative damage occurs to mitochondrial DNA in elderly human brains. Recently, it has been shown that mitochondrial DNA is particularly sensitive to damage that accumulates due to the loss of protective histones, the reduction in repair systems, and the vicinity of the internal mitochondrial membrane to active oxygen species. The hypothesis that free radicals are involved in the weakening of the mitochondrial function has been confirmed by recent discoveries, that is, the fact that the administration of free radical scavengers such as extract of Ginkgo Biloba (Egb761) improves the function of the brain and liver in elderly animals. Astrocytes are interconnecting cells between the neurons and the surrounding connective tissue (fibroblasts, mesenchymal cells, and endothelial cells). Changes to these cells induce modifications to the intercellular relationships and, eventually, to the nervous function. It has been shown that astrocytes are resistant to oxidative stress due to their high antioxidant content and their ability to regenerate glutathione and ascorbate.

Astrocytes therefore act as neuronal protectors defending the neurons against free radicals.

### AGE-RELATED MACULAR DEGENERATION (AMD)

The aim of Ramirez *et al.* (2001) was to study the astrocytes of young human retinas and the parapsycho-logical changes that occur to them with aging and pathologic changes resulting from macular degeneration (AMD). The study was conducted on enucleated human eyes taken from the Spanish eye bank two to four hours post mortem for cornea transplants and were classified in three age groups (young, elderly, and with AMD). The astrocytes of the young subjects had numerous thin protrusions that surrounded the capillaries of the cell ganglion layer (CGL), forming a honeycomb plexus. The astroglial sheath around the vessels is very thick, and the capillaries are held together by many astroglial bundles. The gaps in the astroglial honeycomb plexus in the rear pole of zone A (the area between the second and third divisions of the retinal artery branches, near to the optic disk) are circular and very small in younger individuals, but have a quadrangular form in older individuals. In zone B (from the third division of the retinal artery to the retinal equator, closer to the periphery) the dimensions of the gaps are variable and irregular. In this zone the astrocyte bonds that hold the capillaries together have variable thicknesses, some thick and some thin. In the nerve fibers layer (NFL) of the retina, astrocytes are found parallel to the axons of the ganglion cells and to the radial peripapillary capillaries. The astroglial bundles are very thick near the optic disk.

### ASTROCYTES IN ELDERLY INDIVIDUALS

Astrocytes in elderly individuals have large cell bodies and robust protrusions, particularly those found in the NFL. In the group of subjects aged over 60 years, the astrocytes showed a higher glial fibrillar acidic protein (GFAP) immunoreactivity with respect to the younger subjects, particularly in the NFL. This observation has been confirmed by electron microscopy, which showed a higher density of glial filaments (formed by GFAP) in the astrocyte cytoplasm of the elderly group. In the NFL the lack of GFAP(+) signal between the astrocyte bundles indicates that in this layer the astrocytes lose their protrusions. Occasionally GFAP(+) organelles are found in the CGL and NFL; these correspond to decayed astrocytes. The perivascular astrocytes have few thin protrusions and form a thinner astroglial sheath than in younger individuals. Sporadically, reactive astrocytes are found. The honeycomb structure is not easily distinguished in the CGL, and the gaps in the astroglial plexus have variable forms (circular, square, rectangular); the dimensions, however, are larger than those in younger subjects in both zone A (nearer to the optic disk) and zone B (closer to the periphery). The number of gaps in the astroglial honeycomb plexus in the CGL is lower in the 60 to 89 age group. This signifies that the gaps are larger due

to the disappearance of astrocytes from the vessel walls and the astroglial protrusions that divide the gaps. The reduction in the number of astrocytes increases with age, as is shown by comparing people between 60 and 79 and those over 80. The comparison between young and elderly retinas has therefore again shown that aging causes numerous changes to the retinal astrocytes. There is an increase in the number of intracytoplasmic organelles (mitochondria, ribosomes, polyribosomes, wrinkled endoplasmic reticulum) due to higher cellular activity, an increase in lysosomes and dense bodies (which increase also inside the Müller cells), an increase of the glial intermediate filaments, a thickening of the inner limiting membrane whose constituents are less homogeneous, and the space between the glial protrusions and the basal membrane of the inner limiting membrane increases.

### RETINAL NERVOUS CELLS

All retinal nervous cells have numerous lysosomes in their cytoplasm. In the NFL the axons of the glial cells contain dense bodies, formed from incompletely digested myelin, which causes the axon's swelling. In some cases, in elderly retinas, astrocytes of large dimensions are found that have very elevated cellular activity and a higher density of intermediate filaments; these are called reactive astrocytes. The function of the reactive astrocytes is to protect the neurons (in this case, the ganglion cells) from ischemia producing neurotrophic factors, increasing the expression of antioxidant substances (glutathione, vitamin C) and increasing the production and transport of glucose. However, it has been observed that astrocytes are more vulnerable to oxidative damage during aging. In fact, as the years roll by, the reactive astrocytes cause changes in the geometry and volume of the extracellular space, which slows the diffusion of neuroactive substances.

The extracellular space is not only the microenvironment of the nerve cells but is also an important channel of communication between the neurons and astrocytes. The changes to the diffusion parameters, which arrive with aging, can bring on a disappearance of the transmission signals and increase the sensitivity of the nervous tissue to ischemia. The ischemia is due to an increase in the extracellular acidity with accumulation of potassium and other toxic substances (similar to glutamate) that damage the neurons.

### REACTIVE ASTROCYTES

The reactive astrocytes have an elevated number of organelles (secondary lysosomes and lipofuscin) and an elevated cellular activity. The reactive astrocytes and therefore also the lipofuscin contained within, if exposed to visible light (400–700 nm) at a high concentration of oxygen (70 mm Hg)—conditions ideal for the formation of free radicals—can cause damage to the cellular proteins and the membrane lipids. The reactive oxygen species can cause damage to cellular and nuclear elements. The presence of high concentrations of toxic substances

(glutamate) in the extracellular space (coming from the reactive astrocytes), causes a massive increase of hydrogen and potassium with an increased permeability of the cell membranes, worsened by free radicals, which makes the cell swell. This cellular edema causes the breakage of the intermediate filaments of the astrocytes and therefore the loss of GFAP immunoreactivity and finally cell death. This fact explains why a reduction of the number of astrocytes in the CGL is observed and a disappearance of the protrusions of the NFL astrocytes has been observed in the elderly.

In the elderly, it has also been observed that the basal membrane of the inner limiting membrane is thicker than in the younger group. The increase in thickness impedes the interchange of substances between the retina and the vitreous humor that represents a reserve of glucose, amino acids, potassium and glutathione, and so on for the retina and a deposit for degradation products.

### ISCHEMIA OF THE INNER RETINA

Ischemia of the inner retina, caused by the presence of naked or acellular vessels (formed from a thickening of the basal membrane of the capillaries), will be aggravated by the difficulty of diffusion of nutrients across the inner limiting membrane, and the elimination of catabolites. In the group of people with AMD, the changes are more severe than those in normal individuals of the same age. The changes to the inner retina in individuals with AMD are equivalent to those of the outer retina and represent an advanced aging of the retina. In the studied group of patients with AMD, the basal membrane of the retinal capillaries is considerably thicker than that of normal individuals of the same age with a thick external layer of collagen in contact with the astrocytes and Müller cells. The number of acellular capillaries is higher, especially in cases of AMD in patients aged over 81. In fact, the ischemia that establishes itself in these cases is considerably worse than that of healthy individuals of the same age. In all cases of AMD, there is an elevated number of hypertrophic and reactive astrocytes. Under an electron microscope, it has been seen that these astrocytes phagocytose the residues of the necrotic or apoptotic dead ganglion cells. The astrocytes contain elevated quantities of lysosomes and lipofuscin, as do the ganglion cells and their axons.

The extended retinal ischemia seen in patients with AMD, together with the loss of astroglial cells that occurs with normal aging, cause the death of ganglion cells that are not protected against oxidative stress. Furthermore, the basal membrane of the inner limiting membrane in AMD becomes thicker than that of healthy individuals of the same age, obstructing the metabolic exchange between the retina and the vitreous humor. The reactive astrocytes are overfilled with electron dense material and expel this material into the inner limiting membrane. In all the individuals with AMD, strongly GFAP+ trunk-shaped astroglial protrusions have been found that cross the inner

limiting membrane and enter the vitreous humor. These protrusions are formed of astrocytes with long protrusions parallel to the inner limiting membrane and form a glial membrane. Under an electron microscope, cells have been observed in the vitreous humor, and judging by their ultrastructural properties, they could be astrocytes. These cells possess a clear cytoplasm, a large number of cellular organelles, and dense glial filaments. The protrusions of these cells intercommunicate across many gap junctions. The astrocytes also possess microvilli in contact with the vitreous humor, where there is no basal membrane, allowing direct contact between the vitreous humor and the astrocytes. These cells have ultrastructural characteristics similar to the epiretinal membranes observed in other pathologies. Another type of cell that also has been observed more often, is highly GFAP+ and column-shaped, and lies parallel to the inner limiting membrane, which can be confused with the aforementioned astrocytes. The morphological characteristics of these cells is reminiscent of the Müller cells as they are more robust, column-shaped, and have few protrusions. These cells should be reactive Müller glia, which in pathologic situations express the GFAP.

#### HYPERTROPHIC ASTROCYTES

Madigan *et al.* (1994) alone have described that in retinas with AMD there are distended hypertrophic astrocytes on the internal surface of the retina. Many studies have been performed on the neovascular membrane that is found in AMD, produced by the migration of endothelial choroidal cells across the Bruch's membrane in the subretinal space, but none have talked about epiretinal glial membranes. Many studies have shown that the epiretinal membranes may derive from inflammatory processes, retinal ruptures, or retinal vascular occlusions. The extended retinal ischemia in AMD causes the astrocytes to migrate into the vitreous humor, where they can find metabolic reserves. In this way the vitreous humor guarantees the nutrition of the remaining astrocytes in the inner retina as the intercellular junctions between the astrocytes remain intact. It is not known what factors cause the astrocytes and Müller cells to migrate into the vitreous humor in AMD. It is not known if these membranes are dangerous, that is, if they can, after traction, cause a detachment of the retina.

#### AGING OF THE MICROGLIA

The retinal microglia originate from the hematopoietic cells and enter the retina from the retinal margin and the optic disk, through the blood vessels of the ciliary bodies and iris, and of the retina, respectively. The microglial precursors that are found on the retina before vascularization are positive to some specific immuno-stainings and express the CD45 marker, but are not positive for specific markers of the macrophages. A second category of microglial precursors, which express typical macrophage markers, migrate into the retina together with

vascular precursors. These are localized around the blood vessels in the adult retina and are similar to macrophages or mononuclear phagocytes. The microglial cells are found in the outer plexiform layer, the external nuclear layer, the internal plexiform layer, the ganglionic layer, and the nervous fiber layer of the retina in humans. The retinal macrophages are involved in the defense against viral, bacterial, and parasitic infection, in immunoregulation, in tissue repair, in the catabolism of neurotransmitters and hormones, and in the lipid turnover of nervous tissue. The microglia play an important role in the defense against microorganisms, in immune regulation, and in tissue repair. The occurrence of neurodegenerative phenomena, but also normal aging, cause the conversion of the microglia from resting to reactive. Reactive microglia have the responsibility of phagocytosing the debris and facilitate the regenerative processes. The morphology and localization of the microglia are not the same for all our ages. It has been seen that in newborn mice, the microglia cells are round and amoeboid with thick, squat pseudopodial protrusions distributed in the ganglion and nervous fiber layers, whereas their morphology shows some age-related changes.

#### Aging of the Retinal Vessels

Age-related changes to the retinal vessels have been found both in the superficial and the deeper capillary net. The thickness of the basal ganglion membrane increases by two to three times. In samples of retina of rats aged 28 to 32 months, Glatt and Henkind (1979) noted a reduction in the number of capillary endothelial cells and pericytes. Ramirez *et al.* (2001) also described age-related changes to the retinal vessels. The capillaries show a thickening of the basal membrane, equal to double that of the capillaries of young individuals, with numerous accumulations of lipids. The lumen of the capillaries is more irregular, and the endothelial cells are full of lysosomes and lipids, which are then carried into the lumen of the blood vessels. The pericytes adjacent to the endothelial cells of the vessels have a cytoplasm rich in dense bodies. Moreover, there is a loss of endothelial cells from the peripheral retinal capillaries that become like naked vessels or acellular capillaries. The same happens in the choriocapillary vessels from 60 years onward (Cavallotti *et al.*, 2005). The loss of endothelial cells and the thickening of the basal membrane of the capillaries diminish the passage of oxygen and nutrients to the retinal nervous tissue. This fact causes hypoxia and slowing of the elimination of catabolism products.

#### Age-Related Diseases of the Human Retina

It is very common to encounter senile lesions of the eyes and therefore a reduction in the acuity of vision and also peripheral chorioretinal lesions, which cause severe retinal lesions such as senile retinal detachment. The interest in
