# Contents

Contributors .....	xi
Preface .....	xxi

## I. Introduction

1. Historical Development of Animal Models of Aging .....	1
<i>Richard L. Sprott and Steven N. Austad</i>	
2. Species Selection in Comparative Studies of Aging and Antiaging Research.....	9
<i>João Pedro de Magalhães</i>	
3. Principles of Animal Use for Gerontological Research .....	21
<i>Richard A. Miller</i>	
4. From Primary Cultures to the Aging Organism: Lessons from Human T Lymphocytes .....	33
<i>Rita B. Effros</i>	
5. Models of Systems Failure in Aging....	45
<i>Leonid A. Gavrilov and Natalia S. Gavrilova</i>	
6. Major Issues in Ethics of Aging Research .....	69
<i>Michael D. Smith</i>	
7. Ethical Aspects of Research Involving Elderly Persons .....	79
<i>Paul S. Mueller and C. Christopher Hook</i>	

## II. General Methods

8. SAGE KE and Other Online Sources Related to Aging .....	93
<i>Evelyn Strauss and R. John Davenport</i>	
9. Proteomics in Aging Research .....	99
<i>Christian Schöneich</i>	
10. Application of High-Throughput Technologies to Aging-Related Research .....	109
<i>Matt Kaeberlein</i>	
11. Models of Alzheimer's Disease .....	121
<i>Harry LeVine III and Lary C. Walker</i>	
12. Age-Related Hippocampal Dysfunction: Early Alzheimer's Disease vs. Normal Aging.....	135
<i>Scott A. Small</i>	
13. Epidemiology in Aging Research .....	143
<i>Hermann Brenner and Volker Arndt</i>	
14. Statistical Issues for Longevity Studies in Animal Models .....	153
<i>Chenxi Wang, Scott W. Keith, Kevin R. Fontaine, and David B. Allison</i>	
15. Models for the Study of Infection in Populations .....	165
<i>John R. Williams</i>	

16. Estimation of the Rate of Production of Oxygen Radicals by Mitochondria.....183  
*Alberto Sanz and Gustavo Barja*

### III. Animal Models

#### A. Non-mammalian Systems

17. Telomeres and Aging in the Yeast Model System .....191  
*Kurt W. Runge*

18. Longevity and Aging in Budding Yeast .....207  
*Matt Kaeberlein*

19. From Yeast Methuselah Genes to Evolutionary Medicine .....219  
*Paola Fabrizio and Valter D. Longo*

20. *Strongyloides ratti*: A Nematode with Extraordinary Plasticity in Aging .....229  
*Michael P. Gardner, David Gems, and Mark E. Viney*

21. Insect Models for the Study of Aging .....241  
*Klaus-Günter Collatz*

22. *Drosophila* Models of Aging .....253  
*Satomi Miwa and Alan Cohen*

23. Models of Aging in Honeybee Workers .....267  
*Gro V. Amdam and Olav Rueppell*

24. Ants as Naturally Long-lived Insect Models for Aging .....277  
*Joel D. Parker and Karen M. Parker*

25. Gene Expression and the Extended Longevity Phenotypes of *Drosophila melanogaster* .....283  
*Robert Arking*

26. Annual Fish as a Genetic Model for Aging .....301  
*Pudur Jagadeeswaran*

27. The Use of Mature Zebrafish (*Danio rerio*) as a Model for Human Aging and Disease .....309  
*Evan T. Keller, Jill M. Keller, and Gavin Gillespie*

28. Zebrafish as Aging Models .....317  
*Shuji Kishi*

29. Telomeres in Aging: Birds.....339  
*Susan E. Swanberg and Mary E. Delany*

30. Domestic and Wild Bird Models for the Study of Aging .....351  
*Donna J. Holmes and Mary Ann Ottinger*

#### B. Mammalian Systems

31. A Transgenic Mini Rat Strain as a Tool for Studying Aging and Calorie Restriction .....367  
*Isao Shimokawa*

32. Rat Models of Age-Related Cognitive Decline.....379  
*Jennifer L. Bizon and Michelle M. Nicolle*

33. Aged Rodents for Biogerontology Research .....393  
*Nancy L. Nadon*

34. Life Extension in the Dwarf Mouse .....403  
*Andrzej Bartke*

35. The Canine Model of Human Brain Aging: Cognition, Behavior, and Neuropathology .....415  
*P. Dwight Tapp and Christina T. Siwak*

36. Bats as a Novel Model for Aging Research .....435  
*Anja K. Brunet-Rossinni and Rocco E. Rossinni*

37. Memory in the Aging Hippocampus: What Can Place Cells Tell Us? .....447  
*Iain A. Wilson*

38. The Rhesus Macaque as a Model of Human Aging and Age-Related Disease.....457  
*Mary Ann Ottinger, Julie A. Mattison, Mary B. Zelinski, Julie M. Wu, Steven G. Kohama, George S. Roth, Mark A. Lane, and Donald K. Ingram*

39. Nonhuman Primates as a Models for Reproductive Aging and Human Infertility .....469  
*Barry D. Bavister and Carol A. Brenner*

## IV. Comparative Models

40. Neurobiology of the Aging  
Brain .....485  
*Carlo Bertoni-Freddari, Patrizia Fattoretti, Tiziana Casoli, and Giuseppina Di Stefano*
41. Mitochondrial DNA and Aging .....507  
*Mikhail Alexeyev, Susan P. LeDoux, and Glenn L. Wilson*
42. Models for Apoptosis: From Newborn to Adult .....521  
*Christiane Charriaud-Marlangue and Sylvain Renolleau*
43. Age-related Changes in Hormones and Their Receptors in Animal Models of Female Reproductive Senescence .....533  
*Jacqueline A. Maffucci and Andrea C. Gore*
44. Models of Chaperones in Aging .....553  
*Jens Kröll and J. O. Nehlin*
45. Therapeutic Potential of Stem Cells in Aging-Related Diseases .....563  
*Shannon Whirlledge, Kirk C. Lo, and Dolores J. Lamb*
46. Nuclear Transfer and Cloning: Preservation or Expansion of Proliferative Lifespan? .....575  
*Keith E. Latham*
47. Human Models of Longevity .....585  
*Thomas Perls*
48. Computational Models of Mitochondrial DNA in Aging .....591  
*David C. Samuels*
49. Mouse Models of Accelerated Aging .....601  
*Jan Vijg and Paul Hasty*
51. Fertility and Aging Men: An Introduction to the Male Biological Clock .....631  
*Peter N. Schlegel, Puneet Masson, Sarah M. Lambert, and Harry Fisch*
52. Benign Prostatic Hyperplasia .....641  
*Peter Celec*
53. Murine Models of Infectious Diseases in the Aged .....651  
*Kevin P. High*
54. Studying Infection in the Elderly: Physiopathology, Clinical Symptoms and Causative Agents of Pneumonia .....661  
*Jean-Paul Janssens*
55. Diabetes and Aging .....671  
*Tamas Fülöp, Anis Larbi, Daniel Tessier, and André Carpentier*
56. Diabetes as a Model of Premature Aging .....687  
*Arshag D. Mooradian*
57. Frailty as a Model of Aging .....697  
*Jeremy D. Walston*
58. Osteoporosis and Cardiovascular Disease in the Elderly .....703  
*Samy I. McFarlane, John Nicasio, and Ranganath Muniyappa*
59. Depression in Older Patients .....713  
*Kiran Rabheru*
60. The Aging Human Lung: Age-Associated Changes in Structure and Function ....727  
*Keith C. Meyer*
61. Iceland as a Model for Human Aging .....735  
*Adalsteinn Gudmundsson and Pálmi V. Jónsson*
62. Behavior and Personality in the Study of Successful Aging .....741  
*Judith Corr and Loraine Tarou*

## V. Disease-States and Normal Aging

### A. Disease States

50. Models, Definitions, and Criteria of Frailty .....619  
*David B. Hogan*

### B. Health Issues Affecting the Elderly

63. Andropause .....749  
*Rabih Hijazi and Glenn R. Cunningham*
64. Aging and the Perceptual Organization of Sounds: A Change of Scene? .....759  
*Claude Alain, Benjamin J. Dyson, and Joel S. Snyder*

Contents

65. Models of Immune Function in Aging.....771 <i>Christopher A. Jolly and Zhun Xu</i>	75. Nutrients and Aging .....897 <i>Lawrence J. Whalley</i>
66. Human T Cell Clones in Long-Term Culture as Models for the Impact of Chronic Antigenic Stress in Aging.....781 <i>Graham Pawelec, Erminia Mariani, Rafael Solana, Rosalyn Forsey, Anis Larbi, Simone Neri, Olga Dela Rosa, Yvonne Barnett, Jon Tolson, and Tamas Fülöp</i>	<b>C. Approaches to Treatment and Models</b>
67. Age-Related Changes in the Human Retina.....793 <i>Carlo Cavallotti and Nicola Pescosolido</i>	76. Methods for Studying Hearing Impairment and Auditory Problems of the Aged .....911 <i>Robert D. Frisina and D. Robert Frisina</i>
68. Models of Age-Related Vision Problems .....813 <i>J. Fielding Hejtmancik, Mark Kantorow, and Takeshi Iwata</i>	77. A Model for Understanding the Pathomechanics of Osteoarthritis in Aging.....923 <i>Thomas P. Andriacchi and Annegret Mündermann</i>
69. Health, Functional and Therapeutic Implications of Obesity in Aging .....829 <i>R. Lee Kennedy and E. Y. H. Khoo</i>	78. Aging and Cardiovascular Angiogenesis Models.....937 <i>Andrew Chin, Jacquelyn M. Holm, Inga J. Duignan, and Jay M. Edelberg</i>
70. Age and Joints.....841 <i>Klaus Bobacz and Ilse-Gerlinde Sunk</i>	79. Models for the Study of Stroke .....947 <i>Thiruma V. Arumugam and Mark P. Mattson</i>
71. Sleep Quality in the Elderly .....853 <i>Ragnar Asplund</i>	80. Werner Syndrome as a Model of Human Aging .....961 <i>Raymond J. Monnat, Jr.</i>
72. Atherogenesis and Aging .....865 <i>Cam Patterson</i>	81. Models of Sarcopenia .....977 <i>Alfred L. Fisher</i>
73. Managing Menopausal Symptoms .....873 <i>Mary Ellen Rousseau</i>	82. Aging of Human Skin.....993 <i>Paolo U. Giacomoni</i>
74. Psychological Aging: A Contextual View.....881 <i>Hans-Werner Wahl and Frieder R. Lang</i>	83. Models of Hypertension in Aging.....999 <i>Jane F. Reckelhoff, Radu Iliescu, Licy Yanes, and Lourdes A. Fortepiani</i>
	Glossary .....1011
	Index .....1041

# Contributors

The number in parentheses indicates the chapter to which the author contributed.

**Claude Alain (64)**

Rotman Research Institute, Baycrest Centre for Care, Toronto, Ontario; Department of Psychology, University of Toronto, Ontario, Canada

**Mikhail F. Alexeyev (41)**

Department Cell Biology and Neuroscience, University of South Alabama, Mobile, Alabama

**David B. Allison (14)**

Section on Statistical Genetics, Department of Biostatistics and Clinical Nutrition Research Center, Department of Nutrition Sciences, University of Alabama at Birmingham, Birmingham, Alabama

**Gro V. Amdam (23)**

School of Life Sciences, Arizona State University, Tempe, Arizona

**Thomas P. Andriacchi (77)**

Department of Mechanical Engineering, Stanford University, Stanford, California

**Robert Arking (25)**

Department of Biological Sciences, Wayne State University, Detroit, Michigan

**Volker Arndt (13)**

Division of Clinical Epidemiology and Aging Research, German Cancer Research Center, Heidelberg, Germany

**Thiruma V. Arumugam (79)**

Laboratory of Neurosciences, National Institute of Aging Intramural Research Program, Baltimore, Maryland

**Ragnar Asplund (71)**

Research and Development Unit, Family Medicine Stockholm, Ostersund, Sweden

**Steven N. Austad (1)**

Department of Cellular and Structural Biology, Barshop Institute for Longevity and Aging Studies, University of Texas Health Science Center, San Antonio, Texas

Contributors

**Gustavo Barja** (16)

Department of Animal Biology-II  
(Animal Physiology), Complutense University,  
Madrid, Spain

**Yvonne Barnett** (66)

College of Science and Technology,  
Nottingham Trent University,  
Nottingham, United Kingdom

**Andrzej Bartke** (34)

Departments of Physiology and Internal  
Medicine, Southern Illinois University School  
of Medicine, Springfield, Illinois

**Barry D. Bavister** (39)

Department of Biological Sciences, University  
of New Orleans, New Orleans, Louisiana

**Stephen A. Benjamin**

Department of Microbiology, Immunology  
and Pathology, Colorado State University,  
Fort Collins, Colorado

**Carlo Bertoni-Freddari** (40)

Neurobiology of Aging Laboratory, INRCA  
Research Department, Ancona, Italy

**Jennifer L. Bizon** (32)

Behavioral and Cellular Neuroscience,  
Department of Psychology, Texas A&M  
University, College Station, Texas

**Klaus Bobacz** (70)

Department of Internal Medicine III, Division  
of Rheumatology, Medical University of  
Vienna, Vienna, Austria

**Carol A. Brenner** (39)

Department of Biological Sciences, University  
of New Orleans, New Orleans, Louisiana

**Hermann Brenner** (13)

Division of Clinical Epidemiology and Aging  
Research, German Cancer Research Center,  
Heidelberg, Germany

**Anja Brunet-Rossinni** (36)

Department of Biology, University of  
Wisconsin, La Crosse, Wisconsin

**André C. Carpentier** (55)

Department of Medicine, University  
of Sherbrooke, Quebec, Canada

**Tiziana Casoli** (40)

Neurobiology of Aging Laboratory, INRCA  
Research Department, Ancona, Italy

**Carlo Cavallotti** (67)

Section of Anatomy, Department of  
Cardiovascular, Respiratory and  
Morphological Sciences, University  
“La Sapienza,” Rome, Italy

**Peter Celec** (52)

Biomed Research and Publishing Group,  
Institute of Pathophysiology, Department of  
Molecular Biology, Comenius University,  
Bratislava, Slovakia

**Christiane Charriaut-Marlangue** (42)

Groupe Hypoxie et Ischémie Cérébrale  
Développementale UMR-CNRS 7102,  
Pierre and Marie Curie University,  
Paris, France

**Andrew Chin** (78)

Department of Medicine, Division of  
Cardiology, Weill Medical College of  
Cornell University, New York, New York

**Alan Cohen** (22)

Department of Biology, University of  
Missouri–St. Louis, St. Louis, Missouri

**Klaus-Günter Collatz** (21)

Institut Biologie I (Zoologie),  
University of Freiburg, Freiburg, Germany

**P. Michael Conn**

Oregon National Primate Research Center,  
Beaverton, Oregon; Oregon Health and  
Science University, Portland, Oregon

**Judith Corr** (62)

Department of Anthropology, Grand Valley  
State University, Allendale, Michigan

**Glen R. Cunningham** (63)

St. Luke’s Episcopal Hospital, Houston, Texas

**R. John Davenport** (8)

Brain Science Program, Brown University,  
Providence, Rhode Island

**Mary E. Delany** (29)

Department of Animal Science,  
University of California, Davis, California

**Olga Dela Rosa** (66)

Department of Cellular Biology, Physiology  
and Immunology, Faculty of Medicine,  
University of Cordoba, Cordoba, Spain

**João Pedro de Magalhães** (2)

Department of Genetics,  
Harvard Medical School,  
Boston, Massachusetts

**Giuseppina Di Stefano** (40)

Neurobiology of Aging Laboratory,  
INRCA Research Department, Ancona, Italy

**Inga J. Duignan** (78)

Department of Medicine, Division of  
Cardiology, Weill Medical College of Cornell  
University, New York, New York

**Benjamin J. Dyson** (64)

Department of Psychology, University of  
Sussex, Brighton, United Kingdom

**Jay M. Edelberg** (78)

Department of Medicine, Division of  
Cardiology, Weill Medical College of Cornell  
University, New York, New York

**Rita B. Effros** (4)

Department of Pathology and Laboratory  
Medicine, David Geffen School of Medicine,  
University of California, Los Angeles,  
California

**Paola Fabrizio** (19)

Andrus Gerontology Center,  
Division of Biogerontology,  
University of Southern California,  
Los Angeles, California

**Patrizia Fattoretti** (40)

Neurobiology of Aging Laboratory,  
INRCA Research Department, Ancona, Italy

**Caleb E. Finch**

Ethel Percy Andrus Gerontology, Center  
University of Southern California,  
Los Angeles, California

**Harry Fisch** (51)

College of Physicians and Surgeons,  
Columbia University, New York,  
New York

**Alfred L. Fisher** (81)

Department of Medicine, Division of  
Geriatrics, University of California,  
San Francisco; San Francisco VA Medical  
Center, San Francisco, California

**Kevin R. Fontaine** (14)

Johns Hopkins University School of  
Medicine, Baltimore, Maryland

**Rosalyn Forsey** (66)

Cell Biology and Physiology Unit,  
Unilever Research Colworth, Unilever,  
United Kingdom Central Resources Ltd.  
Sharnbrook, Bedford, United Kingdom

**Lourdes A. Fortepiani** (83)

Department of Physiology and Biophysics,  
University of Mississippi Medical Center,  
Jackson, Mississippi

**D. Robert Frisina** (76)

International Center for Hearing and  
Speech Research, National Technical  
Institute for the Deaf, Rochester Institute of  
Technology, Rochester, New York;  
Otolaryngology Department, University of  
Rochester School of Medicine and Dentistry,  
Rochester, New York

**Robert D. Frisina** (76)

Otolaryngology, Biomedical Engineering  
and Neurobiology and Anatomy  
Departments, University of Rochester  
School of Medicine and Dentistry,  
Rochester, New York; International  
Center for Hearing and Speech Research,  
National Technical Institute for the Deaf,  
Rochester Institute of Technology,  
Rochester, New York

Contributors

**Tamas Fülöp** (55, 66)

Research Center on Aging,  
University of Sherbrooke, Sherbrooke,  
Quebec, Canada

**Michael P. Gardner** (20)

School of Biological Sciences,  
University of Bristol, Bristol,  
United Kingdom

**Leonid A. Gavrilov** (5)

Center on Aging, NORC and the  
University of Chicago, Chicago, Illinois

**Natalia S. Gavrilova** (5)

Center on Aging, NORC and the  
University of Chicago, Chicago, Illinois

**David Gems** (20)

Department of Biology,  
University College London, London,  
United Kingdom

**Paolo U. Giacomoni** (82)

Clinique Laboratories, Melville, New York

**Gavin Gillespie** (27)

University of Michigan, Ann Arbor, Michigan

**Andrea C. Gore** (43)

Division of Pharmacology/Toxicology,  
Institute for Cellular and Molecular Biology,  
and Institute for Neuroscience, The University  
of Texas at Austin, Austin, Texas

**Adalsteinn Gudmundsson** (61)

University Hospital of Iceland-Reykjavik,  
Reykjavik, Iceland

**John C. Guerin**

Ageless Animals, Centenarian Species and  
Rockfish Project, Portland, Oregon

**Paul Hasty** (49)

Department of Molecular Medicine,  
University of Texas Health Science Center,  
San Antonio, Texas

**J. Fielding Hejtmancik** (68)

Ophthalmic Genetics Section,  
Ophthalmic Genetics and Visual  
Function Branch, National Eye Institute,  
National Institutes of Health, Bethesda,  
Maryland

**Kevin P. High** (53)

Sections of Infectious Diseases and Hematol-  
ogy/Oncology and Molecular Medicine,  
Wake Forest University Health Sciences,  
Winston Salem, North Carolina

**Rabih Hijazi** (63)

Department of Medicine, Division of Endo-  
crinology, Baylor College of Medicine;  
Michael E. DeBakey VA Medical Center,  
Houston, Texas

**David B. Hogan** (50)

Professor and Brenda Strafford Foundation  
Chair in Geriatric Medicine, University of  
Calgary, Calgary, Alberta, Canada

**Jacquelyne M. Holm** (78)

Department of Medicine, Division of Cardi-  
ology, Weill Medical College of Cornell  
University, New York, New York

**Donna J. Holmes** (30)

Department of Biological Sciences,  
University of Idaho, Moscow, Idaho

**C. Christopher Hook** (7)

Division of Hematology, Mayo Clinic,  
Rochester, Minnesota

**Radu Iliescu** (83)

Department of Physiology and Biophysics,  
University of Mississippi Medical Center,  
Jackson, Mississippi

**Donald K. Ingram** (38)

Laboratory of Experimental Gerontology,  
Intramural Research Program, Gerontology  
Research Center, National Institute on Aging,  
National Institutes of Health, Baltimore,  
Maryland

Contributors

**Takeshi Iwata** (68)

Laboratory of Cellular and Molecular Biology, National Institute of Sensory Organs, National Hospital Organization Tokyo Medical Center, Tokyo, Japan

**Pudur Jagadeeswaran** (26)

# Preface

Aging research crosses all areas of physiology and also relies upon biological, mathematical, and chemical tools for its study. Accordingly, putting together a volume that aims to cover all models of human aging was a daunting task. The effort was made to cast a large net, but invariably some areas have been overlooked and not every viewpoint has been included. Despite its shortcomings, we hope the *Handbook* will serve as a useful broad-based overview for anyone involved in research on aging and age-related disease.

The editor thanks the authors, selected for their expertise and prominence in the field, for timely submission of well-circumscribed overviews, as well as their inclusion of previously unpublished “insider tips” from their respective disciplines.

I also appreciate the efforts of colleagues at Elsevier for embracing the significance of the project. Finally, I wish to thank Jo Ann Binkerd for assisting in the record keeping associated with this volume.

*P. Michael Conn*

# Historical Development of Animal Models of Aging

Richard L. Sprott and Steven N. Austad

*The use of animal models for research parallels the rise of modern science, beginning in the late 19th century with relatively primitive experiments and increasing in sophistication as relevant science progressed. The science of aging (gerontology) was relatively late in development, and its rise both parallels and is the result of the development of new, effective animal models. Many models, including inbred strains of mice and diet-restricted mice and rats, were first developed for cancer research. As investigators began to explore the underpinnings of cancer reductions and cancer biology in these models, their utility for aging was soon apparent. The creation of the NIA in 1975 provided a powerful boost to the development of models. The NIA developed a deliberate, rational strategy for animal model development, then funded the endeavor. NIA continues to be central to model development through its contract colonies and grant programs. Rodent models now number in the hundreds ranging from strains to “designer” individual genotypes. At the same time, models from a wide variety of other species have been developed and are becoming more generally available. Particular interest is being paid to the development of new, suitable nonhuman primate models.*

## Introduction

The history of animal model development in the United States is inextricably tied to the history of the National Institute on Aging (NIA). The rapid rise of biological, biomedical and behavioral research on aging beginning in the 1970s was a response to the growing realization of both the scientific and political establishments that the American population was aging and that the Baby Boomers would reach retirement in less than 50 years, an eternity for politicians and a moment for scientists. Even before NIA was created, scientists interested in aging began searching for animal models for their study. From the time of Clive McKay’s calorie restriction (CR) studies in the 1930s through Morris Ross’s CR studies in the late 1960s and early 1970s, most aging models resulted from studies actually developed to

study cancer. With the advent of the NIA, the field began to develop rational strategies for selection and provision of animal models. Over the ensuing 3½ decades the variety of animal models developed and available for aging research has grown enormously in quality and sophistication. At the same time, most investigators still make too many choices based on convenience rather than on the basis of a real knowledge of the available models and their suitability for any specific research question.

This chapter treats the historical development of vertebrate models only. We have made no attempt to present the history of invertebrate models or the thousands of “designer” mouse mutants and special stocks which are well covered in subsequent chapters.

## Caloric Restriction (CR)

For a complete history of this topic, see Edward Masoro’s summary in his SAGE KE article “Subfield History: Caloric restriction, slowing aging, and extending life” (Masoro, 2003).

The modern history of the use of animal (at least rodent) models for research on aging begins with the research of Clive McKay, a noted nutritionist in the 1930s. In the course of research on cancer, McKay and his colleagues (McKay *et al.*, 1935) discovered that severe calorie restriction (to 60% of *ad libitum* levels) resulted in significant increases in the lifespan of rats. Interestingly, since McKay was primarily interested in cancer, the increased longevity effects were not followed up until the work of Morris Ross in the 1960s using Sprague–Dawley rats (Ross, 1961). Ross, too, was primarily interested in the impact of CR on tumor incidence and age of occurrence in his rat models. Ross’s very careful studies through the 1960s and early 1970s brought caloric restriction’s effects on longevity to the attention of gerontologists just at the time that gerontological research was receiving an influx of interest and funding in anticipation of the creation of the NIA.

Following the interest created by Ross and others, two major research programs exploring CR’s effects on lifespan using rodent models arose in the 1970s.

One group based in the laboratory of Roy Walford at UCLA began studies of immune function in C57BL/6J mice under CR conditions (M. Gerbasse-Delima *et al.*, 1975). Over a period of years, Walford and his colleagues, most notably Richard Weindruch, studied the effects of CR on models ranging from mouse to rhesus monkeys and humans. These studies are ongoing and provide a lively subtext to the lifespan extension literature, as CR is to date the only intervention that reliably increases lifespan in mammals (Weindruch *et al.*, 1982; Yu *et al.*, 1985; Walford *et al.*, 1992).

At the same time the Walford group was engaged in its program with the objective of developing a human CR research agenda, another rigorous program of rodent CR research was developed by Edward Masoro and B.P. Yu at the University of Texas, Health Science Center, San Antonio using specific pathogen-free (SPF) F344 rats (Masoro *et al.*, 1982). The Masoro group concentrated on F344 rats. The evolution of that group's research has favored the development of more sophisticated rodent models, rather than progressing toward human research. Roger McCarter, now at Penn State, has worked to understand the physiological basis of the CR effect using F344 rats and the involvement of energy metabolism in the mechanism of action of CR using transgenic and nontransgenic C57BL/6 mice (McCarter *et al.*, 1997; McCarter *et al.*, 2002). As will be seen in the rest of this chapter, CR has a central place in the development of animal models for all of basic gerontology, not just in connection with lifespan extension.

## The National Institute on Aging (NIA)

Even before it was formally created, the NIA played a pivotal role in the development of animal models for aging. For a more complete discussion of this topic, see (Sprott, 1991; Sprott and Austad, 1996). In 1970, aging research was the province of a small branch of the National Institute of Child Health and Human Development (NICHD). But it was obvious that a new institute focused on aging was likely to be authorized as the political system was beginning to consider the consequences of the aging of the baby boom cohort. In the very earliest meetings to consider what an institute focused on research on aging might need, it was quickly apparent that the development of readily available, affordable models for basic research would be crucial to development of a robust research enterprise. A small task force was convened and asked to recommend "the best animal model for aging." The task force had no trouble quickly agreeing that no single model would suffice, as different research questions would demand different models, and providing a very detailed set of recommendations for "Development of the Rodent as a model system of aging" (Gibson, 1972). That recommendation was accepted by the research administrators

responsible for planning the resources of a new institute. Not only was the recommendation accepted; to everyone's great surprise, it was actually acted upon. Those recommendations are presented in: *Development of the Rodent as a Model System of Aging Book II* (Gibson, *et al.*, 1979).

In response to the recommendations of the task force, the Aging Branch created the first central colony of aging rodents for use by gerontologists under contract to Charles River Breeding Laboratories in 1974. The NIA was formally established in 1974 and began to function in 1975. The initial rodent colony contained two rat genotypes (F344 and Sprague-Dawley) and three mouse genotypes (C57BL/6J, DBA/2J, and the F<sub>1</sub> hybrid B6D2F1). The first aged animals were available for use by investigators by 1977. A key observation quickly became apparent as these animals were incorporated into aging research programs. By selecting these genotypes and making them broadly and easily available, the NIA had, in effect, seriously channeled the directions in which aging research could go, since the colony soon became the sole source of aged animals in the United States. In addition, it soon became apparent that Sprague-Dawley rats were susceptible to multiple pathologies that shortened lifespan, and that the F44 rats fed normal diets had a high incidence of renal pathology in the environments that were then prevalent. The solutions were twofold. First, there was agreement that the number of mouse and rat genotypes needed to be expanded and that more F<sub>1</sub> hybrids, with hybrid vigor, needed to be made available. In 1978, the number of mouse genotypes was increased to nine (and later reduced to seven). Second, intercurrent diseases in NIA-supported contract facilities and to an even greater extent in the colony spaces utilized by grantees were clearly resulting in much research being conducted on sick and dying animals or on unrepresentative survivors. These environments ranged from what could be charitably called "maintenance" to "clean conventional." In 1980, the institute began to address this disease problem. SPF facilities were just beginning to come into use. In a very controversial move at the time, the institute decided that providing "clean conventional" animals allowed the existing disease problems to persist. NIA decided to provide only SPF animals even though this meant that animals coming from an NIA facility would likely get sick upon arrival in a grantee facility that had an intercurrent disease problem. Nevertheless, this policy was implemented in 1982 in the hope that the result would be a broad improvement in the facilities receiving animals. That decision was in our opinion one of the major factors in the rapid improvement in the quality of animal research being supported by the NIA. Today, SPF barrier facilities are the norm. In subsequent years, the NIA has refined the array of mice and rats available. Current information on available animal resources from NIA is available at

## 1. Historical Development of Animal Models of Aging

<http://www.nia.nih.gov/ResearchInformation/ScientificResources/AgedRodentColoniesHandbook>.

### The National Academy of Sciences (NAS)

In December 1976, NIA held a workshop to address the question of whether an array of species might be needed to serve as models for various human conditions and processes. The outcome of that conference was a recommendation to commission a National Academy of Sciences study of the issues and the state of knowledge about all known mammalian models. The study was carried out by the Institute of Laboratory Animal Resources (ILAR) of the NAS, which created a “Committee on Animal Models for Research on Aging” for that purpose. The report of that committee was issued in book form (*Mammalian Models for Research on Aging*, NAS, 1981).

Subcommittees on carnivores, lagomorphs and rodents other than rats and mice, mice, rats, and nonhuman primates, reviewed the world’s literature in the areas of nervous system and behavior, visual system, auditory system, skeletal system, respiratory system, cardiovascular system, endocrine system, reproductive system and obesity. That review, done nearly 25 years ago, remains the only major assessment of model systems for the broad range of questions of importance to investigators of aging. Given the tremendous advances in model development that have occurred since then, it is surely time for a new assessment. While such an assessment is expensive, it would be expected to more than pay for itself in increased efficiency of agency planning for provision of model animals and investigator choice of suitable models.

### The Search for Biomarkers of Aging (NIA)

As soon as gerontologists began to be interested in interventions that might lengthen life, the question of how to test such interventions arose. The problem is trivial in very short-lived animals such as yeast, nematodes, fruit flies, and mice, since many generations of animals can be tested in the course of a single three-year experiment (NIH grant). However, the problem is far from trivial in longer lived species like dogs, monkeys, and humans. The best solution would be to develop a set of measures that could be used to assess the life-lengthening effects of an intervention in significantly less than the full lifespan of the organism. Such measures are called biomarkers of aging. For a full discussion of the issues see the special issue of *Experimental Gerontology; Biomarkers of Aging* (Sprott and Baker, 1988).

The need for biomarkers of aging also arises from the observation that chronological age and “biological” age are not synonymous. Obviously species age at different rates, but the question of whether individuals within a species do so as well has generated much controversy in

the aging literature. If one assumes that aging is the net result of environmental damage (oxidative damage to DNA for example), then the question is moot. If, on the other hand, one assumes that there are basic aging processes that determine the rate at which organisms age (as there clearly are in annual plants), then assessing the rate of aging becomes a necessary part of the assessment of interventions designed to change that rate. Only in the case of a pure wear and tear or DNA damage theory would biomarkers of aging be an irrelevant concept. Since different species have different, but very predictable, life-spans (fruit flies 2 months; mice 2 to 3 years; chimpanzees as long as 60 years; and humans as long as 120 years), the question of how to compare the biological age status of individuals across species in order to make animal models useful became a primary rationale for the development of biomarkers of aging.

In 1987 the NIA together with the National Center for Toxicological Research (NCTR) established colonies of mice and rats to be used in a ten-year, 18-laboratory effort to develop biomarkers of aging that could eventually be used to test interventions in humans. Since CR was then the only intervention that had ever been reliably been shown to increase longevity (slow the rate of aging?) in any organism, the NIA/NCTR colonies provided both *ad libitum* and calorie-restricted mice and rats on the assumption that any useful biomarker would have to be sensitive to CR as a longevity promoting intervention. These colonies were the first to make CR mice and rats available for widespread use. NIA continues to make CR rats of three genotypes available; see <http://www.nia.nih.gov/ResearchInformation/ScientificResources/AgedRodentColoniesHandbook> for details and current availability.

Twenty percent of all of the animals produced in the biomarker colonies were set aside for pathological assessment (10% cross-sectional and 10% longitudinal). These studies provided the most complete characterization of the pathology of three rat genotypes (Brown Norway, F344, Brown Norway, Brown Norway × F344 F<sub>1</sub>) hybrid and four mouse genotypes (C57BL/6N, DBA/2J, C57BL/6N × DBA2/J F<sub>1</sub> hybrid, and C57BL/6N × C3H hybrid) ever accomplished (Bronson, 1990; Lipman *et al.*, 1999 A and B; Turturo *et al.*, 1999). One of the questions to arise from these studies was whether the *ad libitum* feeding regimen is the optimum regimen or an abnormal one for rodents. While the issue is not yet resolved, interest in some level of CR as the “normal” diet is growing. Differences in diet content and amount between laboratories contribute a great deal of variability to studies of everything from biomarkers to pathology. The NIA Biomarkers Program controlled for this variability by rearing all test animals and shipping them to investigators in the program. In the absence of such control, it is often difficult to make cross-laboratory comparisons. See Hart *et al.* (1995) for a very thorough treatment of this issue.

## The Senescence Accelerated Mouse

The Senescence Accelerated Mouse (SAM) strains of mice were developed by Toshio Takeda at the Chest Disease Research Institute, Kyoto University, as the result of an accidental outcrossing of AKR/J mice and another unknown albino mouse strain in 1968. After receiving several pairs of AKR/J mice Takeda began brother–sister mating to provide animals for his research. He soon began to notice that in some litters of the offspring most of the mice “showed a moderate to severe degree of loss of activity, hair loss and lack of glossiness, periophthalmic lesions, increased lordosis, and early death” (Takeda, 2004). Beginning in 1975 five litters of mice showing the accelerated senescence phenotype were selected to become the progenitors of lines of senescence-prone (P series) mice, while three litters of mice that were resistant to accelerated aging were selected as progenitors of the senescence resistant (R series). Lines from these progenitor litters were then maintained as inbred lines to create three lines of resistant and five prone lines. These lines can be considered a set of recombinant inbred mice resulting from a cross between AKR and at least one (possibly two) unknown albino strains. Genotyping studies are ongoing to determine the genotype of the outcross animals.

Over the ensuing three decades Takeda and his colleagues have characterized these mice for an extraordinary range of characteristics including behavior, pathology, reproductive capacity, lifespan, response to husbandry, and physiology. For the most current exploration of this set of mouse strains, see Nomura *et al.* (2004). This approach to development of models for aging research is very different from that used in the United States. American investigators are very resistant to the use of models of “accelerated” aging, as they believe that it is impossible to distinguish between accelerated aging and the life-shortening effects of disease or environmental insult. Only recently have any investigators in the United States and Europe begun to use these mice. One of the factors in the slight shift in attitude has been the fact that the differences in lifespan among SAM lines have persisted after the mice were moved to SPF facilities (Suzuki *et al.*, 2004). SAM mice are widely used in Asia for pharmacologic and neurodegenerative research, and are obtained in Asia from the SAM Research Council. SAM mice are available in the United States and Western Europe from the International Biogerontology Resource Institute (IBRI) through an arrangement with Harlan Sprague Dawley.

## The International Biogerontology Resources Institute (IBRI)

An international resource development institute (IBRI) was begun at San Pietro al Natisone, Friuli, Italy in 1998.

The mission of IBRI is to foster international collaboration on the biological resources needed to conduct aging research including cells, tissues, organs, and whole organisms, from *C. elegans* to nonhuman primates. Early emphasis has been placed on rats (*Rattus norvegicus*) and mice (*Mus domesticus*) to provide for the shared development of biological resources and for the development of research methods to utilize these resources; provide space, core shared research resources, and a core staff of research scientists with maximum opportunities for international collaboration with visiting scientists and fellows; provide an international education effort regarding the use of animal models in gerontological research; provide maximum barrier facilities to house defined pedigreed stocks and strains of rats, mice, and other animals in one location accessible to the worldwide scientific community; provide guidance, worldwide, for the efficient, cost-effective, and reliable production and distribution of animal models for aging research; and provide a facility for holding international conferences and symposia on biogerontologic resources. This fledgling organization is made up of a consortium of universities from the United States and Europe and its corporate partner, Harlan Sprague Dawley. The SAM Council maintains an active role in the provision and certification of SAM lines maintained by IBRI.

The major objective of IBRI is to collect and maintain all of the major animal models for aging research in one place and make them available to investigators at that facility for pilot experiments, and by shipment to an investigator’s laboratory for more extensive experiments. IBRI hopes to soon develop new rodent and nonhuman primate models as well. Further information about IBRI can be obtained by contacting the first author of this chapter.

## Other Rodents

Laboratory rodents are among the shortest-lived mammals known, which defines in a certain sense their value for life-span studies. Their already short lives may have been further shortened by hundreds of generations of inadvertent selection for rapid growth and high reproductive rate that mass breeding entails. In the 1960s, George Sacher began searching for a longer lived rodent species, similar in size and basic biology to the laboratory mouse, to investigate what it exactly is that longer lived species do better in the “protection-stabilization, and repair of its essential molecules” when compared with a mouse (Sacher and Hart, 1978). In 1962, Sacher began laboratory breeding of wild-caught house mice (*Mus musculus*) and white-footed mice (*Peromyscus leucopus*) trapped near the Argonne Laboratory site in northeast Illinois. The white-footed mouse was abundant near Argonne and had already been used in a variety of biomedical research contexts (King, 1968). Although he noticed that wild-caught house mice lived somewhat

## 1. Historical Development of Animal Models of Aging

longer than laboratory mice, he did not pursue this line of inquiry. The white-footed mouse turned out to live more than twice as long as either wild-caught or laboratory house mice—more than 3.75 years on average with the longest-lived individuals surpassing 8 years. Sacher's laboratory published about a dozen papers comparing house and white-footed mice, as did Ron Hart's laboratory at the National Center for Toxicological Research. In the 1980s and early 1990s George Smith of UCLA began to inbreed *Peromyscus leucopus*. Although Dr. Smith is now retired, the strains he produced have now been inbred for more than 30 generations. They, along with various subspecies of seven species of *Peromyscus* and a variety of mutants, are currently available from the *Peromyscus* Genetics Stock Center (<http://stkctr.biol.sc.edu>) at the University of South Carolina in Columbia, South Carolina.

Although George Sacher did not follow up his observation that wild-caught house mice lived longer than domesticated laboratory mice, he alerted researchers to the possibility that wild populations of house mice might contain longevity-associated genes that had been lost in laboratory mice. Austad (1996) observed that the wide range of mouse body sizes in geographically diverse populations suggested that many wild mouse populations might bear local adaptations that would make them of considerable gerontological interest. Miller and colleagues (1999) pointed out that the history of laboratory mice from their initial derivation from “fancy mice” to their inadvertent selection for rapid growth, high fecundity and cancer-prone genotypes to the extensive inbreeding that had made them so valuable in one sense may have led to shortening of life as well. Mice captured from three field locales (Idaho; Majuro in the Marshall Islands; and Pohnpei in Micronesia) were compared for body size, developmental rate, various hormone parameters, and longevity with a synthetic laboratory stock bred from crossing four inbred strains (Miller *et al.*, 2000, 2002). Mice derived from the wild remained smaller than the laboratory stock even given unlimited food. They also grew more slowly, matured later, and had smaller litters compared with the laboratory mice. Mice from Idaho and Majuro lived somewhat longer than the laboratory stock whereas the Pohnpei mice did not. Associated with their longer life, Idaho mice exhibited reduced serum levels of IGF-1, leptin, and glycosylated hemoglobin compared with laboratory mice. Surprisingly, Majuro mice were hyperglycemic compared to laboratory mice despite their longer lives (Harper *et al.*, 2005). Genes present in these long-lived mice may be valuable tools for the analysis of the physiology and biochemistry of aging mice. Moreover, wild-derived mice have exceptional levels of physical performance, e.g., running speed, endurance, agility, compared with laboratory mice (Dohm *et al.*, 1994) and may be useful in dissecting the genetics of muscle physiology and coordination.

In recent years, a novel rodent species of exceptional gerontological interest has been discovered, the naked mole-rat (*Heterocephalus glaber*). This mouse-sized African species had been studied since the 1970s, mainly for its unique social system that resembles the eusocial colony organization of bees and ants (Sherman *et al.*, 1991). However, as captive colonies were maintained for longer and longer, it became clear that naked mole-rats were equally interesting for their very long lives. The current captive longevity record is more than 28 years, and many individuals live into their teens and twenties (O'Connor *et al.*, 2002; Buffenstein and Jarvis, 2002) and continue to function at a high level. The longevity record-holding male successfully inseminated a female shortly before his death. Rochelle Buffenstein's laboratory along with her many collaborators are now seriously pursuing mechanistic studies to elucidate how this species can live nearly 10 times longer than the similar-sized laboratory mouse.

### Nonhuman Primates

Nonhuman primates have been employed in medical research since the second millennium BC in ancient Egypt; however, their modern medical use began in the late 19th century when they were used mainly to investigate infectious diseases such as syphilis (Fridman, 2002). Elie Metchnikov, the Nobel Prize-winning bacteriologist, was probably the first investigator to consider the study of nonhuman primates for the insights they might offer into human aging. On the occasion of his 70th birthday in 1915, he suggested that primate nurseries be constructed for the captive rearing of monkeys and apes, thus laying the conceptual groundwork for the primate research centers that exist today (Fridman, 2002). In a somewhat embarrassing first direct use of primates to address human aging, S.A. Voronoff developed a colony of baboons and chimpanzees in southern France to provide testicular tissue for transplantation into humans to achieve their “rejuvenation.” This facility also provided primates to other researchers, such as I.P. Pavlov. The first major primate center specifically dedicated to research in the United States was established in Florida by Robert Yerkes in 1930.

The advantage of primates for aging research is their close evolutionary affinity with humans and consequent similarity (compared with rodents) in such traits as complex cognitive abilities, and similarity of response to drugs and vaccines.

Maintaining primates in good physical and mental health in captivity has always presented complex problems. Because of these complex husbandry issues, even defining what is an “aged” individual of a given species has not been easy. For instance, the maximum lifespan of rhesus macaques, capuchin monkeys, and marmosets reported in a 1979 review was 33, 43, and 9 years, respectively (Bowden and Jones, 1979). With improved husbandry, we now know that these three primates

can live at least 40–44 years, 55 years, and 16 years, respectively, some 25–75% longer than previously thought (Roth *et al.*, 2004; Nowak, 1999; Smucny *et al.*, 2004). Their long lives and complex social needs make primate aging research difficult and expensive. However, the human relevance of health problems associated with aging in nonhuman primates is unparalleled. They must be studied.

The NIA has sought to help make aged rhesus macaques available to the research community by supporting their maintenance at several primate research facilities around the United States. Currently, about 150 macaques between 18 and 35 years of age are available for noninvasive research (<http://www.nia.nih.gov/ResearchInformation/ScientificResources/>). The Institute keeps a repository of stored primate tissue as well, also mostly from rhesus macaques.

The most serious and systematic studies of nonhuman primate aging have developed as a consequence of an attempt to determine whether caloric restriction extends life and prevents disease in primates as it does in laboratory rodents. Two such ongoing studies exist. In 1987, the intramural program of the NIA initiated an investigation of long-term caloric restriction in male rhesus macaques and squirrel monkeys. In both species, restriction was imposed at several ages by reducing food intake by 30% relative to age- and size-matched controls. Five years later, female rhesus were added to the study. In the intervening years, various short-term restriction experiments were also added, so that about 200 monkeys in sum are being investigated (Lane *et al.*, 2002; Mattison *et al.*, 2003). Similarly, at the Wisconsin Regional Primate Research Center, a caloric restriction study of 30 rhesus males (15 restricted, 15 controls) was initiated in 1989. Five years later, 30 females and an additional 16 males were added to the study. As in the NIA studies, the experimental animals are restricted to 70% of the control diet (Ramsey *et al.*, 2000). Due to the long life of monkeys (mean thought to be 25–26 years for rhesus, and maximum at least 40 years), definitive results are not yet available for either study. However, a side benefit of these studies is to characterize more thoroughly than ever before, the life- and health-span of very well cared for primates. For instance, squirrel monkeys were chosen as one species for the NIA study, because it was thought that their maximum longevity was less than 20 years. However the oldest animals in that study are now in their mid-to late 20s (J. Mattison, personal communication, 2005). Thus with excellent care, longevity increased fairly dramatically. It will be interesting to see whether there is also such an increase in longevity in the rhesus population.

One approach to making primate aging research less costly and time consuming would be the development of a small primate model (Austad, 1997). Advantages of a small model (rat-sized or smaller) are (1) lower per capita housing and maintenance costs; (2) the potential to

maintain the animals in SPF conditions in standard laboratory animal facilities as is now standard for aging mouse and rat research; and (3) their accelerated life history, being that they reach sexual maturity earlier and are shorter-lived than larger primates. The most promising candidate species for a small primate model for aging research is the common marmoset (*Callithrix jacchus*). This species is native to eastern Brazil and has been used in biomedical research since the early 1960s (Ludlage and Mansfield, 2003). One major advantage of common marmosets compared with other small primates is that they are not listed in Appendix I of the Convention on International Trade in Endangered Species (CITES). Listing in CITES Appendix I severely limits availability of animals for research and prohibits commercial trade in a species. Marmosets are rat-sized, 300–400 g, reach sexual maturity at 12–18 months of age, typically produce twin births, have a mean longevity of 6–7 years (are considered “old” by 8–10 years) (Tardif, personal communication, 2004), and have a record maximum longevity of 16 years (Smucny *et al.*, 2004). Their captive husbandry and clinical care are well-developed (Ludlage and Mansfield, 2003), and they are currently maintained at five major research facilities (Smucny *et al.*, 2004). It is quite possible that the mean and maximum longevity reported for marmosets would creep upward as they begin to be maintained in SPF conditions, but even a 50% increase would still make them an exceptionally attractive primate aging model. Because of their high reproductive rate relative to larger primates, colonies can be expanded comparatively rapidly. Their habit of twinning would also allow littermates to be randomly assigned to treatment and control groups, giving some measure of genetic control in experimental protocols. A further advantage is that as of March 1, 2005 common marmosets have joined the official species queue for complete genome sequencing by the NIH/National Human Genome Research Institute.

## Summary and Conclusions

Modern animal model use for aging research began with the calorie restriction studies of Clive McKay and Morris Ross. This research, initially for cancer, led to studies to understand the CR effect and eventually to the development of special colonies of mice and rats for that purpose. Beginning in the mid-1970s the NIA created central colonies of aged rodents, centrally raised by contract, fed uniform diets, and maintained in barrier facilities. These animals became the models of choice for almost all biological research on aging for a decade. Subsequently, many more rodent models were created and supplied by NIA. Nonhuman primate resources began to be developed and are now just beginning to become available. Currently primate research is conducted in a small number of laboratories at DRR supported primate centers and at the NIA intramural facilities.

## 1. Historical Development of Animal Models of Aging

Other animal models such as nematodes and fruit flies are being used for basic studies of many aging phenomena. These models are discussed in later chapters.

The history of animal model development for aging research is in many ways the history of biological research on aging. Without widely available and suitable animal models for research, the astonishing developments that have occurred in the last 4 or 5 decades in our understanding of aging could not have occurred. It should be obvious that support for models development is absolutely required for the continued development of this field of knowledge.

# Species Selection in Comparative Studies of Aging and Antiaging Research

João Pedro de Magalhães

*A great range of life histories are observed among mammals. Understanding why different species age at different rates may provide clues about the mechanistic and genetic basis of aging. This work focuses on animal species and their use in comparative studies of aging. Firstly, I debate how to compare aging across different species, including physiological parameters and statistical analyses. Afterwards, a selection of species for use in the comparative biology of aging is suggested. Taking into account that the ultimate aim of research on aging is to benefit people, my selection is largely based on primates. Primates feature such a vast range of aging phenotypes that comparative studies of aging need not employ other more distant species, except perhaps a few rodents. A number of animal species that may serve as models of antiaging strategies are also presented. Examples include species that appear not to age, such as some turtles, and animals featuring regenerative mechanisms absent from humans. Studying the genetic and molecular basis of these traits may have potential implications for antiaging research. Sequencing the genome of these species should then be a priority.*

## Introduction

Different species of animals age at radically different paces. A salmon will degenerate and die within days after spawning while some turtles, studied for decades, do not show signs of aging. Among mammals too a great range of life histories are observed. Even under the best laboratory conditions a mouse (*Mus musculus*) will not live past its 5th birthday, the oldest person on record—Jean Calment—died at age 122, but a bowhead whale (*Balaena mysticetus*) may live over 200 years (George *et al.*, 1999). Equally impressive, similar species tend to show great differences in longevity and aging rates. Among primates, for instance, while humans may live over 100 years, dwarf and mouse lemurs do not commonly live more than 20 years and, in their second decade of life, show age-related pathologies typical of elderly people.

Despite great differences in lifespan, the aging phenotype is remarkably similar across mammals (Finch, 1990; Miller, 1999). For example, aged (8–11 year-old) mouse lemurs (*Microcebus murinus*) show senile plaques comparable to those witnessed during human cerebral aging (Bons *et al.*, 1992). Consequently, the principle behind the comparative biology of aging is that studying why different species age at different rates may provide clues about the mechanistic basis of aging. Moreover, identifying which genetic factors determine the pace of aging in mammals could open the possibility of delaying aging and/or age-related diseases in people.

The focus of this work is on animal species and their selection for use in comparative studies of aging. Recently, we developed AnAge, an aging-oriented database featuring over 3,000 animals (de Magalhaes *et al.*, 2005a). All species mentioned in this chapter are featured in our database, and hence additional information and references are available in AnAge. My aims in this chapter are to (1) briefly discuss how to compare the aging process between different species; (2) provide a selection of species for comparative studies of aging; and (3) suggest species that may be models of antiaging strategies. Importantly, the purpose of biomedical research is to improve the human condition. The goal of gerontology is to preserve human health and well-being, and extend healthy life. Consequently, the choice of models employed by researchers must always have humans as the ultimate goal, and this is reflected in this work.

Although the focus of this chapter is not on how to perform comparative studies of aging, but rather on which species to employ, the selection process must take potential experiments into consideration. Numerous parameters may be studied between species with different rates of aging: DNA repair rates, cellular stress resistance, antioxidant concentrations, and many others (Finch, 1990). Some of these experiments require captive populations of the species under study, which may not be readily available and might even be impossible to obtain. Although *in vivo* studies may be highly informative, these may be difficult to conduct in many of the species mentioned herein—such as in bowhead whales. Modern high-throughput technologies like genomics, however,

do not require captive populations or in vivo studies. Furthermore, cellular studies have been proposed as a means to study long-lived species (Austad, 2001; de Magalhaes, 2004), such as stem cells differentiating in culture. Therefore, intact organism studies may not be necessary in comparative biology, particularly since I predict that comparative genomics will become a major tool for comparative studies of aging (de Magalhaes and Toussaint, 2004). My choice of species hence does not take into account potential husbandry costs and difficulties.

## Measures for Comparing Aging

In this work, lifespan is defined as the period of time in which the life events of a species typically occur. So far, I have been mostly referring to maximum lifespan (*t<sub>max</sub>*) as a means to compare aging among different species. There are multiple problems, however, in using *t<sub>max</sub>* as an estimate of aging. For example, feral animal populations may have their *t<sub>max</sub>* limited by predation, accidents, or starvation. Even differences in *t<sub>max</sub>* in captivity may reflect husbandry difficulties, and several species are impossible to maintain in captivity. Therefore, and since *t<sub>max</sub>* is not the only way of comparing aging, it is worthwhile to consider how aging rates can be compared across species before selecting them. After all, since aging is one of the variables under study in comparative studies of aging, we must at least roughly quantify the rate of aging if we are to design appropriate experiments. As an example, I will examine the closest human relative, chimpanzees (*Pan troglodytes*). Chimpanzees live a maximum of 73 years while humans live 122 years, so *t<sub>max</sub>* suggests that chimpanzees age about twice as fast as humans.

### PHYSIOLOGICAL AGING

Aging can be defined as an age-related decline in physiological function (Austad, 2005). Studying aging in model organisms may include numerous anatomical, physiological, and biochemical age-related changes (Finch, 1990). Consequently, one way to determine rate of aging is to study the pace of age-related changes and/or the onset of age-related pathologies (Miller, 2001; de Magalhaes *et al.*, 2005b). This is arguably the most accurate and informative way of studying aging in a given species.

Briefly, the basic aim of physiological studies in aging animals is to investigate typical human age-related changes. These include the major human killers in old age: cancer, heart and neurodegenerative diseases. In fact, while it is not a measure of aging, it is informative to know what animals die of, particularly in captivity where the effects of accidents and predation are minimized. Determining common causes of death for model organisms is insightful regarding the onset of aging and regarding which age-related pathologies in a given

animal model are similar to those seen in people. Equally relevant are reproductive changes with age, which include testis and ovary changes as well as the onset of reproductive senescence such as age of menopause. Many age-related changes and pathologies can also be studied and compared to human aging. A few parameters of interest include, but are not limited to, fat deposits, hormonal levels such as those of growth hormone, insulin and insulin-like hormones, and dehydroepiandrosterone (DHEA), atherosclerotic lesions, osteoporosis, arthritic changes, changes in reaction times with age, changes in senses, and the presence of cerebrovascular  $\beta$ -amyloid protein (Finch, 1990). There are also examples of comparative studies aimed at specific age-related pathologies, and readers should consult other chapters in this book.

In the case of chimpanzees, physiological deterioration appears to occur at earlier ages than in humans (Finch, 1990; Hill *et al.*, 2001; Erwin *et al.*, 2002). This is obvious in, for instance, bone aging: chimpanzees generally develop bone aging—such as fractures and loss of bone density—at earlier ages than people do (Morbeck *et al.*, 2002). Chimpanzees also show tooth erosion at earlier ages than humans (Hill *et al.*, 2001). While chimpanzees, in general, appear to show signs of aging at earlier ages than humans, little is known about the pace of aging in chimpanzees, some age-related changes typical of humans may not occur faster in chimpanzees. For example, cancer rates do not appear to be higher in chimpanzees, though little is known about age-related cancer rates in chimpanzees (Erwin *et al.*, 2002).

### DEMOGRAPHIC AGING

Changes in physiological parameters are interesting for comparative studies of aging but they are potentially expensive and difficult to study. One alternative is to employ demographic measurements of aging. Aging can also be defined as an age-related increase in vulnerability and decrease in viability (Comfort, 1964). One of the features of aging in species with gradual senescence, like most mammals, is an exponential increase in mortality after maturity. For example, in humans, our chance of dying roughly doubles every 8 years after about age 30. This is remarkably similar among different human populations, independently of average lifespan (Finch 1990). Therefore, one way to compare rates of aging across different species is to calculate the rate at which mortality increases with age, which gives a measure of senescence (Pletcher *et al.*, 2000). As an example, Figure 2.1 shows the hazard function—which represents the probability of death—of chimpanzees according to age based on published mortality rates (Hill *et al.*, 2001).

In chimpanzees, hazard rates begin to increase near the end of the second decade of life, while human hazard rates generally begin to climb at the end of the third decade of life. This time it takes for mortality rates to climb has also been suggested as a measure of aging (Finch, 1990),

## 2. Species Selection in Comparative Studies of Aging and Antiaging Research

**Figure 2.1.** Natural logarithm of chimpanzee mortality rates as a function of age. The straight black line represents the estimated adult mortality trajectory based on Gompertz parameters calculated using a weighted linear regression. The data comes from five field studies of chimpanzees (Hill *et al.*, 2001) and was fitted using the T4253H smoothing algorithm from the SPSS package (SPSS Inc., Chicago, IL).

and in this case suggests aging commences earlier ages in chimpanzees than in humans. To calculate the age-related increase in mortality, the Gompertz function is typically used. Although other functions have been proposed (Wilson, 1994), the Gompertz function is generally the most adequate for these calculations, particularly when using small populations as is common in studies of higher vertebrates. It is also the most widely used function, making it a good term for comparisons. The Gompertz equation is  $R_m = R_0 e^{\alpha t}$  where  $R_m$  is the chance of dying at age  $t$ —i.e., the hazard rate— $R_0$  is the nonexponential factor in mortality, and  $\alpha$  is the exponential parameter. Based on the Gompertz equation it is possible to calculate the mortality rate doubling time (MRDT), which is an estimate of rate of aging given by  $MRDT = 0.693/\alpha$  (Finch, 1990; Mueller *et al.*, 1995).

Depending on the quantity and quality of the data, there are different ways of calculating the Gompertz parameters (Mueller *et al.*, 1995), and a certain amount of subjectivity is unavoidable. In this case, and as previously described (de Magalhaes *et al.*, 2005b), the weighted linear regression was obtained from the ln-transformed Gompertz equation:  $\ln(R_m) = \ln(R_0) + \alpha t$ . The chimpanzee curve was estimated as:  $\ln(R_m) = -4.56 + 0.0798t$  with  $r^2 = 0.81$ . Hence,  $\alpha = 0.0798$  with 95% confidence intervals of 0.0627 and 0.0969. This means that the MRDT for chimpanzees is around 8–9 years, similar to that of humans.

The great advantage of the Gompertz function and estimating  $\alpha$  and the MRDT is that it allows us to quantify the rate of aging. As shown above, however, MRDT estimates indicate chimpanzees and humans age at similar paces, which may not be true from a physiological level. Our results from rodents also suggest that MRDT is a good but not perfect estimate of rate of aging (de Magalhaes *et al.*, 2005b). Therefore, even though the MRDT is a useful measurement of aging rates,

it should be used in conjunction with physiological observations.

### CONCLUDING REMARKS

While not being measurements of aging, lifehistory traits such as developmental schedules are relevant for comparative studies of aging. For instance, long development in mammals is typically associated with a long adult lifespan, independently of body size (Harvey and Zammuto, 1985). Age at sexual maturity, gestation or incubation time, and litter or clutch size are all important features of animals, particularly in the context of ecology and to understand the evolutionary forces that shape lifespan.

Other estimates of aging have been used such as adult mortality rates, average longevity, and adult lifespan. Adult mortality rates and average longevity did not correlate well with the MRDT or with physiological aging parameters in rodent cohorts (de Magalhaes *et al.*, 2005b). In the context of comparative studies of aging, there is no strong reason to use these estimates rather than maximum lifespan, though maximum adult lifespan may sometimes be more appropriate than  $t_{max}$ . In contrast, the large amounts of  $t_{max}$  data available make it a good term for comparisons.

In conclusion, the most adequate measure of aging is still  $t_{max}$ . Faster aging organisms will not be able to live as long as slower or nonaging species, which will be reflected in  $t_{max}$ . In fact,  $\alpha$  has been shown to correlate with  $t_{max}$  (Finch and Pike 1996). We also recently showed that  $t_{max}$  correlates with MRDT in rodent cohorts (de Magalhaes *et al.*, 2005b). Certainly, there are inherited problems in quantifying aging using  $t_{max}$  and, at least for species with high mortality rates in the wild,  $t_{max}$  should be estimated from captive populations. Nonetheless, while the use of the methods described above is encouraged, particularly descriptions of physiological,

biochemical, and anatomical changes with age,  $t_{max}$  will continue to be the most widely used estimate of rate of aging. In the remaining of this chapter,  $t_{max}$  is commonly used.

## Species for the Comparative Biology of Aging

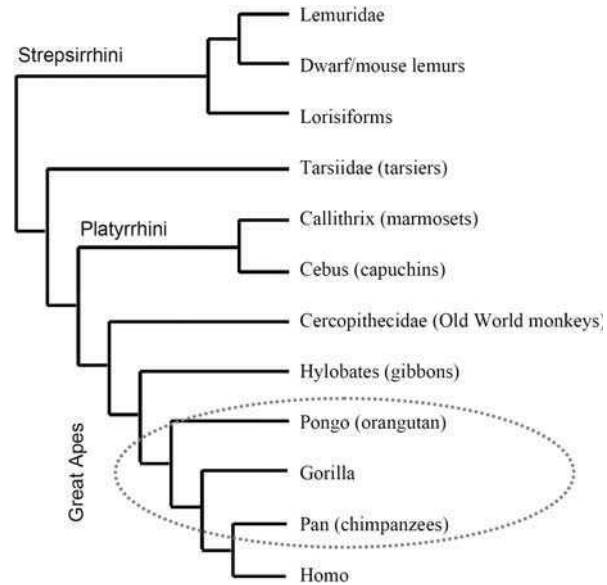

As mentioned above, the ultimate objective of aging research is to benefit people. Consequently, choosing species for the comparative biology of aging must be done having *Homo sapiens* in perspective. Whether model organisms are representative of the human aging process has been debated by many others (Gershon and Gershon, 2000). It is possible that mechanisms of aging are conserved across distant species, and it is possible that they are not (de Magalhaes, 2004). Since there is still no definitive answer to this debate, my position in this work is that species biologically and evolutionarily more distant from humans are less likely to share mechanisms of aging with people, and thus an effort was made to select species closer to humans.

Since among mammals there is a great diversity in the pace of aging, there is no scientific reason to employ nonmammalian species in the comparative biology of aging. On the contrary, incorporating nonmammalian species may lead to the use of species with different biology than humans and thus of more dubious use to understand human aging. In fact, mammals feature unique traits associated with aging such as diphyodont replacement—i.e., two sets of teeth—which is surprisingly common in mammals and is associated with tooth erosion, and a lack of oocyte regeneration, which makes reproductive senescence inevitable in all studied female mammals. These traits suggest that the evolution of aging in mammals may have had unique features (de Magalhaes and Toussaint, 2002). While there may be practical and economical reasons to employ nonmammalian species in aging research, these must be considered as secondary choices and more error-prone than mammalian models.

### PRIMATES AND RODENTS

If the focus of gerontology is on the human species, then it makes sense for us to select our closest relatives as models of aging, provided these species indeed age differently than humans (Figure 2.2).

As mentioned above, our closest living relative is the chimpanzee, in which aging appears to occur earlier than in humans. Similarly, all the great apes show signs of aging at younger ages than humans, though it is unknown whether they age differently from each other (Erwin *et al.*, 2002). As we move further away from humans and great apes, species tend to be smaller, less intelligent, and shorter-lived. This is apparent among Old World monkeys (family: Cercopithecidae), which are generally shorter-lived than apes. Two species of Old World

**Figure 2.2.** Primate phylogeny highlighting potential models for comparative studies of aging. The Platyrrhini infraorder represents New World monkeys. Phylogeny was drawn based on Goodman *et al.* (1998). Branch lengths are not to scale.

monkeys have already been studied in the context of aging: rhesus monkeys and baboons. Both appear to age considerably faster than humans and great apes, making them potentially useful models for comparative studies of aging. Interestingly, baboons have an MRDT of roughly 4 years (Bronikowsky *et al.*, 2002) while rhesus monkeys appear to have an MRDT not smaller than that of humans (Finch, 1990). Nonetheless, physiological studies suggest that rhesus monkeys age about twice as fast as humans (Finch, 1990; also see Chapter 38 by Roth and colleagues in this book and references in AnAge). Baboons and rhesus monkeys demonstrate how comparing aging rates among different species can be difficult and how the MRDT is not always an accurate estimate of rates of aging.

Among New World monkeys, also termed Platyrrhini, we find species much shorter lived than apes and humans. Marmosets are a good example, such as the common marmoset *Callithrix jacchus*. The record longevity for these animals is little over 16 years, and numerous age-related changes have been reported in their second decade of life (see AnAge for references). They also reach sexual maturity at about one year of age—which is much sooner than apes—suggesting shorter generation cycles, shorter lifespans, and hence in accordance with a faster aging process. Therefore, if our choice of species is aimed at discovering what determines rate of aging among primates, with humans as our ultimate goal, then these shorter lived primates are certainly a good choice. In contrast, some New World monkeys are longer lived, attaining sexual maturity at older ages. Examples include members of the genera *Alouatta*, *Ateles*, *Cacajao*,

## 2. Species Selection in Comparative Studies of Aging and Antiaging Research

and Cebus. The white-faced capuchin (*Cebus capucinus*) is a good example with a record longevity of almost 55 years and attaining sexual maturity with at least 5 years of age. Therefore, New World monkeys offer a variety of aging phenotypes suitable for comparative studies of aging. The large variation in rates of aging among such closely related species argues, once again (Miller, 1999), that genetic factors determine rate of aging in primates and makes New World monkeys a valuable source of models of aging.

Moving further away from humans, tarsiers (family: Tarsiidae; genus: *Tarsius*) also appear to be short-lived with short generation cycles (Austad, 1997a). In contrast, a greater diversity is found among Strepsirrhini, one of the two primate suborders (Figure 2.2). Lemurs of the *Lemuridae* genus are relatively long-lived when compared to their closest relatives. The brown lemur can live 37 years, which is impressive considering it reaches sexual maturity at about age 2. It was also reported that a hybrid between a brown and a black lemur lived for 39 years (Jones, 1982). In contrast, dwarf and mouse lemurs (family: Cheirogaleidae) do not live more than 20 years, and age-related changes have been described in their second decade of life (see AnAge). For instance, the fat-tailed dwarf lemur (*Cheirogaleus medius*) has been argued as an example of a fast-aging primate (Austad, 1997a). Lorisiforms such as the slender loris (*Loris tardigradus*) also appear to be short-lived with a fast development (Austad, 1997a), although the slow loris (*Nycticebus coucang*) has been reported to live over 26 years. As in New World monkeys, the Strepsirrhini suborder appears to feature a variety of aging rates.

While there are reasons to focus only on primates in comparative studies of aging (Austad, 1997a), rodents may also serve as a potential model. First of all, mice and rats (*Rattus norvegicus*) are well-established models in biomedical and aging research. Secondly, rodents and primates diverged roughly 58 million years ago (mya), not long before the two primate suborders—Strepsirrhine and Haplorrhini—diverged 49 mya (Springer *et al.*, 2003). Lastly, the short life cycles and fast aging processes of mice and rats have not been observed in any primate. By incorporating rodents and primates, we thus obtain a range of aging rates close to that of the entire Mammalia class. In Table 2.1 I recap all of the species mentioned above.

If we aim to investigate the factors regulating aging in primates having the human species as our priority, then our choice of species need not go further than primates and rodents. As argued before (Austad, 2005), more is learned by the study of closely-related species that differ considerably in the trait of interest. Of course, diversity is always welcomed and other species can be incorporated into the comparative biology of aging. Nonetheless, solely using primates and rodents in the comparative biology of aging may be adequate to determine which genetic factors regulate the human aging rate. Certainly, there are major

difficulties in studying primates, but that depends on which factor is being studied. In the modern age of genomics it may be necessary, not to keep animals in captivity, but rather to have their genome sequenced. It is with this prospect that I suggest these animals as choices for aging research. Hopefully, some of these animals, like short-lived primates, may also be incorporated as experimental models, as suggested before (Austad, 1997a).

### THE INFLUENCE OF BODY SIZE

A number of factors correlate with *t<sub>max</sub>*, and while this work is about species selection, not the methodology of comparative biology, there is one factor that must be mentioned: body size (Promislow, 1993). Clearly, bigger species, including mammals, live longer, on average, than shorter-lived species (Austad, 2005). Exceptions exist and, for example, gorillas (*Gorilla gorilla*) are typically bigger than humans and still do not live longer than us. Likewise, bats live longer than predicted from their body size. Nonetheless, when comparing parameters across species it is crucial to take body size into consideration. Otherwise we could make the mistake of correlating some physiological factor with body size, not with longevity or aging. For example, early studies indicated that DNA repair capacity was higher in longer-lived mammals, arguing that DNA repair was a factor in aging (Hart and Setlow, 1974). Yet it has been argued that the correlation between DNA repair and longevity is due to the fact that bigger animals live longer and, for reasons unrelated to aging, have better DNA repair mechanisms (Promislow, 1994). In other words, the evolution of aging rates and DNA repair may have been related to body size and thus independent from one another. Therefore, body size is a factor that comparative studies of aging must take into consideration. It is necessary that we devise appropriate methods to exclude or at least minimize the impact of body size in such studies, and a careful selection of species may also minimize these problems.

Among primates, longer-lived species tend to be bigger with bigger brains, and hence the problems cited above must also be taken into consideration. One way to minimize these problems is the inclusion of negative controls. For example, pairs of species that age similarly but that differ in body size may be employed: gorillas may age at the same pace as chimpanzees even though the former are considerably bigger. Choosing different species with similar aging processes may then be necessary. Likewise, choosing species that live longer than expected for their body size is important: the white-faced capuchin is a good example of a relatively small primate with a *t<sub>max</sub>* comparable to that of apes (Table 2.1).

Assuming mechanisms of aging are conserved between rodents and humans, which is debatable in itself, it may be worthwhile to consider other rodents besides rats and mice. For instance, long-lived rodents like porcupines (Erethizontidae and Hystricidae families), which may live over 20 years, and the naked-mole rat (*Heterocephalus*

TABLE 2.1  
Species with potential interest for comparative studies of aging, including comparative genomics

Taxon <sup>a</sup>	Name	Species	$t_{max}^b$	$t_{sex}^c$	$M^d$	Observations
Primates	Humans	<i>Homo sapiens</i>	122.5	13	60	
Apes	Chimpanzee	<i>Pan troglodytes</i>	73	9	45	
	Gorilla	<i>Gorilla gorilla</i>	54	9–15	140	
Old World monkeys	Orangutan	<i>Pongo pygmaeus</i>	59	8	65	
	Gibbons	<i>Hylobates</i> genus	40–47	6–8	6–8	
	Hamadryas baboon	<i>Papio hamadryas</i>	45	3–5	15–30	Examples of Old World monkeys
New World monkeys	Rhesus macaque	<i>Macaca mulatta</i>	40	4–6	8	
	Common marmoset	<i>Callithrix jacchus</i>	16.8	1–1.5	0.2–0.4	
	Golden lion marmoset	<i>Leontopithecus rosalia</i>	30	2–3	0.65	Longest-lived marmoset
	White-faced capuchin	<i>Cebus capucinus</i>	54.8	4–8	2	Example of a long-lived Platyrrhini
Tarsiidae	Tarsiers	<i>Tarsius</i> genus	15	1–2	0.1–0.2	Generally short-lived
Strepsirrhini	Brown lemur	<i>Eulemur fulvus</i>	37	2	2	Longest-lived lemur
	Fat-tailed dwarf lemur	<i>Cheirogaleus medius</i>	19.3	1	0.3	
	Lesser mouse lemur	<i>Microcebus murinus</i>	15.5	1	0.06	Fast aging for a primate
Lorisidae	Galago	<i>Galago senegalensis</i>	18.8	<1	0.2	
	Slender loris	<i>Loris tardigradus</i>	16.4	1	0.2–0.3	
	Slow loris	<i>Nycticebus coucang</i>	26.5	2	1	
Rodentia	House mouse	<i>Mus musculus</i>	5	0.1–0.2	0.02	One of the fastest aging mammals
	Norway rat	<i>Rattus norvegicus</i>	6	0.25	0.2	
	Slender-tailed cloud rat	<i>Phloeomys cumingi</i>	13.6	–	2	Long-lived murids
	Muskrat	<i>Ondatra zibethicus</i>	10	0.5–1	1	
Other rodents	Naked mole-rat	<i>Heterocephalus glaber</i>	28	<1	0.03	Longest-lived rodent
	Old World porcupine	<i>Hystrix brachyura</i>	27.3	1	8	
	European beaver	<i>Castor fiber</i>	25	2	25	

<sup>a</sup>Species are typically listed according to their evolutionary distance to humans.

<sup>b</sup>Maximum lifespan in years.

<sup>c</sup>Age at sexual maturity in years. Typical or range of values is displayed.

<sup>d</sup>Adult body mass ( $M$ ), a standard measure of body size, in kilograms. Typical or range of values is displayed.

*glaber*), which may live up to 28 years, could be useful models. Likewise, while mice and rats are short-lived, some species of the Muridae family can live up to 10 years or more, namely, the slender-tailed cloud rat (*Phloeomys cumingi*) and the muskrat (*Ondatra zibethicus*). The phenotypic variation we witness across mammalian orders may bias comparative studies of aging, so again primates and rodents should be preferred (Table 2.1). Of course, we can consider other mammalian orders, and for practical reasons these may even be necessary. Still, I maintain my opinion that studies, such as comparative genomics studies, based on primates and

rodents should suffice to study aging and are the most appropriate to identify genetic factors influencing human aging.

### Putative Models of Antiaging Strategies

Due to obvious practical and economical reasons, the most widely employed models of aging are short-lived. It has been argued, however, that studying short-lived species may be irrelevant to humans because whatever mechanisms limit the lifespans of these species have been evolutionarily “solved” by long-lived species like us.

## 2. Species Selection in Comparative Studies of Aging and Antiaging Research

Studying long-lived species may then be potentially more beneficial to people (Strehler, 1986).

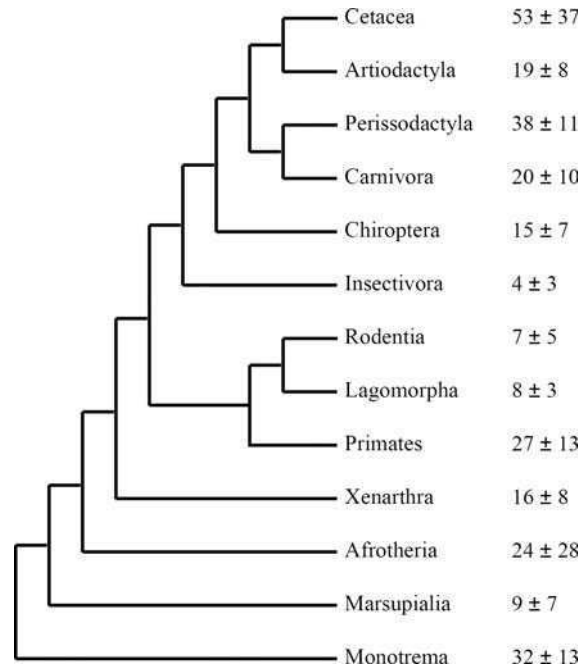

### MAMMALIAN EXAMPLES OF LIFE-EXTENSION

It is well-established that longevity increased in the lineage leading to humans, yet the evolution of longevity occurred in other mammalian lineages as well (Figure 2.3).

Thus it is possible, and even likely, that life-extending strategies vary according to phylogeny. In other words, different mechanisms for long life may have evolved independently in different mammalian lineages. Identifying these mechanisms could potentially allow us to employ them in human medicine.

The best example is certainly the bowhead whale, which has been reported to live over 200 years (George *et al.*, 1999). There is little knowledge of diseases affecting these animals. Still, given that bowhead whales weigh over 75 tons, they must feature some sort of anticancer mechanism(s) to prevent cancer from developing among their huge mass of cells (Austad, 1997b). Other whales too appear to have long lifespans. Animals of the Balaenopteridae family are generally long-lived: examples include the blue whale (*Balaenoptera musculus*) and the fin whale (*Balaenoptera physalus*) which may live over a century. Understanding why these species live so long may yield clues about antiaging mechanisms that are absent from humans, such as anticancer mechanisms. Similar examples include elephants (*Elephas maximus* and *Loxodonta africana*), which can live up to 80 years, and the dugong (*Dugong dugon*), which can live up to 70 years. All these mammals feature a long lifespan, a rate of aging, from what we know, comparable to that of humans, and are considerably bigger than us. The hippopotamus (*Hippopotamus amphibius*), which has a maximum lifespan of 61 years and an MRDT of 7 years, rhinoceros (*Ceratotherium simum* or *Rhinoceros unicornis*), which can live up to 50 years, and maybe even horses (*Equus caballus*), which can live nearly 60 years, may also fit this category. Identifying anticancer mechanisms in these species is thus a promising prospect.

Other specific life-preserving mechanisms may exist in several mammals. For example, the nabarlek (*Petrogale concinna*), a wallaby from northern Australia, apparently features continuous tooth development, termed polyphyodonty (Department of the Environment and Heritage, 2000). Elephants also feature an unusual scheduling of tooth eruption and species of the Sirenia order—i.e., manatees (genus: *Trichechus*) and the dugong—may also feature some form of polyphyodonty (Finch, 1990). While progress in stem cells may allow teeth replacement in humans sooner than later (Ohazama *et al.*, 2004), animals like the nabarlek and manatees demonstrate how numerous species may feature unique mechanisms to cope with nearly universal age-related diseases among mammals that also afflict humans. Even among strains of a given species there may be potentially useful phenotypes,

**Figure 2.3.** Maximum lifespan phylogenetic tree for different mammalian orders. Obtained from AnAge, values represent the average  $t_{max}$  for species of each mammalian order and are expressed in years  $\pm$  standard deviation. Afrotheria is not an order but rather a clade of mammals proposed, based on DNA analysis, to have a common origin. It includes the following families: Macroscelidea ( $n = 4$ ), Tubulidentata ( $n = 1$ ), Sirenia ( $n = 3$ ), Hyracoidea ( $n = 3$ ), Proboscidea ( $n = 2$ ), and Tenrecidae ( $n = 7$ ). Thus, it is normal for Afrotheria to feature a bigger standard deviation than other taxa. Phylogeny was drawn based on Springer *et al.* (2003). Branch lengths are not to scale.

as exemplified in the regeneration capacity observed in the MRL mouse (Heber-Katz *et al.*, 2004).

### Potential Nonmammalian Models of Antiaging Strategies

Long-lived nonmammalian species may also feature antiaging mechanisms of potential use in human medicine that obviate, at least, some human age-related pathologies. The best examples are species that appear not to age, such as many types of turtles (order: Testudines). Species like Blanding's turtle (*Emydoidea blandingii*) and the painted turtle (*Chrysemys picta*) have been reported not to show signs of aging in studies lasting decades (Congdon *et al.*, 2001, 2003). An increased reproductive output with age was also reported, in accordance with reports of *de novo* oogenesis in adult reptiles (Finch, 1990; Patnaik, 1994). Understanding the physiological basis of this phenomenon, also termed negligible senescence (Finch, 1990), has tremendous implications for gerontology but has so far been neglected. Further examples include the Aldabra tortoise (*Geochelone gigantea*) and the Galapagos tortoise (*Geochelone elephantopus*), which likely live over

a century. Anecdotal evidence suggests the Galapagos tortoise reaches sexual maturity only after at least two decades, making it one of the vertebrates with the longest developmental period. Unfortunately, work on turtles is limited. There is some evidence that telomere biology is different in turtles (Girondot and Garcia, 1999), and some results suggest that the brains of turtles have enhanced mechanisms to protect against reactive oxygen species formation and damage (Lutz *et al.*, 2003). Likewise, neurogenesis may be predominant in reptiles (Font *et al.*, 2001). Since other turtles may feature negligible senescence and oocyte regeneration (Finch, 1990), turtles are promising models for antiaging medicine (de Magalhaes, 2004).

Apart from turtles, other species with negligible senescence include bullfrogs (*Rana catesbeiana*), certain fishes such as rockfishes (genus: *Sebastes*) and sturgeons (family: Acipenseridae), as well as many lower life forms (Finch, 1990). It is possible, of course, that many other species feature negligible senescence, or at least slower rates of aging than humans, of which we know nothing about. Since all studied mammals age, incorporating nonaging species in studies of the biology of aging is auspicious. Species with negligible senescence are also promising models for identifying mechanisms that can be used to fight specific human age-related pathologies. For example, it was shown that the rainbow trout (*Oncorhynchus mykiss*) features high levels of telomerase and a continuous molting which may be partly responsible for its continuous growth and negligible rate of aging (Klapper *et al.*, 1998). Moreover, species with negligible senescence are important in understanding how the genetic program, the genome, can be optimized for long-term survival. Certainly, there are great difficulties in studying, for instance, an animal that outlives humans and that is probably why most of these species have not been studied in detail. Modern high-throughput technologies, however, give researchers a host of new experimental opportunities (de Magalhaes and Toussaint, 2004). Sequencing the genome of these species should then be a priority.

Turtles are clearly the reptiles with the greatest potential as models of antiaging strategies. Nonetheless, while some short-lived reptiles show signs of aging, other long-lived reptilian species may be of interest. For example, *de novo* oogenesis has been reported in different reptiles, including alligators and lizards, plus the aforementioned turtles (Patnaik, 1994). The ability to regenerate oocytes in adulthood is crucial to avoid reproductive senescence and, according to evolutionary models, essential for the emergence of negligible senescence. Increased reproductive output with age has also been reported in other reptiles apart from turtles, such as in the northern fence lizard (*Sceloporus undulatus*) and in king snakes (*Lampropeltis getulus*), as well as other species (Finch, 1990; Patnaik, 1994). With the exception of turtles,

the longest-lived reptile is the tuatara (*Sphenodon punctatus*), which lives at least 77 years, but possibly much longer (Patnaik, 1994). Tuataras are the only living descendants from the Rhynchocephalia order and thus have no closely related species. They are found only in New Zealand. Even though tuataras rarely exceed one kilogram in weight, they are long-lived, attaining sexual maturity after at least 10 years. Due to their unique evolutionary history and features, the tuatara is a potential model of antiaging strategies.

There are no confirmed birds with negligible senescence, though fulmars and the Andean condor age very slowly, if they age at all. The northern fulmar (*Fulmarus glacialis*), for example, likely ages more slowly than humans (Gosden, 1996). The longest-lived bird, however, is reported to be the Andean condor (*Vultur gryphus*), which can live up to 75 years. Senescence has not been described in these animals, though detailed studies are lacking (Finch, 1990). In the arctic tern (*Sterna paradisaea*) too no senescence has been demonstrated so far (Gosden, 1996). The record longevity for this species is only 34 years, but this particular 34-year-old individual appeared in excellent health and was actually released in the wild (Terres, 1980). Such cases again suggest that there may be many species aging more slowly than humans and about which we know little. The African grey parrot (*Psittacus erithacus*), the mute swan (*Cygnus olor*), the southern ground hornbill (*Bucorvus cafer*), and the Manchurian crane (*Grus japonensis*) have all been reported as living around 70 years. Interestingly, it has also been suggested that long-lived birds feature enhanced mechanisms of neurogenesis, protection against oxidative damage, and mechanisms against the formation of advanced glycosylation end products (Holmes *et al.*, 2001).

Another bird of potential interest to gerontologists is the raven (*Corvus corax*), a passerine. Typically, Passeriformes, corvids, and other species of the genus *Corvus* are short-lived, but ravens are clearly an exception. In the wild, ravens generally only live a few years, but in captivity their lifespan is likely above 70 years, with anecdotal reports of one raven living up to 80 years in captivity (Boarman and Heinrich, 1999). It would be interesting to know what physiological and genetic mechanisms make ravens live so much longer than their closest relatives. Likewise, more rigorous studies may reveal other long-lived species in the genus *Corvus*.

Although amphibians are not reported to be as long-lived as reptiles or mammals, they may prove useful for gerontology. The longest-lived amphibian is the Japanese giant salamander (*Andrias japonicus*), which reportedly can live up to 55 years. While this pales in comparison to whales and tortoises, amphibians do have some unique traits of potential use to medicine. One of them is how regenerative mechanisms in amphibians are more advanced than those of mammals. For example,

## 2. Species Selection in Comparative Studies of Aging and Antiaging Research

amphibians can regenerate entire limbs while mammalian tissues, such as muscle, can regenerate only as isolated entities (Carlson, 2003). Limb regeneration has been particularly well-studied in newts, and it may have future applications in antiaging research. In one study, protein extracts derived from newts were able to dedifferentiate mouse muscle cells into stem cells. This process of dedifferentiation of adult cells appears then to be modulated by appropriate factors that can be potentially isolated in newts (McGann *et al.*, 2001). Future studies to implement the regenerative capacity of some amphibians to humans are of great medical interest. Furthermore, while short-lived amphibians show signs of aging, long-lived amphibians may feature negligible senescence, polyphyodonty, and oocyte regeneration (Kara, 1994).

Among the large diversity of animals in the world there are certainly multiple processes that can be useful to prevent age-related pathologies in humans. For example, loss of auditory hair cells (AHCs) is a major cause of deafness in people and hence regeneration of these cells has considerable medical interest (Hawkins and Lovett, 2004). It is interesting to note that most mammals, contrary to most birds and amphibians and maybe even some bats (Kirkegaard and Jorgensen, 2002), lose the capacity to regenerate AHCs early in life. Therefore, it has been suggested that genomic tools may be used to understand the basis of this regenerative capacity and eventually apply it to mammals (Hawkins and Lovett, 2004). Another example is heart regeneration. Mammals and amphibians typically have a limited regenerative capacity of the heart muscle. The zebrafish (*Danio rerio*) heart, however, appears to have a robust capacity for regeneration based on the proliferation of cardiomyocytes which can avoid scar formation and allow cardiac regeneration (Poss *et al.* 2002). Thus, zebrafish may also be a powerful system to study antiaging or life-prolonging strategies of specific human age-related diseases (see chapters 27 and 28 in this book about the zebrafish). With the emerging age of genomics, it may soon be possible to employ genomic tools to identify life-extending genes and pathways absent from humans. For example, mammals appear to have lost the CPD-photolyase DNA-repair enzyme (Thoma, 1999). Certainly, other such genes exist and some may turn out to have life-extending functions.

These examples are only the tip of the iceberg. Among the extraordinary diversity of life forms on earth, including the thousands of vertebrates, we are likely to find many novel antiaging strategies. In Table 2.2 I present the examples cited above plus the longest-lived species for a number of vertebrate classes and selected mammalian orders. These represent species in which longevity likely evolved and hence may feature antiaging mechanisms. In theory, the longest-lived animals in each mammalian family are capable of delaying aging in relation to similar species, and thus studying these

animals may allow us to identify not only genetic factors regulating aging rates but even life-extending mechanisms.

### Conclusion

Maximum lifespan will likely continue to be used as the measure of aging in animal species. Even though other measures exist and should be implemented, *t<sub>max</sub>* does give an estimate of rate of aging; it is the easiest method presently at our disposal, and *t<sub>max</sub>* data are widely available—including in AnAge—making comparisons straightforward. It is not a perfect measure for comparing aging across species, but it is arguably the best.

More animal diversity is necessary in comparative studies of aging. Implementing novel models of aging should be welcomed independently of the species used. In the context of comparative studies of aging, though, there is no need to drift away from primates and rodents and certainly not from mammals. With sequencing technology becoming cheaper, in a near future it will become possible to sequence the genome of multiple species, and I predict comparative genomics to become the predominant tool in comparative studies of aging (de Magalhães and Toussaint, 2004). Choosing which species to investigate will then become crucial. My rationale is that the best way to perform comparative genomics studies of aging is by focusing on primates plus a few rodents (Table 2.2).

Mammalian species, with a major bias toward primates and rodents, may allow us to understand the genetic factors that determine the pace of aging. Yet numerous other species, including long-lived mammals, reptiles, amphibians, fishes, and birds, may hold secrets to delay human age-related pathologies and maybe even the aging process itself. From species that appear to have escaped senescence, to animals featuring extreme forms of regeneration, passing by animals possessing specific traits that may be used to delay human age-related pathologies, multiple species may feature applications to antiaging research.

Readers are encouraged to visit the Human Ageing Genomic Resources (<http://genomics.senescence.info>), which features the AnAge database (<http://genomics.senescence.info/species/>).

## ACKNOWLEDGMENTS

Thanks to the many researchers who contributed their knowledge to AnAge, particularly Steven Austad. Further thanks to George Church and Joana Costa for comments on the manuscript. J. P. de Magalhães is supported by NIH-NHGRI CECS grant to George Church.

TABLE 2.2  
Species with potential interest as sources of antiaging strategies

Taxon <sup>a</sup>	Name (species)	<i>t</i> <sub>max</sub> <sup>b</sup>	Observations
Mammalia: Cetacea	Bowhead whale ( <i>Balaena mysticetus</i> )	211	Longest-lived vertebrate
	Fin whale ( <i>Balaenoptera physalus</i> )	116	
	Blue whale ( <i>Balaenoptera musculus</i> )	110	Biggest animal
Artiodactyla	Hippopotamus ( <i>Hippopotamus amphibius</i> )	61	Long-lived artiodactyls
	Camel (genus: <i>Camelus</i> )	50	
Perissodactyla	Horse ( <i>Equus caballus</i> )	60	Long-lived perissodactyls
	Rhinoceros ( <i>Ceratotherium simum</i> or <i>Rhinoceros unicornis</i> )	50	
Afrotheria	Elephant ( <i>Elephas maximus</i> or <i>Loxodonta africana</i> )	80	Biggest land animal
Sirenia	Manatees (genus: <i>Trichechus</i> ) and the dugong ( <i>Dugong dugon</i> )	>50	May feature polyphyodonty
Marsupialia	Nabarlek ( <i>Petrogale concinna</i> )	>10	Appear to feature polyphyodonty
Reptilia: Testudines	Aldabra tortoise ( <i>Geochelone gigantea</i> )	152	
	Mediterranean spur-thighed tortoise ( <i>Testudo graeca</i> )	127	
	Galapagos tortoise ( <i>Geochelone elephantopus</i> )	>100	Long developmental phase
	Blanding's turtle ( <i>Emydoidea blandingii</i> )	75	Featuring negligible senescence
	Painted turtle ( <i>Chrysemys picta</i> )	61	
Diapsida	Tuatara ( <i>Sphenodon punctatus</i> )	90	Longest-lived reptile that is not a turtle
Aves	Andean condor ( <i>Vultur gryphus</i> )	75	Longest-lived bird
	African grey parrot ( <i>Psittacus erithacus</i> )	73	
	Northern fulmar ( <i>Fulmarus glacialis</i> )	48	Likely age very slowly
	Arctic tern ( <i>Sterna paradisaea</i> )	34	
Passeriformes	Raven ( <i>Corvus corax</i> )	69	Longest-lived passeriform
Amphibia	Japanese giant salamander ( <i>Andrias japonicus</i> )	55	
	Common European toad ( <i>Bufo bufo</i> )	40	
	Bullfrog ( <i>Rana catesbeiana</i> )	16	Can increase reproductive output with age
	Red-spotted newt ( <i>Notophthalmus viridescens</i> )	15	One of several species capable of limb regeneration
Osteichthyes	Lake sturgeon ( <i>Acipenser fulvescens</i> )	152	
	Rockfish ( <i>Sebastes aleutianus</i> )	>150	Featuring negligible senescence
	Orange roughy ( <i>Hoplostethus atlanticus</i> )	149	Slow-growing, long-lived species
	Zebrafish ( <i>Danio rerio</i> )	5.5	Capable of heart regeneration

<sup>a</sup>Species are typically listed according to their evolutionary distance to humans.

<sup>b</sup>Maximum lifespan in years.

# Principles of Animal Use for Gerontological Research

Richard A. Miller

*Animals, and in particular rats and mice, have long been a mainstay of experimental work in biological gerontology. This chapter presents ten key principles that should be considered in designing and interpreting reports that use laboratory rodents to learn about aging. In a nutshell, experimenters are implored (1) to use mice that are neither too old nor (2) too young; (3) to use more than two age groups; (4) to use rodents that are demonstrably specific pathogen-free; (5) to consider the use of genetically heterogeneous rodent populations; (6) to obtain necropsy data as a source of important covariates; (7) not to pool across individuals; (8) to reduce cost by judicious distribution of money across age classes; (9) to favor designs that use young mice destined to age at differing rates; and (10) to abandon—or at least subjugate—rodent-oriented research in favor of comparative biology.*

## Introduction

As of this writing, a PubMed search for “aging AND (mouse OR mice OR rat Or rats)” yields 46964 citations, of which 9256 appeared in the current millennium, and 1813 appeared in 2004, a rate of 5 papers per day. (For reference: substitute “fly OR flies OR Drosophila” and you obtain 117 papers in 2004; the analogous search produces 90 papers on aging worms.) Worms and flies, for all their obvious virtues, are organized along alien design principles, and seem sufficiently dissimilar to people, physiologically and developmentally, to make extrapolation of all but the most fundamental findings feel unsafe. Experimental studies of the aging process in humans are stymied by ethical constraints on most interventions of biological interest, inaccessibility of internal tissues, catch-as-catch-can genetics, and discouragingly long life spans. Mice and rats occupy the sweet spot: organized like humans in most ways that count, relatively short-lived, and willing to eat what we give them and to breed with whom we suggest. Rodent-oriented gerontologists are, in addition, blessed by a pre-existing and quickly expanding infrastructure that makes interesting mice and has developed powerful methods for assessing their genetic and physiological characteristics; “mice AND

(transgenic or knockout)” gets you 9466 papers in 2004 alone.

This chapter aims to provide a broad overview, not of the nitty gritty of animal care and manipulation, but of the strategic planning that might help a researcher select a rodent model to answer questions of interest in the biology of aging. Emerging from the “Dear Abby” and Emily Post tradition of *ex cathedra* advice givers, it will employ the imperative voice more often than is typical for an academic review. It will also use the term “mice” to mean “mice and rats” except in those rare cases where the distinction is critical. The chapter will range over Ten Basic Principles for studies of aging rodents. Principles 1–4 and 6–8 are more-or-less conventional wisdom, or minor twists thereon. Principles #5, #9, and #10 are more radical proposals (though not entirely without adherents): these are the ones least likely to be taken seriously, but the ones most worthy of contemplation.

## Principle #1: Do not Use Mice that are too Old

Newcomers to rodent gerontology show a strong preference for the oldest available mice or rats they can get their hands on, on the grounds that the older the animals are, the more they will differ from the young control group, the sooner the work will be finished, and the more striking the effects to be documented. There are three good reasons to avoid very old mice: they are expensive, sick, and unrepresentative.

Expensive: the Gompertz equation, though originally devised in another context, provides a good guide to the estimation of relative mouse costs, too; because the risk of mortality increases exponentially with age, so does the cost of producing a live mouse. Because the mortality rate doubling time for lab mice is about 4 months (Finch, 1990), the cost of producing a 30-month-old mouse is not 25% higher than the cost of a 24-month-old specimen, but roughly 400% higher, given reasonable estimates of the Gompertz parameters for laboratory mice. Table 3.1 presents a sample calculation illustrating the cost for producing mice at various ages, and provides a strong rationale for designs in which the “old” mice are as young

TABLE 3.1  
Sample calculation of production costs for mice at various ages

Mice alive	Deaths/Month	Months of age	Cost/Month	Cumulative cost	Cost per mouse
1000	0	3	\$7000	\$7,000	\$7
1000	0	5	\$7000	\$21,000	\$21
1000	0	7	\$7000	\$35,000	\$35
1000	0	9	\$7000	\$49,000	\$49
1000	0	11	\$7000	\$63,000	\$63
1000	12	13	\$7000	\$77,000	\$77
973	17	15	\$6814	\$90,729	\$93
935	24	17	\$6548	\$103,968	\$111
882	34	19	\$6174	\$116,518	\$132
808	46	21	\$5659	\$128,114	\$158
710	59	23	\$4973	\$138,426	\$195
586	72	25	\$4101	\$147,087	\$251
438	79	27	\$3067	\$153,754	\$351
281	74	29	\$1969	\$158,239	\$563
141	55	31	\$986	\$160,674	\$1,141
46	26	33	\$320	\$161,598	\$3,534
6	5	35	\$43	\$161,779	\$26,578

The values in Table 3.1 were calculated as follows: The cost of a 3-month-old mouse is estimated as \$7. The cost per month thereafter is calculated as \$7 times the number of mice alive at the start of the month. The colony size is 1000 mice initially. It is assumed that no mice die until age 12 months. Mortality rate doubling time is taken as 0.3 years. The risk of death in any given month (after age 12 months) is calculated as  $m(t) = 0.01 * \exp(2.31 * t/12)$ , where  $t = (\text{number of months of age} - 12)$ . Cumulative cost is the sum of cost for all previous months. The cost per mouse is calculated as the cumulative cost divided by the number of live mice at the start of the interval. These calculations were performed for each month of a three-year period, but to save space Table 3.1 shows only the odd-numbered months. The table shows, for example, that the production cost of a 35-month-old mouse is approximately 100-fold higher than that of a 25-month-old mouse, which is itself about twice the cost of an 18-month-old mouse.

as possible consistent with the experimental question under consideration.

Even if one is fortunate enough to locate a supplier (see <http://www.nia.nih.gov/ResearchInformation/ScientificResources/>; and Chapter 33 by Dr. Nancy Nadon in this Handbook) willing to provide you with rodents whose cost is adjusted arithmetically rather than exponentially with age, the burden of illness provides a strong reason to avoid mice in the last third of their lifespan. Very old mice are far more likely than middle-aged mice to have one, or more than one, major form of illness. If the experimental goal is to learn more about a specific form of late life illness, then of course protocols will need to include animals old enough for the illness to have appeared. If the goal is instead to learn something about the aging process, which gradually converts healthy young adults into older ones progressively more vulnerable to multiple forms of debility and illness, then focusing attention on subjects not yet sick is more likely to be informative. A study of the ways in which thymic involution leads to immunodeficiency, for example, is likely to be spoiled by the presence of lymphoma, or indeed any

systemic malignancy, in the experimental subjects, just as unsuspected metabolic adjustments secondary to glomerulonephritis would complicate studies of the effects of aging on fuel usage or hormone responsiveness.

Lastly, very old populations are likely to be unrepresentative, in that individuals subject to early and midlife illnesses, for whatever known or unknown reasons, have already been removed by death. Studies of centenarians (or other cohorts of very long-lived people) often show clearly, for instance, that they resemble much younger populations in many physiological parameters (Franceschi *et al.*, 1995; Perls *et al.*, 2002); cross-sectional tables of such traits would show a retardation, or reversal, of age-specific trends as those with typical patterns of aging are eliminated by death, leaving only atypical survivors. Among men who are healthy at age 60, for example, only about 30% are expected to be alive and healthy at age 80, but those destined for good health at age 80 are typically healthier than average at the age of 60 years (Metter *et al.*, 1992). Differences between 60- and 80-year-olds therefore confound effects of aging (and disease) with those of survivorship.

### 3. Principles of Animal Use for Gerontological Research

Thus studies that focus on very old rodents are not only far more expensive, they are on the whole less informative than those which use younger animals in the aged cohorts, because data on survivor animals, or sick ones, may give few insights into the life-long process of aging. In my own laboratory we prefer to evaluate animals at ages where 90% or more of the population is still alive, and we almost never make experimental use of mice older than the age of median survival.

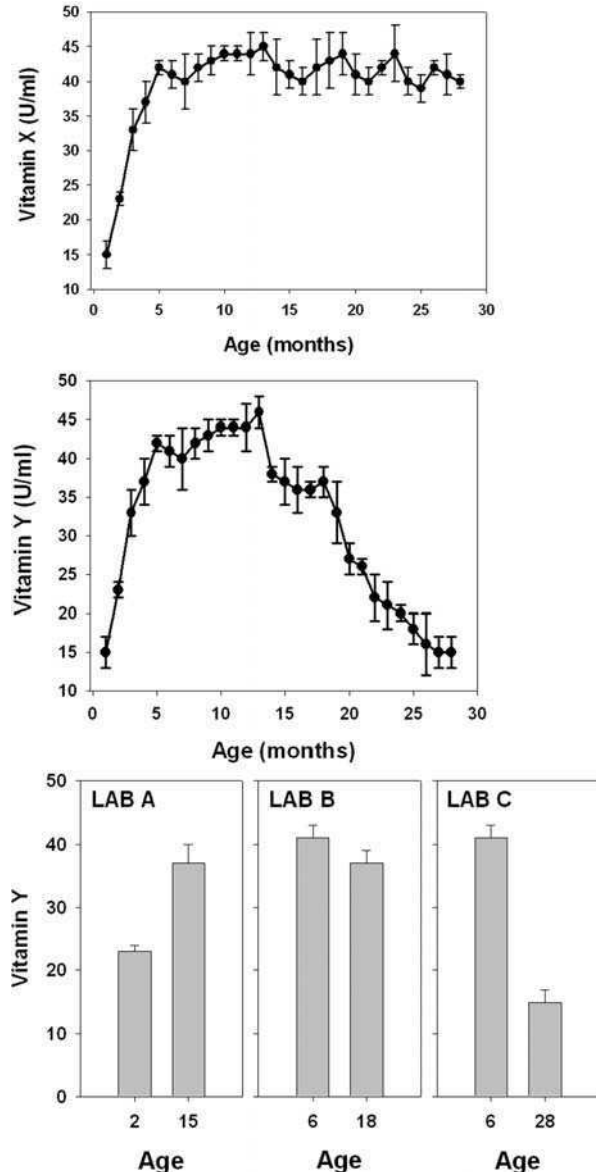

#### Principle #2: Don't Use Mice that are too Young, Either

The goal of this precept is to avoid confusing developmental changes with the effects of aging. Although it takes a mere 8 weeks or so for mice to become reproductively competent, many physiological systems and body dimensions continue to change along developmental trajectories that can, in poorly designed studies, be confused with aging. Consider, for example, the trait shown in the top panel of Figure 3.1, which rises progressively until age 6 months and then remains stable thereafter.

A study which evaluated mice at ages 2 and 20 months would misleadingly conclude that the trait in question “goes up with aging,” although a more judicious interpretation, based on a wider range of ages, would conclude instead that the trait shows increases only in juveniles and young adults, with no effects of aging per se. A human or dog that has completed 25% of its lifespan is likely to be 20 or 3 years old, respectively, well within the “mature young adult” stage of life; a corresponding stage for mice would recommend animals of 6–7 months as the “young” control group of a descriptive study of age trajectory in a variable of interest. Beginners tend to prefer designs that use the youngest available animals, again from a mistaken desire to see maximally-sized effects, and because these are the least expensive and are usually available on short notice. Certainly information on maturational process has its own merits and may even be useful in understanding ways in which early life changes modulate the pace of aging or risks of late-life illnesses, but the use of very young mice under the mistaken impression that they are typical of young adult animals may lead to misleading impressions of the ways in which aging alters the outcomes of interest.

#### Principle #3: Don't Use too Few Age Groups

The common error here is to investigate whether a trait is age-sensitive by comparing its level in two groups, one allegedly young, the other supposedly old. The middle panel of Figure 3.1 shows another hypothetical data set, showing a trait that rises to a plateau in midlife and then declines thereafter. The bottom shows three possible misinterpretations of this data set, compiled by three laboratories, each of which has conducted assays at two

**Figure 3.1.** The top panel shows a hypothetical data set, as an illustration of errors that can occur when a survey of aging effects starts with mice that are too young to be considered fully mature; see text for interpretation. The middle panel shows a second hypothetical data set, as an illustration of the hazards of evaluating only two age groups. The bottom panels represent reports by three different laboratories of the data shown in the middle panel; each laboratory has selected different age groups. Laboratory A, for example, has reported data at 2 and 15 months of age, extracted from the complete data.

arbitrary ages. Laboratory A concludes that the trait increases with age; Laboratory B finds no age effect; and Laboratory C infers that the trait declines with age. None of these conclusions agrees with the other two, and none is very helpful. Two ages may be sufficient for traits that show a simple, monotonic change over the entire age range, but this default assumption fails too often for

comfort and cannot itself be tested without evaluation of a wider range of subject ages. A study of cytokine production in responses to schistosomal egg antigens (Chiu *et al.*, 2002), for example, found several examples of cytokines whose production increased between 6 and 18 months of age and then declined at later ages, helping to resolve conflicts among earlier papers that had disagreed on the extent, and even the direction, of age change in cytokine production based on less comprehensive data sets.

#### **Principle #4: Use Mice that are Specific Pathogen Free and be able to Prove it**

A specific pathogen-free (SPF) rodent colony contains mice or rats that are known not to be infected with any members of a specific, defined list of pathogenic microorganisms and parasites. The animals are *not* free of all bacterial and viral species, i.e., they are not gnotobiotic. Vendors of SPF rodents, and managers of SPF colonies, are able to define the pathogens for which their mice or rats have been tested, and can produce documentation of the diagnostic testing. Our own mouse colonies, for example, are tested routinely for serological evidence of infection by mouse hepatitis virus, mouse parvovirus, minute virus of mice, ectromelia, Sendai, reovirus, lymphocytic choriomeningitis virus, and seven other viruses, and examined for pinworm by cecal inspection. Rat colonies are tested for exposure to each of 13 rat viruses. Testing for viral contamination typically involves looking for antibodies specific to viral antigens; such tests should be negative in rodents never exposed to the pathogen. Tests for pinworm involve direct examination of cecal samples for eggs. Most facilities use a sentinel system, in which the used bedding is pooled for a group of cages or racks, and then transferred to a fresh cage containing a group of mice from a strain known to be susceptible to the viruses of interest. After an interval of several weeks to allow the sentinels to become infected by the viruses or parasites—if these are present—and to form detectable antiviral antibodies, serum from the sentinels is checked for antiviral titers. This procedure is usually repeated 2–4 times per year for the most common viruses and at least annually for the others on the checklist.

Colonies that do not maintain mice under SPF conditions are referred to as “conventional” vivaria; these were in the clear majority until the 1980s, but are now fortunately becoming rare among top-level universities and medical centers. Conventional colonies may or may not have any particular virus or parasite present at any given time; the presence and prevalence of infection may fluctuate from year to year or month to month, and be reluctantly accepted as one source of undocumented “technical” variation in experimental outcomes.

Maintenance of an SPF colony depends upon strict adherence to well-known, but often violated, safety

precautions. The rules seem simple: purchase mice only from a small, predefined list of vendors whose health reports document the SPF status of their colony; do not permit mice removed to a non-SPF colony or laboratory to be returned to the vivarium; be compulsive about use of head and shoe covers and protective gowns for each entry into the colony, and compulsive about the use of filter tops for each mouse cage; restrict access to the housing rooms to those whose duties require them to be there; never allow people or cages or equipment to go from a dirty (conventional) colony to an SPF colony. But the hazards are many. They include the peer review committee whose members wish to see the animal housing area (including one visitor whose own lab is a hotbed of pinworm contamination). They include the new faculty member whose laboratory work requires importation of several knock-out stocks whose construction was the key outcome of her postdoctoral work at her previous laboratory. They include the technician who keeps pet mice at home, or the student who stopped by the conventional colony to drop off some syringes on the way to the SPF part of the facility. Use of cage-washing facilities that service clean and unclean housing areas, or transport of water bottles or cage cards from one area to another are also common, but risky, practices. Hazards of this kind are compounded when animal rooms must be shared by multiple investigators; a slip by any one laboratory can lead to spread of infectious agents to rodents used by many colleagues. The introduction of pinworm eggs or a single virus-infected mouse can place an entire colony at risk, and in some cases eradication of the infection can require removal and elimination of all mice in the colony or a major section of it, a step that is always expensive and often impractical.

Why, then, go to all this fuss? The central basis for the emphasis on SPF rodent colonies, in aging research as in many other areas of science, is the need to be able to reproduce experimental findings at later times and in other places. Viral and parasitic infections have known effects on multiple biochemical and physiological outcomes, and are certain to have undocumented effects on many traits not formally studied in this context. Conventional colonies may well have infectious burdens that influence the outcome of a study of age effects or antiaging interventions, and the level and kind of infection may well fluctuate during the course of a single study with consequences that are unforeseen, unpredictable, irreproducible, and undocumented. The traits affected are not always those, like immune responses, most obviously linked to infectious status. Age-related changes in rat skeletal muscle fiber distribution, for example, have been shown to differ systematically between conventional and specific pathogen-free colonies (Florini, 1989).

A common scenario involves the importation of SPF rodents into a conventional colony, in the mistaken hopes that the experimental subjects can then be considered as

### 3. Principles of Animal Use for Gerontological Research

“almost SPF.” Such a situation can, unfortunately, lead to infection of the newcomers by whatever local agents are then current in the host colony, so that the experimental assessments are conducted on mice at varying stages of an acute infectious process.

Advocates, or apologists, for the use of conventional vivaria sometimes raise the issue that SPF colonies are artificial, and thus fail to mimic the constant exposure to infectious agents that accompanies, and may mold, the aging process in real life. It is fair to acknowledge the potential importance of infectious agents in aging outside the vivarium, and important to encourage analyses of how aging might alter, and be altered by, specific defined pathogens. The point of SPF protocols, however, is not to duplicate some “natural” condition, but to define a set of environmental conditions well enough to permit replication and extension of the study’s results.

#### **Principle #5: Consider the Use of Non-isogenic Stocks**

The large majority of work done with aging mice and rats makes use of inbred stocks, such as the C57BL/6J line of inbred mice, and the F344 stock of inbred rats. These inbred stocks of rats and mice were originally developed by geneticists who wish to have available groups of animals whose genetic characteristics did not change over time and which were uniform from laboratory to laboratory. They were invaluable for working out the basic rules of transplantation biology and played a major role in the development of experimental tumor immunology. Nowadays, many studies of aging rodents start with the assumption that inbred mice or rats should be used, in part because these animals are easy to obtain, and because the published literature contains a great deal of background information about their characteristics. In part, the preference for the use of inbred mouse in rat stocks is based upon a mixture of tradition and inertia, the tendency to use the same animal types that were used for previous studies in one’s own lab and in the laboratory of one’s mentor, and one’s mentor’s mentor.

In many ways, this unthinking attachment to the same old stocks is unfortunate, because the use of inbred rodents has several disadvantages. The first disadvantage is that each inbred line contains only animals of a single genotype. For this reason, it is not possible to tell, without further experimentation, whether the observations about the effects of aging on any specific trait of interest in a given inbred stock will or will not prove to be reproducible when analogous experiments are carried out on any other given inbred stock. Many traits, of course, are strongly influenced by genetic alleles that are polymorphic among the wide range of inbred mouse and rat stocks, and it is for this reason that each stock will have its own particular idiosyncratic properties, including disease susceptibilities and rates of change in

age-dependent traits. Experimental studies of aging are often sufficiently expensive and tedious that most researchers are reluctant to duplicate or triplicate their workload by conducting the same study several times, “merely” to see if they get similar results in a second or third kind of mouse. For this reason, it would seem advisable for the aging research community to develop and to make use of genetically heterogeneous mouse and rat stocks for routine investigation.

A second problem with the routine use of inbred lines is that these mice are not only genetically uniform, but they are also homozygous at every locus. The development of inbred lines from the starting population of genetically heterogeneous mice is, in a sense, an exercise in genetic compromise. Each person or mouse among us carries in our genomes a “genetic load,” a set of genetic alleles each one of which, if homozygous, might lead to early life mortality or to sterility; we are spared these consequences because each of these alleles is rare enough to be heterozygous in most individuals who carry the allele at all. Developing an inbred population, however, requires forcing each locus to the homozygous state. Most homozygous genomes, therefore, produce individuals who die at an early age, are sterile, or show other traits that are rare within the genetically heterogeneous population from which the inbreeding was begun. Genetic combinations that lead to early death or sterility are eliminated during the development of inbred lines, and in fact producing a new inbred line often requires starting many such lines knowing that most will die out during the inbreeding process. Those lines of mice that emerge from this highly selective process contain animals that are able to survive to adulthood and produce live progeny, but may differ in many other ways from the starting population. In particular, inbred lines are almost invariably shorter-lived than mice produced by crosses between any two given inbred stocks (Smith *et al.*, 1967). This lack of robustness and vigor characteristic of inbred rodents, together with strain-specific idiosyncrasies, both well-known and hitherto undocumented, should render the stocks a questionable choice for routine work in biological gerontology.

There are a variety of other options, some attractive and others less so. A cross between two inbred stocks produces an F1 hybrid stock, which like its inbred parents is isogenic—all the mice are genetically identical—but unlike them is heterozygous at multiple loci, i.e., those loci where the two parents differ. F1 hybrid mice are more robust, i.e., longer-lived, than their inbred progenitors, but are vulnerable to the same objection of strain-specific idiosyncrasies that make it hazardous to generalize from data based on a single genotype.

The search for a source of genetic heterogeneity might prompt some researchers to purchase outbred rodents from commercial suppliers. Commercial vendors often sell mice and rats that are marketed as “outbred,” but that in some cases could more justly

be characterized as approximately inbred stocks. In at least two cases, detailed by Miller *et al.* (1999), the vendor's own catalogue copy states that the "outbred" stock originated in a single pair of inbred progenitors. Production of outbred stocks from a single homozygous genotype can only be recommended by someone unaware that the loss of genetic heterogeneity, like the loss of virginity, is not easily reversible by continued reproductive efforts. Leaving aside clear errors of this kind, genetic heterogeneity can be irretrievably lost, inadvertently, if the breeding nucleus is reduced to a single pair or a small number of pairs at any point in the long history of the stock. This seems to be a frequent occurrence: DNA fingerprint analyses of six allegedly outbred rat stocks (Festing, 1995) supports the idea that these stocks contain only limited genetic heterogeneity: within each stock 84–95% of the animals shared any one individual DNA marker, as contrasted to 34% sharing for rats chosen from different inbred strains.

To help mitigate the disadvantages of relying on isogenic stocks for research on aging, a committee chartered by the U.S. National Academy of Science recommended, in 1981, that researchers make greater use of populations that exhibit controlled genetic heterogeneity, and in particular recommended use of four-way cross populations in aging research (Committee on Animal Models for Research on Aging, 1981). Such a population is produced by a cross between males and females of two different F1 hybrid stocks, for example using (BALB/c × C57BL/6)F1 females bred to (C3H × DBA/2)F1 males. Because each of the F1 parents is heterozygous at many loci, each of their offspring will receive different alleles, at multiple loci, from each parent. From the perspective of the nuclear (i.e., nonmitochondrial) genome, each individual in the four-way cross population is a full sib of each other individual; each is genetically unique, but shares 50% of its alleles with any other mouse in the test population. Populations of this kind have genetic heterogeneity, but of a controlled sort, because additional populations with similar genetic structure can be produced at any time, at any place, and in any numbers, as long as the four grandparental inbred stocks are available. Production of such a colony requires no special expertise in genotyping or husbandry, and is rapid, because the F1 hybrids are commercially available and because breeding success and fecundity are typically high. Four-way cross stocks should be strongly considered for descriptive studies, in which the goal is to discover how a trait changes with age, for intervention studies, and for correlational studies, and they are particularly attractive when evaluation of the genetic control of the age-related phenomenon is potentially of interest. The virtues of these stocks have led to their selection by the National Institute on Aging for a multi-center mouse intervention project (Warner and Nadon, 2005), and one such stock has been selected for inclusion among stocks available, at multiple ages, from the NIA's aging rodent

colonies (Nadon, 2005). There is now extensive information on late-life pathology of the population produced by the cross between (BALB/c × C57BL/6)F1 females bred to (C3H × DBA/2)F1 males (Lipman *et al.*, 2004).

## **Principle #6: Necropsy Data Provides Important Covariates**

At a minimum, each researcher should conduct a careful gross inspection of each middle-aged or old mouse used in his/her study. This should include a notation of the presence or absence of masses in the skin, mammary glands, lungs, and abdominal organs, and a check for size of thymus, lymph nodes, and spleen suggestive of hematopoietic malignancy. Signs of bite wounds or scars on the skin should raise a suspicion of chronic or acute infection. Claims in the materials and methods section that the mice used were "apparently healthy" carry little conviction without a gross inspection of this kind, at a minimum. The best idea is to discard all data from mice with any lesions noted, although this advice becomes very expensive to follow, particularly if the mice are older than recommended by Principle #1 above. This recommendation is just as important for protocols in which animals are tested while alive—tests of antibody production or cognitive powers, for example; here, even though it is not necessary to euthanize the mouse to obtain the experimental data of interest, euthanasia as soon as possible after completion of the evaluation should be carried out to identify those mice in which a disease process may have influenced the outcome of the test.

Even better, of course, is to have the animal examined by a professional veterinary pathologist, or by a laboratory technician, with specialized training, working as part of the pathology team. This step will add a cost of approximately \$10 for each mouse examined. Reports are usually returned from the pathology office within a few weeks, making it possible for researchers to go back and eliminate, retroactively, those animals found to have been diseased. A complete histopathological necropsy can cost between \$25 and \$100 per case, and should be strongly considered when the objectives of the study include characterization of a new mutant, drug, or experimental system.

## **Principle #7: Pooling Across Individuals is Hazardous**

Because the proportion of individuals with an illness serious enough to affect the outcome of an experimental test increases dramatically with age, the use of pooled samples from multiple individuals should be avoided whenever possible. In a study of antibody production, for example, sensible experimental designs would exclude those with hematopoietic malignancy. If the proportion of mice with lymphoma is as low as 20%, the chance that a

### 3. Principles of Animal Use for Gerontological Research

pool of five mice will consist only of lymphoma-free mice is only 33%, and pools of samples from 10 mice are 89% likely to contain at least one diseased mouse. In other circumstances, the investigator may be unaware of the ways in which her test outcome might be influenced by specific forms of illness.

For many traits variability may increase in older subjects, and the routine use of pooled samples obscures this variability, and may prevent an appreciation of its effects on the biological question of interest. If, for example, a measure of muscle fatigue differs in important ways in subjects that do or do not have compromised pulmonary function, a study of individuals might reveal a bimodal distribution, with a fatigable subgroup—consisting of those with pulmonary adenomas—at one mode. Even without necropsy information, analysis of unpooled subjects would reveal a bimodal or strongly skewed distribution on the muscle outcome, raising issues about population heterogeneity that require careful follow-up work. Combining subjects into pools, each of which has some compromised individuals, would obscure this relationship, and provide a misleading impression of age effects on muscle function.

In some cases pooling may be required, particularly when the assay method is too insensitive to provide a reliable measure using the amount of material available from an individual donor. In such cases it will be necessary to test multiple pools of individuals from each age or treatment group of interest in order to perform a statistical analysis of the hypothesis. The power of the statistical test, of course, depends on the number of individually tested subjects, or the number of different pools, for which results are available. Thus combining a group of 12 subjects into 4 pools (of 3 subjects each) is certain to diminish statistical power, and the individual protocol will need to balance the practicality, and cost, of testing individual subjects against the loss of power that results from pooling.

#### **Principle #8: Cost-adjusted Power Analyses can Reduce Overall Expense**

Most experimenters are familiar with the uses of statistical power analysis, in which the goal is typically to determine the number of subjects that will need to be examined in order to have a good chance of refuting a null hypothesis of interest. Such an analysis can tell us, for example, that if the mean value of some substance (“Vitamin X”) in controls is  $1200 \pm 200$  units, and we wish to see if the experimental group will differ from the control level by 200 units, we will need to use 17 control and 17 treated mice to have an 80% chance (“80% power”) of documenting the difference at a level of  $p < 0.05$ . The number of mice needed will go up if the change induced by the experimental treatment is smaller; or if the standard deviation is larger; or if the significance criterion

is made more stringent (e.g.,  $p < 0.01$ ); or if we wish to increase our chance of proving the matter from 80% to 90%; or if we plan to test more than two groups; or if we plan to test several hypotheses using the same set of mice. Power analyses are, appropriately, considered a critical element in designing experiments and seeking financial support for them; it may be hard to drum up support for a research protocol that has only a 10% chance of detecting an effect sufficiently large to be worth reporting. An experiment designed to see if mean lifespan is increased 10% by a specific diet, for example, may require 60 control and 60 treated mice to achieve 80% power; an experiment with only 20 mice per group might be judged not worth the effort.

This synopsis above has a hidden assumption, the assumption that the number of animals in the two comparison groups should be the same. The design is “balanced,” in the sense that each group has the same size, and such balanced designs minimize the total number of animals tested. This makes good sense when the cost of each test is the same, but in a typical aging experiment the cost of obtaining and testing an elderly mouse may be a good deal higher than the cost for a young control. As shown in Table 3.1, for example, the production cost of a 25-month-old mouse, under plausible assumptions, may be 10-fold the cost of a 5-month-old mouse. Unbalanced designs, in which groups are permitted to have different numbers of subjects, can minimize the cost of the experimental protocol by using more mice of the less expensive variety. The procedure for conducting a “cost-adjusted” power analysis has two steps. First, you conduct a standard power analysis, along the lines shown above for “Vitamin X,” to estimate the number needed to produce acceptable power using a balanced design. In the example, the balanced design would require  $N_e = 17$  mice per group. Then one calculates  $N_Y$  and  $N_O$ , the numbers of young and old mice needed, using the following formula (developed by Dr. Andrzej Galecki of the University of Michigan’s Geriatrics Center):

$$N_Y = 0.5 * N_e * (1 + \text{SQRT}(C_O/C_Y))$$

$$N_O = 0.5 * N_e * (1 + \text{SQRT}(C_Y/C_O))$$

where  $C_Y$  and  $C_O$  are respectively the cost of each experimental datum for young and old mice.

Consider a specific example, an experiment comparing 5-month-old to 25-month-old mice, for Vitamin X, with mean and standard deviation as given above, so that an experiment using 17 mice/group provides 80% power. In this example, a 5-month-old mouse costs \$21 and a 25-month-old mouse costs \$251 (from Table 3.1). Assuming the test kit and the technical labor add \$10 per sample, the cost for each data point is \$31 for young mice and \$261 for old mice. The formula above suggests that the optimal distribution of resources would involve testing 33 young mice and 11 of the more expensive, old mice. The cost of this experimental series would be \$4011, a savings of

\$953 over the “balanced” design that uses 17 mice of each age. If half of the mice at age 25 months are found to have a tumor or some other illness that requires their exclusion from the test population, then the cost per tested, healthy aged mouse goes to \$512, the optimal distribution changes to 43 young and 11 (tumor-free) old mice, and the savings to \$2500 compared to the balanced design.

### **Principle #9: Prefer Protocols that Compare Young Adults Destined to Age at Different Rates**

The large majority of experiments on rodent aging use an old-fashioned design, in which some trait is measured in rodents of two or more ages, to produce a description of what aging does. It is for this reason that the National Institute on Aging has committed itself to providing aged rodents of multiple ages, and for this reason that most of this chapter has implicitly focused on designs that involve comparisons among age groups. From a different perspective, though, the main goal of biological gerontology should not be to develop an exhaustive catalog of what aging does, at ever-deeper levels of molecular and cellular sophistication, but instead to develop a good idea of how aging works to produce aged individuals from young ones. Descriptions of how aged individuals differ from young ones are only a first, exploratory step in producing and testing hypotheses about aging mechanisms. An alternate design, already in fashion for studies of invertebrate aging, involves comparisons of young or middle-aged subjects that are known to be aging at different rates. There are now at least two diets that slow aging in both rats and mice, one based on caloric restriction (Weindruch and Sohal, 1997) and the other based on restriction of the amino acid methionine (Miller *et al.*, 2005; Orentreich *et al.*, 1993). There are at least eight published mutations that extend lifespan in mice (Bartke *et al.*, 2001; Bluher *et al.*, 2003; Holzenberger *et al.*, 2003; Miller, 2001; Miskin and Masos, 1997; Tatar *et al.*, 2003). Here the increases in maximal lifespan provide presumptive evidence that the aging process has been delayed or decelerated, and in some cases additional work has documented delays in aging effects on collagen cross-linking, immune changes, joint pathology, cataracts, kidney damage, cognitive decline, and tumor rates (Flurkey *et al.*, 2001; Ikeno *et al.*, 2003; Kinney *et al.*, 2001; Silberberg, 1972; Vergara *et al.*, 2004), thus building a strong case for broad effects on aging rate in these mutants. There is also good evidence that mouse stocks recently derived from wild-trapped progenitors retain genetic alleles, lost by inbred mouse stocks, that are responsible for increases in mean and maximal lifespan (Klebanov *et al.*, 2001; Miller *et al.*, 2002).

The availability of multiple varieties of slow-aging mice allows investigators to look at factors that act, throughout early adult life, to determine the rate at which

age changes occur. It is misleading to assume that aging occurs mainly in old age, i.e., at ages at which the signs of aging first become apparent and inconvenient. Because causes precede effects, the processes that begin to induce clear signs of aging in 18-month-old mice (and 50-year-old people) must have been at work at earlier ages. Thus the mechanisms by which calorie-restricted diets or genetic variations and mutations retard the development of aging effects must also be in action during the months prior to the onset of geriatric symptoms. Research designs that compare pairs of strains, similar to one another except for an age-retarding mutation or exposure to an antiaging intervention, are thus powerful tools for seeking, and then testing, ideas about the ways in which the aging process is itself differentially timed. From this perspective, for example, a gene expression survey which focused on comparisons of control, food-restricted, and slow-aging dwarf mutants at early or middle adult ages is expected to be more fruitful than one which instead compiled lists of genes whose expression is age sensitive. Comparisons among differentially aging mice at relatively early ages also have the benefits of being faster, less expensive, and less confounded by disease and survivor effects than experiments which require data from aged organisms.

### **Principle #10: Avoid using Laboratory Rodents for Studies of Aging**

Or, to be more diplomatic about it, avoid using *only* laboratory rodents for studies of aging. This principle has two subcomponents: (a) an argument that laboratory-adopted rodent stocks are a particularly poor choice on which to develop general ideas about aging, and (b) the more important point that important insights into mammalian aging are likely to require data on species that age at different rates.

Theoretical biologists have postulated, and experimentalists have confirmed, that genes whose natural selection depends on their beneficial effects on early life survival and fitness may have ill effects in old age. Studies have shown repeatedly that selection for genes that influence early-life maturation and reproductive performance (Luckinbill *et al.*, 1984; Rose and Charlesworth, 1980) or growth rate (Miller *et al.*, 2000) can have major effects on aging rate and longevity. Similar conclusions emerge from analysis of the actions of evolution in field studies (Austad, 1993) and in domesticated dogs (Li *et al.*, 1996; Miller and Austad, 2005; Patronek *et al.*, 1997). The evolutionary history of the inbred mouse and rat stocks typically used in experimental biology, including biogerontology, features over a hundred generations of selection for rapid early life growth, large body size (an indirect result of selection for large litter size), independence from reproductive linkage to day length, promiscuity in mate selection, tameness, slow speed, and a preference to go into cages rather than out of them. These selection

### 3. Principles of Animal Use for Gerontological Research

pressures were not the result of deliberate experimental decisions, but represent adaptation of the genome to optimal fitness in the laboratory environment and to laboratory breeding schemes. On theoretical grounds, intensive selection for rapid early growth and early maturation might be expected to eliminate polymorphic alleles that delay aging. In confirmation, two analyses of populations of mice recently derived from wild-trapped progenitors have shown increases in mean and maximal longevity compared to inbred strains and to genetically heterogeneous mouse stocks produced by crosses among laboratory-adapted inbred stocks (Miller *et al.*, 2002). Unpublished data (Harper, Austad, and Miller *et al.*) have replicated these findings and shown further that hybrids produced by crosses between wild-derived and laboratory-adapted stocks have intermediate lifespans.

The laboratory mouse is a highly artificial construct, related to real mice in much the same way as a poodle is related to a wolf. Most pertinent for biogerontology, it is a short-lived construct, from which at least some significant antiaging genes have been stripped. Studies of the biology of aging in laboratory-adapted mice thus face some of the same critiques, detailed elsewhere (Miller, 2004a b), to which analyses of mouse models of so-called accelerated aging can be subjected.

More generally, the biogerontology community, by largely restricting its mammalian cadre to work on rodents, seems to have turned its back on the most obvious source of experimental leverage, i.e., availability in nature of species that age at radically different rates. The best that experimentalists can do within a homeothermic species is to tease out an increase in maximum lifespan of about 50%. Long- and short-lived breeds of dogs, single gene mutants in mice, diet-induced lifespan expansion—each produces changes of 50% or less in the pace of aging, functional decline, and change in mortality risks. Evolutionary selective pressures, working on a longer time scheme, can of course do much better. Maximum lifespan within rodents varies from about 4 years in mice to about 30 years in some porcupines and beavers (omitting the naked mole rat on the grounds of poikilothermy). Within the mammals, maximum lifespan seems likely to exceed 200 years in bowhead whales, and species with maximal longevity over 50 years are found within several orders and many genera. The theme of Principle #9—comparison among adults destined to age at different rates—goes double for comparative biology of aging. Gerontologists with an interest in discovering the fundamental basis for alterations in aging rate should be obsessed with exploiting this extremely rich but nearly untapped pool of natural experiments. Environmental niches suitable for evolution of long-lived species arise with regularity and become filled with birds, gliding mammals (Austad and Fischer, 1991), large predators, unpalatable porcupines, large-sized herbivores, whales and fish, and primates with complex social systems. Each of these many kinds of long-lived homeotherms has

evolved separately from shorter-lived progenitors. Yet there is virtually nothing known as to the mechanisms exploited by evolution in pursuit of longevity, nor whether similar mechanisms are repeatedly employed in each circumstance. The challenges to evolutionary potency appear, from a naïve perspective, to be formidable: development of a human-sized animal with a 70-year lifespan from a mouse-size creature built for a maximum of 3–4 years requires the reduction of the rates of neoplastic transformation (per target cell, per day) by about five orders of magnitude (Miller, 1991), and evolution of whales calls for another 10,000-fold improvement. Studies that compare antineoplastic defenses, and more generally antiaging mechanisms, among sets of species that differ radically in aging rate deserve far more attention than they have hitherto received, although initial forays into this area look promising (Busuttil *et al.*, 2003; Kapahi *et al.*, 1999; Ku and Sohal, 1993; Ogburn *et al.*, 1998). Twenty years from now, biogerontologists may view mice and rats not as the main weapon for research on aging in mammals, but as one tool (the shortest-lived one) in a kit developed for disassembling and reconstructing the systems that regulate aging rate in mammals.

## ACKNOWLEDGMENTS

This work has been supported by NIA grants AG08808 and AG13283. I thank Nancy Nadon for her collaboration on an earlier article on closely related topics, and Andrzej Galecki for advice and formulae related to cost-adjusted power analyses.

# From Primary Cultures to the Aging Organism: Lessons from Human T Lymphocytes

Rita B. Effros

*One of the prominent clinical features of human aging is the dramatic increase in morbidity and mortality due to infections. Aging is also the most significant risk factor for developing cancer. Both phenomena are related to the age-associated decline in immune function, particularly within the T cell compartment, the part of the immune system that patrols the body for cells that appear foreign, which would indicate they are infected or cancerous. Development of long-term cell culture protocols for analyzing the effect of chronic antigenic stimulation on primary T cells from young adult donors has led to the identification of multiple characteristics of the terminal stage of replicative senescence in this cell type. These include inability to divide, altered cytokine patterns, resistance to apoptosis, shortened telomeres, reduced antiviral cytolytic function, and loss of expression of a major signaling molecule, CD28. Many elderly persons have high proportions of T cells with similar characteristics, and the abundance of these cells has been correlated with such deleterious outcomes as poor response to vaccination, osteoporotic fractures, reduced immunity to infection, and even early mortality. Thus, cell culture studies have provided novel insights into the cellular basis for an important facet of immune system aging that has significant effects on a variety of human age-related pathologies.*

## Introduction

Among the most significant clinical problems associated with aging are infections and cancer. Indeed, influenza and pneumonia rank as the 5th leading cause of death in U.S. adults age 65 and older. In addition to actual mortality, morbidity and prolonged periods of illness due to infections are substantially increased with age. With respect to cancer, epidemiological studies show that old age—even more than known harmful lifestyle factors, such as smoking—is the greatest risk factor for the development of cancer. One of the major contributory factors to the age-related changes in

infection and cancer is the waning protective function of the immune system.

The complex changes that occur within the immune system of aged humans are due both to intrinsic events, such as the decrease in thymic size and function, as well as to environmental factors, mainly the lifelong exposure to various pathogens. The combined effects of these intrinsic and extrinsic factors lead to major alterations in immune function with age, changes that have been implicated in the deleterious effects of pathogens and cancer in the elderly. Ironically, vaccination, which is aimed at manipulating the immune system in ways that would prevent infection or retard cancer progression, is far less effective in the elderly (McElhaney *et al.*, 1998). Even immune memory to certain pathogens that is generated early in life declines during aging.

In order to develop strategies for enhancing immune function of the elderly, a thorough understanding of the mechanisms responsible for age-associated immunological changes is clearly essential. In this chapter, we will focus on one particular component of the immune system, the T lymphocyte, and demonstrate how primary cell culture analysis of T cells has led to novel insights into an important and previously unrecognized facet of the immune system in elderly humans, namely, the accumulation of cells with characteristics of replicative senescence. Information from these studies provides evidence suggesting that senescent T cells may affect not only immune function *per se*, but a variety of age-related pathologies. The high correlation between characteristics identified *in vitro* and T cells present *in vivo* suggests that the long-term T cell culture model will also be informative for evaluating therapeutic interventions to retard or prevent a variety of deleterious clinical problems associated with aging.

## How Does the Immune System Work?

### INNATE AND ADAPTIVE IMMUNITY

The fundamental purpose of the immune system is to distinguish between self and non-self. Foreign antigens

are eliminated in a variety of ways by both the so-called innate and adaptive components of the immune system. The innate immune system deals with foreign invaders through rapid, albeit fairly nonspecific, responses. Moreover, there is no recall or memory within the innate immune system. By contrast, the adaptive immune system takes a bit longer to respond, but retains memory for the specific antigen, and is able to respond in an accelerated fashion in the event of re-encounter with the same antigen. Indeed, it is this ability to “learn” and remember specific antigens that is the basis for vaccination.

The two major types of lymphocytes that comprise the adaptive immune system are B cells and T cells. Both are derived from hematopoietic stem cells in the bone marrow, but they function in entirely different ways. B cells produce soluble proteins known as antibodies, which can neutralize or otherwise inhibit the activity of foreign pathogens. Thus, B cells are responsible for the so-called humoral immune response. T cells, on the other hand, cannot recognize anything foreign unless it has actually entered another cell. The infected cell, which expresses parts of the virus or bacterium on its surface, is recognized as non-self by the T cells, eliciting what is known as “cellular immunity.”

How do B cells and T cells recognize foreign pathogens that enter the body? The recognition structures, known as antigen receptors, are generated through a unique and complex set of genetic events, which allows a limited number of genes to create an immune system with an enormous range of specificities. Briefly, during the development of lymphocytes, one member of a set of gene segments is randomly joined to other gene segments by an irreversible process of DNA recombination. The consequence of this mechanism is that just a few hundred different gene segments can combine in a variety of ways to create thousands of receptor chains. This diversity is further amplified by the pairing of two different chains, each encoded by distinct sets of gene segments, to form a functional antigen receptor. Each lymphocyte bears many copies of its antigen receptor, and once generated, the receptor specificity of a lymphocyte does not change. Thus, only one specificity can be expressed by a single lymphocyte and its progeny (Janeway Jr *et al.*, 2001).

#### CLONAL EXPANSION—WHAT ABOUT THE HAYFLICK LIMIT?

Because of the random nature of the genetic events that create lymphocyte receptors, a small amount of genetic material is utilized to generate at least  $10^8$  different specificities. The corollary to this is that since each lymphocyte bears a different antigen receptor, the number of lymphocytes that can recognize any single foreign antigen is exceedingly small. Therefore, when a mature lymphocyte interacts with a particular antigen that is recognized by its receptor, that lymphocyte becomes

activated and must begin dividing, giving rise to a clone of identical progeny bearing identical receptors for antigen. Antigen specificity is thereby maintained as the dividing cells continue to proliferate and differentiate into effector cells. Once antigen is cleared, a small number of memory cells persist, all bearing the same antigen receptor. When the same antigen is encountered again, the process of activation and clonal expansion is repeated (Janeway Jr *et al.*, 2001).

From what has been described above, it becomes clear that cell proliferation is a central feature of adaptive immunity. One wonders, then, how the so-called Hayflick Limit might affect the behavior of cells within the immune system. This innate barrier to unlimited cell division, known as replicative senescence, has been documented for a variety of cell types, and would seem to be highly relevant to T cells, whose ability to fight infections is critically dependent on extensive cell division.

From the cell culture data on other cell types, a preliminary estimate would suggest that the degree of proliferation achievable by each T cell is so large that the finite replicative lifespan would not necessarily be biologically meaningful *in vivo*. For example, if a T cell has an average proliferative lifespan of 35 population doublings, and even if all daughter cells continue to grow unchecked, the resulting yield of more than  $10^{10}$  cells would appear to be more than sufficient. However, because T-cell immune responses include both extensive proliferation and apoptotic removal of excess cells, the finite proliferative lifespan of T cells might allow only two or three rounds of antigen-driven expansion before the end stage of replicative senescence is reached. The above crude estimate suggests that the limited proliferative potential might indeed be detrimental *in vivo*, particularly by old age (Effros and Pawelec, 1997).

Based on the importance of cell proliferation in maintaining effective immune function, we sought to examine the changes that T cells undergo as they progressed through their proliferative lifespan. In order to ensure that we were studying the same population of T cells over time, the most suitable method to address this issue is in cell culture, where it is possible to conduct a virtual longitudinal study on a specific set of cells. Long-term cell culture analyses had been performed on other cell types, including fibroblasts, epithelial cells, endothelial cells and keratinocytes, to characterize the unique features of each cell type under conditions of enforced, extensive proliferation (Campisi, 1997). Ironically, until fairly recently, T cells, whose function is critically dependent on clonal expansion, had never been examined with respect to the process of replicative senescence (Adibzadeh *et al.*, 1995; Effros, 1996). In the following section, we describe our adaptation of the long-term culture techniques to human T cells, and summarize the main features of replicative senescence in this cell type.

## Primary Cultures of Human T Cells

### SUMMARY OF THE CULTURE PROTOCOL

Our cell culture studies have focused on the analysis of the CD8<sup>+</sup> T cell subset, the cell type responsible for controlling viral infections, which are a major clinical problem in the elderly. In preliminary experiments, aimed at optimizing long-term growth and viability of human T cells, we verified that the most reproducible growth patterns of human T cells, whether from neonates or adults, were obtained in AIMV serum-free medium. In these early studies, we observed that some batches of fetal calf serum or even human serum inhibited the growth of T cells, particularly T cells derived from neonates (Perillo *et al.*, 1989).

Our initial cell culture protocol used in defining the proliferative lifespan for human T cells involved stimulation of peripheral blood mononuclear cells with an irradiated allogeneic lymphoblastoid cell line in the continued presence of the T cell growth factor, Interleukin-2 (IL-2). After an initial burst of proliferation over approximately 2–3 weeks, the cells reached quiescence, at which time the culture was restimulated with the same antigen and IL-2. This process was repeated until the point at which the culture showed no cell number increase in response to two rounds of antigen stimulation, at which time it was considered to have reached the end stage of replicative senescence.

Since T cells grow in suspension culture, accurate cell counts could be performed at each passage, allowing us to calculate the total number of population doublings achieved by that culture. Using this cell culture protocol, which favors the generation of CD8<sup>+</sup> T cell cultures, we followed over 100 T cell cultures, derived from peripheral blood samples from both adults and neonatal donors, and reported that the number of population doublings (PDs) ranged from 11 to 57, with a mean of  $23 \pm 7$  (Perillo *et al.*, 1989). Similar ranges of proliferative potential of human T cells have been reported by other groups as well.

In our experiments, there was a significant difference in the PDs achieved by cells from adult versus neonatal donors ( $p < 0.025$ ). However, among the adult donors, there was no correlation between *in vitro* lifespan and chronological age (Perillo *et al.*, 1989). In terms of function, our studies showed that for alloantigen-stimulated cultures, antigen-specific cytotoxic function was retained even at senescence, and the cells in senescent cultures were able to upregulate expression of the alpha chain of the IL-2 receptor in response to specific antigen, despite the inability to enter cell cycle when exposed to the same antigen (Perillo *et al.*, 1993).

### CHARACTERISTICS OF SENESCENT T CELL CULTURES

Certain notable changes in critical cellular functions were observed in alloantigen-specific cultures that reached

replicative senescence. Similar to senescent fibroblasts (Wang, Lee, and Pandey, 1994), CD8<sup>+</sup> T cell cultures that reach senescence became resistant to apoptosis and expressed increased levels of bcl2 (Spaulding *et al.*, 1999). Stimuli such as antibody to Fas, IL-2 withdrawal, mild heat shock, galectin-1 and staurosporine, all of which caused robust apoptosis in the early passage cells, caused only minimal cell death in the senescent cultures. A second major change involved the reduced ability of senescent cultures to respond to stress by upregulation of the major mammalian stress protein, hsp70 (Effros, Zhu, and Walford, 1994b). This defect is reminiscent of the overall reduction in responsiveness to physical and oxidative stress that is believed to play a major role in organismic aging (Golden *et al.*, 2002).

One of the main advantages of studying T cells in long-term culture is the ability to monitor changes in expression over time in the large spectrum of known T cell surface markers reflecting lineage, activation status, adhesion, and memory. Using flow cytometry, we demonstrated that for nearly all such markers, there was no change in expression between early passage and senescent cultures (Perillo *et al.*, 1993). The single exception was CD28, a key T cell-specific signaling molecule that plays diverse roles in T cell biology, including delivering the costimulatory second signal that is essential for activation/proliferation, stabilizing cytokine mRNAs, modulating cell trafficking, and regulating glucose metabolism. As T cells progress to senescence in culture, the proportion of cells that are CD28<sup>-</sup> increases, and senescent cultures are >99% CD28<sup>-</sup> (Effros *et al.*, 1994a). The loss of CD28 expression is associated with complete suppression of gene expression of this key T cell signaling molecule.

Whereas characterization of senescence-associated changes using long-term primary T cell cultures has the advantage of allowing longitudinal analysis of the same population of cells over time, the model admittedly suffers from the absence of the *in vivo* milieu, which undoubtedly plays a role in marker expression patterns changes that occur in the context of the whole organism. Indeed, although loss of CD28 expression has been presumed to be the ultimate senescence-associated change based on cell culture analysis, it is possible that other cell surface antigens identified on *ex vivo* samples may delineate a more precise phenotype for the true end-stage senescent CD8<sup>+</sup> T cell. One such marker change is the acquisition of CD57, which has been documented for virus-specific CD8<sup>+</sup> T cells from HIV-infected persons that have undergone multiple rounds of proliferation (Brenchley *et al.*, 2003). Interestingly, many features are shared by CD57<sup>+</sup> and CD28<sup>-</sup> T cells isolated *ex vivo*, reinforcing the notion that both the loss of CD28 expression and the acquisition of CD57 can be considered markers of senescent T cells (Demarest *et al.*, 2001; Mach *et al.*, 1997; Posnett *et al.*, 1999; Weekes *et al.*, 1999). Additional markers that have been identified on putatively senescent

CD28<sup>-</sup> T cells isolated *ex vivo* are the KLRG1 NK inhibitory lectin-like receptor and CD56, an NK marker bearing the HNK-1 epitope (Ouyang *et al.*, 2003a; Tarazona *et al.*, 2000), findings that may explain earlier reports of MHC-unrestricted NK function in senescent cultures (Pawelec *et al.*, 1986).

As CD8<sup>+</sup> T cells undergo increasing numbers of cell divisions in long-term culture, they show a variety of alterations that would be predicted to dramatically affect *in vivo* immune function. For example, alloantigen-specific cultures from healthy donors produce increasing amounts of two pro-inflammatory cytokines, IL-6 and TNF $\alpha$ , as they approach replicative senescence (Effros *et al.*, 2005), and virus-specific CD8<sup>+</sup> T cells show decreased antigen-specific production of IFN $\gamma$  (Dagarag *et al.*, 2004). HIV-specific CD8<sup>+</sup> T cell cultures initiated from T cells of HIV-infected persons show a progressive decline in the ability to perform antigen-specific lysis of target cells pulsed with HIV peptides, a change that is accompanied by reduced expression of perforin (Dagarag *et al.*, 2004; Yang *et al.*, 2005). Moreover, one of the key antiviral activities believed to function protectively *in vivo*—inhibition of HIV replication—is markedly reduced in senescent HIV-specific CD8<sup>+</sup> T cells (Dagarag *et al.*, 2003). One can envision that such functional changes might exert pleiotropic influences on a variety of physiological processes *in vivo*, both in the context of aging and in chronic HIV infection.

## TELOMERASE AND T CELLS

It is generally accepted that the “clock” that keeps track of cell divisions and signals cell cycle arrest in human cells is the telomere, a region at the end of each chromosome that consists of multiple repeats of a specific DNA sequence (Campisi *et al.*, 2001). Due to the end-replication problem in copying the full length of the lagging DNA strand, normal somatic cells undergo progressive telomere shortening with cell division. Once the telomere reaches a certain critical length, the DNA damage signaling pathway is activated, with the concomitant up-regulation of cell cycle inhibitors. The process of replicative senescence is a stringent characteristic of human somatic cells, whereas in germ cells, in certain stem cells, and in tumor cells, telomere shortening and replicative senescence are prevented by the activity of an enzyme called telomerase, which uses its RNA template to synthesize the telomere sequence.

Human and mouse cells show fundamental differences with respect to telomere size and telomerase activity. Because of the significantly longer telomeres in laboratory strains of inbred *Mus musculus*, and the high levels of telomerase present in most mouse tissues, it is unlikely that mouse cells undergo telomere-based senescence (Akbar *et al.*, 2000). Indeed, the barrier to unlimited proliferation may actually be less stringent in murine cells, since, unlike human cells, mouse cells undergo frequent spontaneous immortalization in cell culture. Thus, there is

a major difference between mice and humans with respect to this important facet of cell biology. In terms of the aging immune system as well, the life-long exposure to pathogens also differentiates elderly humans from aged mice housed in barrier facilities, further underscoring the value of using a human cell culture model for analysis of the role of T cell replicative senescence in human aging.

Our cell culture analysis of human T cells has documented that telomere length undergoes progressive shortening with increasing rounds of antigen-driven proliferation, reaching 5–7 kb at senescence (Vaziri *et al.*, 1993). Although this telomere length was similar to that of other cell types that reach senescence in cell culture, we were somewhat perplexed by the observed telomere shortening in T cells, since lymphocytes are unique among human somatic cells in that they induce high levels of telomerase activity in concert with the activation process (Weng *et al.*, 1996). Indeed, the levels of telomerase activity in antigen or mitogen-stimulated T cells are comparable to those of tumor cells (Bodnar *et al.*, 1996).

To address this issue, we performed a detailed kinetic analysis in cell culture of CD8<sup>+</sup> T cell telomerase activity induced by activation. We showed that after mitogen or T cell receptor (TCR)-mediated activation, the telomerase activity peaks at 3–5 days, then undergoes a gradual decline, becoming undetectable at approximately 3 weeks. A second wave of telomerase activity can be induced by a subsequent exposure to the same antigen, and during the period of high telomerase activity, telomere length remains stable (Bodnar *et al.*, 1996). However, in CD8<sup>+</sup> T cells, the antigen-induced upregulation of telomerase in response to stimulation with antigen is markedly reduced by the third stimulation, and is totally absent in all subsequent encounters with antigen (Valenzuela and Effros, 2002).

One of the unexpected findings in our cell culture studies was the significant difference between helper (CD4<sup>+</sup>) and cytotoxic (CD8<sup>+</sup>) T cell subsets with respect to telomerase. This observation was made by culturing CD4<sup>+</sup> and CD8<sup>+</sup> T cell subsets that were isolated from the same individual, using the identical stimulatory schedule. The initial stimulation by alloantigen elicited a 45-fold and 53-fold increase in telomerase activity in the CD8<sup>+</sup> and CD4<sup>+</sup> cell cultures, respectively. However, by the 4th antigenic stimulation, telomerase activity was undetectable in the CD8<sup>+</sup> T cells, whereas CD4 T cells still showed robust telomerase activity even as late as the 10th round of antigenic stimulation.

The divergent patterns of telomerase activity between CD4<sup>+</sup> and CD8<sup>+</sup> T cells paralleled the pattern of CD28 expression changes. By the 7th antigenic stimulation, 90% of the cells in the CD8<sup>+</sup> culture no longer expressed CD28, whereas at that same stage, the CD4<sup>+</sup> cultures were still 75% CD28<sup>+</sup> (Valenzuela *et al.*, 2002). The intimate relationship between telomerase activation and CD28 signaling was further demonstrated in experiments

#### 4. Human T Cell Senescence *in vitro* and *in vivo*

using antibodies to block CD28 binding to its ligand on antigen-presenting cells, which resulted in a significant reduction in telomerase activity. Finally, the distinct contribution of CD28 to telomerase activation was evident in experiments using Cyclosporin, a TCR signaling inhibitor. Cyclosporin was not able to inhibit telomerase in T cells activated by a combination of antibodies to CD3 and CD28, whereas potent inhibition was observed when only anti-CD3 was used for stimulation (Valenzuela *et al.*, 2002).

##### REVERSAL/RETARDATION OF T CELL REPLICATIVE SENESCENCE IN CELL CULTURE

Given the central role of telomere shortening in the replicative senescence “program” in T cells, our main approach at modulating senescence has focused on strategies to enhance telomerase activity in CD8<sup>+</sup> T cells. An excellent model system for these studies is the virus-specific CD8<sup>+</sup> T cell response, which is known to decline with age as well as during chronic infections, such as HIV. Therefore, using the long-term culture system described above, we followed HIV-specific CD8<sup>+</sup> T cells that had been isolated from persons infected with HIV, and tested the effect of gene transduction with the catalytic component of telomerase (hTERT). Comparisons were made between the hTERT-transduced cultures and the empty-vector-transduced cultures.

Results of these experiments showed significant effects of hTERT on proliferative and functional aspects of the T cells. Briefly, we observed that hTERT transduction led to telomere length stabilization and reduced expression of the p16<sup>INK4A</sup> and p21<sup>WAF1</sup> cyclin-dependent kinase inhibitors, implicating both of these proteins in the senescence program (Dagarag *et al.*, 2004). Indeed, the transduced cultures showed indefinite proliferation, with no signs of change in growth characteristics or of karyotypic abnormalities. In terms of protective immune function, the “telomerized” HIV-specific CD8<sup>+</sup> T cells were able to maintain the production of IFN $\gamma$  for extended periods, and showed significantly enhanced capacity to inhibit HIV replication. The loss of CD28 expression was delayed considerably, although ultimately not prevented, suggesting that additional genetic manipulation of the CD28 gene itself may be required for full correction of this important senescence-associated alteration. Similarly, virus-specific cytolytic function was not restored by hTERT transduction (except in selected clones). Thus, hTERT corrects most, but not all, the alterations associated with replicative senescence in CD8<sup>+</sup> T cells isolated from HIV-infected persons. Ongoing studies are addressing whether these same effects will be seen in hTERT transduced cells from healthy donors, and whether transduction at earlier timepoints along the trajectory to senescence will enhance the telomerase effects.

Telomerase enhancement may also be achieved using nongenetic strategies, which would offer more practical approaches to therapeutic interventions in the elderly.

For example, it is known that estrogen is able to enhance telomerase activity in reproductive tissues. The complex formed when estrogen binds to its receptors migrates to the nucleus and functions as a transcription factor. In normal ovarian epithelial cells, this complex actually binds to the hTERT promoter region (Misiti *et al.*, 2000). It has been known for some time that T cells can bind to estrogen via specific estrogen receptors. Thus, we tested whether pre-incubation of T cells to 17 $\beta$ -estradiol prior to activation might augment telomerase activity. Our preliminary data suggest that estrogen does, in fact, enhance T cell telomerase activity. The enhancement is observed in both CD4 and CD8 subsets, and can also be seen when estrogen is conjugated to BSA, indicating that surface estrogen receptor interaction may be sufficient to mediate the telomerase effect (Effros, manuscript in preparation).

Our data on estrogen effects in T cells *in vitro* are reminiscent of an earlier study in which we documented the reversal of some of the age-related T cell changes in postmenopausal women treated with hormone replacement therapy (Porter *et al.*, 2001). In another set of preliminary experiments with small molecule activators of telomerase, we have shown a significant enhancement of telomerase activity in T cells from both healthy and HIV-infected persons (Fauce *et al.*, manuscript in preparation). Thus, therapeutic approaches that are based on telomerase modulation would seem to be promising candidates for clinical interventions in the elderly that are aimed at reversing or retarding the process of replicative senescence in T cells. The major question to be addressed is whether the process of replicative senescence, characterized so extensively in cell culture, has any relationship to events within the immune system during normal human aging. As will be described below, this certainly does seem to be the case.

##### Is T Cell Replicative Senescence Occurring *in vivo*?

###### SENESCENT CD8<sup>+</sup> T CELLS ACCUMULATE WITH AGE AND WITH CHRONIC INFECTION

The results of our cell culture studies were invaluable in transitioning to *in vivo* analysis of the possible occurrence of replicative senescence during normal aging. Based on the absence of CD28 expression as a marker of senescence, we compared 20 adults (age 25–69) and 21 healthy centenarians for the presence of cells with a similar phenotype, using flow cytometry. We showed that there was a significant increase ( $p < 0.01$ ) in the proportion of T cells lacking CD28 expression in the elderly, with some aged individuals having >60% CD28<sup>-</sup> T cells within the CD8<sup>+</sup> T cell subset, compared to the mean young adult value of <10%. Importantly, since the decrease in the percentage of CD28<sup>+</sup> T cells with age was not associated with an alteration in the intensity or

standard deviation of mean fluorescence, our analysis indicated that the expression of CD28 was normal on those cells that were registered as being CD28<sup>+</sup> (Effros *et al.*, 1994a).

There was an intriguing correlation between the presence of high proportions of CD28<sup>-</sup> T cells and the reversal of the youthful ratio between CD4<sup>+</sup> and CD8<sup>+</sup> T cells. Our data showed that those elderly persons who had the highest proportion of CD28<sup>-</sup> T cells also had CD4/8 ratios that reflected an increased proportion of CD8<sup>+</sup> T cells (Effros *et al.*, 1994a). Interestingly, altered CD4/8 ratios have also been reported in elderly persons who have large expansions of clonal populations of CD8<sup>+</sup> T cells (Posnett *et al.*, 1994). These oligoclonally expanded populations actually resemble cells in senescent cultures in terms of their increased level of activation, the absence of CD28 expressions and their inability to proliferate.

Importantly, cells lacking CD28 expression do not suddenly appear in old age; there is a progressive increase over the lifespan in the proportion of T cells that lack CD28 expression (Boucher *et al.*, 1998). Moreover, chronological age is not unique in its association with T cell replicative senescence. Chronic infection with HIV is also associated with the progressive accumulation over time of CD8<sup>+</sup> T cells that are CD28<sup>-</sup> (Borthwick *et al.*, 1994). In early reports, this unusual subset was suggested to have arisen as a distinct lineage, possibly related to some unusual aspect of HIV disease pathogenesis. However, based on our cell culture studies, we suspected that these cells were the descendants of cells that previously did express CD28, but that had undergone extensive proliferation and reached the end stage of replicative senescence. To test this idea, we performed telomere analysis on purified cell populations from persons infected with HIV. We first isolated the CD8<sup>+</sup> T cells from peripheral blood, then sorted them further into CD28<sup>+</sup> and CD28<sup>-</sup> populations. Using Southern blot analysis, we showed that the telomere length of the CD28<sup>-</sup> population was significantly shorter than that of the CD28<sup>+</sup> population from the same donor. In fact, the mean telomere length of the CD8<sup>+</sup>CD28<sup>-</sup> T cells from persons infected with HIV (mean age 43 years) was the same range as that of PBMC isolated from centenarians (Effros *et al.*, 1996).

As further evidence in support of the notion that replicative senescence was actually occurring *in vivo*, the sorted CD8<sup>+</sup>CD28<sup>-</sup> T cells tested immediately *ex vivo* showed minimal proliferative ability, even when the stimulation bypassed cell surface-mediated activation signals. Although it is impossible to formally prove that the cells with characteristics of senescence arose by the same mechanism as those in senescent cell culture, the overwhelming similarity between the two cell populations is highly suggestive that replicative senescence is not a cell culture artifact. Indeed, the cell culture model is thus far highly predictive of the functional, genetic, and phenotypic traits of certain CD8<sup>+</sup> T cells present *in vivo*.

## THE DRIVING FORCE

We have recently proposed that latent infection with herpes viruses may constitute a major antigenic stimulus leading to the accumulation of senescent CD8<sup>+</sup> T cells *in vivo* (Pawelec *et al.*, 2004). Elderly persons have large numbers of dysfunctional CD8<sup>+</sup> T cells bearing antigen receptors for a single dominant cytomegalovirus (CMV) epitope (Ouyang *et al.*, 2003b). Even in younger persons who are infected with HIV and whose immune systems are thought to age prematurely, there are substantial numbers of CD8<sup>+</sup>CD28<sup>-</sup> T cells that are specific for CMV as well as for Epstein-Barr virus (EBV). These sorts of data suggest that the cost of maintaining control over these latent infections is the progressive generation of senescent CD8<sup>+</sup> T cells (Pawelec *et al.*, 2004). The apoptosis resistance of these cells leads to a situation where they occupy progressively more and more of the memory T cell pool in the elderly, restricting the repertoire of the remaining T cells.

Latent viruses associated with certain forms of cancer can also drive CD8<sup>+</sup> T cells to senescence, as illustrated by the accumulation of CD8<sup>+</sup>CD28<sup>-</sup> T cells with reactivity to the human papilloma virus E7 antigen in cervical cancer patients (Pilch *et al.*, 2002). Other viruses associated with chronic infection, such as Hepatitis C, also seem to elicit expanded populations of CD8<sup>+</sup> T cells that lack CD28 expression (Kurokohchi *et al.*, 2003). The common thread in all of these situations is chronic antigenic stimulation, which seems to result in massive cell division of antigen-reactive CD8<sup>+</sup> T cells, ultimately causing them to reach what might be considered the end-stage of their differentiation pathway, namely replicative senescence. Clearly, most memory T cells encounter their nominal antigen only once or twice over an individual's lifespan, and it is only those CD8<sup>+</sup> T cells with reactivity to antigens that are never cleared from the body that have the potential to continue dividing extensively, eventually reaching senescence.

## IN VIVO IMMUNE EFFECTS OF SENESCENT T CELLS

The CD28<sup>-</sup> T cells present *in vivo* are similar by a variety of criteria to CD28<sup>-</sup> cells in senescent cultures, suggesting that they arose by the same mechanism. Extensive research on replicative senescence in non-immune cell types indicates that once senescent cells are generated, they not only suffer from an inability to enter the cell cycle, but can also affect a variety of physiological processes or organ system functions. For example, senescent human fibroblasts stimulate premalignant and malignant, but not normal, epithelial cells to proliferate in culture and also to form tumors in SCID mice, suggestive of a potential role in age-related cancers (Krtolica *et al.*, 2001). In addition, whereas *normal* fibroblasts function to create intracellular matrix, *senescent* fibroblasts secrete collagenase and other

#### 4. Human T Cell Senescence *in vitro* and *in vivo*

matrix-destroying enzymes, leading to altered tissue integrity (Campisi, 1998).

The significant correlation between high proportions of CD8<sup>+</sup>CD28<sup>-</sup> T cells and poor antibody response to influenza vaccination documented in two independent clinical studies (Goronzy *et al.*, 2001; Saurwein-Teissl *et al.*, 2002) provides an example of putative suppressive effects of senescent CD8<sup>+</sup> T cells on the function of other immune cells. Senescent CD8<sup>+</sup> T cells have also been associated with suppressive effects in organ transplant patients. Donor-specific CD8<sup>+</sup>CD28<sup>-</sup> T cells are detectable in the peripheral blood of those patients with stable function of heart, liver and kidney transplants, whereas no such cells were found in patients undergoing acute rejection (Cortesini *et al.*, 2001). Although in the context of organ transplantation, suppression may lead to a favorable outcome, in many other contexts, the CD8<sup>+</sup>CD28<sup>-</sup> T cell populations are associated with deleterious effects. For example, expanded populations of CD8<sup>+</sup>CD28<sup>-</sup> T cells are present in ankylosing spondylitis patients, and, in fact, correlate with a more severe course of this autoimmune disease (Schirmer *et al.*, 2002).

In addition to the role that putatively senescent CD8<sup>+</sup> T cells may play in regulating functions of other immune cell types, these cells also show alterations in the normal functional attributes of CD8<sup>+</sup> T cells. First, CD8<sup>+</sup>CD28<sup>-</sup> T cells isolated *ex vivo* are unable to proliferate (like their cell culture counterparts), even in response to signals that bypass cell surface receptors, such as PMA and ionomycin (Effros *et al.*, 1996). This observation is consistent with extensive research on replicative senescence in a variety of cell types documenting the irreversible nature of the proliferative block, and its association with upregulation of cell cycle inhibitors and p53-linked checkpoints (Campisi, 2001). If the CD8<sup>+</sup>CD28<sup>-</sup> T cells present in elderly persons are virus-specific, their inability to undergo the requisite clonal expansion in response to antigen re-encounter will compromise the immune control over that particular virus. Indeed, as noted above, senescent HIV-specific CD8<sup>+</sup> T cells are markedly reduced in lytic activity, IFN $\gamma$  production, and antiviral suppressive function (Dagarag *et al.*, 2004). Thus, CD8<sup>+</sup>CD28<sup>-</sup> T cells in elderly persons may contribute to emergence of latent infections, such as varicella zoster virus (shingles) and EBV (some lymphomas), as well to the reduced control over acute infection with a repeatedly encountered virus (influenza), well-documented in elderly persons (Effros, 2001). Second, since CD28 ligation enhances the binding affinity of T cells to endothelial cells, T cells lacking CD28 may be altered in their trafficking patterns between tissue and blood. Third, if the putatively senescent T cells present *in vivo* produce high levels of IL-6 and TNF $\alpha$  like their *in vitro* counterparts, their presence *in vivo* may be contributing to the well-documented pro-inflammatory milieu present in many elderly persons. Indeed, enhanced inflammation is now believed to play a role in many of the diseases of

aging that had not been previously considered immune-mediated pathologies. Ovariectomy-induced bone loss in mice, for example, has been specifically linked to TNF $\alpha$ -secreting T cells present within the bone marrow (Raggia *et al.*, 2001).

The apoptosis resistance of CD8<sup>+</sup>CD28<sup>-</sup> T cells tested immediately *ex vivo* (Posnett *et al.*, 1999) leads to their persistence, which, in turn, affects the quality and composition of the total memory pool, as discussed above. Moreover, since the CD28<sup>-</sup> T cells are usually part of oligoclonal expansions (Posnett *et al.*, 1994), their accumulation would presumably also lead to a reduction in the overall spectrum of antigenic specificities within the T cell pool. Elderly persons with high proportions of CD8<sup>+</sup> T cell that are CD28<sup>-</sup> do, in fact, have reduced repertoires of antigenic specificities (Ouyang *et al.*, 2003b).

A final aspect of senescent T cells that could have broad physiological consequences relates to the role of stress in the aging process. T cells that undergo replicative senescence in culture show transcriptional down-regulation of the *hsp70* gene in response to heat shock (Effros *et al.*, 1994b), and T cells from elderly persons show attenuation in the molecular chaperone system *hsp70*, in the steroid binding *hsp90*, and the chaperonin *hsp60*. These immune cell changes may contribute to the well-documented reduction in ability to respond to stress that characterizes organismic aging.

### Global Effects of Senescent T Cells on the Aging Organism

#### BONE HOMEOSTASIS

Senescent CD8<sup>+</sup> T cells may affect other organ systems as well. Indeed, there is accumulating evidence implicating chronic immune activation in bone loss (Arron and Choi, 2000). Although much of the research on “osteimmunology” relates to CD4<sup>+</sup> T cell/bone interaction in the context of rheumatoid arthritis, there is increasing evidence suggesting a link between the CD8<sup>+</sup> T cell subset and bone resorption activity (John *et al.*, 1996) as well as with osteoporotic fractures in the elderly (Pietschmann *et al.*, 2001).

One of the central regulators of bone resorption is a molecule known as “RANKL” (receptor activator of NF $\kappa$ B ligand), which binds to RANK on osteoclasts, inducing these bone-resorbing cells to mature and become activated (Kong *et al.*, 2000). Importantly, RANKL is expressed on and secreted by activated T cells. Normally, the bone-resorbing activity induced by RANKL is kept in check by IFN $\gamma$ , a cytokine also produced by the activated T cells. However, we have shown that CD8<sup>+</sup> T cell IFN $\gamma$  production is markedly reduced when the cells reach replicative senescence (Dagarag *et al.*, 2004). A second facet of the T cell/bone connection relates to the fact that activated T cells can also modulate bone

mass by producing cytokines that inhibit the bone-forming activity of osteoblasts. Specifically, the cytokine TNF- $\alpha$  whose production is increased in senescent cultures, inhibits osteoblast bone forming activity, and also affects bone mass by inducing formation of certain cytokines by osteoblasts that increase bone resorption (Lorenzo, 2000). Thus, senescent T cells have the potential to play a significant role in bone mass changes during aging.

#### ALZHEIMER'S DISEASE AND ATHEROSCLEROSIS

There is some evidence that chronic activation of T cells, leading to increased proliferation and telomere shortening, may be involved in other age-related diseases as well. The etiology of Alzheimer's disease (AD) is not known, but our recent studies suggest a possible involvement of T cells. We observed that the telomere length of T cells, but not of B cells or monocytes, correlates with mental function tests in AD patients (Panossian *et al.*, 2002). Those patients with lower Mini Mental Status Examination (MMSE) scores, which is a marker of disease status, had T cells with shorter telomeres than those persons with higher MMSE scores. These findings suggest that the immune system of AD patients is perturbed in some way and may not necessarily respond normally to therapeutic vaccines aimed at retarding AD disease progression. Interestingly, one such therapeutic vaccine trial was recently interrupted due to unanticipated brain inflammation in some participants (Nicoll *et al.*, 2003).

A second age-related pathology in which chronically-activated T cells may play a role is atherosclerosis. Immune involvement in cardiovascular disease (CVD) is suggested by both epidemiological data and experimental animal models. T cells are present in atherosclerotic lesions (Libby *et al.*, 1995), and interaction of CD40 on T cells with vascular endothelial cells, smooth muscle cells, and macrophages has been documented (Mach *et al.*, 1997).

Importantly, several types of infections have been hypothesized to increase the risk of CVD by causing systemic inflammation, or by triggering autoimmunity, for example, by cross-reactivity of heat shock proteins (hsp) with bacterial antigens (Mayr *et al.*, 1999). Indeed, clinically healthy volunteers with sonographically documented carotid artery atherosclerosis have significantly increased antibody titers to hsp 65 compared to controls with no lesions, and in follow-up studies, those with highest titers showed highest mortality. The blocking of the hsp65 effect by T cell immunosuppressive agents further implicates specific immunity in the pathogenesis of atherosclerosis. Most recently, there was a report showing expanded populations of senescent CD8<sup>+</sup> T cells in patients with coronary artery disease as compared to controls, further underscoring the potential involvement of chronic antigen-driven proliferation in atherosclerosis (Jonasson *et al.*, 2003).

#### SENESCENT T CELLS AND MORTALITY

The ultimate effect of T cells on aging is with respect to mortality itself. Early work suggested a connection, based on correlative data, between T cell proliferative responses in cell culture and mortality over the subsequent few years (Wikby *et al.*, 1998). More recently, telomere analysis of total lymphocytes in a group of 60 year olds was shown to be predictive of mortality many years later (Cawthon *et al.*, 2003). In these studies, it was shown that the individuals who had telomeres in the lowest quartile were 7–8 times more likely to die from infections compared with those with the longest telomeres. Longitudinal studies of elderly Swedes over several decades confirm the link between immune parameters and lifespan. These data show that early mortality is associated with a so-called immune risk phenotype, which includes a cluster of T cell parameters, including high proportions of senescent CD8<sup>+</sup> T cells (Nilsson *et al.*, 2003). Interestingly, the presence of these risk factors is strongly correlated with chronic CMV infection (Wikby *et al.*, 2002). Moreover, the predictive value of the immune profile is retained for a variety of causes of death. In sum, there is accumulating evidence that immune system function is intimately linked with a variety of age-related pathologies, some of which are actual causes of death.

#### Concluding Remarks

The phenomenon of replicative senescence has been documented and characterized in cell culture for a variety of cell types. The basic phenotype of a senescent cell is a dysfunctional, permanently growth-arrested cell with reduced ability to undergo apoptosis. It is now clear that cells with similar characteristics do increase in frequency during aging, particularly within the immune system. However, analysis of T cell replicative senescence has led to a paradigm shift regarding the role of replicative senescence in organismic aging.

Early data showing correlations between *in vitro* cell growth and species lifespan had reinforced the notion that analysis of cells in culture would yield mechanistic insights into the process of aging. In hindsight, it appears that this goal might not have been realistic. It has become evident that senescent cells do affect lifespan, but probably not in the sense originally proposed. In other words, rather than affecting the basic aging process, senescent cells exert their impact on the aging organism by contributing to or enhancing certain age-related pathologies. Thus, senescent cells may affect lifespan only indirectly, not by modulating the rate of aging, but rather by affecting the risk of mortality. This altered view of the relationship between aging in cell culture and *in vivo* aging does not diminish the value of using cell culture models in the study of aging. It merely changes the hypotheses and interpretations of the experiments.

## ACKNOWLEDGMENTS

The research described in this chapter has been supported by various NIH grants, as well as by funding from the University of California Discovery Program, Geron Corporation, the Universitywide AIDS Research Program, and the Plott Endowment. The author holds the Elizabeth and Thomas Plott Endowed Chair in Gerontology.

# Models of Systems Failure in Aging

Leonid A. Gavrilov and Natalia S. Gavrilova

*Mathematical models of systems failure are critically important for understanding the mechanisms of aging because aging of organisms is associated with increased risk of failure of its physiological systems.*

*Theoretical analysis of systems failure in aging leads naturally to apply the existing general theory of systems failure, which is also known as the reliability theory. Reliability-theory approach to biological aging is useful for three reasons. (1) It provides a useful scientific language (definitions and cross-cutting principles) helping to create a general theoretical framework for organizing numerous and diverse observation on aging into a coherent picture. This is very important for researchers, because it helps them to understand each other despite a disruptive specialization of aging studies. (2) It allows researchers to develop a scientific intuition and understanding of the main principles of the aging process by considering simplified mathematical models of systems failure, having some general features of real aging organisms. (3) It helps to generate and test specific predictions on age-related dynamics of systems failure, and to get deeper insights in the mechanisms of aging by more creative analysis of already collected data.*

*This chapter reviews the existing theoretical reliability models and approaches, which help us to understand the mechanisms and age-dynamics of systems failure. Empirical observations on systems failure in aging are also reviewed (the Gompertz and Weibull failure laws, the compensation law of systems failure, and the late-life failure rate leveling-off), and are theoretically explained through the observed decline in system's redundancy with age. The causes of failure rate increase with age are discussed and explained using five simple mathematical models of systems failure in aging as an illustration.*

## Introduction

This introductory-overview chapter sets a stage for introducing theoretical models of systems failure in aging. Mathematical models of systems failure are important for the studying of human aging, because aging is associated with increased risk of failure in human physiological systems. Theoretical analysis of systems failure in aging invites us to consider the general theory

of systems failure known as reliability theory (Barlow and Proshian, 1975; Barlow *et al.*, 1965; Gavrilov, 1978; Gavrilov and Gavrilova, 1991, 2001, 2003a, 2004a, 2005; Gavrilov *et al.*, 1978).

Reliability theory was historically developed to describe failure and aging of complex electronic (military) equipment, but the theory itself is a very general theory based on mathematics (probability theory) and systems approach (Barlow and Proschan, 1975; Barlow *et al.*, 1965). It may therefore be useful to describe and understand the aging and failure of biological systems too. Reliability theory may be useful in several ways: first, by providing a kind of scientific language (definitions and cross-cutting principles), which helps to create a logical framework for organizing numerous and diverse observations on aging into a coherent picture. Second, it helps researchers to develop an intuition and an understanding of the main principles of the aging process through consideration of simple mathematical models, having some features of a real world. Third, reliability theory is useful for generating and testing specific predictions, as well as deeper analyses of already collected data. The purpose of this chapter is to review the theoretical reliability models and approaches, which help to understand the mechanisms and dynamics of systems failure in aging.

## Reliability Approach to System's Failure in Aging

Reliability theory is a body of ideas, mathematical models, and methods directed to predict, estimate, understand, and optimize the lifespan and failure distributions of systems and their components (adapted from Barlow and Proschan, 1975). Reliability theory allows researchers to predict the age-related failure kinetics for a system of given architecture (reliability structure) and given reliability of its components.

## DEFINITIONS OF SYSTEM'S FAILURE AND AGING

The concept of failure is important to the analysis of system's reliability. In reliability theory failure is defined as the *event* when a required function is terminated (Rausand and Houland, 2003). In other words, failure is such an outcome when the system deviates from

optimistically anticipated and desired behavior (“fails”). Failures are often classified into two groups:

1. degradation failures, where the system or component no longer functions properly, and
2. catastrophic or fatal failures—the end of system’s or component’s life.

Good examples of degradation failures in humans would be an onset of different types of health impairments, diseases, or disabilities, while catastrophic or fatal failures obviously correspond to death. The notions of aging and failure are related to each other in the following way: when the risk of failure outcomes increases with age (“old is not as good as new”)—this is aging by definition. Note that according to reliability theory, aging is not just growing old; instead aging is a degradation leading to failure (adverse health outcomes)—becoming sick, disabled, frail and dead. Therefore, from a reliability-theory perspective the notion of “healthy aging” is an oxymoron like a healthy dying, or a healthy disease. More appropriate terms instead of “healthy aging” or “aging well” would be a delayed aging, postponed aging, slow aging, arrested aging, or negligible aging (senescence).

Because the reliability definition of biological aging is linked to health failures (adverse health outcomes, including death), aging without diseases is just as inconceivable as dying without death. Diseases and disabilities are an integral part (outcomes) of the aging process. Not every disease is related to aging, but every progression of disease with age has some relevance to aging: aging is a “maturation” of diseases with age.

Note that a system may have an aging behavior for one particular type of failure, but it may remain to be as good as new for some other type of failure. Thus the notion of aging is outcome-specific—it requires specifying for which particular type of failure (or group of failures) the system deteriorates. Consequently, the legitimate antiaging interventions may be outcome-specific too, and limited to postponing some specific adverse health outcomes. Aging is likely to be a summary term for many different processes leading to various types of degradation failures, and each of these processes deserves to be studied and prevented.

## BASIC FAILURE MODELS

*Reliability* of the system (or its component) refers to its ability to operate properly according to a specified standard (Crowder *et al.*, 1991). Reliability is described by the *reliability function*  $S(x)$ , which is the probability that a system (or component) will carry out its mission through time  $x$  (Rigdon and Basu, 2000). The reliability function (also called the *survival function*) evaluated at time  $x$  is just the probability  $P$ , that the *failure time*  $X$ , is beyond time  $x$ . Thus, the reliability function is defined in the following way:

$$S(x) = P(X > x) = 1 - P(X \leq x) = 1 - F(x)$$

where  $F(x)$  is a standard *cumulative distribution function* in the probability theory (Feller, 1968). The best illustration for the reliability function  $S(x)$  is a survival curve describing the proportion of those still alive by time  $x$  (the  $l_x$  column in life tables).

*Failure rate*,  $\mu(x)$ , or instantaneous risk of failure, also called the *hazard rate*,  $h(x)$ , or mortality force is defined as the relative rate for reliability function decline:

$$\mu(x) = -\frac{dS_x}{S_x dx} = \frac{-d \ln S_x}{dx}$$

In those cases when the failure rate is constant (does not increase with age), we have *nonaging system* (component) that does not deteriorate (does not fail more often) with age:

$$\mu(x) = \mu = \text{const}$$

The reliability function of nonaging systems (components) is described by the *exponential distribution*:

$$S(x) = S_0 e^{-\mu x}$$

This *failure law* describes “lifespan” distribution of atoms of radioactive elements, and, therefore, it is often called an exponential decay law. Interestingly, this failure law is observed in many wild populations with high extrinsic mortality (Finch, 1990; Gavrilov and Gavrilova, 1991). This kind of distribution is observed if failure (death) occurs entirely by chance, and it is also called a “one-hit model,” or a “first order kinetics.” The non-aging behavior of a system can be detected graphically when the logarithm of the survival function decreases with age in a linear fashion.

Recent studies found that at least some cells in the aging organism might demonstrate nonaging behavior. Specifically, the rate of neuronal death does not increase with age in a broad spectrum of aging-related neurodegenerative conditions (Heintz, 2000). These include 12 different models of photoreceptor degeneration, “excitotoxic” cell death *in vitro*, loss of cerebellar granule cells in a mouse model, and Parkinson’s and Huntington’s diseases (Clarke *et al.*, 2000). In this range of diseases, five different neuronal types are affected. In each of these cases, the rate of cell death is best fit by an exponential decay law with constant risk of death independent of age (death by chance only), arguing against models of progressive cell deterioration and aging (Clarke *et al.*, 2000, 2001a). An apparent lack of cell aging is also observed in the case of amyotrophic lateral sclerosis (Clarke *et al.*, 2001a), retinitis pigmentosa (Burns, 2002; Clarke *et al.*, 2000, 2001a; Massof, 1990) and idiopathic Parkinsonism (Calne, 1994; Clarke *et al.*, 2001b; Schulzer *et al.*, 1994). These observations correspond well with another observation that “an impressive range of cell functions in most organs remain unimpaired throughout the life span” (Finch, 1990, p. 425), and these unimpaired functions might reflect the “no-aging” property known as “old as good as new” property in survival

## 5. Models of Systems Failure in Aging

analysis (Klein and Moeschberger, 1997, p. 38). Thus we come to the following fundamental question about the origin of aging: How can we explain the aging of a system built of nonaging elements? This question invites us to think about the possible systemic nature of aging and to wonder whether aging may be a property of the system as a whole. We would like to emphasize the importance of looking at the bigger picture of the aging phenomenon in addition to its tiny details, and we will suggest a possible answer to the posed question in this chapter.

If failure rate increases with age, we have an *aging system* (component) that deteriorates (fails more often) with age. There are many failure laws for aging systems, and the most famous one in biology is the *Gompertz law* with exponential increase of the failure rates with age (Finch, 1990; Gavrilov and Gavrilova, 1991; Gompertz, 1825; Makeham, 1860; Strehler, 1978):

$$\mu(x) = Re^{\alpha x}$$

An exponential (Gompertzian) increase in death rates with age is observed for many biological species including fruit flies *Drosophila melanogaster* (Gavrilov and Gavrilova, 1991), nematodes (Brooks *et al.*, 1994; Johnson, 1987, 1990), mosquitoes (Gavrilov, 1980), human lice, *Pediculus humanus* (Gavrilov and Gavrilova, 1991), flour beetles, *Tribolium confusum* (Gavrilov and Gavrilova, 1991), mice (Kunstyr and Leuenberger, 1975; Sacher, 1977), rats (Gavrilov and Gavrilova, 1991), dogs (Sacher, 1977), horses (Strehler, 1978), mountain sheep (Gavrilov, 1980), baboons (Bronikowski *et al.*, 2002) and, perhaps most important, humans (Finch, 1990; Gavrilov and Gavrilova, 1991; Gompertz, 1825; Makeham, 1860; Strehler, 1978). According to the Gompertz law, the logarithm of failure rates increases linearly with age. This is often used in order to illustrate graphically the validity of the Gompertz law—the data are plotted in the semilog scale (known as the Gompertz plot) to check whether the logarithm of the failure rate is indeed increasing with age in a linear fashion.

For technical systems one of the most popular models for failure rate of aging systems is the Weibull model, the power-function increase in failure rates with age (Weibull, 1939):

$$\mu(x) = \alpha x^{\beta} \text{ for } x \geq 0, \text{ where } \alpha, \beta > 0$$

This law was suggested by Swedish engineer and mathematician W. Weibull in 1939 to describe the strength of materials (Weibull, 1939). It is widely used to describe aging and failure of technical devices (Barlow and Proschan, 1975; Rigdon and Basu, 2000; Weibull, 1951), and occasionally it was also applied to a limited number of biological species (Eakin *et al.*, 1995; Hirsch and Peretz, 1984; Hirsch *et al.*, 1994; Janse *et al.*, 1988; Ricklefs and Scheuerlein, 2002; Vanfleteren *et al.*, 1998). According to the Weibull law, the logarithm of failure rate increases linearly with the *logarithm* of age with a slope coefficient equal to parameter  $\beta$ . This is often

used in order to illustrate graphically the validity of the Weibull law—the data are plotted in the log–log scale (known as the Weibull plot) to check whether the logarithm of the failure rate is indeed increasing with the *logarithm* of age in a linear fashion.

We will show later that both the Gompertz and the Weibull failure laws have a fundamental explanation rooted in reliability theory. Therefore it may be interesting and useful to compare these two failure laws and their behavior.

Figure 5.1a presents the dependence of the logarithm of the failure rate on age (Gompertz plot) for the Gompertz and the Weibull functions.

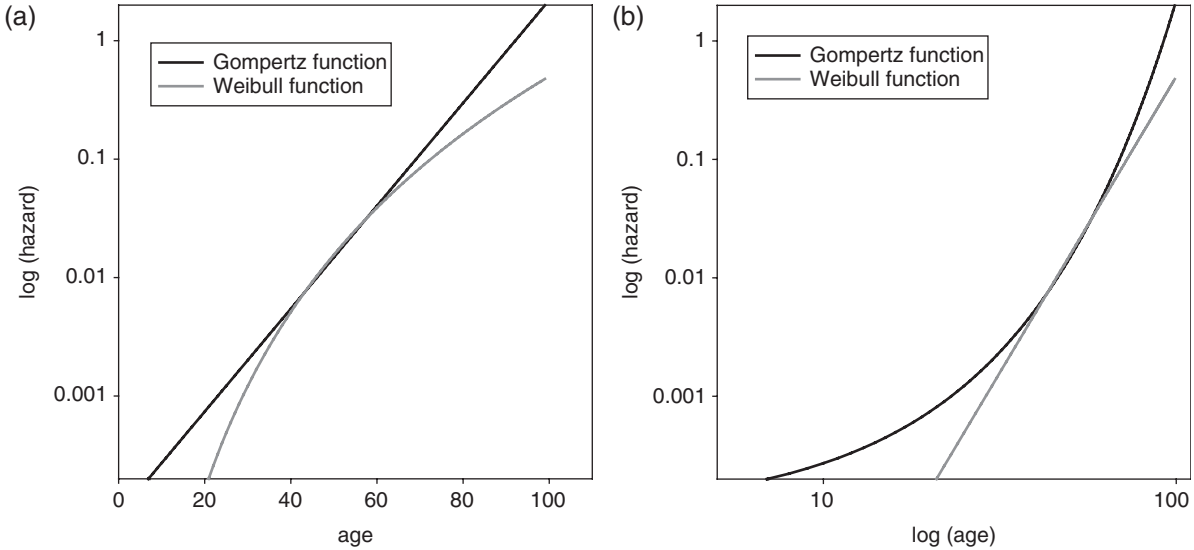

Note that in Figure 5.1a this dependence is strictly linear for the Gompertz function (as expected), and concave-down for the Weibull function. So the Weibull function looks like decelerating with age if compared to the Gompertz function.

Figure 5.1b presents the dependence of the logarithm of the failure rate on the *logarithm* of age (Weibull plot) for the Gompertz and the Weibull functions. Note that this dependence is strictly linear for the Weibull function (as expected), and concave-up for the Gompertz function. So the Gompertz function looks like the accelerating one with the *logarithm* of age if compared to the Weibull function.

There are two fundamental differences between the Weibull and the Gompertz functions.

First, the Weibull function states that the system is immortal at starting age—when the age  $X$  is equal to zero, the failure rate is equal to zero too, according to the Weibull formula. This means that the system should be initially ideal (immortal) in order for the Weibull law to be applicable to it. On the contrary, the Gompertz function states that the system is already vulnerable to failure at starting age—when the age  $X$  is equal to zero, the failure rate is already above zero, equal to parameter  $R$  in the Gompertz formula. This means that the partially damaged systems having some initial damage load are more likely to follow the Gompertz failure law, while the initially perfect systems are more likely to follow the Weibull law.

Second, there is a fundamental difference between the Gompertz and the Weibull functions regarding their response to misspecification of the starting age (“age zero”). This is an important issue, because in biology there is an ambiguity regarding the choice of a “true” age, when aging starts. Legally, it is the moment of birth, which serves as a starting moment for age calculation. However, from a biological perspective there are reasons to consider a starting age as a date either well before the birth date (the moment of conception in genetics, or a critical month of pregnancy in embryology), or long after the birth date (the moment of maturity, when the formation of a body is finally completed). This uncertainty in starting age has very different implications for data analysis with the Gompertz or the Weibull functions.

**Figure 5.1.** Plots of Gompertz and Weibull functions in different coordinates. (a) semilog (Gompertz) coordinates, (b) log-log (Weibull) coordinates. Source: Gavrilov and Gavrilova, 2005.

For the Gompertz function a misspecification of a starting age is not as important, because the shift in the age scale will still produce the same Gompertz function with the same slope parameter  $\alpha$ . The data generated by the Gompertz function with different age shifts will all be linear and parallel to each other in the Gompertz plot. The situation is very different for the Weibull function—it is linear in the Weibull plot for only one particular starting age, and any shifts in a starting age produce a different function. Specifically, if a “true” starting age is larger than assumed, then the resulting function will be a nonlinear concave-up curve in the Weibull plot indicating model misspecification and leading to a bias in estimated parameters. Thus, researchers choosing the Weibull function for data analysis have first to resolve an uneasy biological problem—at what age does aging start?

An alternative graceful mathematical solution of this problem would be to move from a standard two-parameter Weibull function to a more general three-parameter Weibull function, which has an additional “location parameter”  $\gamma$  (Clark, 1975):

$$\mu(x) = \alpha(x - \gamma)^\beta, \quad x > \gamma, \quad \text{and equal to zero otherwise}$$

Parameters of this formula, including the location parameter  $\gamma$ , could be estimated from the data through standard fitting procedures, thus providing a computational answer to a question “when does aging start?” However, this computational answer might be shocking to researchers, unless they are familiar with the concept of initial damage load, which is discussed elsewhere (Gavrilov and Gavrilova, 1991; 2001; 2004b; 2005).

In addition to the Gompertz and the standard two-parameter Weibull laws, a more general failure law was also suggested and theoretically justified using the systems

reliability theory. This law is known as the *binomial failure law* (Gavrilov and Gavrilova, 1991; 2001; 2005), and it represents a special case of the three-parameter Weibull function with a negative location parameter:

$$\mu(x) = \alpha(x_0 + x)^\beta$$

The parameter  $x_0$  in this formula is called the *initial virtual age of the system, IVAS* (Gavrilov and Gavrilova, 1991; 2001; 2005). This parameter has the dimension of time and corresponds to the age by which an initially ideal system would have accumulated as many defects as a real system already has at the starting age (at  $x = 0$ ). In particular, when the system is initially undamaged, the initial virtual age of the system is zero and the failure rate grows as a power function of age (the Weibull law). However, as the initial damage load is increasing, the failure kinetics starts to deviate from the Weibull law, and eventually it evolves to the Gompertz failure law at high levels of initial damage load. This is illustrated in Figure 5.2, which represents the Gompertz plot for the data generated by the binomial failure law with different levels of initial damage load (expressed in the units of initial virtual age).

Note that as the initial damage load increases the failure kinetics evolves from the concave-down curves typical to the Weibull function, to an almost linear dependence between the logarithm of failure rate and age (the Gompertz function). Thus, biological species dying according to the Gompertz law may have a high initial damage load, presumably because of developmental noise, and a clonal expansion of mutations occurred in the early development (Gavrilov and Gavrilova, 1991; 2001; 2003a; 2004b).

## 5. Models of Systems Failure in Aging

**Figure 5.2.** Failure kinetics of systems with different levels of initial damage. Dependence 1 is for initially ideal system (with no damage load). Dependence 2 is for system with initial damage load equivalent to damage accumulated by 20-year-old system. Dependencies 3 and 4 are for systems with initial damage load equivalent to damage accumulated respectively by 50-year-old and 100-year-old system. Source: Gavrilov and Gavrilova, 2005.

### SYSTEM'S FAILURE AND RELIABILITY STRUCTURE

A branch of reliability theory, which studies reliability of an entire system given the reliability of its components and components' arrangement (reliability structure), is called system reliability theory (Rausand and Hoyland, 2003). System reliability involves the study of the overall performance of systems of interconnected components. The main objective of system reliability is the construction of a model that represents the times-to-failure of the entire system based on the life distributions of the components, from which it is composed. Consideration of some basic ideas and models of the system reliability theory is important because living organisms may be represented as structured systems comprised of organs, tissues and cells.

System reliability theory tells us that the component arrangement strongly affects the reliability of the whole system. The arrangement of components that are important for system reliability is also called reliability structure and is graphically represented by a schema of logical connectivity. It is important to understand that the model of logical connectivity is focused only on those components that are relevant for the functioning ability of the system. Components that do not play a direct role in the system's reliability usually are not included in the analyzed reliability structure (Rausand and Hoyland, 2003). For example, organs of vision are not included in the reliability structure of living organisms if death is the only type of failure to be analyzed (complete failure of

vision does not cause an immediate death of the organism). On the other hand, if disability is the type of failure under consideration, then organs of vision should be included in the schema of reliability structure. Therefore, reliability structure does not necessarily reflect a physical structure of the object.

There are two major types of components arrangement (connection) in the system: components connected in series and components connected in parallel (Rausand and Hoyland, 2003). Here we consider a simple system of  $n$  statistically independent components, where failure of one component does not affect the failure rate of other components of the system.

#### *Components connected in series*

For a system of  $n$  independent components connected in series, the system fails if any one of the components fails, as in electrical circuits connected in series. Thus, failure of any one component results in failure of the whole system as in the Christmas tree lighting chains. Figure 5.3a shows a schema of the logical connectivity of the system in series.

This type of system is also called a weakest-link system (Ayyub and McCuen, 2003). In living organisms many organs and tissues (heart, lung, liver, brain) are vital for the organism's survival—a good example of series-connected components. Thus, the series connection means a logical connectivity, but not necessarily a physical or anatomical one.

The reliability of a system in series (with independent failure events of the components),  $P_s$ , is a product of reliabilities of its components:

$$P_s = p_1 p_2 \dots p_n$$

where  $p_1 \dots p_n$  are reliabilities of the system's components. This formula explains why complex systems with many critical components are so sensitive to early failures of their components.

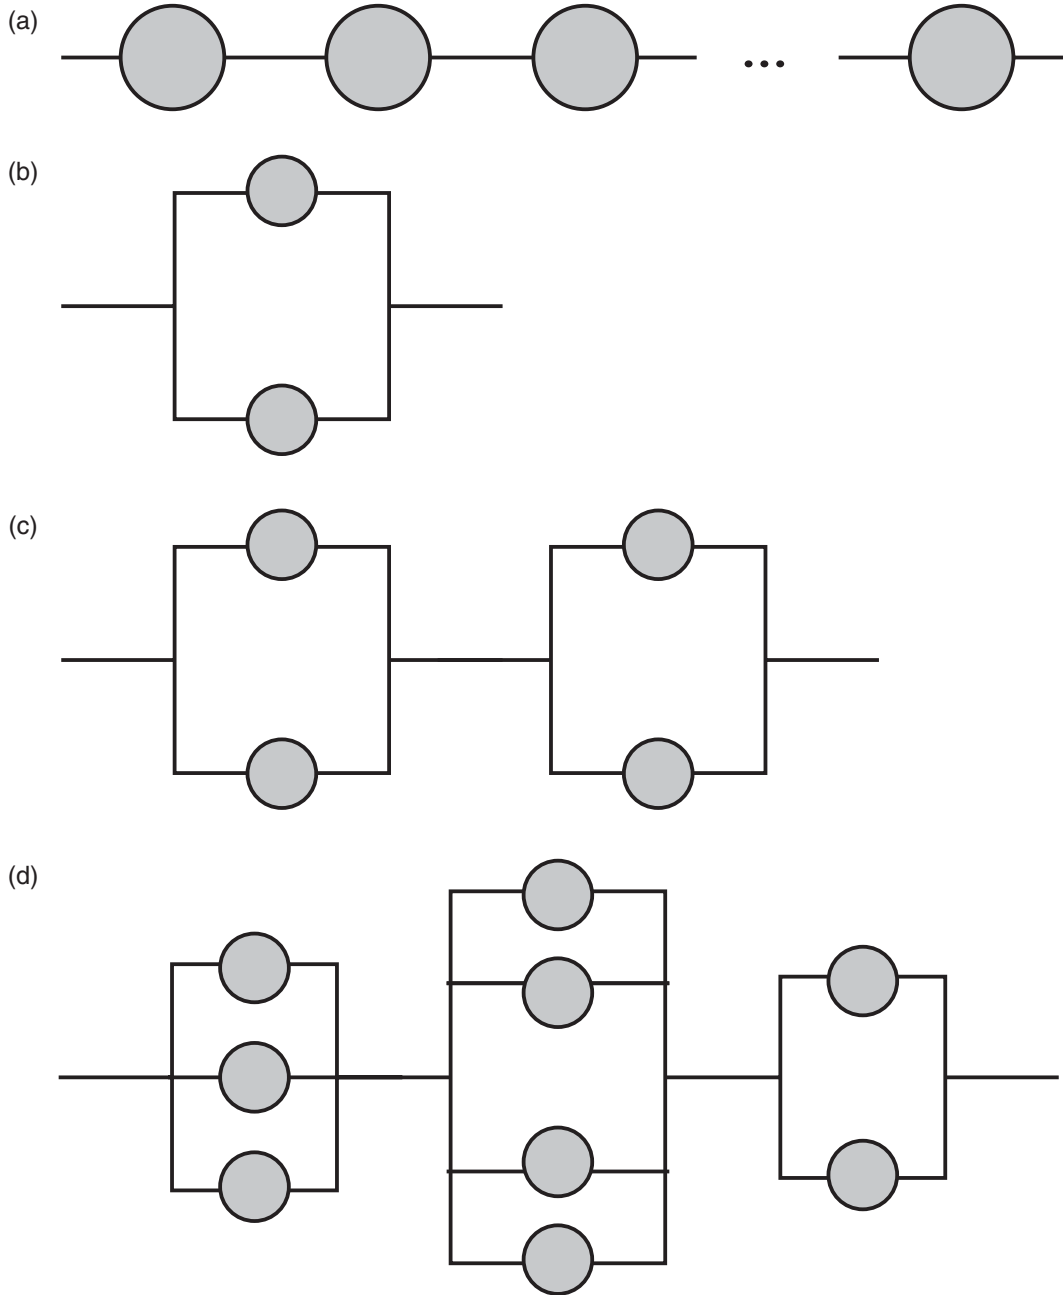

For example, for a system built of 458 critical components, the initial period of the components' life when their cumulative risk of failure is only 1% corresponds to the end of the system's life when 99% of systems have already failed. This difference between the lifetimes of systems and the potential lifetimes of their components is increasing further with system complexity (numbers of critical components). Therefore, the early failure kinetics of components is so important in determining the failure kinetics of a complex system for its entire life.

The failure rate of a system connected in series is the sum of failure rates of its components (Barlow *et al.*, 1965):

$$\mu_s = \mu_1 + \mu_2 + \mu_i \dots + \mu_n$$

If the failure rates of all components are equal, then the failure rate of the system with  $n$  components is  $n\mu$ . It follows from this formula that if the system's

**Figure 5.3.** Logical schemas of systems with different types of elements connectivity: (a) system connected in series, (b) system connected in parallel, (c) series-parallel system, (d) series-parallel system with distributed redundancy, Source: Gavrilov and Gavrilova, 2005.

components do not age ( $\mu_i = \text{const}$ ), then the entire system connected in series does not age either.

*Components connected in parallel*

A parallel system of a  $n$  independent components fails only when all the components fail (as in electrical circuits connected in parallel). The logical structure of parallel system is presented in Figure 5.3b.

An example of a parallel system is a system with components all performing an identical function. This function will be destroyed only in the case when all the components fail. The number of additional components in parallel structure with one and the same function is called the redundancy or reserve of the system. In living organisms vital organs and tissues (such as liver, kidney, or pancreas) consist of many cells performing one and the same specialized function.

## 5. Models of Systems Failure in Aging

For a parallel system with  $n$  independent components the probability of the system's failure,  $Q_s$ , is the product of the probabilities of failure for its components,  $q_i$ :

$$Q_s = q_1 q_2 \dots q_n$$

Hence the reliability of a parallel system,  $P_s$ , is related to the reliabilities of its components in the following way:

$$P_s = 1 - Q_s = 1 - (1 - p_1)(1 - p_2) \dots (1 - p_n)$$

The reliability of a parallel system with components of equal reliability,  $p$ , is

$$P_s = 1 - (1 - p)^n$$

What is very important is the emergence of aging in parallel systems—a parallel system is aging even if it is built of nonaging components with a constant failure rate (see more details in the section on causes of failure rate increase with age).

In a real world most systems are more complex than simply series and parallel structures, but in many cases they can be represented as combinations of these structures.

### *More complex types of reliability structure*

The simplest combination of the two reliability structures is a series-parallel system with equal redundancy shown in Figure 5.3c.

A general series-parallel system is a system of  $m$  subsystems (blocks) connected in series, where each block is a set of  $n$  components connected in parallel. It turns out that even if the components themselves are not aging, the system as a whole has an aging behavior—its failure rate grows with age according to the Weibull law and then levels off at advanced ages (Gavrilov and Gavrilova, 1991; 2001, 2003a). This type of system is important to consider, because a living organism can be presented as a system of critical organs and tissues connected in series, while each organ consists of specialized cells connected in parallel. A reliability model for this type of system is described in more detail in the section on causes of failure rate increase with age.

Another type of reliability structure, a series-parallel system with distributed redundancy, was introduced by Gavrilov and Gavrilova in 1991 (Gavrilov and Gavrilova, 1991; 2001). The series-connected blocks of this system have nonequal redundancy (different numbers of elements connected in parallel), and the elements are distributed between the system's blocks according to some particular distribution law (see schema in Figure 5.3d).

Gavrilov and Gavrilova (1991; 2001) studied the reliability and failure rate of series-parallel systems with distributed redundancy for two special cases: (1) the redundancy distributed within an organism according to the Poisson law or (2) according to the binomial law. They found that the failure rate of such systems initially grows according to the Gompertz law (in the case of the Poisson distributed redundancy) or binomial failure law in the

case of the binomially distributed redundancy (Gavrilov and Gavrilova, 1991; 2001). At advanced ages the failure rate for both systems asymptotically approaches an upper limit (mortality plateau). Reliability models for this type of system are described in more detail in the section on theoretical models of systems failure in aging.

Now that the basic concepts of reliability theory have been discussed, we may proceed to linking them to empirical observations on aging and mortality.

## Empirical Observations on Systems Failure in Aging

### GENERAL OVERVIEW OF FAILURE KINETICS

There is a striking similarity between living organisms and technical devices in the general age pattern of their failures—in both cases the failure rate usually follows the so-called bathtub curve (Figure 5.4).

The bathtub curve of failure rate is a classic concept presented in all textbooks on reliability theory (Ayyub and McCuen, 2003; Barlow and Proshian, 1975; Rausand and Hoyland, 2003).

The bathtub curve consists of three periods. Initially the failure rates are high and decrease with age. This period is called the “working-in” period and the period of “burning-out” of defective components. For example, the

**Figure 5.4.** Bathtub mortality curves for humans and fruit flies. Mortality is estimated on a daily basis; age is expressed in a median lifespan scale (a similar approach was used by Pearl and Miner, 1935 and Carnes *et al.*, 1998). Mortality for *Drosophila melanogaster* was calculated using data published by Hall (1969). Mortality for humans was calculated using the official Swedish female life table for 1985 (ages 0-80 years), and the 1980-90 decennial life table for Swedish females available in the Kannisto-Thatcher Database on Old Age Mortality, <http://www.demogr.mpg.de/databases/ktdb> (ages over 80 years), Source: Gavrilov and Gavrilova, 2005.

risk for a new computer to fail is often higher at the very start, but then those computers that did not fail initially work normally afterwards. The same period exists early in life for most living organisms, including humans, and it is called the “infant mortality” period. Then follows the second period called “the normal working period,” corresponding to an age of low and approximately constant failure rates. This period also exists in humans, but unfortunately it is rather short (10–15 years) and ends too soon. Then the third period, “the aging period,” starts, which involves an inexorable rise in the failure rate with age. In most living organisms, including humans, this rise in failure rates follows an explosive exponential trajectory (the Gompertz curve). For humans, the aging period lies approximately within the interval 20–100 years. Thus there is a remarkable similarity in the failure patterns of technical and biological systems. This similarity is reinforced further by the fact that at extreme old ages there is one more, the fourth period common to both technical devices and living organisms (Economos, 1979). This period is known in biology as a period of late-life mortality leveling-off (Carey and Liedo, 1995; Clark and Guadalupe, 1995; Economos, 1979; Fukui *et al.*, 1993; 1996; Vaupel *et al.*, 1998), and also as the late-life mortality deceleration law (Fukui *et al.*, 1993; 1996; Khazaeli *et al.*, 1996; Partridge and Mangel, 1999).

#### FAILURE LAWS IN SURVIVAL STUDIES

Attempts to develop a fundamental quantitative theory of aging, mortality, and lifespan have deep historical roots. In 1825, the British actuary Benjamin Gompertz discovered a law of mortality (Gompertz, 1825), known today as the Gompertz law (Finch, 1990; Gavrilov and Gavrilova, 1991; Olshansky and Carnes, 1997; Strehler, 1978). Specifically, he found that the force of mortality increases in geometrical progression with the age of adult humans. According to the Gompertz law, human mortality rates double about every 8 years of adult age.

Gompertz also proposed the first mathematical model to explain the exponential increase in mortality rate with age (Gompertz, 1825). In reality, system failure rates may contain both nonaging and aging terms as, for example, in the case of the *Gompertz–Makeham law* of mortality (Finch, 1990; Gavrilov and Gavrilova, 1991; Makeham, 1860; Strehler, 1978):

$$\mu(x) = A + Re^{\alpha x}$$

In this formula the first, age-independent term (Makeham parameter,  $A$ ) designates the constant, “non-aging” component of the failure rate (presumably due to external causes of death, such as accidents and acute infections), while the second, age-dependent term (the Gompertz function,  $Re^{\alpha x}$ ) designates the “aging” component, presumably due to deaths from age-related degenerative diseases like cancer and heart disease.

The validity of the Gompertz–Makeham law of mortality can be illustrated graphically, when the logarithms of death rates without the Makeham parameter ( $\mu_x - A$ ) are increasing with age in a linear fashion. The log–linear increase in death rates (adjusted for the Makeham term) with age is indeed a very common phenomenon for many human populations at ages 35–70 years (Gavrilov and Gavrilova, 1991).

Note that the slope coefficient  $\alpha$  characterizes an “apparent aging rate” (how rapid is the age-deterioration in mortality)—if  $\alpha$  is equal to zero, there is no apparent aging (death rates do not increase with age).

At advanced ages (after age 70), the “old-age mortality deceleration” takes place—death rates are increasing with age at a slower pace than expected from the Gompertz–Makeham law. This mortality deceleration eventually produces “late-life mortality leveling-off” and “late-life mortality plateaus” at extreme old ages (Curtisinger *et al.*, 1992; Economos, 1979; 1983; Gavrilov and Gavrilova, 1991; Greenwood and Irwin, 1939; Vaupel *et al.*, 1998). Actuaries (including Gompertz himself) first noted this phenomenon and proposed a logistic formula for mortality growth with age in order to account for mortality fall-off at advanced ages (Perks, 1932; Beard, 1959; 1971). Greenwood and Irwin (1939) provided a detailed description of this phenomenon in humans and even made the first estimates for the asymptotic value of human mortality (see also review by Olshansky, 1998). According to their estimates, the mortality kinetics of long-lived individuals is close to the law of radioactive decay with half-time approximately equal to 1 year.

The same phenomenon of “almost nonaging” survival dynamics at extreme old ages is detected in many other biological species. In some species the mortality plateau can occupy a sizable part of their life (see Figure 5.5).

Biologists have been well aware of mortality leveling-off since the 1960s. For example, Lindop (1961) and Sacher (1966) discussed mortality deceleration in mice. Strehler and Mildvan (1960) considered mortality deceleration at advanced ages as a prerequisite for all mathematical models of aging to explain. Later A. Economos published a series of articles claiming a priority in the discovery of a “non-Gompertzian paradigm of mortality” (Economos, 1979; 1980; 1983; 1985). He found that mortality leveling-off is observed in rodents (guinea pigs, rats, mice) and invertebrates (nematodes, shrimps, bdelloid rotifers, fruit flies, degenerate medusae *Campanularia Flexuosa*). In the 1990s the phenomenon of mortality deceleration and leveling-off became widely known after some publications demonstrated mortality leveling-off in large samples of *Drosophila melanogaster* (Curtisinger *et al.*, 1992) and medflies *Ceratitis capitata* (Carey *et al.*, 1992), including isogenic strains of *Drosophila* (Curtisinger *et al.*, 1992; Fukui *et al.*, 1993; 1996). Mortality plateaus at advanced ages are observed for some other insects: house fly *Musca vicina* and blowfly *Calliphora erythrocephala* (Gavrilov, 1980), bruchid

## 5. Models of Systems Failure in Aging

**Figure 5.5.** Mortality leveling-off in a population of 4,650 male house flies. Hazard rates were computed using life table of house fly, *Musca domestica*, published by Rockstein and Lieberman (1959). Source: Gavrilov and Gavrilova, 2005.

beetle *Callosobruchus maculatus* (Tatar *et al.*, 1993), fruit flies *Anastrepha ludens*, *Anastrepha obliqua*, *Anastrepha serpentina* and a parasitoid wasp *Diachasmimorpha longicaudis* (Vaupel *et al.*, 1998).

Interestingly, the failure kinetics of manufactured products (steel samples, industrial relays, and motor heat insulators) also demonstrates the same “nonaging” pattern at the end of their “lifespan” (Economos, 1979). This phenomenon is presenting a theoretical challenge to many models and theories of aging. One interesting corollary from these intriguing observations is that there seems to be no fixed upper limit for individual lifespan (Gavrilov, 1984; Gavrilov and Gavrilova, 1991; Wilmoth, 1997).

This observation calls for a very general explanation of this apparently paradoxical “no aging at extreme ages” phenomenon, which will be discussed in this chapter.

Another empirical observation, the *compensation law of mortality*, in its strong form refers to *mortality convergence*, when higher values for the parameter  $\alpha$  (in the Gompertz function) are compensated by lower values of the parameter  $R$  in different populations of a given species:

$$\ln(R) = \ln(M) - B\alpha$$

where  $B$  and  $M$  are universal species-specific invariants. Sometimes this relationship is also called the Strehler-Mildvan correlation (Strehler, 1978; Strehler and Mildvan, 1960), although that particular correlation was largely an artifact of the opposite biases in parameters estimation caused by not taking into account the age-independent mortality component, the Makeham

**Figure 5.6.** Compensation Law of Mortality. Convergence of mortality rates in different populations at advanced ages. Death rates (with removed age-independent external mortality component) are plotted in a log scale as a function of age in the following countries: 1 – India, 1941–1950, males. 2 – Turkey, 1950–1951, males. 3 – Kenya, 1969, males. 4 – Northern Ireland, 1950–1952, males. 5 – England and Wales, 1930–1932, females. 6 – Austria, 1959–1961, females. 7 – Norway, 1956–1960, females. Adapted from Gavrilov and Gavrilova, “The Biology of Life Span,” 1991.

term  $A$  (see Gavrilov and Gavrilova, 1991; Golubev, 2004). Parameter  $B$  is called the species-specific lifespan (95 years for humans), and parameter  $M$  is called the species-specific mortality rate ( $0.5 \text{ year}^{-1}$  for humans). These parameters are the coordinates for convergence of all the mortality trajectories into one single point (within a given biological species), when extrapolated by the Gompertz function (Gavrilov and Gavrilova, 1979; 1991). This means that high mortality rates in disadvantaged populations (within a given species) are *compensated* for by a low apparent “aging rate” (longer mortality doubling period). As a result of this compensation, the relative differences in mortality rates tend to decrease with age within a given biological species (Figure 5.6).

In those cases when the compensation law of mortality is not observed in its strong form, it may still be valid in its weak form—i.e., the relative differences in mortality rates of compared populations tend to decrease with age in many species. Explanation of the compensation law of mortality is a great challenge for many theories of aging and longevity (Gavrilov and Gavrilova, 1991; Strehler, 1978).

There are some exceptions from both the Gompertz law of mortality and the compensation law of mortality

that have to be understood and explained. There were reports that in some cases the organisms die according to the Weibull (power) law (see the section on basic failure models). The Weibull law is more commonly applicable to technical devices (Barlow and Proschan, 1975; Rigdon and Basu, 2000; Weibull, 1951), while the Gompertz law is more common in biological systems (Finch, 1990; Gavrilov and Gavrilova, 1991; Strehler, 1978). As was already noted, the exponential Gompertzian increase in age-specific mortality is observed for many biological species including fruit flies *Drosophila melanogaster*, nematodes, mosquitoes, human lice, flour beetles, mice, rats, dogs, horses, mountain sheep, baboons and humans. Comparative meta-analysis of 129 life tables for fruit flies as well as 285 life tables for humans demonstrates that the Gompertz law of mortality provides a much better data fit for each of these two biological species, compared to the Weibull law (Gavrilov and Gavrilova, 1991, pp. 55–56, 68–72). Possible explanations why organisms prefer to die according to the Gompertz law, while technical devices typically fail according to the Weibull law are provided elsewhere (Gavrilov and Gavrilova, 1991; 2001; 2005) and will be discussed later in this chapter (see the section on theoretical models of systems failure in aging).

Both the Gompertz and the Weibull failure laws have a fundamental explanation rooted in reliability theory (Barlow and Proschan, 1975) and are the only two theoretically possible *limiting extreme value distributions* for systems whose lifespans are determined by the first failed component (Gumbel, 1958; Galambos, 1978). In other words, as the system becomes more and more complex (contains more vital components, each being critical for survival), its lifespan distribution may asymptotically approach one of the only two theoretically possible limiting distributions—either Gompertz or Weibull (depending on the early kinetics of failure of system components). The two limit theorems in the statistics of extremes (Gumbel, 1958; Galambos, 1978) make the Gompertz and the Weibull failure laws as fundamental as are some other famous limiting distributions known in regular statistics, e.g., the normal distribution and the Poisson distribution. It is puzzling, however, why organisms prefer to die according to the Gompertz law, while technical devices typically fail according to the Weibull law. One possible explanation of this mystery is suggested later in this chapter.

Thus, a comprehensive theory of species aging and longevity should provide answers to the following questions:

1. Why do most biological species deteriorate with age (i.e., die more often as they grow older) while some primitive organisms do not demonstrate such a clear mortality growth with age (Austad, 2001; Finch, 1990; Haranghy and Balázs, 1980; Martinez, 1998)?
2. Specifically, why do mortality rates increase exponentially with age in many adult species (Gompertz law)? How should we handle cases when the Gompertzian mortality law is not applicable?
3. Why does the age-related increase in mortality rates vanish at older ages? Why do mortality rates eventually decelerate compared to predictions of the Gompertz law, occasionally demonstrate leveling-off (late-life mortality plateau), or even a paradoxical decrease at extreme ages?
4. How do we explain the so-called compensation law of mortality (Gavrilov and Gavrilova, 1991)?

Any theory of human aging has to explain these last three rules, known collectively as mortality, or failure, laws. And reliability theory, by way of a clutch of equations, covers all of them (see the section on theoretical models of systems failure in aging, and Gavrilov and Gavrilova, 1991, 2001, 2005).

## DECLINE IN SYSTEMS' REDUNDANCY WITH AGE

Many age changes in living organisms can be explained by cumulative effects of cell loss over time. For example, the very common phenomenon of hair graying with age is caused by depletion of hair follicle melanocytes (Commo *et al.*, 2004). Melanocyte density in human epidermis declines gradually with age at a rate approximately 0.8% per year (Gilchrest *et al.*, 1979). Hair graying is a relatively benign phenomenon, but cell loss can also lead to more serious consequences.

Recent studies found that such conditions as atherosclerosis, atherosclerotic inflammation, and consequent thromboembolic complications could be linked to age-related exhaustion of progenitor cells responsible for arterial repair (Goldschmidt-Clermont, 2003; Libby, 2003; Rauscher *et al.*, 2003). Taking these progenitor cells from young mice and adding them to experimental animals prevents atherosclerosis progression and atherosclerotic inflammation (Goldschmidt-Clermont, 2003; Rauscher *et al.*, 2003).

Age-dependent decline in cardiac function is also linked to the failure of cardiac stem cells to replace dying myocytes with new functioning cells (Capogrossi, 2004). It was found that aging-impaired cardiac angiogenic function could be restored by adding endothelial precursor cells derived from the young bone marrow (Edelberg *et al.*, 2002).

Chronic renal failure is known to be associated with decreased number of endothelial progenitor cells (Choi *et al.*, 2004). People with diminished numbers of nephrons in their kidneys are more likely to suffer from hypertension (Keller *et al.*, 2003), and the number of glomeruli decreases with human age (Nyengaard and Bendtsen, 1992).

Humans generally lose 30–40% of their skeletal muscle fibers by age 80 (Leeuwenburgh, 2003), which

contributes to such adverse health outcomes as sarcopenia and frailty. Loss of striated muscle cells in such places as rhabdosphincter from 87.6% in a 5-week-old child to only 34.2% in a 91-year-old has obvious implications for urological failure—incontinence (Strasser, 2000).

A progressive loss of dopaminergic neurons in substantia nigra results in Parkinson's disease, loss of GABAergic neurons in striatum produces Huntington's disease, loss of motor neurons is responsible for amyotrophic lateral sclerosis, and loss of neurons in cortex causes Alzheimer's disease over time (Baizabal *et al.*, 2003). A study of cerebella from normal males aged 19–84 years revealed that the global white matter was reduced by 26% with age, and a selective 40% loss of both Purkinje and granule cells was observed in the anterior lobe. Furthermore a 30% loss of volume, mostly due to a cortical volume loss, was found in the anterior lobe, which is predominantly involved in motor control (Andersen *et al.*, 2003).

The phenomenon of human aging of menopause also is caused by loss of ovarian cells. For example, the female human fetus at age 4–5 months possesses 6–7 million eggs (oocytes). By birth, this number drops to 1–2 million and declines even further. At the start of puberty in normal girls, there are only 0.3–0.5 million eggs—just only 4–8% of initial numbers (Gosden, 1985; Finch and Kirkwood, 2000; Wallace and Kelsey, 2004). It is now well established that the exhaustion of the ovarian follicle numbers over time is responsible for menopause (reproductive aging and failure), and women having higher ovarian reserve have longer reproductive lifespans (Wallace and Kelsey, 2004). When young ovaries were transplanted to old post-reproductive mice, their reproductive function was restored for a while (Cargill *et al.*, 2003). This example illustrates a general idea that aging largely occurs because of cell loss, which starts early in life.

Loss of cells with age is not limited to the human species and is observed in other animals as well. For example, a nematode *C. elegans* demonstrates a gradual, progressive deterioration of muscle, resembling human sarcopenia (Herndon *et al.*, 2002). The authors of this study also found that the behavioral ability of nematodes was a better predictor of life expectancy than chronological age.

Interestingly, caloric restriction can prevent cell loss (Cohen *et al.*, 2004; McKiernan *et al.*, 2004), which may explain why caloric restriction delays the onset of numerous age-associated diseases and can significantly increase lifespan in mammals (Masoro, 2003).

In terms of reliability theory the loss of cells with age is a loss of system redundancy, and therefore this chapter will focus further on the effects of redundancy loss on systems aging and failure.

## Causes of Failure Rate Increase with Age

### THE ORIGIN OF AGE-RELATED INCREASE IN FAILURE RATES

The aging period for most species occupies the greater part of their lifespan; therefore any model of mortality must explain the existence of this period. It turns out that the phenomena of mortality increase with age and the subsequent mortality leveling-off are theoretically predicted to be an inevitable feature of all reliability models that consider aging as a progressive accumulation of random damage (Gavrilov and Gavrilova, 1991). The detailed mathematical proof of this prediction for some particular models is provided elsewhere (Gavrilov and Gavrilova, 1991; 2001) and is briefly described in the next sections of this chapter.

The simplest schema, which demonstrates an emergence of aging in a redundant system, is presented in Figure 5.7.

If the destruction of an organism occurs not in one but in two or more sequential random stages, this is sufficient for the phenomenon of aging (mortality increase) to appear and then to vanish at older ages. Each stage of destruction corresponds to one of the organism's vitally important structures being damaged. In the simplest organisms with unique critical structures, this damage usually leads to death. Therefore, defects in such organisms do not accumulate, and the organisms themselves do not age—they just die when damaged. For example, the inactivation of microbial cells and spores exposed to a hostile environment (such as heat) follows approximately a nonaging mortality kinetics; their semilogarithmic survival curves are almost linear (Peleg *et al.*, 2003). This observation of nonaging survival

**Figure 5.7.** Redundancy creates both damage tolerance and damage accumulation (aging). Systems without redundancy (on the top) fail every time when they are damaged, and therefore damage is not accumulated among survivors (no aging). Redundant systems (on the bottom) can sustain damage because of their redundancy, but this damage tolerance leads to damage accumulation (aging).

dynamics is extensively used in the calculation of the efficacy of sterilization processes in medicine and food preservation (Brock *et al.*, 1994; Davis *et al.*, 1990; Jay, 1996). A similar nonaging pattern of inactivation kinetics is often observed for viruses (Andreadis and Palsson, 1997; Kundi, 1999) and enzymes (Kurganov, 2002; Gouda *et al.*, 2003).

In more complex systems with many vital structures and significant redundancy, every occurrence of damage does not lead to death (unless the environment is particularly hostile) because of their redundancy. Defects accumulate, therefore, giving rise to the phenomenon of aging (mortality increase). Thus, aging is a direct consequence (trade-off) of a system's redundancies, which ensure increased reliability and an increased lifespan of more complex organisms. As defects accumulate, the redundancy in the number of elements finally disappears. As a result of this *redundancy exhaustion*, the organism degenerates into a system with no redundancy (that is, a system with elements connected in series, in which any new defect leads to death). In such a state, no further accumulation of damage can be achieved, and the mortality rate levels off.

Reliability theory predicts that a system may deteriorate with age even if it is built from nonaging elements with a constant failure rate. The key issue here is the system's redundancy for irreplaceable elements, which is responsible for the aging phenomenon. In other words, each particular step of system destruction/deterioration may seem to be apparently random (no aging, just occasional failure by chance), but if a system failure requires a sequence of several such steps (not just a single step of destruction), then the system as a whole may have an aging behavior.

The positive effect of systems' redundancy is *damage tolerance*, which decreases the risk of failure (mortality) and increases lifespan. However damage tolerance makes it possible for damage to be tolerated and accumulated over time, thus producing the aging phenomenon.

The next section provides a mathematical illustration for these ideas.

## THE SIMPLEST RELIABILITY MODEL OF AGING

In this section we show that a system built of nonaging components demonstrates an aging behavior (mortality growth with age) and subsequent mortality leveling-off.

Consider a parallel system built of  $n$  nonaging elements with a constant failure rate  $\mu$  and reliability (survival) function  $e^{-\mu x}$  (see also Figure 5.3b). We already showed (see the system's failure and reliability structure section) that in this case the reliability function of the entire parallel system is

$$S(x) = 1 - (1 - p)^n = 1 - (1 - e^{-\mu x})^n$$

This formula corresponds to the simplest case when the failure of elements is statistically independent. More

complex models would require specific assumptions or prior knowledge on the exact type of interdependence in elements failure. One such model known as "the model of the avalanche-like destruction" is described elsewhere (see pp. 246–251 in Gavrilov, Gavrilova, 1991) and is briefly summarized in the theoretical models of systems failure in aging section.

Consequently, the failure rate of the entire system  $\mu_s(x)$ , can be written as follows:

$$\begin{aligned} \mu_s(x) &= \frac{-dS(x)}{S(x)dx} = \frac{n\mu e^{-\mu x}(1 - e^{-\mu x})^{n-1}}{1 - (1 - e^{-\mu x})^n} \\ &\approx n\mu^n x^{n-1} \end{aligned}$$

when  $x \ll 1/\mu$  (early-life period approximation, when  $1 - e^{-\mu x} \approx \mu x$ );

$$\approx \mu$$

when  $x \gg 1/\mu$  (late-life period approximation, when  $1 - e^{-\mu x} \approx 1$ ).

Thus, the failure rate of a system initially grows as a power function  $n$  of age (the Weibull law). Then the tempo at which the failure rate grows declines, and the failure rate approaches asymptotically an upper limit equal to  $\mu$ .

Here we should pay attention to three significant points. First, a system constructed of nonaging elements is now behaving like an aging object: aging is a direct consequence of the redundancy of the system (redundancy in the number of elements). Second, at very high ages the phenomenon of aging apparently disappears (failure rate levels off), as redundancy in the number of elements vanishes. The failure rate approaches an upper limit, which is totally independent of the initial number of elements, but coincides with the rate of their loss (parameter  $\mu$ ). Third, the systems with different initial levels of redundancy (parameter  $n$ ) will have very different failure rates in early life, but these differences will eventually vanish as failure rates approach the upper limit determined by the rate of elements' loss (parameter  $\mu$ ). Thus, the compensation law of mortality (in its weak form) is an expected outcome of this illustrative model.

Note also that the identical parallel systems in this example do not die simultaneously when their elements fail by chance. A common view in biology is the idea that all the members of homogeneous population in a hypothetical constant environment should die simultaneously so that the survival curve of such a population would look like a rectangle. This idea stems from the basic principles of quantitative genetics, which assume implicitly that every animal of a given genotype has the same genetically determined lifespan so that all variation of survival time around a genotype mean results from the environmental variance. George Sacher (1977) pointed out that this concept is not applicable to longevity and used an analogy with radioactive decay in his arguments.

## 5. Models of Systems Failure in Aging

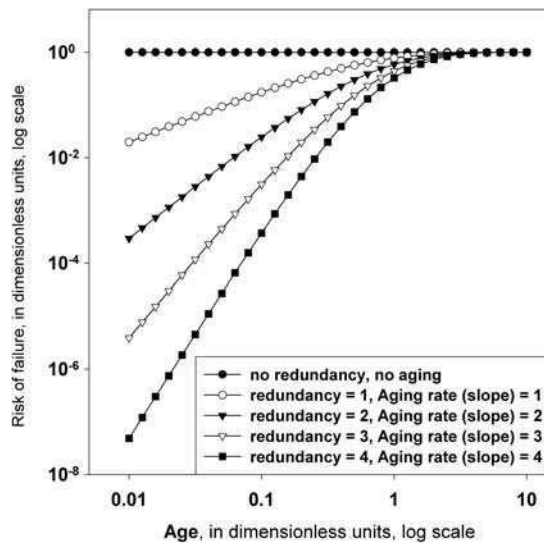

Even the simplest parallel system has a specific lifespan distribution determined entirely by a stochastic nature of the aging process. In order to account for this stochasticity it was proposed to use a stochastic variance component of lifespan in addition to genetic and environmental components of phenotypic lifespan variance (Gavrilov and Gavrilova, 1991). The stochastic nature of the system's destruction also produces heterogeneity in an initially homogeneous population. This kind of induced heterogeneity was observed in isogenic strains of nematodes, in which aging resulted in substantial heterogeneity in behavioral capacity among initially homogeneous worms kept in controlled environmental conditions (Herndon *et al.*, 2002).

The graph shown in Figure 5.8 depicts mortality trajectories for five systems with different degrees of redundancy.

System 1 has only one unique element (no redundancy), and it has the highest failure rate, which does not depend on age (no aging). System 2 has two elements connected in parallel (one extra element is redundant), and the failure rate initially increases with age (aging

appears). The apparent rate of aging can be characterized by a slope coefficient that is equal to 1. Finally, the failure rate levels off at advanced ages. Systems 3, 4, and 5 have, respectively, three, four, and five elements connected in parallel (two, three, and four extra elements are redundant), and the failure rate initially increases with age at an apparent aging rate (slope coefficient) of 2, 3, and 4, respectively. Finally, the mortality trajectories of each system level off at advanced ages at exactly the same upper limit to the mortality rate.

This computational example illustrates the following statements: (1) Aging is a direct consequence of a system's redundancy, and the expression of aging is directly related to the degree of a system's redundancy. Specifically, an apparent relative aging rate is equal to the degree of redundancy in parallel systems. (2) All mortality trajectories tend to converge with age, so that the compensation law of mortality is observed. (3) All mortality trajectories level off at advanced ages, and a mortality plateau is observed. Thus, the major aging phenomena (aging itself, the compensation law of mortality, late-life mortality deceleration, and late-life mortality plateaus) are already observed in the simplest redundant systems. However, to explain the Gompertz law of mortality, an additional idea of initial damage load should be taken into account (see next section).

**Figure 5.8.** Failure kinetics of systems with different levels of redundancy. The dependence of the logarithm of mortality force (failure rate) on the logarithm of age in five systems with different levels of redundancy (computer simulation experiment). The scales for mortality rates (vertical axis) and for age (horizontal axis) are presented in dimensionless units ( $\mu_s/\mu$  for mortality rates, and  $\mu x$  for age), to ensure the generalizability of the results (invariance of graphs on failure rate of the elements in the system, parameter  $\mu$ ). Also, the log scale is used to explore the system behavior in a wide range of ages (0.01–10 units) and failure rates (0.00000001–1.0 units). Dependence 1 is for the system containing only one unique element (no redundancy). Dependence 2 is for the system containing two elements connected in parallel (degree of redundancy = 1). Dependencies 3, 4 and 5 are for systems containing, respectively, 3, 4 and 5 elements connected in parallel (with increasing levels of redundancy). Source: Gavrilov and Gavrilova, 2005.

### Theoretical Models of Systems Failure in Aging

#### HIGHLY REDUNDANT SYSTEM REPLETE WITH DEFECTS

It was demonstrated in the previous section that the failure rate of a simple parallel system grows with age according to the Weibull law. This model analyzed initially ideal structures in which all the elements are functional from the outset. This standard assumption may be justified for technical devices manufactured from pretested components, but it is not justified for living organisms, replete with initial defects (see Gavrilov and Gavrilova, 1991; 2001; 2004b; 2005).

Following the tradition of the reliability theory, we start our analysis with reliability of an individual system (or homogeneous population). This model of series-parallel structure with distributed redundancy was suggested by Gavrilov and Gavrilova in 1991 and described in more detail in 2001.

Consider first a series-parallel model in which initially functional elements occur very rarely with low probability  $q$ , so that the distribution of the organism's subsystems (blocks) according to the initial functioning elements they contain is described by the Poisson law with parameter  $\lambda = nq$ . Parameter  $\lambda$  corresponds to the mean number of initially functional elements in a block.

As has already been noted, the failure rate of a system constructed out of  $m$  blocks connected in series is equal to the sum of the failure rates of these blocks,  $\mu_b$  (Barlow *et al.*, 1965):

$$\mu_s = \sum \mu_b = \sum_{i=1}^n m P_i \mu_b(i) = m C e^{-\lambda} \sum_{i=1}^n \frac{\lambda^i \mu_b(i)}{i!}$$

where  $P_i$  is the probability of a block to have  $i$  initially functioning elements. Parameter  $C$  is a normalizing factor that ensures the sum of the probabilities of all possible outcomes being equal to unity (see Gavrilov, Gavrilova, 1991; 2001). For sufficiently high values of  $n$  and  $\lambda$ , the normalizing factor turns out to be hardly greater than unity.

Using the formula for failure rate of a block of elements connected in parallel (see the simplest reliability model of aging section), we obtain the final expression for the series-parallel system with distributed redundancy:

$$\mu_s = \mu \lambda m C e^{-\lambda} \sum_{i=1}^n \frac{(\lambda \mu x)^{i-1}}{(i-1)!} \approx R(e^{\alpha x} - \varepsilon(x)) \approx R e^{\alpha x}$$

where  $R = C m \lambda \mu e^{-\lambda}$ ,  $\alpha = \lambda \mu$

$\varepsilon(x)$  is close to zero for large  $n$  and small  $x$  (initial period of life; see Gavrilov, Gavrilova, 1991, 2001 for more detail).

In the early-life period (when  $x \ll 1/\mu$ ) the mortality kinetics of this system follows the exponential Gompertzian law.

In the late-life period (when  $x \gg 1/\mu$ ), the failure rate levels off and the mortality plateau is observed:

$$\mu_s(x) \approx m \mu$$

If the age-independent mortality ( $A$ ) also exists in addition to the Gompertz function, we obtain the well-known Gompertz–Makeham law described earlier. At advanced ages the rate of mortality decelerates and approaches asymptotically an upper limit equal to  $m\mu$ .

The model explains not only the exponential increase in mortality rate with age and the subsequent leveling-off, but also the compensation law of mortality:

$$\ln(R) = \ln(Cm\alpha) - \frac{\alpha}{\mu} = \ln(M) - B\alpha$$

where  $M = Cm\alpha$ ,  $B = 1/\mu$ .

According to this model, the compensation law is inevitable whenever differences in mortality arise from differences in the parameter  $\lambda$  (the mean number of initially functional elements in the block), while the “true aging rate” (rate of elements’ loss,  $\mu$ ) is similar in different populations of a given species (presumably because of homeostasis). In this case, the species-specific lifespan estimated from the compensation law as an expected age at mortality convergence (95 years for humans, see Gavrilov and Gavrilova, 1991) characterizes the mean lifetime of the elements ( $1/\mu$ ).

The model also predicts certain deviations from the exact mortality convergence in a specific direction because the parameter  $M$  proved to be a function of the parameter  $\alpha$  according to this model (see earlier). This prediction could be tested in future studies.

It also follows from this model that even small progress in optimizing the processes of ontogenesis and increasing the numbers of initially functional elements ( $\lambda$ ) can potentially result in a remarkable fall in mortality and a significant improvement in lifespan.

The model assumes that most of the elements in the system are initially nonfunctional. *This interpretation of the assumption can be relaxed, however, because most nonfunctional elements (e.g., cells) may have already died and been eliminated by the time the adult organism is formed.* In fact, the model is based on the hypothesis that the number of *functional* elements in the blocks is described by the Poisson distribution, and the fate of defective elements and their death in no way affects the conclusions of the model. Therefore, the model may be reformulated in such a way that stochastic events in early development determine later-life aging and survival through variation in initial redundancy of organs and tissues (see, for example, Finch and Kirkwood, 2000). Note that this model does not require an assumption of initial population heterogeneity in failure risks. Instead the model is focused on distributed redundancy of physiological systems within a given organism, or a group of initially identical organisms.

## PARTIALLY DAMAGED REDUNDANT SYSTEM

In the preceding section, we examined a reliability model for a system consisting of  $m$  series-connected blocks with numbers of elements distributed according to the Poisson law. In this section, we consider a more general case in which the probability of an element being initially functional can take any possible value:  $0 < q \leq 1$  (see Gavrilov and Gavrilova, 1991; 2001 for more detail).

In the general case, the distribution of blocks in the organism according to the number of initially functional elements is described by the binomial rather than Poisson distribution.

If an organism can be presented as a system constructed of  $m$  series-connected blocks with binomially distributed elements, its failure rate is given by the following formula:

$$\mu_s \approx C m n (q\mu)^n \left[ \frac{1-q}{q\mu} + x \right]^{n-1} = C m n (q\mu)^n (x_0 + x)^{n-1}$$

$$\text{where } x_0 = \frac{1-q}{q\mu}$$

It is proposed to call a parameter  $x_0$  the *initial virtual age of the system, IVAS* (Gavrilov and Gavrilova, 1991; 2001). Indeed, this parameter has the dimension of time, and corresponds to the age by which an initially ideal system would have accumulated as many defects as a real

## 5. Models of Systems Failure in Aging

system already has at the initial moment in time (at  $x = 0$ ). In particular, when  $q = 1$ , i.e., when all the elements are functional at the beginning, the initial virtual age of the system is zero and the failure rate grows as a power function of age (the Weibull law), as described in the causes of failure rate increase with age section. However, when the system is not initially ideal ( $q < 1$ ), we obtain the *binomial law of mortality* (see basic failure models).

In the case when  $x_0 > 0$ , there is always an initial period of time, such that  $x \ll x_0$  and the following approximation to the binomial law is valid:

$$\begin{aligned} \mu_s &\approx Cmn(q\mu)^n x_0^{n-1} \left[ 1 + \frac{x}{x_0} \right]^{n-1} \\ &\approx Cmn(q\mu)^n x_0^{n-1} \exp \left[ \frac{n-1}{x_0} x \right] \end{aligned}$$

Hence, for any value of  $q < 1$  there always exists a period of time  $x$  when the number of newly formed defects is much less than the original number, and the failure rate grows exponentially with age.

So, if the system is not initially ideal ( $q < 1$ ), the failure rate in the initial period of time grows exponentially with age according to the Gompertz law. A numerical example provided in Figure 5.2 (see the reliability approach to system's failure in aging section) shows that increase in the initial system's damage load (initial virtual age) converts the observed mortality trajectory from the Weibull to the Gompertz one.

The model discussed here not only provides an explanation for the exponential increase in the failure rate with age, but it also explains the compensation law of mortality (see Gavrilov and Gavrilova, 1991; 2001).

The compensation law of mortality is observed whenever differences in mortality are caused by differences in initial redundancy (the number of elements in a block,  $n$ ), while the other parameters, including the "true aging rate" (rate of elements' loss  $\mu$ ), are similar in populations of a given species (presumably because of homeostasis—stable body temperature, glucose concentration, etc.). For lower organisms with poor homeostasis there may be deviations from this law. Our analysis of data published by Pletcher *et al.* (2000) revealed that in *Drosophila* this law holds true for male–female comparisons (keeping temperature the same), but not for experiments conducted at different temperatures, presumably because temperature may influence the rate of element loss.

The failure rate of the blocks asymptotically approaches an upper limit which is independent of the number of initially functional elements and is equal to  $\mu$ . Therefore the failure rate of a system consisting of  $m$  blocks in series tends asymptotically with increased age to an upper limit  $m\mu$ , independently of the values of  $n$  and  $q$ .

Thus the reliability model described here provides an explanation for a general pattern of aging and mortality in biological species: the exponential growth of failure rate in the initial period, with the subsequent mortality deceleration and leveling-off, as well as the compensation law of mortality.

This model might also be called the model of series-connected blocks with varying degrees of redundancy or distributed redundancy. The basic conclusion of the model might be reformulated as follows: *if vital components of a system differ in their degree of redundancy, the mortality rate initially grows exponentially with age (according to the Gompertz law) with subsequent leveling-off in later life.*

### HETEROGENEOUS POPULATION OF REDUNDANT ORGANISMS

In the previous sections, we examined a situation in which series-connected blocks have varying degrees of redundancy within each organism, while the organisms themselves were considered to be initially identical to each other and to have the same risk of death. This latter assumption can be justified in some special cases (see Gavrilov and Gavrilova, 1991) and also when the focus is on the analysis of the individual risks of failure. In a more general case the population heterogeneity needs to be taken into account, because there is a large variation in the numbers of cells for the organisms of the same species (Finch and Kirkwood, 2000).

In this section, we demonstrate that taking into account the heterogeneity of the population provides an explanation for all the basic laws of mortality. This model of heterogeneous redundant systems was proposed by Gavrilov and Gavrilova in 1991 (pp. 264–272).

The model considers the simplest case when the organism consists of a single vital block with  $n$  elements connected in parallel with  $q$  being the probability that an element is initially functional. Then the probability of encountering an organism with  $i$  initially functional elements out of a total number  $n$  of elements is given by the binomial distribution law.

The final formula for failure rate in heterogeneous population,  $\mu_p(x)$ , is (see Gavrilov and Gavrilova, 1991 for more details):

$$\begin{aligned} \mu_p(x) &= \frac{F'(x)}{1 - F(x)} = \frac{nq\mu e^{-\mu x}(1 - qe^{-\mu x})^{n-1}}{1 - (1 - qe^{-\mu x})^n} \\ &\approx Cnq\mu(1 - q + q\mu x)^{n-1} \quad \text{for } x \ll 1/\mu \\ &\approx \mu \quad \text{for } x \gg 1/\mu \end{aligned}$$

where  $C$  is a normalizing factor.

Thus the hazard rate of a heterogeneous population at first grows with age according to the binomial law

of mortality, then asymptotically approaches an upper limit  $\mu$ :

$$\begin{aligned}\mu_p(x) &\approx Cn(q\mu)^n \left[ \frac{1-q}{q\mu} + x \right]^{n-1} \\ &= Cn(q\mu)^n (x_0 + x)^{n-1} \quad \text{for } x \ll \frac{1}{\mu} \\ \mu_p(x) &\approx \mu \quad \text{for } x \gg \frac{1}{\mu}\end{aligned}$$

where  $x_0 = (1-q)/q\mu$ , a parameter which we propose to call the initial virtual age of the population. This parameter has the dimension of time, and corresponds to the age by which an initially homogeneous population would have accumulated as many damaged organisms as a real population actually possesses at the initial moment in time (at  $x = 0$ ). In particular, when  $q = 1$ , i.e., when all the elements in each organism are functional at the outset, the initial virtual age of the population is zero and the hazard rate of population grows as a power function of age (the Weibull law), this being the case described in causes of failure rate increase with age. However when the population is not initially homogeneous ( $q < 1$ ), we arrive at the already mentioned binomial law of mortality. Thus, the heterogeneous population model proposed here can also provide a theoretical justification for the binomial law of mortality.

If a population is initially heterogeneous ( $q < 1$ ), the hazard rate in the initial period of time grows exponentially with age (according to the Gompertz law).

The heterogeneous population model not only provides an explanation for the exponential growth in the failure rate with age, but also the compensation law of mortality (Gavrilov and Gavrilova, 1991). The compensation effect of mortality is observed whenever differences in mortality are brought about by inter-population differences in the number of elements in the organism ( $n$ ), while the other parameters, including the rate of aging (the rate of irreversible elements failure  $\mu$ ), are similar for all compared populations of a particular species (presumably because of homeostasis in physiological parameters). It is not difficult to see the similarity between this explanation for the compensation effect of mortality and the explanations which emerge from the models of individual system described in preceding sections.

Figure 5.9 presents the age kinetics of failure rate in heterogeneous population where redundancy is distributed by the Poisson law (a special case of binomial distribution) with different mean number of functional elements ( $\lambda = 1, 5, 10, 15$  and  $20$ ).

Note that the logarithm of the failure rate is increasing with age in almost a linear fashion, indicating a reasonable applicability of the Gompertz law in this case. Also note that the slope of the lines is increasing with higher mean redundancy levels ( $\lambda$ ), and the lines

**Figure 5.9.** Failure kinetics in mixtures of systems with different redundancy levels. Initial period. The dependence of failure rate as a function of age in mixtures of parallel redundant systems having Poisson distribution by initial numbers of functional elements (mean number of elements,  $\lambda = 1, 5, 10, 15, 20$ ). Source: Gavrilov and Gavrilova, 2005.

have a tendency for convergence (compensation law of mortality).

The heterogeneous population model leads in principle to the same conclusions as the previously discussed model of series-connected blocks with varying degrees of redundancy. However, we are dealing with two fundamentally different models: whereas in the first model the individual risk of death is the same for all organisms and grows exponentially with age, in the second model there initially exist  $n$  subpopulations of living organisms with different risks of death which grow as a power function rather than exponential function of age. However, these different models seem to lead to virtually coincident interpretations of certain mortality phenomena. For example, the compensation effect of mortality is only possible, according to any of the models, when the rate of irreversible age changes is approximately constant within a given species. This interpretation of the compensation effect of mortality is not only a feature of the three models examined in this chapter, but also of other models (Gavrilov, 1978; Gavrilov *et al.*, 1978; Strehler and Mildvan, 1960).

Thus, the heterogeneous population model provides an explanation for all the basic mortality phenomena (the exponential growth of the force of mortality in the initial period, with the subsequent mortality deceleration, as well as the compensation effect of mortality) even in the simplest case when the organism consists of a single vital block with  $n$  parallel elements. Generalizing the model to the case of  $m$  blocks connected in series in each organism does not present any problems if the blocks are

## 5. Models of Systems Failure in Aging

independent of each other with respect to their reliability (Gavrilov and Gavrilova, 1991).

### MODELS OF AVALANCHE-LIKE DESTRUCTION

For want of a nail the shoe was lost,  
 For want of a shoe the horse was lost,  
 For want of a horse the rider was lost,  
 For want of a rider the battle was lost,  
 For want of a battle the kingdom was lost,  
 And all for the want of a horseshoe nail.  
 — English nursery rhyme (ca. 1390)

The models described in previous sections assumed that the failures of elements in the organism occur independently of each other. This assumption may be acceptable as the first approximation. In real biological systems many aging phenomena may be represented as a “cascade of dependent failures” which occurs when one of the organism’s systems randomly fails (Gavrilov, 1978; Gavrilov *et al.*, 1978). The idea that an avalanche-like mechanism is involved in the destruction of an organism during natural aging is worth further consideration. In fact, it is well-known that defects in an organism have a tendency to multiply following an avalanche-like mechanism. For example, if there are  $n$  cancer cells in the organism, each of which is capable of division, the rate at which the organism is transformed into a state with  $n + 1$  cancer cells increases with the growth of the number of cancer cells ( $n$ ) already accumulated. Infections of the organism follow similar regularities. The positive feedback between the degree and the rate of an organism’s destruction also follows from the fact that when parts of the structure fail, the load on the remaining structures increases, accelerating the wearing-out. It seems that aging may be caused by similar cascades of dependent failures developing over long periods in a hidden, preclinical form. Therefore mathematical models of the avalanche-like destruction of the organism are of particular interest.

Consider the simplest model of the avalanche-like destruction of the organism (Gavrilov and Gavrilova, 1991). Let  $S_0, S_1, \dots, S_n$  denote the states of an organism with  $0, 1, 2, \dots, n$  defects. Let  $\lambda_0$  be the background rate at which defects accumulate being independent on the stage of destruction, which the organism has reached. Correspondingly, let  $\mu_0$  be the age-independent mortality (the Makeham term). In the simplest case, both of these quantities arise from random harmful effects of the external environment. In tandem, there is also an induced rate of deterioration (parameter  $\lambda$ ) and an induced failure rate (parameter  $\mu$ ) which grow as the number of defects increases. At a first approximation, it can be assumed that both the induced rate of deterioration and the induced failure rate are proportional to the number of defects, so that for an organism with  $n$  defects the induced rate

**Figure 5.10.** Avalanche-like mechanism of organism’s destruction with age. In the initial state ( $S_0$ ) organism has no defects. Then, as a result of random damage, it enters states  $S_1, S_2, \dots, S_n$ , where  $n$  corresponds to the number of defects. Rate of new defects emergence has avalanche-like growth with the number of already accumulated defects (horizontal arrows). Hazard rate (vertical arrows directed down) also has an avalanche-like growth with the number of defects.

of deterioration is equal to  $n\lambda$ , and the induced failure rate is  $n\mu$ .

With these assumptions, we can present the avalanche-like destruction of the organism by the schema presented in Figure 5.10.

This schema corresponds to the following system of differential equations:

$$\begin{aligned} dS_0/dx &= -(\lambda_0 + \mu_0)S_0 \\ dS_1/dx &= \lambda_0 S_0 - (\lambda_0 + \mu_0 + \lambda + \mu)S_1 \\ dS_n/dx &= [\lambda_0 + (n - 1)\lambda]S_{n-1} - [\lambda_0 + \mu_0 + n(\lambda + \mu)]S_n \end{aligned}$$

A similar system of equations (not taking into account the age-independent mortality) was obtained and solved in a mathematical model linking the survival of organisms with chromosome damage (Le Bras, 1976). However, this “chromosomal” interpretation of the avalanche model could be applicable only to unicellular organisms, while for multicellular organisms including humans, where chromosomes are compartmentalized in separate cells, this model needs to be revised, or provided with a different “nonchromosomal” interpretation (as it is suggested in this section).

In the particular case when the rate at which defects multiply, the parameter  $\lambda$  is significantly greater than the induced failure rate, parameter  $\mu$ , ( $\lambda \gg \mu$ ), the hazard rate of an organism in the initial stage (with low values of  $x$ ) grows according to the Gompertz–Makeham law:

$$\begin{aligned} \mu(x) &\approx \mu_0 + \frac{\mu\lambda_0(1 - e^{-(\lambda+\mu)x})}{\lambda e^{(\lambda+\mu)x}} \approx A + R e^{\alpha x} \\ \text{where } A &= \mu_0 - \frac{\mu\lambda_0}{\lambda}; \quad R = \frac{\mu\lambda_0}{\lambda}; \quad \alpha = \lambda + \mu \end{aligned}$$

This model of the avalanche-like destruction of the organism not only provides a theoretical justification for the well-known Gompertz–Makeham law, but also explains why the values of the Makeham parameter  $A$  sometimes turn out to be negative (when age-independent mortality,  $\mu_0$ , is small as for populations in the developed countries and the background rate of destruction,  $\lambda_0$ , is large).

Another advantage of the avalanche-like destruction model is that it correctly predicts mortality deceleration (deviations from the Gompertz–Makeham law) at very

old ages. In this extreme age-range, the failure rate grows with age according to the formula

$$\mu(x) \approx \mu_0 + \lambda_0(1 - e^{-(\lambda+\mu)x})$$

Thus the model predicts an asymptotic growth of failure rate with age with an upper limit of  $\mu_0 + \lambda_0$ .

Alongside the strengths already listed, the avalanche-like destruction model has one significant limitation: it does not conform to the compensation law of mortality in its strong form (Gavrilov and Gavrilova, 1991). Nevertheless, the idea that organisms undergo cascade destruction is one of the promising ideas in further mathematical modeling of aging.

### ACCUMULATION OF DEFECTS WITH CONSTANT RATE OF DAMAGE FLOW

A wide variety of concepts about the destruction of the organism can lead to the model where the rate of damage flow, numerically equal to the mean number of “hits” per unit of time, is practically independent of the state of the organism and is on average constant in time. In the simplest case, the model corresponds to a situation in which the organism is affected by a random flow of traumatic loads with an on average constant rate independent of the state of the organism (exogenous environmental damage like cosmic radiation, viruses, etc.)

However, there is also the possibility of other mechanisms of destruction leading to this particular model of the accumulation of defects. In particular, this model can be obtained after a critical reinterpretation of the assumptions underlying the previously described models. In fact, these models contain an assumption that the death of the organism occurs only when all the elements in a block fail. It is possible that this hypothesis may be justified for some of the organism’s systems (stem cell populations, for example). However, in the majority of cases this hypothesis seems contentious. For example, it is hard to imagine that a single surviving liver cell (hepatocyte) can assume the functions of an entire destroyed liver. Significantly more realistic is the hypothesis that the system initially contains an enormous number of elements that greatly exceeds the critical number of defects leading to the death of the organism. In this case we arrive at a schema for the accumulation of damage in which the rate of damage flow (equal to the product of the number of elements and their failure rate) turns out to be practically constant in view of the incommensurability of the high initial numbers of elements, and the much smaller permitted number of defects (Gavrilov and Gavrilova, 1991).

Another advantage of this model is that it allows us to take into account the influence of living conditions on the value for the critical number of defects incompatible with the survival of the organism. The key to the solution of this problem is the replacement of the parallel connection hypothesis (assumed in previously described models) with

the more realistic assumption that there exists a critical number of defects incompatible with the survival of the organism. In this case, it is natural to expect that under harsher conditions the critical number of defects leading to death might be less than under more comfortable living conditions. In particular, in the wild, when an animal is deprived of care and forced to acquire its own food, as well as to defend itself against predators, the first serious damage to the organism can lead to death. It is therefore not surprising that the mortality of many animals (in particular, birds) is practically independent of age in the wild. This follows directly from the single-stage destruction of the organism model. On the other hand, the greater the number of defects the organism can accumulate while remaining alive, the greater its lifespan will be.

If the rate of the damage flow equals  $k$ , and an organism dies after the accumulation of  $n$  defects, the density of the survival distribution is identical to the density of the gamma function (see Barlow and Proschan, 1965; 1975). At the initial moment in time, this distribution corresponds to a power (Weibull) law of mortality with an exponent equal to  $(n - 1)$ .

A fundamentally different result is obtained when the initial damage of organisms is taken into account (Gavrilov and Gavrilova, 1991). If at the initial moment in time the average number of random defects in the population equals  $\lambda$ , the probability of encountering a living organism,  $P_i$ , with  $i$  defects may be approximated by the Poisson law (see Gavrilov and Gavrilova, 1991, pp. 272–276, for more detail).

Since the death of an organism with  $i$  defects occurs after  $n - i$  additional hits, the density of the lifespan distribution for such organisms is given by

$$f_i(x) = \frac{k(kx)^{n-i-1} e^{-kx}}{(n-i-1)!}, \quad \text{where } i < n$$

The density of the survival distribution for the whole population, which is a mixture of organisms with  $i = 0, 1, 2, \dots, n - 1$  initial defects, equals

$$\begin{aligned} f(x) &= \sum_{i=0}^{n-1} P_i f_i(x) = Ck e^{-(\lambda+kx)} \sum_{i=0}^{n-1} \frac{\lambda^i (kx)^{n-i-1}}{i!(n-1-i)!} \\ &= \frac{Ck(\lambda+kx)^{n-1} e^{-(\lambda+kx)}}{(n-1)!} \end{aligned}$$

It is not difficult to see that at the initial moment in time this model leads to the binomial law of mortality, with an initial virtual age of the population equal to  $\lambda/k$ . A more detailed analysis of the model is formally similar to the analysis of the other models described in previous sections. We merely note that during the initial time period when  $x \ll \lambda/k$ , the model leads to an exponential growth of failure rate with age (the Gompertz law) with an exponent,  $\alpha$ , of  $k(n-1)/\lambda$  and a pre-exponential factor,  $R$ , of  $Ck\lambda^{n-1}/(n-1)!$ . It is

## 5. Models of Systems Failure in Aging

easy to see that an inverse relationship between these Gompertz parameters (the compensation effect of mortality) can arise both as a result of variation in parameter  $\lambda$  (the degree to which the organisms are initially damaged) and of variation in parameter  $n$  (the critical number of defects, dependent on the harshness of living conditions).

Thus the basic mortality phenomena can equally be explained within the framework of the model of accumulation of defects with the constant rate of damage flow, as long as the organisms initially contain a significant number of defects.

Summarizing this brief review of reliability models, we note the striking similarity between the formulas and conclusions of the considered models. It must, however, be noted that we are dealing only with a superficial similarity in behavior between fundamentally different and competing models. The existence of a multitude of competing models is therefore compatible with the reliable and meaningful interpretation of a number of mortality phenomena, since pluralism of models does not preclude their agreement on a number of issues. All these models predict a mortality deceleration, no matter what assumptions are made regarding initial population heterogeneity, or its complete initial homogeneity. Moreover, these reliability models of aging produce mortality plateaus as the inevitable outcome for any values of considered parameters (Gavrilov and Gavrilova, 1991). The only constraint is that the elementary steps of the multistage destruction process of a system should occur only by chance, independent of age. The models also predict that an initially homogeneous population will become highly heterogeneous for risk of death over time (acquired heterogeneity).

### Conclusions

Theoretical reliability models of system failure in aging considered in this book chapter lead to the following conclusions:

1. *Redundancy* is a key notion for understanding aging and the systemic nature of aging in particular. Systems, which are redundant in numbers of irreplaceable elements, do deteriorate over time (fail more often with age), even if they are built of nonaging elements. The positive effect of systems' redundancy is *damage tolerance*, which decreases mortality and increases lifespan. However damage tolerance makes it possible for damage to be tolerated and accumulated over time, thus producing the aging phenomenon.
2. An apparent aging rate or expression of aging (measured as age differences in failure rates, including death rates) is higher for systems with higher redundancy levels (all other things being equal). This is an important issue, because it helps

to put a correct perspective on fascinating observations of negligible senescence (no apparent aging) observed in the wild and at extreme old ages. Reliability theory explains that some cases of negligible senescence may have a trivial mechanism (lack of redundancies in the system being exposed to challenging environment) and, therefore, will not help to uncover "the secrets of negligible senescence." The studies of negligible senescence make sense, however, when the death rates are also demonstrated to be negligible.

3. Reliability theory also persuades a re-evaluation of the old belief that aging is somehow related to limited economic or evolutionary investments in systems longevity. The theory provides a completely opposite perspective on this issue—aging is a direct consequence of investments into systems reliability and durability through enhanced redundancy. This is a significant statement, because it helps to understand why the expression of aging (differences in failure rates between the younger and the older age groups) may be actually more profound in more complicated redundant systems, designed for higher durability.
4. During the life course the organisms are exhausting the reserve numbers of their cells (Gosden, 1985; Herndon *et al.*, 2002), losing reserve capacity (Bortz, 2002; Sehl and Yates, 2001), and this *redundancy depletion* explains the observed "compensation law of mortality" (mortality convergence at older ages) as well as the observed late-life mortality deceleration, leveling-off, and mortality plateaus.
5. Living organisms seem to be formed with a high *load of initial damage*, and therefore their lifespan and aging patterns may be sensitive to *early-life conditions* that determine this initial damage load during early development. The idea of early-life programming of aging and longevity may have important practical implications for developing early-life interventions promoting health and longevity.

The theory also suggests that aging research should not be limited to the studies of qualitative changes (like age changes in gene expression), because changes in *quantity* (numbers of cells and other functional elements) could be an important driving force of aging process. In other words, aging may be largely driven by a process of redundancy loss.

The reliability theory predicts that a system may deteriorate with age even if it is built from nonaging elements with constant failure rate. The key issue here is the system's redundancy for irreplaceable elements, which is responsible for the aging phenomenon. In other words, each particular step of system destruction/deterioration may seem to be apparently random (no aging, just occasional failure by chance), but if a system failure

requires a sequence of several such steps (not just a single step of destruction), then the system as a whole may have an aging behavior.

Why is this important? Because the significance of beneficial health-promoting interventions is often undermined by claims that these interventions are not proven to delay the process of aging itself, but instead simply delay or “cover-up” some particular manifestations of aging.

In contrast to these pessimistic views, reliability theory says that there may be no specific underlying elementary “aging process itself”—instead aging may be largely a property of a redundant system as a whole, because it has a network of destruction pathways, each being associated with particular manifestations of aging (types of failure). Therefore, we should not be discouraged by only partial success of each particular intervention, but instead we can appreciate an idea that we do have so many opportunities to oppose aging in numerous different ways.

Thus, the efforts to understand the routes and the early stages of age-related degenerative diseases should not be discarded as irrelevant to understanding the “true biological aging.” On the contrary, the attempts to build an intellectual firewall between biogerontological research and clinical medicine are counterproductive. After all, the main reason why people are really concerned about aging is because it is related to health deterioration and increased morbidity. The most important pathways of age changes are those that make older people sick and frail (Bortz, 2002).

Reliability theory suggests general answers to both the “why” and the “how” questions about aging. It explains “why” aging occurs by identifying the key determinant of aging behavior—system redundancy in numbers of irreplaceable elements. Reliability theory also explains “how” aging occurs, by focusing on the process of redundancy loss over time as the major mechanism of aging.

Ageing is a complex phenomenon (Sehl and Yates, 2001), and a holistic approach using reliability theory may help to analyze, understand, and perhaps to control it. We suggest, therefore, adding theoretical reliability models of system failure in aging to the arsenal of methodological approaches for the studying of human aging.

# Major Issues in Ethics of Aging Research

Michael D. Smith

*This chapter discusses some of the significant issues that arise when principles for the ethical treatment of research subjects are applied to aging subjects. Some of the ways in which researchers have addressed those issues in the design and execution of their own research are identified. After a brief review of sources for ethical principles in research, several kinds of ethical issues are examined: the complexity of respecting the human autonomy of older research subjects in the consent process, how the nursing home environment creates new ethical issues for research, and a contemporary debate that questions the goodness and rightness of aging research itself.*

## Introduction

Ethics in human subject research has generated robust discussion and a growing body of literature for at least 50 years. During the same time period the scientific study of aging has emerged. There is now substantial agreement on the basic principles of human research ethics—principles that apply to all subjects regardless of age. Still, the process of normal aging, diseases associated with aging, and the environments in which we age all give rise to ethical issues and concerns not typically related to research with younger subjects. This chapter will discuss some of the significant issues that arise when principles for the ethical treatment of research subjects are applied to aging subjects. I shall also point to some of the ways in which researchers have addressed those issues in the design and execution of their own research.

After a brief review of sources for ethical principles in research, I will look at several kinds of ethical issues. First, we will look at the complexity of respecting the human autonomy of older research subjects. Then we will look at how the environment, in this case the nursing home environment, itself creates new ethical issues for the conduct of research. Finally, we will look at a contemporary debate that questions the goodness and rightness of aging research itself.

## The Basic Principles of Research Ethics

Through the 1940s little explicit attention had yet been paid to issues of research ethics, but at the end of the decade the Nuremberg War Crime Trials changed that.

Nazi physicians and soldiers were brought to trial before an international tribunal for atrocities committed in the Holocaust. The defendants justified their actions as scientific research. The Nuremberg Code was developed to serve as a set of 10 standards in judging that defense (Nuremberg Code, 1949). The code insisted that the free and informed consent of human subjects was essential to all ethical research. It also addressed the prevention of suffering by subjects and the necessity that researchers be qualified and their research well designed.

Several years later, the Helsinki Code described ethically important differences between clinical and nonclinical human research (World Medical Association, 1964). Research intended to be therapeutic for subjects is different from that in which the subjects are primarily a means to the welfare of others. That distinction moved the ethics of nontherapeutic research into the mainstream: misuse of research subjects did not have to be at the level of a Nazi atrocity to be unethical. The Helsinki Code proposed also that research consent by a proxy (a substitute decision-maker) might in some cases be ethical. The Helsinki Code has since then undergone several revisions, but consensus had begun to build about the fundamental ethical principles of human research ethics.

Soon after, the disclosure of several instances of research abuse in the United States made it clear that the recently articulated principles would have to become more specific and be embodied in policy and regulation. The Tuskegee Syphilis Study (Mitford, 1972), the Willowbrook Studies (Ramsey, 1970), and the Jewish Chronic Disease Hospital study (Langer, 1966) all used subjects whose free and informed consent to participate was at best questionable in studies in which potential harm to the subjects was disproportionate to the potential benefit. Federal committees and task forces worked throughout the 1970s to make clear and precise what is ethical in the use of human subjects in research. The most significant of their outputs was the *Belmont Report* (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979). That report is the basis for much informed dialogue about research ethics, the IRB process, and FDA and other government regulations.

The authors of the *Belmont Report* proposed three broad principles as fundamental to ethical human subjects research: respect for persons, beneficence, and justice.

These general principles would not by themselves solve particular ethical problems. Instead, they “provide an analytical framework that will guide the resolution of ethical problems.”

### RESPECT FOR PERSONS

The *Belmont Report* draws on a fundamental belief about what persons *are* in order to state how they *ought to be treated*. Human beings are autonomous, i.e., they are capable of self-determination by comprehending information and making considered judgments based on their own preferences. In ordinary life, this leads to the ethical principle that human beings should be respected by being given maximum freedom to make their own choices. In research, this same principle recognizes research participation as elective and that research subjects, with full information and comprehension, make a voluntary choice to participate. Voluntariness must be maintained; i.e., subjects are free to withdraw at any time. Informed consent includes all the processes leading up to and maintaining the voluntariness of the choice to participate in research, both before and during the research. It is not just the signed consent form or even the act of signing it.

Persons' abilities to receive and comprehend information, relate it to their own preferences, and then make a decision are sometimes limited. Their own immaturity or disability can limit free choice. So also can some feature of the environment in which the consent process takes place. Respect for persons requires that we protect from harm those whose self-determination is diminished. At the extreme, it may require overriding the individual's judgment in order to do what is in that person's best interests. Still, the first duty of respect is to honor the autonomy of persons. Research with older subjects can test the richness of this principle as an analytical framework. Some older adults are well able to make their own decisions; others may require accommodation or assistance in making decisions; and some cannot make their own decisions even with assistance. We will return to this topic. There are other implications to respect for autonomy. The duty to protect confidentiality has its roots not just in agreements made but in respect for persons; controlling disclosure of intimate knowledge concerning oneself is a way of preserving one's own autonomy.

### BENEFICENCE

The Hippocratic maxim “First, do no harm” is important but not sufficient to guide the ethics of research. The risk of harm must be compared with the potential benefits, through a form of cost-benefit analysis which takes place on three levels: for the sake of the individual research subject, for all those affected by the protocol, and for society-at-large. Good research design and execution are ethical, insofar as they minimize harm and maximize benefit. The metaphor of “balancing” risks with benefits may, however, disguise some of the complexity and

ambiguity involved in such a calculus (Weijer, 2000). Older adults have fewer remaining years than their younger counterparts to experience either the benefits or harm related to research participation. They may be more inclined to altruistic behavior than younger persons (Midlarsky *et al.*, 1994). While cost-benefit analysis provides an analytic technique, it does not itself resolve some of the underlying questions in ethics.

### JUSTICE

The *Belmont Report* uses the term “justice” to refer to “fairness in distribution.” This is different from the word's common association with enforceable rights and penalties within a legal system but consistent with general usage in the field of bioethics. Justice in this context involves the ethical allocation of a fair share of risks or possible harms incurred in research and the allocation of benefits expected to result from the research. Research risks can range from minor inconvenience, to discomfort, to actual harm. For an individual or group to carry a large share of risks of research without getting a proportionate share of the benefits seems unfair, even if it is difficult to say exactly what constitutes a fair and equitable distribution. The early history of human subject research is replete with examples of disadvantaged or vulnerable populations (prisoners, disabled elderly, developmentally disabled persons, etc.) serving as research subjects and risking harm in the quest for knowledge expected to benefit some other population. Study design and subject selection distribute potential harm among subjects. The knowledge acquired in research and the research activity itself (particularly in therapeutic clinical research) can be a source of tremendous benefits; the nature of the study itself and its subject recruitment and selection determine who will get those benefits.

### Autonomy and Protection of Older Adults in Research: How Much Is Enough?

The aging process presents some unique challenges to respect for autonomy among older adults, particularly in relation to obtaining informed consent; and in the research environment those challenges are even more exquisitely complex. We will consider three possibilities that correspond roughly to the variations in decision-making capacities of older adults. The first two possibilities address recognizing and supporting the capacity of older adults to consent to research. The third addresses the possible and actual loss of that capacity.

*Many older adults are as capable of informed consent for research as are other members of the population whose capacity to consent is not in question.* The ethics of their participation as research subjects should not be presumed to be different from that of other adults. Some groups have been classified as vulnerable. Children, the developmentally disabled, the mentally ill, and prisoners and

## 6. Major Issues in Ethics of Aging Research

other institutionalized groups have all been at various times considered vulnerable groups, due to their inability to exercise fully independent and informed judgment, their lack of information or comprehension, their inability to decide, or some coercive influence. Identifying a group as vulnerable has important ethical implications for research: membership in the group confers protections that may limit or even prevent one from consenting to participate. Being identified with that group, rather than one's individual capacities, becomes the criterion for whether one is allowed to choose to participate or not to participate. Robert Butler, the first director of the National Institute on Aging, coined the term "ageism" to describe the process of systematic stereotyping and discrimination against people because they are old (Butler, 1969). In practice, it is most ethical to assume that older adults are as competent as others to make their own choices. If there is doubt in an individual case or the subject population for a specific study, the protocol should include ways of confirming the capacity to make a decision.

*Some older adults, due to conditions commonly associated with aging, are capable of informed consent, but require additional accommodation to exercise it.* Older adults typically undergo changes that may affect the informed consent process. Changes in vision and hearing are among them. More than 37% of noninstitutionalized persons 65 and over report trouble hearing and 17.5% report trouble seeing (National Center for Health Statistics, 2002). Visual acuity, color discrimination, and sensitivity all tend to decrease with age (Fozard *et al.*, 2001).

Cognitive changes include increased difficulty with selective and sustained attention (Rogers *et al.*, 2001) and slowing of information processing and retrieval (Madden, 2001). In making decisions, older adults typically use less information and have more difficulty accurately using comparative information (Park, 1999; Hibbard *et al.*, 2001).

These changes are sufficiently prevalent among the aging that they should be routinely considered in informed consent by older adults. The changes are typically moderate and their onset gradual, so that persons adapt (through eyeglasses and hearing aids, avoiding noisy restaurants, taking additional time for decision-making, etc.) and continue to lead autonomous lives. Accommodating these needs in the informed consent process is ethically important to ensure that older adults receive and comprehend the information they would use to make a considered and free judgment about participation. Such needs are not an indication that they should be protected by bypassing their own free choice.

Informed consent documents and recruiting materials should be high in visual contrast, with a simple large font. Discussions concerning participation should be held in an environment with a high light level, and minimal ambient noise and without visual and auditory distractions

(Metlife, 1999). Completing the consent process in several stages on separate occasions can help some older adults to have sufficient time to comprehend the study and perhaps to consult with a trusted friend (Tymchuk *et al.*, 1990). These may be merely amenities or courtesies for younger subjects. With older adults they become ethically important as routine means of enabling them to exercise freely their autonomy.

*Some older adults may not be able to provide informed consent.* Various neurological, vascular, or psychiatric disorders, depression, or stroke can all affect an older person's capacity to consent. In the course of research a subject's lack of capacity may become evident. Concerns may develop during an initial interview or consent process, or in a run-in sometimes used prior to randomization (Ouslander *et al.*, 1993). Or they could arise in the course of neuropsychological testing integral to the protocol. In any case, study procedures for addressing such findings or concerns should be addressed explicitly, from the time of initial submission to an IRB for approval (Kapp, 1998). General guidelines are available for assessing the capacity of impaired individuals (National Bioethics Advisory Commission, 1998). Although tests are available to measure specific capacities, there is no consensus on which of these tests should be used for determining capacity to consent to research (Curry, 2002).

Testing for cognitive impairment in the research context may create additional ethical issues. The investigator may receive evidence of a previously undiagnosed condition in a potential research subject. Keeping that information confidential might prevent the subject from accessing needed therapeutic assistance. Disclosing it might violate an expectation of confidentiality. To manage such issues, some studies retain an appropriate health professional or ask subjects to consent to disclosure of relevant study information to an identified primary care physician.

Should those who have lost the capacity to consent be barred from being research subjects? While this might be consistent with an ethical principle that all research participation should be voluntary, it could work against the best interests of those same persons. Individually, it could prevent access to promising new therapies available only in clinical trials. On a broader level, it could stifle progress in the very diseases or conditions that render persons cognitively incapable of consenting. Nevertheless, it should always be determined whether a study *must* include subjects who have lost the capacity to consent. If the study could proceed as well without them, then it is best to use only subjects able to consent.

Federal regulations effectively defer to state law by insisting that consent in such cases involve the subject's legally authorized representative. States have laws to address decision-making for incapacitated persons, but those laws are for the most part designed to address the need for health care decision-making in urgent situations.

The fit of those rules to research consent is at best inexact, and at times irrelevant to the research environment (Hoffman *et al.*, 1998). As a result, there is active ethics discussion about how to act in the absence of laws and about what laws should be enacted. We will look specifically at two common features in state laws, proxy consent and advance directives, and discuss their application to the research environment.

In health care a proxy or surrogate makes decisions for the person who is incapable of consenting to treatment. While the specific method varies from state to state, there are generally two different ways. The person can, in advance of becoming incapable, name a proxy by granting power-of-attorney. In the absence of such a designation, the next of kin in an ordered list defined by state law becomes the decision-maker. The ethical expectation behind proxy consent is that the surrogate will have known the patient well enough and be sufficiently empathetic to the patient to make the decision the patient would have made. If what the patient would have decided is unknowable, the proxy must then make the decision that is in the best interests of the subject. Proxies in decision-making for nontherapeutic research are more problematic, because there is no expected benefit to the person beyond the altruistic satisfaction of contributing to the welfare of other humans in the future (Hoffman *et al.*, 1998; Kapp, 1994). In such situations proxy consent for research could result in abusively using demented persons to the benefit of others. For that reason, the American Geriatrics Society holds that proxy consent should not be used where the subject is incapacitated, is unlikely to directly benefit, and will undergo more than minimal risk (American Geriatrics Society, 1998). The Alzheimer's Association has taken a similar position (Alzheimer's Association, 1997).

Both of those organizations consider an advance directive for research as a tool that is useful in ways that a proxy consent is not. The health care advance directive, frequently embodied in a living will, is intended to direct end-of-life care. Just as in health care, an advance directive for research does not involve substituting one person's judgment for another's; it is a documented decision by a competent person which is to be honored if and when that person becomes incapacitated (Dresser, 2001). Advance directives differ from proxy consent in that they rely directly on a person's own previously expressed and documented choice. A common criticism of advance directives in health care is that persons are seldom able to envision the specific end-of-life circumstances in which others will be expected to apply the directive (Fagerlin *et al.*, 2004). It is at least as difficult to envision the kinds of research one might be a candidate for at some indefinite future date and how one's own needs and preferences might have changed by that time. For that reason, it is best not to assume an advance directive for research to be informed consent already given. It can serve as supportive documentation to guide

a surrogate decision-maker (Sachs, 1994). Advance directives may also be helpful when a person is in the early stages of a progressive dementing illness, but still able to consent to participate in longitudinal research. Such an advance directive may guide the proxy when the subject is in later stages of the disease and no longer able to consent to continuing in or withdrawing from the study.

How great a risk may a surrogate consent to on behalf of an incapacitated research subject? What I shall call the "conservative approach" holds that nontherapeutic research that creates any risk of harm greater than minimal (i.e., greater than the risk of harm experienced in everyday living) should never be conducted on an incapacitated subject, even with proxy consent or an advance directive (Keyserlingk *et al.*, 1995). Positions more favorable to proxy consent for research have begun to emerge. The Alzheimer's Association has taken the position that, in research involving more than minimal risk, subjects who stand to benefit individually and have a proxy's consent should be allowed to participate. Scientific progress in understanding and fighting diseases that rob older adults of their ability to remain autonomous may require research on persons who are unable to consent to or benefit from that research.

Although respect for autonomy is ethically good, human beneficence (contributing to the common good) is also good; and respect for individual autonomy should not always take priority over beneficence. The American Geriatrics Society proposes developing a mechanism for future consideration of subjects who cannot consent and who have neither an advance directive nor reasonable expectation of benefit, but only in studies especially promising in the benefit they eventually provide to society. Similarly, Stephen Post has advocated recently that, recognizing that defeating Alzheimer disease (the most prevalent older adult dementia) is a high priority for our common good, we should think differently about risk in this category of research (Post, 2003). The issue should not be whether a study poses only "minimal risk," but where to set the upper threshold of allowable risk ("maximal potential risk"); and it should be set in a consensus conference of experts with due consideration of the social good.

The ethical waters do quickly become murky when we accept proxy consent or advance directives in research, or when we consider increasing the amount of risk an incapacitated subject may be asked to incur in support of some socially desirable outcome. When we do that, it becomes increasingly important to maintain other forms of respect for autonomy. A free consent can be withdrawn at any time. To maintain the freedom to withdraw, either the proxy or a "monitor" or "research intermediary" must be continuously involved on behalf of the incapacitated subject (Kapp, 1998). Monitors or proxies, along with the investigator, in such situations must watch for not only the best interests of the subject but also for the

## 6. Major Issues in Ethics of Aging Research

subject's continued assent to participate. Even a subject who is not cognitively able to consent to participate may at any point resist continued participation or express a strong preference for withdrawing, and such preferences should be noticed and honored.

In summary, there is ethical agreement that older adults should be able to consent or refuse to consent to participate in research, even if that requires some additional assistance. There is also agreement that incapacitated persons deserve special protection. The question is still open on whether the goal of controlling or eliminating diseases that affect older adults can be a societal good so important that it justifies increasing the maximum permissible risk to subjects who cannot consent.

### Your Home/My Lab: The Ethics of Research in Nursing Homes

#### A VULNERABLE POPULATION

Long-term care includes not only nursing homes but other environments such as day health centers, day hospitals, assisted living facilities, and home health services. Long-term care services all deal with concentrations of older adults who have significant ongoing needs for health care and various forms of personal assistance, depend on professionals to meet those needs, and spend substantial time in environments controlled by those professionals. The nursing home will be the focus of this discussion, but much of what is said about it will be applicable to other sites of long-term care as well.

Data from the National Nursing Home Survey provide a fairly illustrative picture of nursing home residents in the United States (Jones, 2000). More than 1.6 million persons 65 years and over reside in nursing homes. More than 90% are age 65 or over, and 46% age 85 or over. The current population has an average length of stay of 892 days. Those discharged from nursing homes have an average stay of 272 days. Many nursing home residents require help with basic needs such as bathing (94%), dressing (87%), toileting (56%), and eating (47%); 47.7% have an active diagnosis of dementia (U.S. Department of Health and Human Services, 1998).

Together, these data show that nursing home populations are vulnerable in several important respects. They depend on others to meet the most basic of human needs as well as their specific health needs. A high percentage have limited or questionable capacity for decision-making. The facility is home for its residents; but they do not have the same control over their home environment that we ordinarily use to gain privacy. They are subject to schedules and routines imposed for the good of the whole. They can be solicited for research participation in their home.

The nursing home can be an attractive and efficient site for aging research. It has an unusually high concentration

of older residents; human and environmental variables are monitored, measured, and controlled; health records are close by; and professional resources are available. These very features that make the nursing home attractive for research can also make its population vulnerable and make the ethical conduct of research more complex.

#### VULNERABILITY AND RESEARCH CONSENT IN THE NURSING HOME

Informed consent for research in the nursing home is ethically complex. The same health problems that result in nursing home admissions can also affect the capacity to consent. Ordinarily, we assume persons have the capacity to consent and then watch and check for exceptions *during* and after the recruitment and consent processes. In the nursing home, there is a higher probability that each individual is incapable of consent or requires some additional assistance. Consequently, potential subjects should be screened for capacity by a knowledgeable and disinterested party *before* recruitment or consent. Making this initial determination of capacity ensures that the appropriate approach is then taken to the consent process itself. Some advocate the use of an ethics or research committee for screening (Cassel, 1988). Others recommend using knowledgeable nursing home staff, such as nurses or social workers (Ouslander *et al.*, 1993). In either case, the researcher must still ensure that the consent process itself is monitored, that proxies are used as appropriate, and that the research is monitored for ongoing consent or assent.

Nursing home residents have significant health care needs and are accustomed to the continual presence of professionals charged with meeting those needs. They (and their families) do not typically regard the nursing home as a research site; teaching and research nursing homes are uncommon. When research is conducted in the same environment as the one in which persons typically receive health care, they may assume that the research is related to their care and that it is in their best interests to participate (Lidz *et al.*, 2002). This assumption, the therapeutic misconception, can result in a consent based on misunderstanding. Ethical researchers take steps to prevent such mistaken assumptions. To prevent such misconceptions, it may be important to have someone not identified as a regular caregiver to discuss consent with the subject and proxy and to conduct any interventions that are related to the study protocol.

Understanding the consent process for treatment can be helpful for those who seek research consent in the nursing home. That process can become complex. Staff may have an interest in providing correct health care and in an orderly routine to benefit the residents as a group. Family members of residents may vacillate between wanting the best health care and wanting them to be as free as possible to continue their preferred living patterns. Residents may experience the same ambivalence, complicated occasionally by confusion and forgetfulness.

Residents, family members and staff as a group must make decisions that direct health care, respect the autonomy of the resident, and maintain the orderly operation of the nursing home. This is frequently done in care planning meetings in which all groups and interests are represented. Afterwards, it may be difficult to identify a point in this process at which consent actually takes place. In some respects, it is more like a negotiation process (Moody, 1996). Still, it is highly adapted to the vulnerability and possible incapacity of the resident.

Researchers in nursing homes may find a similar process taking place with research consent. Multiple parties may participate, and they may bring various considerations to bear on the decision. It can be challenging to avoid deviating from the protocol during such a process. The researcher needs to view this unfamiliar and complex process as responsive to the unusual situation of a vulnerable population. To ignore it is to disregard the imperfect supports in place to protect persons in an ethically ambiguous situation.

#### VULNERABILITY AND DISTRIBUTIVE JUSTICE

To do research with a nursing home population solely for the convenience it presents for the researcher raises questions of distributive justice or fairness. Putting a vulnerable population at risk for the benefit of some other group can be unethical. Nontherapeutic research, not reasonably expected to provide medical benefit to vulnerable subjects, might appear unethical; but even the calculation of risks and benefits in the nursing home environment is complex. Rigorously insulating nursing home populations from risk can ignore other human needs and deprive them of stimulation, social involvement, and the opportunity to contribute to society, features already frequently lacking in the lives of nursing home residents. "Such participation in the human community should not be automatically withheld from a whole class of persons in the name of protecting them from exploitation" (Cassel, 1988). The opportunity for involvement should be considered in this cost-benefit analysis, and its value should be considered in relation to the nursing home resident's unique situation. It must, however, be used in good faith; as risk increases and the capacity to consent is diminished, that justification becomes less reasonable.

We should also consider studies that are especially promising in their potential to improve nursing home living. Such studies, by their nature, may have to involve members of the population they are intended to benefit. The vulnerability of the nursing home population should not by itself prevent that research. Research into the diseases that result in nursing home admission, into optimal nursing home practices or into conditions such as decubiti, incontinence, environmentally induced depression, and nosocomial infection will benefit the nursing home population as a whole, even if not all subjects will individually receive the benefits. The question of whether

the nursing home population may ethically be recruited for such research is distinct from whether an individual resident may be recruited. Whether an individual resident should participate is still a function of the informed consent process, which still is especially complex in the nursing home.

#### MANAGING RESEARCH IN THE NURSING HOME

Nursing homes are neither designed nor staffed for research purposes. Their mission, and primary ethical obligation, is to provide the health care personal services needed while offering residents maximum autonomy in a homelike atmosphere. The researcher who is given access to a nursing home must design and conduct research that does not interfere with the nursing home's own obligations, which are also the rights of its residents.

The Institutional Review Board, or IRB, is a federally mandated committee whose role is to review research proposals and monitor research so as to protect human subjects. In reviewing proposals to conduct research in nursing homes, IRBs may require the investigator to submit documentation from the facility's administrator agreeing to the research, identifying an onsite person who will attest to the study's appropriateness with that facility's population, and ascertaining the facility's capabilities to perform the research. If nursing home staff are to be involved in data collection, the administrator may also need to provide assurance that they have appropriate expertise and will follow IRB-approved procedures. Such a requirement can elicit the kind of understanding, communication, and agreement between the investigator and the nursing home that is needed for nursing home research to be ethical and successful.

IRBs are typically university-based and are most familiar with research sites such as laboratories and acute and primary care facilities. They may lack the knowledge to oversee research in nursing homes and sometimes use a consultant to assist in reviewing and monitoring such research. The researcher will need to be prepared to explain to an IRB how the protocol meets its ethical standards in an environment unfamiliar to that committee.

The nursing home must make a considered decision about permitting a research project to take place within its walls. Nursing homes may find it difficult to review research opportunities due to the lack of familiarity with research. They need to address questions related to the rights and welfare of their residents during the research. They may need also to address facility-wide issues such as disruption of routine, resource consumption, and potential benefits to the facility. A nursing home's participation in research is elective; producing new and generalizable knowledge is usually not at the core of its mission and must be weighed against competing priorities. One author tells of a facility in which 17 different research proposals were received in one year (Daly *et al.*, 2000). It is unlikely that a facility would have the resources to

## 6. Major Issues in Ethics of Aging Research

accommodate that many requests; if it did, competition for enrollment could easily doom all studies. Research committees in nursing homes, as Daly describes, can analyze such issues. Such committees are still uncommon, but developing one is worth considering in a facility planning to be open to research. Nursing home ethics committees are somewhat more common and present another possible avenue for consideration of protocols (Cassel, 1988). Such committees function in ways analogous to hospital ethics committees, by consulting and sometimes educating on issues related to ethical decisions in the institution (Hoffman *et al.*, 1995).

In summary, research in the nursing home is complex ethically. The presence of a subject in the nursing home raises initial concerns for that person's ability to consent that must be addressed in study design and execution. The facility itself has an ethical mandate different from that of the researcher, and honoring it may require adaptation of the protocol and persistent communication. Research in nursing homes should be guided by an interest in the specific characteristics of its residents and structure, and not by the apparent convenient access to older subjects.

### Is Aging Research Anti-Aging?

This is truly an odd question. It is a question about ethics, but one that operates at a level different from the "how-to" of ethical research practices discussed so far in this chapter. It has more to do with the fundamental values, direction, and purpose that underlie one's engagement in aging research. Such fundamental values influence one's choice of research areas and beliefs about the benefits of that research.

Much of aging research involves understanding and addressing the diseases and conditions that occur in an aging population. That sort of aging research is not ethically controversial and clearly not anti-aging; words like "disease" and "disability" already carry with them the implication that they should be controlled, avoided, or eradicated. Other research begins from the belief in an organism-wide process of aging, a unified process of senescence that is distinct from various specific processes of degeneration and must be dealt with as one would deal with disease. Discovering and controlling that process, just as one would research and address a disease, is "age retardation" (President's Council on Bioethics, 2003).

Age retardation seems to be a neutral or even a praiseworthy enterprise, but it has encountered significant objections with bases in ethics. Common to those objections is the belief that aging and mortality are so fundamental to human existence that, without them, we would lack something essential to human flourishing. "Old age is an inevitable human condition, one that should not be defined as a medical problem to be conquered. ..." (Joint International Research Group, 1994). Let us consider several of those objections.

First, significant increases in lifespan could create significant societal problems (Capron, 2004). A longer lifespan could result in a larger aging population and a longer period of decline for humans. Significant gains in age retardation could upset delicate social institutions related to health care, employment, retirement, marriage, etc. In so doing they could be destructive of the common good and create issues of distributive justice and inter-generational equity.

Second, the enticement of eternal youth is a powerful tool for taking unfair advantage of those who most fear aging, disability, and mortality. Our culture places great value on staying young. A promise of a miracle treatment can waste money, actually cause harm, and dissuade the gullible from doing what is best known to support one's chances of aging well—a healthy lifestyle.

Third, the pursuit of a cure for biological aging seems to ignore or deny anything positive about psychosocial aging. Human life is shaped by our understanding of our own finitude and imperfection. It underlies our perception of youth and of maturity, and of unique wisdom that does not come without years of life and the recognition that it will end. In short the quest for age retardation is an expression of ageism, as described by Butler (1969).

It can be plausibly argued that a researcher in basic science is essentially neutral on the age retardation issue. The scientist does not choose how the knowledge developed in the laboratory might be used by others. Unlocking the secrets of cellular aging might just as well support the efforts to prevent or retard cancer as to retard aging. The legitimacy of that perspective begins to fade along a continuum that begins with basic science and culminates in clinical trials. Translational science moves one closer to exploring specific applications of the knowledge discovered. Clinical research and trials are farther along the same continuum.

It can also be argued that, with informed planning, the calamities that age retardation could rain upon us could just as well be blessings. Most importantly, the recurring debates about the uses of new knowledge in society would suffer dramatically without the involvement of the scientists who create that knowledge. The rate of scientific progress frequently outruns the adjustment of social policy that must occur with the new knowledge. So it was with nuclear energy, the Internet, and, more recently, stem cell therapies. We cannot afford to repeat the experience with the significant new knowledge emerging in biogerontology. Without scientific input, social policy would still change, but just in time and in ill-informed and counterproductive ways.

### Conclusion

Applying principles of ethics to aging research is more than one project. It consists in part of artfully and ethically responding to the obvious, using accepted principles of ethics. We know, for example, that some

persons are impaired, that impairment makes it difficult to get informed consent, and that we ought to take additional measures to protect those persons. We know some of the measures that can be effective in enhancing informed consent or in protecting those who cannot consent.

Some ethical problems are sufficiently identified and articulated, but still lack a satisfactory response around which consensus can be built. There are still open questions about whether the pursuit of the common good should be allowed to override the individual interests of a research subject with a surrogate decision-maker. Other problems are so new and the science supporting them so seminal that the best interests of society will be served only by a broad base of participation in establishing social policy sufficiently robust to accommodate new research findings in aging. “Doing ethics” becomes something more than learning and accepting rules and principles. It also involves active participation in developing that ethics.

### Some Recommended Resources

Ethics in aging research is actually the intersection of three different studies, gerontology, ethics, and research methodology, each of which has its own literature. Among periodicals, consider the *Hastings Center Report*, *IRB: Ethics and Human Research*, the *Journal of the American Geriatric Society*, and the *American Journal of Bioethics*. Disease-specific periodicals can be helpful as well. The Alzheimer’s research community has sustained a long and fruitful discussion related to capacity for consent, much of which is in *Alzheimer’s Disease and Related Disorders*.

The literature of research ethics is in some respects different from publications that report research findings. Frequently authors, in trying to get to core issues, work with principles that were not recently discovered. It is not at all uncommon for a seminal book or article from several decades ago to continue to be valuable. See, for example, *The Patient as Person*, which appeared in the wake of the research scandals of the 1960s (Ramsey, 1970).

Consider also the work of associations with an interest in aging and research. Much of their contributions can be accessed through the respective websites of the Alzheimer’s Association, the American Geriatric Society, and the Association for the Accreditation of Human Research Protection Programs. Websites for are listed in the References section.

# Ethical Aspects of Research Involving Elderly Persons

Paul S. Mueller and C. Christopher Hook

*The number of elders living in the U.S. is rapidly growing. Elders are uniquely burdened with illnesses and account for most deaths. In order to reduce morbidity and mortality experienced by elders, research involving elderly human subjects is needed. Contemporary codes of ethics and regulations governing research involving human subjects derive from the ethical principles of respect for persons, beneficence and justice. Investigators conducting research involving elders should be familiar with and adhere to these general ethical principles. In addition, investigators should acknowledge and address the potential ethical challenges of research involving elderly persons. These challenges include obtaining adequate informed consent by conveying sufficient information and ensuring subject voluntariness and decision-making capacity. Research involving elders with impaired decision-making capacity is especially challenging. In this chapter, the history of human subjects research, the general ethical principles of research, and ethical challenges specifically associated with conducting research involving elders are discussed. In addition, an approach to these challenges and a list of resources for investigators engaged in research involving elders are described.*

## Introduction

Because of advances in public health and medicine, Americans are living longer. By the year 2020, nearly 54 million elderly (older than 65 years) persons (also known as “elders”) will be living in the United States (U.S. Census Bureau, 2000). However, compared to younger persons, elders are uniquely burdened with illnesses. On average, an elderly person has 3 to 4 illnesses and a 20% annual risk of hospitalization. Furthermore, elders are the largest consumers of prescription drugs and account for most deaths (Jahnigen, D., and Schrier, R., 1986; Swift, C., 1988; U.S. Census Bureau, 2000). As a result of these factors, clinicians will care for an increasing number of elderly persons with multiple medical problems, some of which are uniquely associated with aging itself (e.g., Alzheimer disease).

Medical care that improves the outcomes (e.g., mortality, morbidity, and quality of life) of elderly persons depends on research advances. This research, in turn, depends on the involvement of elderly patients in research studies. Research on health-related problems of elders is important not only because of demographic trends, but also because of a lack of previous research involving elders and poor understanding of the processes associated with aging itself and what constitutes normal aging (Zimmer *et al.*, 1985; Kaye, J. *et al.*, 1990; Sachs, G. and Cassel, C., 1990). Hence, research involving elders is needed. If one accepts the need for research involving elderly subjects, then the ethical aspects of human subjects research in general and research involving elders specifically should be considered (Denham, M., 1984). In this chapter, we discuss the history of human subjects research and the unique aspects and potential ethical challenges of conducting research involving elders. In addition, we provide suggestions for conducting research involving elders that yields ethically valid and fruitful results not only for the good of elders but also for society in general.

## History of Human Subjects Research

### THE NUREMBERG CODE

Before World War Two, no internationally acknowledged code of ethics for human subjects research existed. During the war, Nazi physicians conducted many experiments of dubious value on thousands of prisoners. The experiments were conducted without the prisoners’ informed consent and many prisoners were mutilated and killed. The discovery of the atrocities committed by the Nazi physicians under the guise of experimentation led to the Nuremberg War Crimes Physicians Trial of Nazi physicians for “crimes against humanity” consisting of experiments upon concentration camp prisoners and others without their voluntary consent resulting in “murders, brutalities, cruelties, tortures, atrocities and other inhuman acts” (The Nuremberg Code, 1947). The trial judges included in their 1947 verdict a list of rules for

TABLE 7.1.  
The Nuremberg Code: "Permissible Medical Experiments" (Excerpted from The Nuremberg Code, 1947)

1. The voluntary consent of the human subject is absolutely essential.
2. The experiment should be such as to yield fruitful results for the good of society, unprocurable by other methods or means of study, and not random and unnecessary in nature.
3. The experiment should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problem under study that the anticipated results will justify the performance of the experiment.
4. The experiment should be so conducted as to avoid all unnecessary physical and mental suffering and injury.
5. No experiment should be conducted where there is an a priori reason to believe that death or disabling injury will occur, except, perhaps, in those experiments where the experimental physicians also serve as subjects.
6. The degree of risk to be taken should never exceed that determined by the humanitarian importance of the problem to be solved by the experiment.
7. Proper preparations should be made and adequate facilities provided to protect the experimental subject against even remote possibilities of injury, disability, or death.
8. The experiment should be conducted only by scientifically qualified persons. The highest degree of skill and care should be required through all stages of the experiment of those who conduct or engage in the experiment.
9. During the course of the experiment the human subject should be at liberty to bring the experiment to an end if he has reached the physical or mental state where continuation of the experiment seems to him to be impossible.
10. During the course of the experiment the scientist in charge must be prepared to terminate the experiment at any stage, if he has probably cause to believe, in the exercise of the good faith, superior skill and careful judgment required of him that a continuation of the experiment is likely to result in injury, disability, or death to the experimental subject.

"Permissible Medical Experiments" which later became known as the Nuremberg Code and was the first internationally recognized code of ethics for experimentation on human subjects. The rules included requirements that (a) subject voluntary consent be obtained; (b) the study benefits outweigh the risks; (c) the study should be conducted to avoid unnecessary harm, with no experiment to be conducted if there is *a priori* belief that death or injury will occur; and (d) the subject has the right to withdraw from the study at any time (Table 7.1).

#### WORLD MEDICAL ASSOCIATION DECLARATION OF HELSINKI

Notably, the Nuremberg Code only addresses research involving healthy subjects. In an effort to address the ethical aspects of research involving patients, the World Medical Association drafted the Declaration of Helsinki in 1964 (World Medical Association Declaration of Helsinki, 1964). As with the Nuremberg Code, informed consent, the need for favorable risk-to-benefit ratios, and subject voluntariness are central features of the Declaration. However, the Declaration also addresses proxy consent (e.g., when potential subjects have impaired decision-making capacity), the use of control groups and placebos, and nontherapeutic research.

#### Human Subjects Research in the United States after World War Two

Despite the Nuremberg Code and the Declaration of Helsinki, medical research after World War Two con-

tinued to be tainted by revelations of widespread abuse of human subjects. Henry K. Beecher described some of these revelations in an article published in the *New England Journal of Medicine* in 1966 (Beecher, H., 1966). In this article, Beecher described 22 studies conducted at prestigious institutions and published in leading medical journals in which human research subjects were subjected to excessive risks (i.e., risk to benefit ratio) often without their knowledge or consent. Beecher concluded that (a) it is "absolutely essential" to obtain informed consent from research subjects; (b) consent is not valid if the patient doesn't understand "what is to be undertaken" in the study; (c) "the gain anticipated from an experiment must be commensurate with the risk involved"; (d) research reports should explicitly state that ethical "proprieties have been observed"; and (e) data obtained unethically should not be published. Notably, Beecher hypothesized that these ethical breaches were due partly to the growth of public funding for research coupled with the need for investigators to publish to obtain such funding and advance professionally.

A number of studies cited by Beecher became notorious on their own. In a study of immunity to cancer at the Jewish Chronic Disease Hospital (New York), investigators injected live cancer cells into human subjects without obtaining informed consent. Another study involved the deliberate induction of infectious hepatitis (to understand better the natural history of the disease) in mentally impaired children who were residents at the Willowbrook State School for the Retarded (New York). The ethical concerns raised by this study were the

## 7. Ethical Aspects of Research Involving Elderly Persons

deliberate exposure of the children to harm, and the deception and coercion that occurred during the parental informed consent process (Weyers, W., 2003).

Another study that achieved notoriety was the Tuskegee (Alabama) syphilis study. The purpose of this study, which was funded by the U.S. government and conducted by the U.S. Public Health Service from 1932 to 1972, was to determine the natural history of untreated late-stage syphilis in poor African-American men. The men were not told that they had syphilis, did not receive effective treatment for the disease, and were not informed that they were participating in an experiment. Instead, subjects were told they had “bad blood” and that the examinations they underwent were treatments. In fact, the study continued after effective treatment for syphilis became available. A widely publicized media report of the study resulted in public outrage, a class-action lawsuit, a congressional investigation, and the study’s termination (Weyers, W., 2003).

### The National Commission

Revelations of the aforementioned unethical studies led to public scrutiny and debate regarding human subjects research and ultimately regulatory attempts to prevent abuse. Particular concerns were respect for persons (i.e., research subjects) and the equitable distribution of the burdens and benefits of research. Congressional hearings led to the passage of the National Research Act in 1974. This act mandated the establishment of institutional review boards (IRBs) for the independent review of research at institutions receiving federal support for human subject research and created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. A major achievement of the National Commission was the influential Belmont Report (The Belmont Report, 1979).

### THE BELMONT REPORT

The Belmont Report begins by recognizing that while research involving human subjects has produced important social benefits including reduced morbidity, greater longevity and improved quality of life, this research has also posed challenging and troubling ethical questions. The report also explicitly distinguishes clinical practice and medical research. The purpose of clinical practice is to enhance the well-being of the patient by using interventions for which there is an expectation for success. On the other hand, the purpose of medical research is to gain new knowledge; research involves testing hypotheses and drawing conclusions through experiments from which research subjects may or may not derive benefits. Notably, clinical practice and medical research often occur in the same setting. However, subjects in the clinical setting may not recall that they are participating in a research study (Riecken, H. and Ravich, R., 1982). It is important for

research subjects to be informed of and understand these differences (American College of Physicians, 2005).

The Belmont Report also recognizes that the Nuremberg Code and later codes were drafted to assure the ethical conduct of human subjects research. However, these codes consist primarily of rules for conducting research that do not address every potential research scenario (e.g., a scenario that the rules do not cover or conflict with each other). To address these deficiencies of the codes, the authors of the Belmont Report describe three *prima facie* ethical principles for conducting human subjects research that provide a basis on which specific rules may be established, appraised and interpreted. These three principles are respect for persons, beneficence (nonmaleficence) and justice.

#### 1. Respect for persons

The principle of respect for persons requires that investigators acknowledge that individual human research subjects are autonomous (the word *autonomy* derives from the Greek *autos* for “self” and *nomos* for “rule”) agents with the right of self-determination (Beauchamp, T. and Childress J., 2001). The centrality of informed consent in research derives from this principle. Informed consent consists of three elements: (a) adequate information regarding the research study and its potential risks and benefits and subject understanding of the information; (b) subject decision-making capacity; and (c) subject voluntary involvement (i.e., without coercion). Respect for persons is maximized when the elements of informed consent are fully realized. Notably, not every person is capable of self-determination. Hence, this principle also requires that investigators protect subjects with diminished autonomy (e.g., due to impaired decision making capacity) from exploitation and harm.

#### 2. Beneficence

The principle of beneficence requires that investigators act to secure the well-being of human research subjects, maximize benefits and minimize risks and harm. The Belmont Report, however, recognizes that the goal of avoiding harm may, in fact, require that research be done to determine what is harmful and what is beneficial and, hence, may involve exposing research subjects to risks. The dilemma for investigators is to determine when benefits should be forgone because of risks and when benefits should be sought despite the risks. Research protocols should be designed in ways that maximize benefit while at the same time minimizing harm. Proposed research questions must also be worth answering. Research studies involving human subjects, even those involving minimal risk, are not justifiable if the research does not generate scientifically valid and worthy new knowledge. Hence, proper study design and methods are not only scientific, but also ethical, obligations.

The Belmont Report also declares that: (a) inhumane treatment of human subjects is never morally justified;

(b) investigators should determine if human subjects are necessary and, if so, the risks should be reduced to those necessary or alternative means used to reach the research objective; (c) if the research involves risk of harm, the risk should be justified; (d) the appropriateness of involving vulnerable populations in research should be demonstrated; and (e) risks and benefits should be clearly stated in informed consent documents.

### 3. Justice

The principle of justice refers to the equitable distribution of the benefits and burdens of research. Injustice occurs when one receives (or is denied) benefits or when one bears (or does not bear) burdens without good reason. Applied to research involving human subjects, the benefits and burdens of participating in research should be distributed fairly. In fact, the Belmont Report explicitly notes the legacy of unjust prior research studies (and specifically mentions the Tuskegee study) in which the burdens of being research subjects fell primarily upon disadvantaged (e.g., poor) persons, while the benefits of improved healthcare was realized primarily by privileged patients.

Instead, the selection of research subjects should be based on the needs of the study. Furthermore, publicly-funded research should not unduly involve individuals who will not likely benefit from therapeutic innovations that derive from the research, and when such research results in therapeutic innovations, the innovations should not provide advantages only to those who can afford them.

General applications of the three prima facie ethical principles described in the Belmont Report are described in Table 7.2.

## UNITED STATES FEDERAL REGULATIONS (THE COMMON RULE)

While the principles described in the Belmont Report provide a basis for ethically conducting human subjects research, the report has been variably interpreted and used (High, D., 1992). Nevertheless, the Belmont Report became the basis for the Code of Federal Regulations Title 45 Part 46 (“Protection of Human Subjects”) issued in 1981 by what is now known as the Department of Health and Human Services (DHHS). Since then, these regulations have undergone a number of modifications. Most, but not all, federal agencies that sponsor and fund research involving human subjects have formally adopted these regulations as the Federal Policy for the Protection of Human Subjects or “Common Rule” (45 CFR 46) (Department of Health and Human Services). The Common Rule articulates requirements for compliance by institutions involved in research, informed consent, and for IRB membership and responsibilities. The Common Rule also articulates measures for protecting especially vulnerable research subjects (e.g., children and prisoners).

TABLE 7.2.  
Ethical principles of the Belmont Report and their applications to human subjects research (data from The Belmont Report, 1979 and Cohen, J.)

Principles	Applications
Respect for Persons	<ul style="list-style-type: none"> <li>• Informed consent</li> <li>• Protection of vulnerable research subjects (e.g., persons with impaired decision-making capacity and institutionalized persons)</li> <li>• Proxy consent and subject assent for persons with impaired decision-making capacity</li> </ul>
Beneficence	<ul style="list-style-type: none"> <li>• Maintenance of subject confidentiality</li> <li>• Scientifically valid study design</li> <li>• Research question worth answering</li> <li>• Study minimizes harms and maximizes benefits</li> </ul>
Justice	<ul style="list-style-type: none"> <li>• Equitable distribution of benefits and burdens of research (i.e., fair recruitment and selection of subjects)</li> </ul>

Today, the Office for Human Research Protections (OHRP), which is part of the DHHS, oversees matters related to protecting human research subjects participating in studies conducted or supported by the DHHS. The OHRP (a) establishes criteria for and approves assurances of compliance for protecting human subjects with institutions engaged in research conducted or sponsored by the DHHS; (b) provides clarification and guidance on involving human subjects in research; (c) develops and implements educational programs and resource materials; and (d) promotes the development of approaches to enhance human subject protections. Under the direction of the OHRP, more than 10,000 research institutions have agreed to comply with the regulations for protecting human subjects found in the Common Rule (Office for Human Protections).

In addition to designing and conducting research studies that adhere to the ethical principles of the Belmont Report and comply with federal regulations, investigators engaged in human subjects research have a number of specific responsibilities regarding their local IRBs. These responsibilities are listed in Table 7.3.

## Research Involving Elderly Persons

In general, the ethical principles for protecting elderly human subjects in research are the same as those for protecting younger subjects (Sachs, G. and Cassel C., 1990). However, elders who are potential research subjects are of two types; those who are vigorous, independent, and autonomous (the majority of elders), and those who

## 7. Ethical Aspects of Research Involving Elderly Persons

TABLE 7.3.  
Responsibilities of investigators engaged in research involving human subjects (data from Cohen, J.)

1. Design and conduct research in alignment with the ethical principles described in the Belmont Report
2. Comply with all federal regulations related pertaining to the protection of human subjects
3. Obtain approval for all research involving human subjects from the appropriate institutional IRB
4. Comply with all IRB policies, procedures and decisions and other requirements
5. Conduct research as approved by the IRB
6. Obtain IRB approval for all changes to the study protocol
7. Obtain and document informed consent and assent from subjects in compliance with federal regulations and as approved by the IRB
8. Report progress of research to the IRB as prescribed by the IRB
9. Report to the IRB any adverse events or unanticipated problems involving subjects or others
10. Retain research documents (e.g., signed consent forms) for at least three years following completion of the study

are dependent, decisionally impaired, or dependent on others. Persons who comprise the former group do not differ from younger persons in any way except for chronological age, and the ethical principles governing research in general are sufficient to encompass research involving them. Research involving the latter group, however, is more complex; these elders are vulnerable, often institutionalized, and many lack decision-making capacity (Dubler, N., 1987). In fact, there are a number of unique aspects and potential ethical challenges of conducting research involving elderly subjects that merit special attention (Sachs, G. and Cohen, H., 2003). The remainder of this chapter will address these unique aspects and challenges.

### Unique Aspects and Potential Ethical Challenges of Conducting Research Involving Elderly Persons

Compared to other research subjects, elders may be unique for a variety of reasons: (a) greater prevalence among elders of conditions [e.g., hearing and vision loss, diminished cognition, etc.] that may impair informed consent; (b) greater prevalence among elders of comorbid illnesses and other potential confounding variables that may make interpretation of study results difficult; (c) the captive nature of some populations of elders (e.g., residents of nursing homes) making them susceptible to coercion and breaches of confidentiality; and (d) evidence that elders have been unjustly excluded from research studies including those especially relevant to elders.

#### ELDERLY PERSONS' WILLINGNESS TO PARTICIPATE IN RESEARCH STUDIES

Elders are less willing to participate in research studies (Kaye *et al.*, 1990; Sachs, G. and Cassel, C., 1990). For elders who have sensory deficits, the informed consent process may be prolonged and frustrating, thereby

reducing participation (Sugarman *et al.*, 1998). Furthermore, some elders refuse to sign, fear the implications of, or are otherwise inexperienced with consent forms, and some may insist that family members be involved in the informed consent process, thereby adding to the efforts of investigators. These factors may frustrate both potential research subjects and investigators and lead to reduced participation (Kaye, J., Lawton, P. and Kaye, D., 1990). Transportation, mobility issues and medical conditions that require frequent attention may reduce participation or cause some elders to drop out of studies (Sachs, G. and Cassel, C., 1990). When recruiting elders for research studies, investigators should consider and address these and other factors that may adversely affect participation.

#### OBTAINING INFORMED CONSENT FROM ELDERLY PERSONS

As articulated by the Nuremberg Code and the Belmont Report, and codified in federal regulations, research involving human subjects may be done only with the subjects' voluntary informed consent. However, any element of the informed consent process (relevant and sufficient information, decision-making capacity and subject voluntariness) may be compromised when conducting research involving elderly research subjects.

##### 1. Information

Meaningful and ethically valid informed consent requires that research subjects be given relevant and sufficient information including the purpose of the study, potential risks and alternatives to participation, and the subject's right to withdraw from the study at any time. Furthermore, investigators should inform potential research subjects that the primary objective of research is to acquire new knowledge and that personal clinical benefit may or may not occur (American College of Physicians, 2005).

Subjects must also understand the disclosed information. Investigators should ensure that subjects understand the information conveyed during the informed consent process since harm may occur as a result of the subject making a misinformed choice (i.e., a choice they would not have made if they had understood the information) (Ratzan, R., 1980). However, many research subjects, especially those who are ill or poorly educated, do not understand the purposes and risks of the studies in which they are participating even after consent has been obtained (Sachs, G. and Cassel, C., 1990). Informed consent forms can be long, complex and difficult to understand (LoVerde *et al.*, 1989). Furthermore, research subjects participating in studies in a clinical setting may forget that they are, in fact, research subjects (Riecken, H. and Ravich, R., 1982).

Notably, systematic reviews of studies of the informed consent process have found that reduced understanding of conveyed information was associated with older age (Sugarman *et al.*, 1998; Flory, J. and Emanuel, E., 2004). In addition, compared to younger persons, elders may have more difficulty in recalling information conveyed (Sachs, G. and Cassel, C., 1990). Impaired understanding and recalling of information by elders may be due to sensory deficits (e.g., vision and hearing), comorbid illnesses, diminished cognition, and other factors (Sugarman *et al.*, 1998).

However, a number of strategies can improve the understanding of information. Simplified consent forms, multimedia approaches (e.g., video), quizzes, multiple disclosure sessions and especially generous one-on-one time with a study team member or educator are effective means of improving understanding (Sugarman *et al.*, 1998; Flory, J. and Emanuel, E., 2004). Another promising tool for maximizing informed consent among potential research subjects who are frail and elderly is “experienced consent.” In a study of frail elders, a week-long trial of noninvasive testing to gain experience with a research study’s methods resulted in significant increases in comprehension of the study methods and the number of subjects capable of weighing the risks associated with the study (Olde Rikkert, M., *et al.*, 1997).

## 2. *Voluntariness*

The first item of the Nuremberg Code is that “the voluntary consent of the human subject is absolutely essential” (Nuremberg Code, 1947) (Table 7.1). Subsequent codes, reports and regulations have reiterated this principle. Subjects, to the degree that they are capable, must be allowed to decide what shall and what shall not happen to them. Notably, despite the crucial role of voluntariness in the informed consent process, little empirical data regarding voluntariness has been published (Sugarman *et al.*, 1998).

Autonomy may be limited for residents of long-term care institutions (e.g., nursing homes), most of whom are elders. When to eat and go to bed, choosing a roommate

and other activities are largely controlled by the institution. Hence, it is not surprising that concerns exist about the possibility of obtaining voluntary consent for research from residents of long-term care institutions. Residents depend on the institution for food, shelter, medications and care. In the context of consent for research, this dependency may foster coercion; i.e., residents may not feel free to refuse to participate in research out of fears that their care will suffer if they refuse, especially if their clinicians are also the investigators (Bell, J., *et al.*, 1987; Sachs, G. and Cassel, C., 1990; Sachs, G. and Cohen, H., 2003). Whereas independent research subjects can freely choose to continue or withdraw from a research study, institutionalized persons may perceive less freedom to choose because of needs for attention and care, and fear of rejection (Dubler, N., 1987).

## 3. *Decision-making Capacity*

Decision-making capacity refers to a potential research subject’s ability to understand, make and express a reasoned and meaningful choice about whether to participate in a research study. Of the elements of the informed consent process, decision-making capacity is often the most problematic for elders, since elders represent an age group most susceptible to illnesses that affect mental functioning (Marson, D., *et al.*, 1994). Nevertheless, society and law assume that all adults are competent. In fact, the term *competent* is a legal term, and only a court can declare a person incompetent. Clinicians and investigators, however, may care for and work with elders who cannot effectively comprehend or manipulate information in a way that allows for weighing of the risks and benefits of, and alternatives to, a proposed intervention or research protocol. These patients lack decision-making capacity. Unlike competency, clinicians and investigators determine if a person has decision-making capacity.

Having a mental illness or an illness that affects cognition does not necessarily mean an individual lacks decision-making capacity (AGS Ethics Committee, 1998; Alzheimer’s Association, 2004). Indeed, many elders with diminished cognition are not only legally competent, but also have decision-making capacity and can consent to participate in research. Capacity to consent need not be based on an overall state of competence. A patient can have diminished cognition (e.g., due to dementia) and still understand the purpose of the study (e.g., that it is research and may not provide a therapeutic benefit), the risks of participating in the study, and that he or she may refuse to participate. Instead, consent for participating in research studies of varying complexity requires varying levels of capacity. For example, a person may be able to effectively consent to participate in a minimal risk study (i.e., a study in which the risk and magnitude of harm to the subject are no greater than what the subject would encounter in daily life or during the performance of routine physical or psychological examinations or

## 7. Ethical Aspects of Research Involving Elderly Persons

tests), but not a trial of a new drug or procedure (Dubler, N., 1987; Sachs, G. and Cohen, H., 2003).

Assessing the decision-making capacity of potential research subjects is an important step in the informed consent process. Capacity to consent for participating in research should include the following abilities: (a) ability to evidence a choice (i.e., ability to reach a decision and effectively communicate the decision); (b) ability to understand the nature of the research study and other information relevant to participants disclosed by the investigator; (c) ability to understand and appreciate the risks and consequences of participating or not participating in the study, and the procedures to follow if adverse events occur and if withdrawal from participation is desired; and (d) ability to manipulate information rationally (Alzheimer's Association, 2004; American Psychiatric Association, 1998).

Unfortunately, clinicians and investigators are uncommonly trained to assess the decision-making capacity of potential subjects and thereby have difficulty assessing capacity. In fact, those who are experienced in assessing decision-making capacity may disagree with each other. Furthermore, no universally accepted standardized tool for assessing decision-making capacity for research consent exists. Because of these facts, investigators assessing capacity have relied on subjective impressions and brief mental status tests (Marson, D., *et al.*, 1994). One promising approach, however, is for investigators to incorporate details of a given study into open-ended questions that assess the aforementioned decision-making capacity abilities of a potential subject for the study (Karlawish, J., 2003).

Research protocols should describe how assessment of subject decision-making capacity will be done. The extent of the assessment should correlate with the risks of the research. For minimal risk studies, an informal assessment by a research team member should suffice. For higher risk studies, using an independent qualified professional skilled in assessing decision-making capacity should be considered (Alzheimer's Association, 2004).

Notably, some subjects may lose decision-making capacity during a study. If at the time of enrollment subjects have capacity to consent, but are at risk of losing capacity during the study, then investigators should describe in their protocols how periodic capacity reassessments will be done. Furthermore, investigators should offer subjects the opportunity to name a proxy decision-maker and ask the subject to provide guidance to the proxy on what to do should loss of capacity occur. In addition, some subjects with impaired capacity and enrolled in research studies via proxy consent may later regain capacity. In these situations, the investigator must obtain informed consent from the subject for continued participation (Alzheimer's Association, 2004).

### RESEARCH INVOLVING ELDERLY PERSONS WITH IMPAIRED DECISION-MAKING CAPACITY

#### 1. Background

Approximately 10 percent of elders older than 65 years and 22 percent older than 80 years have dementia. Furthermore, a majority of nursing home residents have some form of cognitive impairment (Cassel, C., 1988). In addition, many elders experience delirium during hospitalizations for acute illnesses (Rummans, T., *et al.*, 1995). Many of these patients are incapable of giving valid informed consent. Nevertheless, to better understand illnesses that uniquely afflict elders including those illnesses that impair decision-making capacity, research that involves decisionally impaired elders may be necessary. Restrictive approaches that bar subjects with impaired capacity from research may cause harm; these individuals would be deprived of research-derived medical advances on the very conditions that limit their capacity and be deprived of the benefits of participating in research. Nevertheless, informed voluntary consent to research requires decision-making capacity. Hence, is it ever legitimate to enroll in research studies individuals with impaired decision-making capacity?

The permissibility of enrolling decisionally impaired persons in research has evolved over time. The authors of the Nuremberg Code did not allow for the involvement of decisionally impaired persons in research even if such research was potentially therapeutic. The prevailing view was that studies involving subjects with impaired capacity that do not directly benefit or are potentially harmful to the subjects should not be done (Capron, A., 1999). The Declaration of Helsinki, however, allowed for legally recognized surrogates of decisionally impaired persons to provide consent for therapeutic research (Capron, A., 1999; Michels, R., 1999). Later the National Commission went beyond the Nuremberg Code and the Declaration of Helsinki by claiming that prohibiting such research might harm an entire class of decisionally-impaired persons by depriving them of potential benefits of research (Michels, R., 1999). Indeed, proxy consent for minimal risk studies and greater than minimal risk studies with potential direct benefits to subjects is now widely accepted (Capron, A., 1999).

The National Commission, however, noted that investigators may need to make special provisions for protecting subjects with impaired decision-making capacity. Later, in 1983, the President's Commission reiterated the National Commission's concern (Shamoo, A. and Khin-Maung-Gyi, F., 2002). Nevertheless, despite the reports of these two commissions, specific federal regulations aimed to protect research subjects with impaired decision-making capacity have not been adopted. Even so, the Common Rule (45 CFR 46) does state that "if an IRB regularly reviews research that involves a vulnerable category of subjects, such as ... mentally disabled persons, consideration shall be given to the inclusion of

one or more individuals who are knowledgeable about and experienced in working with these subjects” (Department of Health and Human Services). Nevertheless, in the absence of federal regulations, IRBs must decide what constitutes impaired decision-making capacity, what constitutes greater than minimal risk, and when decisionally impaired subjects are not at excessive risk of harm (Shamoo, A. and Khin-Maung-Gyi, F., 2002).

In 1998, the National Bioethics Advisory Commission (NBAC) issued its report, “Research Involving Persons with Mental Disorders That May Affect Decisionmaking Capacity,” in which it stated that a “case can be made for requiring additional special protections in research involving subjects persons with impaired decision making capacity” (National Bioethics Advisory Commission, 1998). Specific recommendations made by NBAC include: (a) IRBs involved in reviewing protocols involving populations with impaired decision-making capacity should contain at least two members who are familiar with the disorders causing the impaired capacity and with the concerns of the population being studied; (b) for greater than minimal risk protocols, IRBs should require independent and professionally qualified assessment of potential subjects’ capacity to consent; (c) for greater than minimal risk protocols that offer no prospect of direct medical benefit to subjects, the protocol should be referred to a national Special Standing Panel for a decision. NBAC advised that its recommendations become part of the Common Rule and that, until the recommendations become federal regulations, IRBs adopt voluntarily the recommendations. To date, these recommendations have not become part of the Common Rule (Sachs, G. and Cohen, H., 2003).

### 2. Advance Directive for Research

Advance care planning consists of informal and formal healthcare planning by a decisionally capable person to guide healthcare decision-making for a future time in which they no longer have decision-making capacity. A discussion with family members, friends and healthcare providers is an example of informal advance care planning. A written advance directive for healthcare decisions is an example of formal planning (Sachs, G., 1994). For research involving persons with impaired decision-making capacity, NBAC recommended that these subjects could be enrolled in research studies if the subject gave prospective authorization via an advance directive for research completed at a time when the subject had decision-making capacity, and in the absence of an advance directive for research, consent from a legally authorized proxy is obtained and the subject assents to the research study (National Bioethics Advisory Commission, 1998).

Like the advance directive for healthcare decisions, the advance directive for research (also known as advance consent) is a legal document executed by a decisionally capable person that authorizes their enrollment in

research studies for the time the person lacks decision-making capacity (Kapp, M., 1994; AGS Ethics Committee, 1998). In an advance directive for research, persons can designate their proxy decision-maker, the types of research and risks that would be acceptable, and other values (e.g., religious values) and goals (Sachs, G., 1994).

The advance directive for research, however, has important limitations. First, only 10–20% of Americans adults have advance directives for healthcare treatment decisions (Sachs, G., 1994; Hanson, L. and Rodgman, E., 1996), and it is likely that even fewer have advance directives for research. Many people who complete advance directives for healthcare decisions are motivated to avoid invasive procedures and burdensome life-sustaining treatments (e.g., respirators) at the end-of-life and to prevent prolongation of the dying process. There is no equivalent motivating factor for completing an advance directive for research. Second, by the time it is recognized that a person has lost decision-making capacity, it is unlikely that she or he can complete a detailed advance directive for research. Finally, requiring a written advance directive for research in order for persons with impaired decision-making capacity to participate in research would substantially limit the number of potential subjects and deprive them of the benefits of being research participants and deprive others with their condition of the benefits derived from the discovery of new knowledge (Sachs, G., 1994).

### 3. Proxy Consent for Research

In the absence of an advance directive for research, investigators must obtain consent for research from a legally authorized proxy (AGS Ethics Committee, 1998; Alzheimer’s Association, 2004). Typically, the person at the top of the decision-making hierarchy is a court-appointed guardian followed by the person or persons named in an advance directive. If no advance directive exists, investigators should identify and seek consent from a legally authorized proxy. Notably, hierarchies of proxy decision-making vary from jurisdiction to jurisdiction (Karlawish, J., 2003).

Proxies should base their decisions to enroll the decisionally impaired subjects they represent in research studies on the subjects’ previously expressed wishes, values and goals (i.e., substituted judgment). However, as with healthcare decision-making, proxies frequently do not know the previously expressed wishes, values and goals of subjects and, hence, do not consistently make substituted judgments for enrollment in research (Sachs, G., 1994; Karlawish, J., 2003). Indeed, in a study (Warren, J., *et al.*, 1986) of proxy consent, investigators examined the decisions by proxies for 168 nursing home residents about whether to permit the residents’ participation in a minimal risk study. In all but one instance, the proxies were family members. Fifty-five proxies were of the opinion that the residents that they represented would refuse to participate (if capable) in the study. Of these

## 7. Ethical Aspects of Research Involving Elderly Persons

proxies, however, 17 (31%) gave consent to participate. Another study (Sachs, G., *et al.*, 1994) involving patients with dementia, proxies and well elders found that some demented patients were capable of giving informed consent and most were capable of identifying a proxy decision-maker. The investigators commented that many patients regard designating a trusted proxy as more important than the decisions a proxy would make and that designating a proxy requires less decision-making capacity than the informed consent process for research. Finally, using research scenarios, the investigators found that proxies were more likely to take risks for themselves and protect patients from greater than minimal risk studies (e.g., trials involving drugs and procedures). On the other hand, proxies made decisions contrary to what the patient would want in scenarios in which the risk was perceived to be low and the benefit for others perceived to be present. The results of these studies and others suggest that while proxies do not always use substituted judgments for enrollment in research, they do make decisions that minimize harm to patients. In addition, evidence suggests that patients care more about who is making the decisions for them than the decisions being made (Sachs, G., 1994).

### 4. Subject Assent for Research

Despite impaired decision-making capacity and proxy consent, subject assent is essential and subjects should be allowed to refuse to participate. Assent can be judged based on subject behavior and cooperativeness. Subject dissent should be respected, and when it occurs, subjects should be withdrawn from the study (Capron, A., 1999; Alzheimer's Association, 2004). Notably, in some situations, assent is not possible (e.g., coma and persistent vegetative state). In these situations, investigators must rely solely on the proxy decision-maker for consent.

### 5. Acceptable Risks of Research Involving Elders with Impaired Decision-Making Capacity

The American Geriatrics Society (AGS Ethics Committee, 1998), the Alzheimer's Association (Alzheimer's Association, 2004) and NBAC (National Bioethics Advisory Commission, 1998) have provided similar guidelines regarding acceptable risks of research involving individuals with impaired decision-making capacity. Provided that informed consent (via an advance directive for research or proxy consent) has been obtained and subject assent, subjects with impaired capacity may be enrolled in research if involvement in the study offers direct health-related benefit to the subject, and, if not, then the study should not expose the subject to more than a minor increment above minimal risk and should have the prospect of yielding generalizable new knowledge about the subject's illness or condition. Enrollment in studies of greater than a minor increment above minimal risk should be offered only to persons who have decision-making capacity or to persons with impaired capacity who have

an advance directive for research that allows enrollment in such a study. However, the AGS and NBAC recommend a national panel for considering, on a case-by-case basis, approval of especially promising studies that pose risks greater than a minor increment above minimal risk involving subjects lacking decision-making capacity who have not executed an advance directive for research. To date, such a panel has not been established.

## CONDUCTING RESEARCH FOR THE GOOD OF ELDERLY PERSONS

The principle of beneficence requires that investigators maximize benefit and minimize harm to human research subjects. This principle also demands that investigators protect subjects from exploitation. Indeed, the Belmont Report states that "the appropriateness of involving vulnerable populations in research should be demonstrated" (The Belmont Report, 1979).

Elders, especially those with diminished cognition and living in nursing homes or other institutions, are vulnerable to exploitation (e.g., they may be viewed as convenient subjects for research). Investigators and proxy decision-makers have a duty to protect potential research subjects, especially those who lack decision-making capacity, from harm. Persons who lack capacity should not be enrolled in research studies that provide no benefit to them or to persons with similar conditions, expose them to undue risks, or disrupt their normal routines (Bell *et al.*, 1987).

Beneficence requires that elders be included in research studies. Lack of research involving elderly human subjects leads to inadequate clinical care of elderly patients (Cassel, C., 1985). In fact, the results of clinical trials and other studies involving younger human subjects are often extrapolated to elders. However, changes associated with normal aging (e.g., altered drug metabolism, reduced glomerular filtration rate, etc.), comorbid illnesses, concurrent use of medications, and other factors make the extrapolation of the results of studies involving younger subjects to elders risky (Bell *et al.*, 1987).

Participating in research has a number of benefits aside from direct medical benefit to the individual elderly subject. These benefits include deriving meaning and purpose from the altruistic act of being a research subject, socialization, remuneration, and other benefits. Notably, in a study (Kaye *et al.*, 1990) of elders, those who consented to being research subjects had more positive feelings about being a research subject, helping others, and finding out about problems as a means of passing time compared to those who did not consent. Reasons for participating included interest in the project and benefiting others. This study and others (Leader, M. and Neuwirth, E., 1978; Lipsitz *et al.*, 1987) have also found that elders are more likely to participate in research that directly benefits them and less likely to participate in research that offers no direct benefit.

The principle of beneficence suggests that investigators avoid involving vulnerable elders in research. Yet, many elders suffer from conditions that not only leave them vulnerable, but also have a predilection for elders (e.g. dementia). Ideally, research of such conditions would involve subjects with those conditions. However, if vulnerable elders are excluded from research in order to avoid harm, then these elders would never benefit from research. Indeed, prohibiting research involving vulnerable elders may in fact cause significant harm by not allowing discovery of new knowledge that would help them (Ratzan, R., 1980).

Unfortunately, investigators who conduct studies involving elders infrequently or imprecisely describe ethical considerations (e.g., IRB processes, consent, decisional capacity, funding sources, and confidentiality) in their research reports even when the research involves vulnerable persons (Lane *et al.*, 1990). It is imperative that investigators describe these considerations in their protocols and research reports.

#### JUST INVOLVEMENT OF ELDERS IN RESEARCH

The burdens and benefits of research should be distributed equally, and elders should not bear burdens or receive benefits more than other age groups. Nevertheless, elders may be unjustly included or excluded from research studies. Investigators may find elderly residents of nursing homes and other institutions convenient subjects for research. In fact, before the 1970s, nursing homes were common sites for research primarily because of convenient access to captive subjects, most of whom were elders (Cassel, C., 1985). Furthermore, nursing home residents were commonly used for experiments that were not directly relevant to their own illnesses or elders in general (e.g., the Jewish Chronic Disease Hospital study). Instead, the selection of research subjects should be based on the needs of the study, not the convenience of the investigator or the accessibility of subjects.

The National Commission examined the issue of conducting research involving institutionalized human subjects. The Commission noted that investigators should preferentially involve subjects who are living freely in the community rather than those living in institutions. The Commission also stated that the convenience of subjects is not sufficient rationale to conduct research in an institution (Cassel, C., 1985).

On the other hand, elders, especially the oldest-old (age >85 years), have been unjustly excluded from research studies (Sachs, G. and Cohen, H., 2003). For example, a review of original research papers published in four journals during 1996 and 1997 found that one-third of the studies unjustifiably excluded elders (Bugeja *et al.*, 1997). Another study of research protocols on topics relevant to elders that were submitted to a hospital "ethics committee" (institutional review board) found that a majority of the protocols had unjustifiable upper age limits (Bayer, A. and Tadd, W., 2000). A study of human

subjects consecutively enrolled in 164 study protocols of an oncology study group found substantial underrepresentation of elders (Hutchins, L., *et al.*, 1999). A recent review of 59 randomized controlled trials between 1985 and 1999 of interventions for congestive heart failure (a disease that afflicts elders more than any other age group) found that elders were underrepresented in the trials (Heiat *et al.*, 2002). Other studies have had similar results (Morse, A., *et al.*, 2004; Avorn, J., 1997). Elders bear more illnesses, use more medications, and experience more deaths than any other age group. Hence, investigators should not exclude elders from research studies and should include enough elders in order to generate valid results that can be generalized to elderly populations.

Investigators may be tempted to exclude elders from research for a number of reasons. For example, investigators may avoid elders with impaired decision-making capacity because involving proxy decision-makers is time-consuming and costly (Bugeja *et al.*, 1997). Investigators may be unwilling to enroll elders in research studies because elders are more likely to have sensory deficits, mobility issues, comorbid illnesses, and other confounding variables. Conducting long-term studies involving elders is difficult because of their relatively high mortality rates (Sachs, G. and Cassel, C., 1990). Finally, compared to other age groups, elders are less willing to participate in research studies (Kaye *et al.*, 1990; Sachs, G. and Cassel, C., 1990). Nevertheless, while these reasons for excluding elders from research are not trivial, investigators should make efforts to address them in order to conduct valid research, the results of which can be generalized to elderly populations for their benefit.

Injustice also occurs when elders are excluded from their fair share of the benefits of being involved in research. These benefits include altruistic feelings of meaning and purpose associated with being a research subject, attention and socialization that accompanies being a research subject, medical supervision and other benefits (Cassel, C., 1985; Sachs, G. and Cassel, C., 1990).

#### GENETIC RESEARCH INVOLVING ELDERS

Genetic research (i.e., the identification of genetic variants) has the potential for discovering important preventive and therapeutic interventions for diseases associated with aging. For example, the identification of genetic mutations in familial Alzheimer disease and other diseases has yielded information regarding the mechanisms of the sporadic, yet more prevalent, forms of these diseases (Banks, D. and Fossel, M., 1997; Blacker, D., *et al.*, 1997; Longo, V. and Finch, C., 2002). Hence, it is not surprising that the interest in and conducting of genetic research in elders are growing.

While the aforementioned principles of research also apply to genetic research, the implications of genetic information obtained through research can be complex for subjects, their blood relatives, clinicians, and investigators (American Society of Human Genetics, 1996).

## 7. Ethical Aspects of Research Involving Elderly Persons

Indeed, genetic research raises a number of important ethical concerns, particularly those related to informed consent and subject confidentiality that are applicable to all subjects regardless of age.

The American Society of Human Genetics (ASHG) has published a statement on informed consent that provides guidance to investigators who wish to conduct genetic research involving human subjects including elders (American Society of Human Genetics, 1996). Subjects should be informed not only about the physical discomforts associated with collecting specimens (e.g., blood), they should also be informed about the types of

information that can result from genetic research including potentially unexpected findings (e.g., carrier status, paternity, children affected by genetic disease, etc.). Needless to say, these findings may be alarming to subjects and, hence, geneticists and/or genetic counselors should be directly involved or available in genetic studies in order to communicate accurately the results to subjects. Subjects should be informed if specimens will be stored for future studies and should be given options regarding the scope of future studies involving the specimens (including after the subject's death). Investigators should not seek "blanket consent" for unspecified future genetic

TABLE 7.4.

Checklist for addressing the unique aspects and potential ethical challenges of conducting research involving elderly persons

---

1. Adhere to responsibilities listed in Table 7.3
  2. Employ beneficent research design and methods
    - Scientifically valid
    - Protocol clearly describes ethical considerations (e.g., IRB processes, informed consent, assessment of decisional capacity, etc.)
    - Requires the involvement of elders
    - Minimizes harms and maximizes benefits to elders
    - Protects vulnerable elderly subjects (e.g., due to impaired decision-making capacity)
  3. Address barriers to enrollment of elders (e.g., sensory impairments, mobility issues, etc.)
  4. Ensure elements of informed consent are realized
    - Adequate amount of information about the study is conveyed to and understood by subject
    - Subject voluntariness (i.e., free of coercion)
    - Subject decision-making capacity
  5. Assess decision-making capacity
    - Ability to evidence a choice
    - Ability to understand the nature of the research study and other information relevant to participants disclosed by the investigator
    - Ability to understand and appreciate the risks and consequences of participating and the procedures to follow if adverse events occur or if withdrawal from participation is desired
    - Ability to manipulate information rationally
  6. Adhere to requirements for enrolling subjects with impaired decision-making capacity
    - Consent articulated in an advance directive for research
    - Consent by a legally authorized proxy
    - Subject assent regardless of level of decision-making capacity
  7. Adhere to acceptable standards of risk when conducting research involving subjects with impaired decision-making capacity
    - Study has direct therapeutic benefit to the subject
    - If no direct benefit to the subject, no more than a minimal increment greater than minimal risk and has the prospect of yielding generalizable new knowledge about the subject's illness or condition
    - For studies of greater than a minor increment above minimal risk, enrollment should be offered only to potential subjects who have an advance directive for research that allows enrollment in such a study
  8. Ensure that research involving elders is just
    - Study does not unfairly include or exclude elders
    - Study includes sufficient numbers of elders to facilitate understanding of the physiologic processes, diseases and other factors that pertain to elders
-

research studies using the specimens. Investigators who use and maintain identified or identifiable specimens must scrupulously maintain subject confidentiality. Information derived from these specimens must not be divulged to anyone (e.g., family members, insurance companies, etc.) without the explicit written permission of the subject. Subjects should be given the opportunity to decide whether or not to receive the information discovered by the investigation (i.e., some subjects may not want to know the results of testing if nothing can be done constructively with the information).

Beyond the ASHG statement, investigators should consider additional ethical aspects of genetic research. First, because genetic research usually involves blood, buccal, and/or stool specimens, investigators may regard these studies as minimal risk. However, risk must be understood as something larger than the discomforts associated with collecting specimens. Indeed, the ASHG statement recognizes that the risks of genetic research include psychosocial risks such as disrupted family dynamics caused by the discovery of genetic information (e.g., carrier status) and employment and insurance discrimination (American Society of Human Genetics, 1996). Hence, these studies should be regarded as greater than minimal risk. Second, information derived from genetic research that is disclosed to the subject or the proxy decision-maker should be recorded in the subject's medical record, since such information may influence clinical practice. Care, however, must be taken to avoid inappropriate disclosure of this information. Third, investigators should inform subjects of situations in which disclosure of information to subjects may be ethically obligatory (e.g., information that, if not known and addressed by the subject, poses high risk of harm) and how such disclosure will be done. Fourth, genetic research

may have implications for blood relatives of subjects. Investigators, for various reasons, may desire to contact relatives. Investigators should obtain consent from subjects to contact relatives where appropriate. Relatives should be contacted in a nonthreatening way (e.g., certified letter) that explains (a) how their name was obtained; (b) the nature of the research involving the subject (without divulging the research results pertaining to the subject); (c) the possible implications of the research for the relatives; and (d) how to contact the investigator for more information (e.g., counseling regarding the study).

## Conclusions

The number of elders living in the United States is rapidly growing. Elders are uniquely burdened with illnesses (some of which are associated with aging) and account for most deaths. In order to reduce morbidity and mortality experienced by elders, research involving elderly human subjects is needed. Contemporary codes of ethics and regulations governing research involving human subjects derive from the ethical principles of respect for persons, beneficence, and justice. Investigators conducting research involving elders should be familiar with and adhere to these general ethical principles. In addition, investigators should acknowledge and address the unique aspects and potential ethical challenges of research involving elderly persons. A checklist for addressing these unique aspects and potential ethical challenges is found in Table 7.4. A list of useful Web-based resources for investigators engaged in research involving elderly persons is found in Table 7.5. Following this approach should yield ethically valid and fruitful results not only for the good of elders but also for society in general.

# SAGE KE and Other Online Sources Related to Aging

Evelyn Strauss and R. John Davenport

*Researchers are making rapid headway in uncovering details about aging and its associated maladies. Yet the field faces a number of challenges. In particular, investigators from a wide range of disciplines who do not necessarily interact are generating daunting quantities of new data. A number of online resources can help researchers organize and manage the barrage of new results and can spark discussions. These Web sites publish summaries of the latest findings, offer tools with which to manipulate data, supply opportunities for direct communication with colleagues, and explore societal implications of the work. They are building bridges between different realms of the field and fostering creative thinking.*

## Introduction

Many of us wish for a 48-hour day—or that we could function on half as much sleep. Online resources in the field of aging can't alter planetary movements or physiology, but these Web sites can help researchers squeeze more out of their available time. They provide information, analysis, and tools that enhance efficiency and productivity—even in the wee hours before a grant deadline.

Online resources fulfill a variety of needs. Some offer up-to-date commentary on recent findings or high-level backgrounders on key topics in the field of aging; some supply tools such as databases of genes that have been implicated in aging or lists of animals and tissue sources that are of particular use for experiments in this arena; others post data and analysis in realms such as policy that influence progress in aging-related research. This chapter is not an exhaustive catalog of aging-related Web sites, nor does it completely explore the sites that it mentions; instead, it gives readers a taste of what's available on the Web.

## Staying Informed; Digging Deep

Researchers from diverse subspecialties compose the field of aging. These human geneticists, molecular geneticists, evolutionary biologists, physiologists, neurobiologists, demographers, and cell, structural, and molecular

biologists don't necessarily encounter one another while carrying out their professional activities: No single meeting brings everyone together, they don't all read one another's primary journals, nor does any journal publish papers from every discipline. Furthermore, research in the area is booming, posing a challenge to scientists struggling to keep up with relevant research even in their own corners of the field. In 2000, editors at the American Association for the Advancement of Science (AAAS) reasoned that a virtual community might catalyze interactions and creative thinking by bringing together researchers from many disciplines to exchange information and discuss ideas.

To that end, AAAS launched the Science of Aging Knowledge Environment in October 2001. The site aims to keep researchers in the field abreast of the latest scientific developments and to provide an online meeting place for the community. In particular, it strives to render information and commentary accessible to investigators with a broad range of backgrounds.

SAGE KE employs several strategies to inform scientists about research advances that have been published in other journals or presented at meetings. It posts critical summaries of the latest developments, written by both science journalists and investigators. The pieces by professional writers (News Focus) are based on interview material as well as literature research, and represent multiple viewpoints; their language and level of explanation assume scientific proficiency—but not that a reader is well informed about the particular matter at hand. Many of these stories attempt to entertain as well as educate (see Figure 8.1).

The articles by scientists (Perspectives) afford detailed commentary by experts. SAGE KE's editors attend meetings and maintain ongoing contact with researchers and journals, so news stories and Perspectives cover the latest findings as soon as they are publicly released. Editors also list additional articles of interest in each weekly issue. As a result, the site introduces newcomers to relevant topics in a timely fashion, and provides caveats and expert opinions to fully educate the reader as quickly as possible. Visitors can comment on the articles, a feature

**Figure 8.1.** Party on. Calorie restriction and the *Prop-1* mutation collaborate to confer longer life than either one does alone [Credit: Terry E. Smith].

that provides an opportunity to extend the discussions further.

In addition to keeping readers informed about new discoveries in the field, some sites offer overview articles that provide in-depth information about key topics. The pieces differ in their styles and accessibility. SAGE KE's reviews are written by scientists and assume a fairly sophisticated audience. They cover diverse subjects, including oxidative mutagenesis and mismatch repair; a critical look at microarray analysis; senescence in plants; and ubiquitin, proteasomes, and brain aging. These articles provide a comprehensive look at research in particular areas. Other types of overviews present information in a less dense form. For example, SAGE KE's feature stories (News Synthesis) tie together multiple findings and place them in a broad context. Like the other journalist-written content, they rely on interview material and are informed by multiple opinions and viewpoints. Newcomers to the field should find SAGE KE's Hot Topic Orientations particularly worthwhile. In these pieces, writers introduce central and often controversial topics; the current collection includes subjects such as oxidative damage, the relation between cell and organismal aging, pain, the immune system, and Alzheimer's disease. Finally physicians have produced a series of case studies aimed at the basic researcher. These articles describe aspects of age-related diseases (mostly neurodegenerative ones so far) from the clinician's and pathologist's point of view. They put a human face on these illnesses for people whose professional home is the lab bench.

Other sites focus on single aspects of aging-related research. For example, Alzheimer Research Forum (Alzforum) targets Alzheimer's disease. It posts summaries of new findings, which include interview material, and houses a collection of seminars, online journal club discussions, recorded talks, and other presentations that describe a variety of hypotheses about the pathogenesis of Alzheimer's disease. Alzforum material assumes proficiency with the terminology of molecular biology.

### Don't Know Much about History

SAGE KE's Classic Papers section offers PDFs of key papers published before 1990. This resource provides a way to gain historical perspective on aging-related research and sheds old light on unresolved problems. It includes, for example, Denham Harman's 1956 article on the free radical theory of aging and George C. Williams's 1957 article entitled Pleiotropy, Natural Selection, and the Evolution of Senescence as well as other seminal works.

The site also invites readers back in time through another route—with its historical reviews by luminaries in particular research areas. For instance, Edward Masoro's description of how the study of calorie restriction has unfolded reaches back to 1914 in its narrative. These articles include items of historical interest; Thomas Johnson's piece on *Caenorhabditis elegans* as a system for studying the genetics of aging contains the agenda for the 1979 Gordon Research Conference on the Biology of Aging.

## Genes and Interventions That Influence Aging

These days, a significant proportion of research findings in the field relate to genes or environmental factors that adjust the rate of aging—usually in model organisms. A number of databases summarize key findings about such genes and interventions.

The U.S. National Library of Medicine's Online Mendelian Inheritance in Man (OMIM) catalogs human genes and disorders. Although it doesn't focus on aging-related conditions, it contains information about many diseases that disproportionately affect the elderly. For example, searching for "Parkinson's Disease" produces a list of several dozen genes. The summaries include information about the chromosomal location of the gene, activities of the protein it encodes and its purported or established role in disease, how the gene was cloned, a discussion of relevant animal models, and the history of its implication in disease. The write-ups are detailed and extensively referenced. NIH's Genetics Home Reference, too, supplies details about genes that have been associated with many aging-related disorders as well as other information on these illnesses. It includes entries for Alzheimer's disease, Parkinson's disease, and Hutchinson-Gilford progeria syndrome, among many others.

For individuals who are interested in particular disorders with known or suspected genetic underpinnings, the Web serves up a number of focused resources. For example, Alzforum contains a database of genes and mutations that have been implicated in AD. The University of Washington's "Werner Syndrome" (WS) site hosts a repository for data on this premature aging disorder. The site's curators have compiled a list of mutations in the *WRN* gene that are associated with the condition, as well as diagnostic criteria, a historical overview of the topic, and a list of key papers. And the Diabetes Genome Anatomy Project homes in on the genetic underpinnings of this metabolic disease, whose risk increases with age.

Two databases focus specifically on genes that appear to alter the pace of aging: SAGE KE's Genes/Interventions Database and GenAge, directed by Pedro de Magalhães at Harvard University. SAGE KE's database catalogues published genes and interventions—such as calorie restriction—that affect longevity or selected age-related diseases in any organism. Each of the more than 200 entries for genes and 400 entries for interventions includes the organism, a description of the gene or treatment, a list of related genes in other organisms (for gene entries), pertinent references, and links to other databases such as WormBase and LocusLink. These write-ups function as crib sheets for the gene or intervention at hand and its association with aging. Visitors can search by organism, gene, key word, and other categories. Because few experiments have linked genes to mammalian aging, it contains only a few dozen

mammalian longevity genes, a handful of which are from humans. GenAge takes a different tack, focusing on human genes that might influence the aging process. Its creators selected 20 genes that speed or slow mammalian decline, excluding some that might affect predisposition to disease rather than the aging process itself. Next, they picked other genes that work closely with those in the first set—for instance, those whose protein products operate in the same molecular pathway. This process yielded a list of more than 200 human genes that might alter aging, although solid data don't exist for every one. GenAge excludes genes in model organisms such as worms or yeast. Each entry includes a description of the rationale for inclusion, selected references, protein and DNA sequence information, and links to other databases such as Swiss-Prot and Ensembl. GenAge entries also supply a list of molecules that team up with the protein produced by each gene. For instance, the insulin receptor page specifies 11 molecules that grab the protein in cells, and one click reveals a diagram of those connections.

The sites mentioned thus far center on any genes that influence aging or its maladies, but another spotlights genetic changes in a specific cell structure that has been connected with aging. According to some theories, glitches in mitochondrial DNA accumulated over years might cause organisms to break down by hampering energy production and increasing the generation of pernicious free radicals. MitoMap can aid in probing that idea. The site, curated by researchers at the University of California, Irvine, contains the sequence of the human mitochondrial genome, and organizes mitochondrial mutations into different categories, such as mutations that cause disease, inversions, and deletions. The site also features illustrations such as a mitochondrial genome diagram, a map of world migrations by humans based on data from mitochondrial DNA sequencing, and a model of how metabolic changes in the mitochondria might contribute to diabetes. MitoMap also lists links to other Web sites related to mitochondria.

For a different way to manage the literature, check out Telemakus. Produced by researchers at the University of Washington, the resource aims to organize publications in particular research areas and illuminate connections between related studies. The first database created by the project covers calorie restriction, a treatment that extends lifespan in many organisms. Users can browse the database by author, research findings, or organism, or can search for keywords. The description of each piece of work offers a summary of the study design, including the organisms studied, and the number, sex, and age of animals used. Entries also include a list of tables and figures from the publication and, in many cases, the figures and tables themselves, enabling visitors to quickly review a study's findings without leaving Telemakus or having to track down the original paper.

## Animals and Reagents

SAGE KE provides an experimental resources section that includes sources for tissues, cell lines, and animals of particular use in aging-related research, as well as a list of articles that consider issues of experimental design or data analysis. Of special interest are the write-ups on rodent strains and genetically-altered mice. The rodent-strain tables provide detailed information about commonly used inbred and hybrid laboratory strains, including their history and genetic background, caveats about using these animals, and the results of major studies on them. The entries aim to provide information so researchers can easily compare the strains and select an appropriate animal for a particular study. The genetically altered mice tables provide key references and information about the gene changed, the resulting phenotype, and the corresponding human phenotype for selected mutant, transgenic, and knock-out mice. These mice include strains that are exceptionally long lived, those that serve as models of neurodegenerative disease and other age-related conditions such as osteoarthritis, and animals that carry mutations in genes involved in processes related to aging, such as DNA repair.

The National Institute on Aging's (NIA's) "Scientific Resources" section offers information about the rhesus monkeys that are available for research on aging and the nonhuman primate tissue bank, which offers archived tissue to researchers in the field. The site also describes its rodent resources, human biospecimens, Aging Cell Repository, and microarrays, among other experimental tools available to scientists.

## Population Studies

NIA's Scientific Resources section also highlights a different type of experimental tool: longitudinal studies. The site contains an extensive list of such studies and provides a searchable database that allows the user to identify those that relate to a keyword (or keywords) of interest.

Other sites also cover this topic. In SAGE KE, "Taking the Long View," the article discusses longitudinal studies in general and summarizes the goals of some on the NIA list as well as several others. Some population studies don't track people for many years; rather, they target—at least as their primary subjects—very old people with the hope of discovering keys to long life. The Okinawa Centenarian Study and the New England Centenarian Study, for instance, aim to uncover genetic and lifestyle characteristics that predispose people to outstanding health.

## Demography, Mortality, and Health Statistics

The last century has seen a dramatic longevity rise in the industrialized world. Some Web sites aim to document this phenomenon and to provide information that might lead researchers to the factors that have caused this life-span gain. The Human Mortality Database, a joint effort between researchers at the University of California, Berkeley and the Max Planck Institute for Demographic Research in Rostock, Germany, currently provides detailed mortality and population data for 23 countries. Visitors can download and analyze these statistics to compare mortality trends in different regions over time. The site also provides links to other resources that contain useful information, such as cause of death, that is not included in the Human Mortality Database.

The National Center for Health Statistics at the United States Center for Disease Control and Prevention contains a Data Warehouse on Trends in Health and Aging on its aging activities page. Users can view, chart, and download data on life expectancy, disability, insurance utilization, socioeconomic status and other measures for United States citizens over the last century or so. Furthermore, the site provides downloadable software for manipulating the information and tailoring it to individual needs. Some sites document types of demographic data other than mortality trends. For instance, the Utah Population Database contains an extensive set of Utah family histories, including medical information for individual family members. This database contains a cancer registry and information about cause of death. Access is free, but requires advance approval for use of the data.

The United States Administration on Aging provides statistics on the elderly, and the U.S. Census Bureau compiles census numbers relevant to aging.

For researchers focused on species other than our own, the Web-accessible book, *Longevity Records: Life Spans of Mammals, Birds, Amphibians, Reptiles, and Fish*, contains data on the highest documented age for more than 3000 mammals, birds, amphibians, reptiles, and fish.

## Policy Matters

As research in the field of aging is blossoming, so are questions about its implications for society. The importance of these issues is compounded by the fact that populations in industrialized nations are growing older. Several Web sites address policy-related topics that intersect the science of aging.

SAGE Crossroads, a collaboration between the Alliance for Aging Research and AAAS, wrestles with the policy implications of aging-related research. It has tackled numerous thorny questions with policymakers,

## 8. SAGE KE and Other Online Sources Related to Aging

journalists, and the public in mind. Some individuals worry, for example, that “artificially” extending human lives would cheapen our existence, whereas others point out that the modern medical enterprise has already drastically increased lifespans with no ill effects on society. Other subjects that the site has explored include the paucity of older people included in clinical trials; the wisdom of using human growth hormone to combat symptoms of aging despite data suggesting that the substance curtails lifespan; and how we might improve our flu-combating measures. It has discussed nanotechnology, hormone replacement therapy, guidelines for keeping bones strong, and chronic pain, as well as age-related voice changes and hearing loss. SAGE Crossroads ponders such topics in News and Views articles as well as through Webcasts in which experts debate and discuss such matters.

To gain insight into how lawmakers address these and other age-related policy issues, visit the U.S. Senate Special Committee on Aging Web site. Visitors can view video or read testimonies from hearings, which the committee uses to guide recommendations for new legislation to the United States Senate.

### **Talk amongst Yourselves**

The Web fosters the opportunity to interact with peers in addition to providing an efficient conduit for collecting information. At SAGE KE’s bulletin board, visitors can post questions and items for discussion with the goal of eliciting feedback. With the site’s Listserv, individuals can communicate by Email with others who want to toss around ideas informally.

For stimulating, real-life contact with colleagues, attending scientific meetings is hard to beat. SAGE KE’s Meetings and Events calendar can help with the planning.

### **Reaching beyond Researchers**

A number of Web sites aim to inform the general public, but prove useful for researchers. They can help with teaching or setting scientific work in a broader context. The American Federation for Aging Research’s Info-Aging, for example, offers explanations of a number of topics under several headings. Topics in the “Biology of Aging” section include oxidative damage, telomeres, stem cells, and biomarkers of aging. Each one summarizes crucial issues, addresses basic questions, provides links to related research, and points readers toward other resources; in addition, they are reviewed by experts in each field. The “Disease Center” similarly contains key information and questions on some age-related illnesses, such as Alzheimer’s disease, macular degeneration, and osteoporosis, and the “Healthy Aging Center” discusses issues such as nutrition, stress, hearing, and immunization.

AgeLine, hosted by AARP, formerly known as the Association for the Advancement of Retired People, catalogs publications related to social gerontology as well as age-related topics in psychology, sociology, social work, economics, public policy, and the health sciences. The site features abstracts of journal articles, books and chapters, research reports, dissertations, and educational videos, and provides links to purchase or view the full text.

Other resources explain particular age-related diseases. The Centers for Disease Control Cardiovascular Health site contains information for lay people such as fact sheets on topics that include cholesterol, heart attacks, and high blood pressure. Of particular interest to researchers are the interactive maps that supply heart attack and stroke mortality rates for the state, gender, and racial/ethnic group of choice. The site includes a list of Morbidity and Mortality Reports that relate to cardiovascular disease as well as other statistical and public-health information. NIH’s Osteoporosis and Related Bone Diseases–National Resource Center offers background articles on topics of interest to researchers as well as lay people; these include “Vitamin A and Bone Health,” “Phytoestrogens and Bone Health,” and “Bone Mass Measurement: What the Numbers Mean.”

The Merck Manual of Geriatrics provides detailed information and guidelines on the care of older people for health professionals. This online book is searchable and covers conditions from falls to dementia to urinary tract disorders. The Merck Manual of Health and Aging is a work in progress, offering demographic information and explanations about how the body ages in language that is intended for the general public.

The Web provides a wealth of tools to help researchers tackle the wide-ranging topics related to aging, tame the sea of data, and make contact with investigators in a variety of subspecialties. These resources can seem invaluable when burning the midnight oil, but they also hold up well in the light of day.

### **Recommended Resources**

In addition to the Web sites mentioned in the text, see SAGE KE’s Web links section.

# Proteomics in Aging Research

Christian Schöneich

*The process of biological aging is a complex phenomenon, depending on a manifold of different parameters, including nature of the organism, lifestyle, diet, and so forth. In order to compare different aging phenotypes, a global qualitative and quantitative proteomic analysis of different species is necessary. Proteomic data need to be interpreted relative to complementary genomic and functional analysis. The present article surveys several proteomic methods and their direct application and/or potential relevance for the characterization of the "aging proteome." Specific emphasis has been given to the analysis of post-translational protein modifications.*

## Introduction

Biological aging is controlled to various extents by several closely related parameters, which include metabolic rate, caloric intake, genetics, lifestyle, and environmental factors (Jazwinski, 1996; Sohal and Weindruch, 1996; Smith and Pereira-Smith, 1996; Finch and Tanzi, 1997; Morrison and Hof, 1997; Lamberts *et al.*, 1997). Over the years, a number of different theories for the aging process have been formulated (Masoro, 1993) such as the "rate-of-living theory," the "somatic mutation theory," the "error catastrophe theory," the "cross-linkage theory," and the "free radical theory of aging." Some of these theories are based on common phenomena. For example, the rate-of-living theory correlates higher metabolic rates with shorter lifespan. Higher metabolic rates lead to higher levels of reactive oxygen species, available for the transformation of biomolecules, linking the rate of living theory with the cross-linkage theory and the free radical theory of aging. Ultimately, each one of these theories seems to favor a rather unique mechanism as the predominant cause of aging, and this may be considered the general shortcoming of these theories.

Aging represents a complex developmental phenomenon, depending on the global interplay between genes and gene products. The rate of aging will certainly depend on gene identity, gene polymorphism, the rate of translation, developmental regulation of translation, the residence time of gene products in the organism, and post-translational modification of the gene products. A thorough understanding of the aging process requires the evaluation of all these processes, and this is where

aging research will greatly benefit from genomics and proteomics studies. Various genomics studies have started to address the general quantification of age-dependent changes in gene expression (Kayo *et al.*, 2001) and the effects of nutrition and/or genetic modification (i.e., deletion or overexpression of genes affecting life span) on gene expression profiles. Currently, the role of proteomic studies is to provide quantitative information on the generation of gene products including the profiling of native proteins, protein isoforms, splice variants, mutants, and post-translationally modified species. In addition, proteomic studies need to define networks of protein-protein interactions. Bioinformatics studies are then necessary to combine both genomics and proteomics data into a multidimensional network of time-dependent, developmentally regulated interaction of genes. Such an effort is underway with the development of GenAge (available on the World Wide Web: <http://genomics.senescence.info/genes/>), a curated database of genes related to human aging (de Magalhaes and Toussaint, 2004). Ultimately, we hope that proteomic studies will not only further our basic understanding of the aging process but also yield reliable biomarkers for the early diagnosis of age-dependent diseases, preferentially in easily accessible biological fluids. The present article will review commonly used proteomic techniques and their application to the profiling of protein expression and post-translational modification.

## Proteomic Techniques

### TWO-DIMENSIONAL GEL ELECTROPHORESIS (2DE)

The last years have witnessed an immense improvement in the techniques available for the analysis of the proteome. This is largely due to advances in mass spectrometry (MS) analysis, where electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) represent soft ionization techniques suitable for native and most post-translationally modified peptides (Aebersold and Goodlett, 2001). However, it has been realized that none of the individual methods will be sufficient to provide satisfactory answers to all questions of interest. Each of the proteomic techniques has certain strengths and shortcomings as outlined below. Two-dimensional gel

electrophoresis (2DE) has been and continues to be a widely used technique due to its relatively low cost and maintenance requirements. Continuous improvements are made with regard to reproducibility, solubility (especially of membrane proteins), alternative protein stains, and the differential display of proteins during *in-gel* electrophoresis (DIGE). For DIGE, two separate pools of proteins from cells/tissue of different origin are labeled with two distinct fluorescent dyes, such as 1-(5-carboxypentyl)-1'-propylindocarbocyanine halide (Cy3) *N*-hydroxy-succinimidyl ester and 1-(5-carboxypentyl)-1'-methylindodi-carbocyanine halide (Cy5) *N*-hydroxy-succinimidyl ester, which can then be individually excited for exclusive monitoring of the labeled proteins from one specific pool (Zhou *et al.*, 2002a). Specific software allows for the three-dimensional representation of the individual protein spots on the gel. Importantly, the fluorescent dyes should be similar in molecular weight and charge so that identical proteins labeled with different dyes comigrate during 2DE. Two labeling strategies for DIGE have been developed, (i) minimal labeling and (ii) saturation labeling (Shaw *et al.*, 2003). During minimal labeling, fluorescent dyes are covalently attached to protein Lys residues. Based on the abundance of Lys residues in proteins, the labeling stoichiometry may exceed more than one molecule of dye per protein. Proteins with multiple dye molecules may migrate differently on 2DE compared to proteins with a single dye or precipitate due to the hydrophobicity of the dyes, enhancing the complexity of samples and rendering the relative quantitation of proteins from different tissues a difficult task. Hence, minimal labeling is run under conditions that ensure that not more than one dye molecule is attached to a single protein. Under these conditions, a significant fraction of proteins remains unlabeled, resulting in an overall loss of sensitivity. The latter may require larger sample volumes for the relative quantitation of low abundance proteins. A new generation of fluorescent dyes has been developed for saturation labeling (Shaw *et al.*, 2003). These dyes are covalently attached to protein Cys residues, which usually show a lower abundance in proteins relative to Lys residues. Saturation labeling is achieved under conditions where each protein Cys residue is labeled. This technique results in a greater sensitivity of the analysis but may

still suffer from the precipitation of individual proteins. One drawback of the saturation labeling technique is the potential age-dependent oxidation of protein Cys residues, resulting in the age-dependent loss of labeling sites. In such a scenario the lower stoichiometric labeling of a protein from aged tissue could be misinterpreted as lower expression. The ICAT methodology, described below, suffers from the same problem.

## MULTIDIMENSIONAL CHROMATOGRAPHY METHODS

Alternative to 2DE, proteins and peptides can be separated by multidimensional (micro) liquid chromatography methods and/or capillary electrophoresis on-line coupled to multidimensional mass spectrometry (MS<sup>n</sup>) (Shen and Smith, 2002). Protein mixtures are proteolytically digested, and a large number of the resulting peptides are resolved and identified in a single run, a strategy termed "multidimensional protein identification technology" (MudPIT) (Washburn *et al.*, 2001; Wolters *et al.*, 2001). Orthogonal separation modes of any choice can be coupled, provided that the eluate composition of an earlier separation mode is compatible with the following separation mode. Prefractionation of protein families (e.g., through affinity purification, solution isoelectric focusing, etc.) (Righetti *et al.*, 2005), followed by one- or multidimensional separation, increases the dynamic range of the analytical method allowing for the monitoring of even low abundance proteins (Gygi *et al.*, 2002). This is necessitated by the MS detector, where large amounts of high-abundance peptides can suppress the ionization of lower abundant peptides.

To achieve relative quantitation of proteins during 2DE or chromatographic runs, Aebersold and coworkers have developed the isotope-coded affinity tag (ICAT) methodology (Gygi *et al.*, 1999): in the original approach proteins/peptides are derivatized with a bifunctional reagent (structure 1, as shown in Figure 9.1) which contains an electrophile on one end and biotin on the other end.

The electrophile affords covalent derivatization of Cys, and the biotin moiety enables affinity purification of the labeled proteins/peptides. An organic linker between the functional groups of the reagent contains

Figure 9.1. Structure 1.

either normal (H) or heavy (D) hydrogen isotopes. When two pools of proteins are labeled with the normal or heavy isotope-containing ICAT reagent, their relative abundance can be determined by quantitative MS analysis of the ratio of normal to heavy ICAT-derivatized peptides of specific proteins. During 2DE, normal and heavy isotope ICAT-derivatized proteins comigrate, ensuring an accurate relative quantification of the proteins from different sources (Smolka *et al.*, 2002). However, slight differences in the elution profiles of normal and heavy isotope ICAT-labeled peptides have been noted during reverse-phase chromatography (Zhang *et al.*, 2001). Therefore, an accurate relative quantification of ICAT-labeled peptides requires MS analysis at the respective peak maxima of the individual chromatographic peaks of normal and heavy isotope ICAT-labeled peptides. Complications have also been noted with the recovery of ICAT-labeled peptides during biotin-avidin affinity purification (Gygi *et al.*, 2002), and with tandem MS sequencing of ICAT-labeled peptides.

Recent improvements of ICAT reagents include the design of a solid-phase isotope tagging method, avoiding biotin, and incorporation of a photocleavable linker (structure **2**, as shown in Figure 9.2); after solid-phase purification of ICAT-labeled peptides and photolysis, the remaining peptides essentially contain an additional normal or heavy isotope-containing Leu residue (Zhou *et al.*, 2002b).

Using the ICAT methodology, complex mixtures of peptides from digested proteins can be reduced to one or a few peptides per protein (essentially as many peptides as the protein contains reduced or reducible Cys residues). Such a reduction in sample size significantly enhances the dynamic range of the proteomic analysis. For example, using the codon bias value as a measure for protein expression, Gygi *et al.* (2000) showed that traditional 2D gel electrophoresis was not able to indicate low abundant proteins with codon bias values of  $<0.1$ , whereas many of these proteins were detected with a multidimensional

separation strategy including ICAT-labeling and affinity purification (Gygi *et al.*, 2002). We note that irreversibly oxidized Cys residues (to cysteic acid) will not be amenable to ICAT labeling.

Surface-enhanced laser desorption/ionization (SELDI) represents a concept with great promise for sample size reduction and enrichment of specific classes of analytes (Merchant and Weinberger, 2000). Protein-chips with specifically modified surfaces allow the affinity purification of analytes prior to on-chip digestion and MALDI-TOF MS analysis. Various different chemical and biochemical surfaces have been designed containing immobilized hydrophobic, ionic, or mixed-mode phases or antibodies; IMAC supports; polynucleotides; or specific enzymes or receptors.

### PROTEIN ARRAYS

The advent of high-throughput protein expression systems has enabled the construction of protein arrays for the rapid screening of protein–biomolecule interactions (Smith *et al.*, 2005). This includes the interaction of proteins with small molecules, other proteins, polynucleotides, phospholipids, and antibodies. For example, these platforms allow evaluation of the specificity (or cross-reactivity) of a given antibody toward a large matrix of different proteins. Another form of microarray is the tissue microarray (TMA). This can now be produced with good accuracy, permitting the rapid screening of a large number of human tissue sections for individual proteins (Uhlen and Ponten, 2005).

### Protein Expression Profiling

The relative quantitation of protein expression profiles between young and normally aged or prematurely aged tissue as well as tissue suffering from age-dependent disease provides an important basis for the global proteomic analysis of aging. These analyses will be supplemented by the proteomic analysis of age-dependent

Figure 9.2. Structure 2.

post-translational protein modification and functional proteomics, as described in more detail below. So far, 2DE has been the method of choice for profiling cell culture models of aging or aging tissue (Dierick *et al.*, 2002a; Gromov *et al.*, 2002; Benvenuti *et al.*, 2002a; 2002b) and the effect of environmental stresses (Dierick *et al.*, 2002b; 2002c). Chang *et al.* have characterized the reproducibility and sensitivity of proteomic analysis of mitochondrial proteins from aged mouse skeletal muscle, suggesting that a sample size of 10 animals will be sufficient to detect a 100% difference in 97% of the 505 mitochondrial proteins resolved in their 2D electrophoresis separation (Chang *et al.*, 2003). The senescent-accelerated mouse represents a convenient animal model for the proteomic characterization of aging and age-dependent pathologies. Cho *et al.* compared the liver proteome of the senescence-prone strain SAMP8 (senescence-accelerated mouse senescence prone) with that of the senescent-resistant SAMR1 (senescence-accelerated mouse senescence-resistant) and detected age-dependent changes of 64 proteins between both strains, whereas 18 proteins showed age-dependent changes in both SAMP8 and SAMR1 mice (Cho *et al.*, 2003). Surprisingly, Poon *et al.* quantified age-dependent changes between 12- and 4-month-old SAMP8 for only five brain proteins (Poon *et al.*, 2004). Proteomic analysis revealed a gender-specific alteration in the age-dependent relative expression of glycolytic and mitochondrial cardiac proteins in monkeys (Yan *et al.*, 2004). A limited proteomic analysis was also presented for the Hutchinson–Gilford Progeria Syndrome (Robinson *et al.*, 2003). This premature aging disease is associated with mutations in the gene for lamin; a comparison of lamin expression levels between 10 and 13 years old progeria patients with their age-matched controls showed significantly reduced lamin levels. Moreover, the lamin of the progeria patients displayed ca. 0.3 units more basic pI value, consistent with the loss of a C-terminal phosphorylation site. The proteome of human cerebrospinal fluid (CSF) was profiled as part of an ongoing search for biomarkers of age-dependent pathologies (Zhang *et al.*, 2005). Using shotgun proteomics in conjunction with the ICAT methodology, a series of proteins changing between 20 and 100% between the CSF of young and old donors was monitored, and, for specific proteins, these changes were confirmed by complementary Western blot analysis. An important aspect of these proteomic experiments is the elimination of highly abundant proteins such as albumin and immunoglobulin prior to the analysis, which was achieved with sequential precipitation of CSF proteins by an organic solvent, acetonitrile.

### Proteomic Analysis of Post-translational Modifications

Post-translational protein modifications significantly expand the portfolio of proteins with specific properties

encoded by the genetic code. They allow for the production of multiple variants of a single gene product through specific, potentially reversible, covalent alterations of amino acid side chains. To date, about 200 distinct post-translational protein modifications are known (Khidekel and Hsieh-Wilson, 2004). However, we are just at the beginning of a thorough qualitative and quantitative characterization of only a few of these post-translational modifications in the “aging proteome.” Importantly, proteins will not necessarily only incorporate a single modification, but often multiple modifications accumulate specifically on long-lived proteins in tissues with low protein turnover (e.g., the crystallins in the lens). Considering the progressive age-dependent functional changes of most cell types and tissues, an accurate profile of age-dependent post-translational protein modifications is mandatory. The following paragraphs will focus on the proteomic characterization of selected post-translational protein modifications such as phosphorylation and oxidation.

### PHOSPHORYLATION

Age-dependent changes in protein phosphorylation have been noted for individual proteins, e.g., the crystallins (Ueda *et al.*, 2002) and various sarcoplasmic reticulum proteins (Xu and Narayanan, 1998). The sensitive analysis of phosphopeptides and/or phosphoproteins requires a separation of phosphorylated peptides or proteins from excess nonphosphorylated species. While few proteomic studies have focused on the characterization of the “phosphoproteome” of aging tissue, much research effort has been placed on method development for the analysis of the phosphoproteome (Mann *et al.*, 2002; Conrads *et al.*, 2002). Importantly, antibodies against phosphoserine, phosphothreonine and phosphotyrosine allow for the enrichment of phosphoproteins prior to chromatographic separation and mass spectrometric analysis of phosphopeptides, resulting in a reduction of sample complexity (Grønborg *et al.*, 2002; Pandey *et al.*, 2002). During mass spectrometric analysis, phosphopeptides can be recognized through specific fragmentation processes, i.e., the loss of  $\text{PO}_3^-$  (79 Da) from all phosphoamino acids in the negative electrospray ionization (ESI) mode or the neutral losses of  $\text{HPO}_3$  (80 Da) or  $\text{H}_3\text{PO}_4$  (98 Da) from phosphoserine and phosphothreonine in the positive ESI mode (Schlosser *et al.*, 2001). Moreover phosphopeptides can be monitored through the appearance of characteristic immonium ions from phosphotyrosine (Steen *et al.*, 2002) or chemically modified (into dimethylamine-containing sulfenic acids) phosphoserine and phosphothreonine (Steen and Mann, 2002a). The resolution of such immonium ions from other small peptide fragments is possible because the reporter ions contain a higher incidence of mass-deficient atoms (O, P, S), creating an inherent *Mass-Deficient Mass Tag* (MaDMaT) (Steen and Mann, 2002b). The chemical modification of phosphoserine and phosphothreonine can be achieved after  $\beta$ -elimination at alkaline pH, generating

dehydroalanine, which can be derivatized via Michael addition of appropriate nucleophiles. This chemistry enables biotinylation of original phosphoserine and phosphothreonine residues for affinity purification (Oda *et al.*, 2001), selective immobilization on solid phases (Zhou *et al.*, 2001), and introduction of a cleavage-site for a lysine-specific protease (Knight *et al.*, 2003).

A further reduction of sample complexity can be achieved by metal-affinity chromatography (IMAC) of phosphopeptides on chromatographic supports containing trivalent metal ions such as  $\text{Fe}^{3+}$  or  $\text{Ga}^{3+}$  (Zarling *et al.*, 2000; Riggs *et al.*, 2001; Ficarro *et al.*, 2002; Chen *et al.*, 2002). Optimal resolution of phosphorylated from nonphosphorylated peptides requires chemical esterification of peptide carboxylate groups (Ficarro *et al.*, 2002), and the selectivity of the method towards phosphopeptides can be improved when proteins are digested with endoproteinase Glu-C instead of trypsin, reducing the number of acidic residues per peptide (Seeley *et al.*, 2005). For relative quantitation of phosphopeptides, Ga(III) IMAC has been combined with stable isotope labeling of peptides at the *N*-terminal amino group (Riggs *et al.*, 2005).

## OXIDATIVE MODIFICATIONS

### *Analysis of protein-associated carbonyls*

Consistent with the “free radical theory” of aging, many tissues show an age-dependent increase of the steady-state concentrations of oxidized proteins. So far most reports on the accumulation of oxidized proteins have analyzed “protein-associated carbonyls.” The term “protein-associated carbonyl” classifies a carbonyl-containing covalent protein modification, which results either from the direct chemical transformation of an amino acid residue into a carbonyl product or from the covalent attachment of a carbonyl-containing molecule (e.g., 4-hydroxynonenal, 4-HNE) (Berlett and Stadtman, 1997). The most frequently used analytical method for the detection of protein-associated carbonyls is derivatization with 2,4-dinitrophenylhydrazine (Scheme 1, as shown in Figure 9.3), followed by UV spectroscopy or Western blot detection with anti-2,4-dinitrophenyl antibodies (Shacter *et al.*, 1994).

The specificity of these antibodies was evaluated through specific reaction with DNP conjugated to proteins (Eshhar *et al.*, 1980; Shacter *et al.*, 1994), and 1 pmol was reported as a lower limit of detection of protein-associated carbonyls (Shacter *et al.*, 1994). A comparable detection limit (0.64 pmol) was recently achieved with a slight modification of the methodology, using biotin-hydrazide labeling of the carbonyls followed by staining with fluorescein isothiocyanate (FITC)-labeled avidin (Yoo and Regnier, 2004). A number of studies have used stationary phase bacterial cells as a model for aging somatic cells of higher eukaryotic organisms in order to delineate the routes leading to the accumulation of

Figure 9.3. Scheme 1.

oxidized proteins (Dukan and Nyström, 1999; Nyström, 2002; Aguilaniu *et al.*, 2001; Ballesteros *et al.*, 2001). Experiments with growth-arrested *Escherichia coli* demonstrated that protein carbonylation is fairly selective to specific proteins. Misfolded proteins are especially susceptible to the formation of protein-associated carbonyls (Dukan *et al.*, 2000). Mechanistically, not the rate of respiration *per se* but the degree of coupling in the mitochondrial respiratory apparatus appears to be responsible for the increased accumulation of oxidized proteins (Aguilaniu *et al.*, 2001). A remarkable observation was that mother cells retain a large fraction of oxidized proteins during cell division, somehow protecting their daughter cells from the consequences of protein oxidation (Aguilaniu *et al.*, 2003). Such a result would suggest that old tissues would have a reduced ability to resist oxidative stress; however, recently experiments with *Arabidopsis thaliana* demonstrated a mechanism in plants, where old leaves can eliminate oxidized proteins prior to bolting and flowering of the plant (prior to reproduction) (Johansson *et al.*, 2004).

Predominantly Western blot analysis demonstrated a quite selective age-dependent accumulation of carbonylated proteins in *Drosophila melanogaster* (Das *et al.*, 2001) and human Alzheimer's disease brain (Castegna *et al.*, 2002a; 2002b). Selective protein carbonyl-association was also detected in the brain of SAMP8 mice (Poon *et al.*, 2004) and model experiments where the Alzheimer's disease  $\beta$ -amyloid peptide was directly injected into rat brain (Boyd-Kimball *et al.*, 2005). However, all these Western blot-based experiments identified only a small subset of carbonylated proteins compared to the more than 100 carbonyl-containing proteins identified in brain via a complementary approach, where proteins were derivatized with a biotin-containing hydrazide, and the so biotinylated proteins immunoenriched with immobilized streptavidin (Soreghan *et al.*, 2003). An important

caveat in the analysis of carbonylated proteins is their inherent instability towards further covalent modification such as Schiff base-formation (Mirzaei and Regnier, 2005). The latter would not be detected via any of the carbonyl-specific methods involving derivatization with hydrazines. Another problem with most of the proteomic data so far presented on protein carbonyl formation is the general lack of tandem mass spectrometry data which would (1) confirm the carbonyl content by a complementary technique, and (2) locate the modified amino acids. A potential source of error in the immunochemical identification of carbonyl-containing proteins only by Western blot could be the contamination of a nonmodified protein in a 2D gel spot by a trace amount of a second, carbonylated, protein. Mirzaei and Regnier (2005) demonstrated that tandem mass spectrometric information on the carbonyl-containing peptide sequences can be obtained after biotin hydrazide derivatization of protein carbonyls, followed by immunoenrichment on immobilized monomeric avidin columns.

#### *Analysis of 3-Nitrotyrosine*

Increasing evidence is accumulating that the formation of 3-nitrotyrosine *in vivo* is associated with changes in protein structure and function and represents a valid biomarker for conditions of oxidative stress (Ischiropoulos and Beckman, 2003). To date, most proteomic strategies for the detection of 3-nitrotyrosine utilized 2DE followed by Western blot detection of 3-nitrotyrosine (Aulak *et al.*, 2001; Miyagi *et al.*, 2002; Turko *et al.*, 2003; Casoni *et al.*, 2005). Analogous to the proteomic analysis of protein-associated carbonyls, the age-dependent accumulation of 3-nitrotyrosine is rather selective to a subset of proteins (Kanski *et al.*, 2003; 2005a; 2005b). Interestingly, predominantly cytosolic proteins displayed an age-dependent increase in 3-nitrotyrosine in skeletal muscle (Kanski *et al.*, 2003; 2005b) while cardiac aging caused 3-nitrotyrosine accumulation to a significant extent also on mitochondrial proteins (Kanski *et al.*, 2005a). It remains to be shown whether complementary analytical strategies can confirm this rather unexpected selectivity.

Most of the 2DE analysis of 3-nitrotyrosine-containing proteins *in vivo* suffer from the absence of tandem mass spectrometric sequence information, confirming the presence of 3-nitrotyrosine on the identified proteins. Exceptions are noted for the 2DE analysis of human pituitary (Zhan and Desiderio, 2004) and rat cardiac proteins (Kanski *et al.*, 2005a). This general lack of tandem mass spectrometric information is likely due to the actual yield and recovery of 3-nitrotyrosine-containing peptides/proteins from biological tissue. However, when skeletal muscle proteins were resolved by solution isoelectric focusing/SDS-PAGE instead of 2DE, permitting significantly higher sample loads, eleven 3-nitrotyrosine-containing proteins were identified and confirmed by tandem mass spectrometric data (Kanski *et al.*, 2005b).

Information on the actual location of 3-nitrotyrosine in the identified proteins led to some interesting observations. In the cytosolic creatine kinase, age-dependent tyrosine nitration occurred predominantly on residues at positions Tyr<sup>14</sup> and Tyr<sup>20</sup>. Instead, the exposure of creatine kinase to peroxynitrite (ONOO<sup>-</sup>) *in vitro* led to nitration of predominantly Tyr<sup>82</sup>, a residue not affected *in vivo*. Peroxynitrite forms through the reaction of nitric oxide (NO) with superoxide (O<sub>2</sub><sup>-</sup>) and represents one important tyrosine-nitrating species *in vivo*. However, additional nitrating systems are known such as the peroxidase-nitrite system, affording nitrogen dioxide (\*NO<sub>2</sub>). Moreover, while identifying nitrated proteins *in vivo* we must always be aware of the fact that any observed selectivity will be the result not only of the nitration chemistry, but also of protein turnover and repair. Nitrated proteins are subject to accelerated turnover, and Murad and coworkers have identified a potential repair enzyme for nitrated proteins, a putative "denitrase," which targets selected nitrated proteins such as histone H1.2 (Irie *et al.*, 2003). Proteomic studies in isolated mitochondria have indicated that nitrated proteins can be repaired quite rapidly when the oxygen tension decreases (Aulak *et al.*, 2004; Koeck *et al.*, 2004).

#### *Analysis of Cys oxidation and S-glutathiolation*

Cys oxidation is one of the most prevalent protein modifications under conditions of oxidative stress. Proteomic evidence for Cys oxidation has been obtained through tandem MS characterization of cysteine acid-containing peroxiredoxins in Jurkat T-cell lymphoma cells exposed to an organic peroxide or glucose oxidase (Rabilloud *et al.*, 2002). Lin *et al.* (2002) utilized a lipophilic cation, (4-iodobutyl)triphenylphosphonium (IBTP), which enriches inside the mitochondria, and an antibody directed against the triphenylphosphonium moiety, for the proteomic characterization of mitochondrial protein thiols, which are sensitive towards oxidation. Intracellular proteins encounter large concentrations of the endogenous antioxidant glutathione (GSH). Therefore, S-glutathiolation is a common endogenous process, and proteomic methods for the detection of S-glutathiolated proteins have been developed, using either biotinylated GSH ester for the selective immuno-affinity purification of glutathiolated proteins (Sullivan *et al.*, 2000), or [<sup>35</sup>S]-labeled GSH for the specific detection of [<sup>35</sup>S] incorporation into proteins resolved on 2D gels (Fratelli *et al.*, 2002). Obviously, these methods are applicable only to cell cultures or tissue homogenates but cannot be performed *in vivo*. S-glutathiolation *in vivo* would need to be characterized by direct tandem MS analysis of S-glutathiolated peptide sequences isolated from tissue. A subset of proteins, which are susceptible to S-glutathiolation by S-nitrosoglutathione, was identified utilizing S-nitrosoglutathione-sepharose (Klatt *et al.*, 2000).

*Analysis of protein glycation*

The accumulation of advanced glycation endproducts (AGEs) is a hallmark of age-dependent protein modification. AGEs represent a class of chemical structures generated via breakdown or cross-linking of initial sugar-protein adducts. Poggioli *et al.* (2002) could demonstrate that age-dependent glycation does not occur randomly but appears to selectively target a few proteins, though no mass spectrometric studies to characterize these proteins were presented. In contrast, Crabb *et al.* (2002) performed both HPLC-tandem MS and Western blot experiments to identify proteins, including AGE-modified proteins, present in debris-like material, referred to as “drusen,” accumulating below the retinal pigment epithelium on Bruch’s membrane during age-related macular degeneration (AMD).

**Conclusion**

To date, proteomics studies have just begun to unravel small details of the “aging proteome.” Continuous improvements of proteomics methodology are necessary, specifically with regard to sample preparation and presentation, in order to cover as large parts of the entire proteome as possible and to extract biologically meaningful information. Experimental studies need to be accompanied by bioinformatics studies, which provide information about protein interaction networks. These studies are in progress and will yield important information on the “aging proteome” in, hopefully, not too distant time.

# Application of High-Throughput Technologies to Aging-Related Research

Matt Kaeberlein

*The development and application of high-throughput methods to study aspects of aging-related biology are among the key forces driving the field. New hypotheses are being developed, and new questions are being asked on a genome-wide scale. High-throughput technologies offer many advantages over traditional methods, but they also present new pitfalls for the unwary. Rather than provide detailed protocols for different methods, this chapter attempts to give an overview of some of the ways that high-throughput methods are currently being applied to aging-related research, along with a discussion of both the successes and the difficulties associated with these new technologies.*

## Introduction

Many areas of biological research have benefited from the technological advances of the past several years. The human genome is sequenced, along with genomes from dozens of other organisms; genome-wide protein-protein interaction maps have been generated for most of the major model systems; simultaneous gene expression profiling for tens of thousands of genes has become routine; and an almost inconceivable amount of primary data are only a mouse-click away via the Internet.

One of the most important questions facing the field of biogerontology is how to integrate and optimize the use of new technologies for the study of aging and age-associated disease. Application of new technologies to aging-related biology has often lagged relative to other fields, such as cancer biology. In the past, aging-related research has been driven largely by gene-specific or model-driven studies based on prior assumptions or knowledge. More recently, however, that trend seems to be changing as researchers recognize the opportunities associated with genome-scale approaches. In many cases, new technologies are being developed with the specific goal of tackling a particular aspect of aging-related research.

Along with the advantages of high-throughput methodologies, however, there are also risks, such as higher false positive and false negative rates. This is particularly

likely to be the case when a high-throughput method departs substantially from the standard method, and, in extreme cases, can result in artifacts that threaten the validity of entire lines of research (see the section on targeted screens for small molecules that slow aging). It is also often the case that statistical methods for dealing with new types of data generated from high-throughput methods are underdeveloped. This issue, which has plagued microarray studies for several years, is now better appreciated. Potential problems with large-scale methods can generally be avoided by independent replication of key data points using a more standard methodology, such as real-time quantitative polymerase chain reaction (PCR), to verify gene expression changes from microarray studies (see Applications of Microarrays to Aging-Related Research).

## Gene Expression Microarrays in Aging-Related Research

Microarrays have provided researchers with the ability to monitor gene expression changes across tens of thousands of genes in a single experiment. The potential applications of this technology are profound, and there are many cases where global gene expression profiling has been particularly useful, for example, in identifying cell cycle and stress-dependent transcriptional networks and characterizing gene expression signatures associated with different types of human cancers. The application of microarrays to aging-related research was initially received with great enthusiasm. That enthusiasm has been tempered somewhat, as a realization of the technical difficulties and limitations, some of which are specific to aging-related features, has emerged.

When considering the application of microarray technology to an aging-related question, there are several important issues that determine appropriate experimental design, and there are numerous examples in the literature of poorly designed microarray experiments and over-interpretation of microarray data. Recent reviews discuss many of the most important considerations associated with microarrays and provide advice for appropriate ways

to deal with them (Hudson *et al.*, 2005; Melov and Hubbard, 2004; Nair *et al.*, 2003). It is highly recommended that anyone considering the use of microarrays in their research program consult these resources and develop a detailed experimental plan prior to initiating experiments.

## GENERAL CONSIDERATIONS WHEN USING MICROARRAYS

### *Choosing microarray technology*

Microarrays afford the possibility of measuring gene expression levels for thousands of genes simultaneously. This is accomplished by obtaining RNA from a cell, tissue, or organism, and quantifying the amount of mRNA present for each gene being assayed. One of the most basic considerations when designing a microarray experiment is the type of microarray technology to use. There are two common types of gene expression microarrays: (1) “cDNA arrays,” usually PCR amplified open reading frames (ORFs) spotted onto glass slides, and (2) oligonucleotide arrays. It is generally accepted that for most applications, oligonucleotide arrays, while more expensive than cDNA arrays, also tend to provide higher specificity (Hudson *et al.*, 2005). Several commercially available oligonucleotide array platforms exist, including Affymetrix GeneChip microarrays, Agilent Oligo microarrays, and Amersham Biosciences (GE Healthcare) CodeLink Bioarrays (Hudson *et al.*, 2005).

The most commonly utilized microarray platforms employ either a two-color or one-color design. Two-color experiments involve co-hybridization of cDNAs derived from two different RNA samples on the same slide. Each set of cDNAs is labeled with a different fluorescent dye (e.g., Cy3 and Cy5). For each gene being assayed the relative expression level in sample #1 versus sample #2 is obtained by the ratio of Cy3 fluorescence to Cy5 fluorescence. One-color platforms, such as Affymetrix (“Affy” chips), are simpler, in that only one labeled cDNA is hybridized per chip. For each experimental sample, a fluorescence value is associated with each gene present on the microarray. This value can then be compared against the fluorescence value for that gene obtained with a common reference sample, to generate a ratio value analogous to that of a 2-color design.

### *Replication, variation, and validation*

A primary criticism against many aging-related microarray studies is a lack of sufficient replication (Melov and Hubbard, 2004). While the number of replicates required for interpretation of microarray data will vary based on many different factors, including the type of experimental design and the organism under study, there are standard approaches that can help determine the degree of replication needed to obtain statistically meaningful gene expression changes (Hudson *et al.*, 2005). Of particular import when considering replication is the

difference between biological and technical replicates. Technical replicates are replicates derived from the same biological sample (e.g., the same pool of RNA), and can refer either to the same probe spotted at different places on a microarray slide or to parallel hybridization of the same sample to multiple slides. In either case, technical replication can provide information only about the error in the measurement and gives no indication of the variation within the population from which the samples originated. Biological replication refers to analysis of samples obtained from different individuals or pools of individuals. When considering the number of *independent* replicates necessary for statistical analysis, only biological replicates should be counted.

A higher number of replicates may be necessary for aging-related microarray studies relative to microarray studies that examine other aspects of biology. Unlike gene expression changes associated with cancer, for example, which can be several-fold in magnitude for the most up- or down-regulated transcripts, age-associated changes tend to be relatively small in magnitude and can easily be masked by variation between individuals (Hudson *et al.*, 2005). In addition, there is evidence that gene-specific variation increases with age, perhaps due to dysregulation of transcription in older individuals. Thus, the most relevant transcriptional changes in an age-related study may be smaller in magnitude and require a greater number of replicates to be statistically detectable.

The first look a researcher usually gets at the data from a microarray experiment is in the form of an image file, where each “spot” corresponds to the fluorescence intensity associated with the expression of a particular gene. The process of getting from the raw data to a list of genes that are up- or down-regulated involves several steps, each of which can have a substantial impact on the quality of the data set. The image must first be processed, which involves manual inspection of the image files for anomalies, followed by spot quantification, quality control, and normalization. Many software packages are available to assist with visual inspection and spot quantification, and the appropriate choice will depend of several factors, including platform and cost (Hudson *et al.*, 2005).

In the early days of microarray use, researchers would often carry out experiments with two or three replicates (sometimes only one), apply minimal normalization procedures, calculate the average fold-change in mRNA levels for each gene, select an arbitrary fold-change cutoff (usually 2-fold), and report a list of genes that are “significantly” up- or down-regulated (Melov and Hubbard, 2004). Fortunately, those days are (mostly) gone. Although there are no universally accepted standards for processing, analyzing, and presenting microarray data, it is now expected that rigorous statistical methods be applied to any microarray data prior to publication. Several detailed reviews are available on statistical methods for analyzing microarray data

## 10. Application of High-Throughput Technologies to Aging-Related Research

(Churchill, 2002; Kerr and Churchill, 2001; Kerr *et al.*, 2000; Lee and Whitmore, 2002). In most cases a statistician should be consulted both during the design phase of the microarray experiment and during the data analysis phase.

A well-designed microarray experiment will result in a set of genes that, following appropriate statistical analysis, show statistically significant changes in mRNA level as a function of the experimental condition under study. Unfortunately, many studies go no further, in terms of validation, than to list the set of genes that meet this description. In any microarray experiment, independent validation of the observed changes in mRNA levels, or at least a subset of the most important observed mRNA changes, is essential. At a minimum, real-time quantitative PCR (RT-PCR) or some other method should be used to demonstrate the expected change in mRNA level. If biological relevance of a particular gene expression change is to be inferred, then a change in protein level, or even better protein activity, should be shown. Since translational or post-translational regulation can offset changes in mRNA level, there is no guarantee that the activity of the encoded protein has been altered even if mRNA levels are dramatically changed.

### APPLICATIONS OF MICROARRAYS TO AGING-RELATED RESEARCH

#### *Comparing young versus old*

The most common application of microarrays to aging-related research is an experimental design that compares gene expression in young organisms to gene expression in old organisms. Studies of this type have been carried out in all of the major model systems, as well as in humans (Hudson *et al.*, 2005). Most often, the goal of this type of study is to identify genes for which transcription either increases or decreases as a function of age, in other words, biomarkers of age. It is important to recognize that the gene expression changes observed from this type of design don't confer any information about genes that determine longevity or rate of aging. Also, as is true of any microarray experimental design, the observed gene expression changes can be stated to correlate with the condition being studied (biological age, in this case), but no information is obtained regarding whether the gene products themselves play a causal role.

An important question when designing an experiment of this type is how to define the "young" and "old" populations. There is no single "correct" answer to this question; however, there are several considerations that should be taken into account. Without exception, two age-point designs (one young and one aged) are less favorable than multiple age-point designs where gene expression profiles are obtained at several different ages. As a rule of thumb, experiments of this type should examine the maximum number of different age-points

possible while still maintaining sufficient replication at each age-point for meaningful statistical analysis.

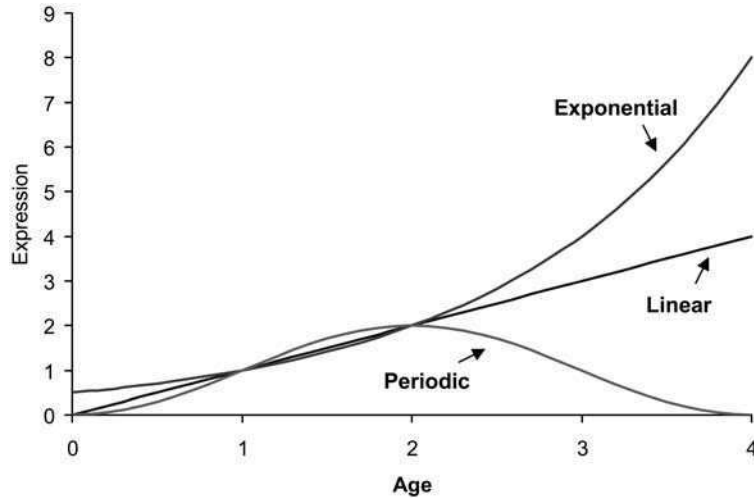

The importance of appropriate timing and spacing of age-points in the interpretation of gene expression studies should not be underestimated. Data regarding the kinetics of age-associated gene expression changes can provide valuable information for developing hypotheses regarding the functional consequences of the observed changes. In addition, both the structure and interpretation of the data may differ substantially depending on the number and spacing of age-points and the type of gene expression changes that occur (Figure 10.1).

In most cases, it will be desirable that animals are reproductively and developmentally mature at the youngest age-point. In order to define the oldest age-point, statistical parameters of the population life span can be used as a guideline. For example, an old age-point could be defined as 50% or 75% of the median longevity. It must be kept in mind, however, that the older an animal is at the latest age-point, the more likely that age-associated degenerative changes will obscure the relevant age-associated gene expression changes.

A majority of the published microarray studies examining age-correlated gene expression suffer from an inadequate number of age-points (Melov and Hubbard, 2004), a fact that must be considered when analyzing and interpreting these data. Nonetheless, some interesting trends have been observed in multiple studies across a variety of species. For example, up-regulation of genes involved in the response to oxidative stress and other types of stress seems to be a common theme in aged invertebrates (Landis *et al.*, 2004; Pletcher *et al.*, 2002; Zou *et al.*, 2000) and mammals (Kayo *et al.*, 2001; Weindruch *et al.*, 2001). This is consistent with the idea that oxidative damage increases during aging, and is interesting in light of the observations that some long-lived mutants show increased expression of oxidative stress response genes as well as increased oxidative stress resistance as young animals (McElwee *et al.*, 2003; Murphy *et al.*, 2003).

#### *Comparing short- and long-lived*

There are currently no commonly accepted biomarkers of aging rate (biomarkers of longevity) (Butler *et al.*, 2004), and this lack is one of the key problems in aging-related research. Microarrays provide the opportunity to assay many thousands of potential gene expression biomarkers in order to detect a subset of genes whose expression predicts individual longevity. In order to identify gene expression biomarkers of aging rate, the gene expression profile of more slowly aging individuals must be compared to the gene expression profile of more quickly aging individuals. The most reliable method for accomplishing this is to carry out microarray analysis on long-lived individuals relative to individuals with a normal life span. In theory, short-lived "premature aging" mutants can also be used;

	Old = 2	Old = 3	Old = 4
<b>Gene A (Linear)</b>	2X ↑	3X ↑	4X ↑
<b>Gene B (Exponential)</b>	2X ↑	4X ↑	8X ↑
<b>Gene C (Periodic)</b>	2X ↑	NC	> 8X ↓

**Figure 10.1** Importance of age-points in microarray analyses of aging. Age-related gene expression is shown for three hypothetical genes: expression of Gene A increases linearly with age; expression of Gene B increases exponentially with age; Gene C shows a periodic expression pattern, where expression increases at young age, then decreases during old age. For a two age-point design (one “young” and one “old”) specifying age-point 1 as the young age-point, different conclusions are reached depending on which age-point is used as the old age-point. If age-point 2 is used, all three genes show the same 2-fold increase in expression. If age-point 3 is used, genes A and B both appear to be up-regulated, while gene C shows no age-associated change (NC) in expression. If age-point 4 is used, gene A appears to be up-regulated by 4-fold, gene B is dramatically up-regulated by 8-fold, and gene C is down-regulated by more than 8-fold with age. The only design that provides an accurate picture of the (relatively simple) age-associated gene expression kinetics for these genes employs at least 3 age-points.

however, there are no short-lived mutants that recapitulate all aspects of normal aging, and it is extremely difficult to differentiate premature aging from nonspecific deleterious effects.

Several studies have reported gene expression profiles corresponding to long-lived mammalian models, as a result of environmental changes such as calorie restriction (CR) (Park and Prolla, 2005b), as well as longevity-enhancing mutations, such as the Ames dwarf, the growth hormone receptor knock-out (GHR-KO) (Dozmorov *et al.*, 2001; Miller *et al.*, 2002; Tsuchiya *et al.*, 2004), and the fat-specific insulin receptor knock-out (FIRKO) (Bluher *et al.*, 2004). In *C. elegans*, the transcriptional changes associated with longevity-determining mutations in the insulin-like/IGF-1 pathway have been well characterized by microarray, resulting in the identification of several previously unknown aging genes (McElwee *et al.*, 2003; Murphy *et al.*, 2003).

One popular design for microarray studies of aging combines both a longevity component and an age component. This approach allows for the identification of several classes of gene expression biomarkers that would otherwise be obscured (Hudson *et al.*, 2005). A classic study of this type (Lee *et al.*, 1999) compared the gene expression profile in gastrocnemius muscle from young and old mice, either fed ad libitum or calorie restricted, and reported that many of the age-correlated gene expression changes are attenuated by CR. While the limitations of this study (small number of replicates and no statistical analysis) have been amply documented (Melov and Hubbard, 2004; Miller *et al.*, 2001), this represents the basic design strategy for all microarray studies of this type. Subsequent studies have validated the idea that CR retards age-associated gene expression changes in a variety of tissues (Park and Prolla, 2005a) and have begun to address the question of determining

## 10. Application of High-Throughput Technologies to Aging-Related Research

which CR-induced changes in mRNA might be relevant for increased life span (see Biomarkers of calorie restriction).

### *Biomarkers of calorie restriction*

An important class of longevity biomarkers consists of biomarkers of CR. The discovery of CR mimetics—drugs that recapitulate the longevity benefits of CR without necessarily requiring a decrease in nutrient consumption—has obvious applications to human health. One approach that might be taken to identify CR mimetics is to use microarrays to define a pattern of gene expression changes that is characteristic of the calorie-restricted state. Animals can then be fed a putative CR mimetic and the corresponding effect on gene expression assayed. The higher the similarity between gene expression associated with CR and the observed gene expression profile, the greater the likelihood the compound will have a beneficial effect on longevity, at least in theory. Although yet to be proven, this approach is appealing because it does not require the time and expense of life-span assays—a limiting factor in mammalian aging studies—for each compound.

Gene expression biomarkers of CR have begun to be used to address important questions regarding the mechanism and temporal kinetics of CR. Dhahbi and colleagues used microarrays to compare the changes in hepatic gene expression of young and old mice in response to CR after 2, 4, and 8 weeks (Dhahbi *et al.*, 2004). The striking result of this study is that old mice switched to CR late in life showed a rapid shift toward the gene expression profile of animals subjected to long-term CR, while old mice switched from a long-term CR diet to a control diet showed a corresponding shift in gene expression profile toward animals maintained on a control diet for their entire life. These data are consistent with evidence from both mice (Dhahbi *et al.*, 2004) and flies (Mair *et al.*, 2003) that CR initiated late in life reduces mortality to a comparable extent as life-long CR, and suggests that at least some of the observed gene expression changes correlate well with the ability of CR to slow aging.

### *Gene expression meta-analyses*

As the number of aging-related microarray studies increases, the opportunity presents itself to carry out bioinformatic comparisons between multiple organisms or multiple models of enhanced longevity. In the first such meta-analysis of aging, gene expression changes correlated with age were compared between worms and flies (McCarroll *et al.*, 2004). A phylogenetic analysis was used to first identify orthologous gene pairs for which the pattern of expression change with age has been reported from prior work. From this analysis, the authors define a “shared transcriptional profile of aging” involving genes involved in a variety of processes, including mitochondrial metabolism, DNA repair, catabolism,

peptidolysis and cellular transport. As with many of the microarray studies already described, valid criticisms of the statistical methods employed in this meta-analysis have been raised (Melov and Hubbard, 2004), and it remains to be seen how much of the shared profile of aging is conserved in mammals. Nonetheless, this represents an important step forward in the application of bioinformatics to aging-related data sets.

At this writing, no large-scale meta-analysis of multiple models of enhanced longevity has been reported. An initial foray in this direction has been carried out by Miller and colleagues who have compared gene expression patterns in two long-lived mouse models, the GHR-KO and Snell dwarf, with CR (Miller *et al.*, 2002). More recently, a comparative analysis of longevity versus microarray and other data for 22 lines of inbred recombinant mice was reported (de Haan and Williams, 2005). As global gene expression profiles are generated for additional longevity models and bioinformatic approaches to analyzing microarray data improve, more opportunities to carry out meaningful comparative analyses of this sort will arise.

### APPLICATIONS OF MICROARRAYS TO HUMAN AGING

The application of microarrays to study aging-related processes in humans is, for obvious reasons, more difficult than in model organisms. Availability of samples from healthy donors, genetic and environmental heterogeneity, and variation in sample quality and preparation are just a few of the possible confounding issues. Of particular concern in samples obtained from elderly people is the possibility that medications or other interventions prescribed for a variety of age-associated ailments might alter the normal gene expression profile.

Many studies have reported changes in gene expression as a function of age in humans, and age-correlated gene expression profiles have been described for several tissue types, including retina (Yoshida *et al.*, 2002), muscle (Welle *et al.*, 2004; Welle *et al.*, 2003), kidney (Rodwell *et al.*, 2004), and brain (Lu *et al.*, 2004). Microarrays have also been used to examine gene expression profiles of human cells cultured *in vitro*. This approach has the benefit of being more controlled and less resource limited than assaying expression in tissues directly from donors, but is subject to a host of caveats associated with the process of obtaining and maintaining stable cell lines *in vitro*. In addition, the relevance of *in vitro* replicative senescence to *in vivo* cellular aging has yet to be determined.

*In vitro* gene expression profiles have been generated for two progeroid syndromes, Werner syndrome (Kyng *et al.*, 2003) and Hutchinson–Guilford progeria syndrome (Csoka *et al.*, 2004). It has been suggested that most of the changes in gene expression associated with normal aging are recapitulated in cell lines derived from Werner syndrome patients (Kyng *et al.*, 2003), although

methodological problems make this interpretation questionable (Prolla, 2005). Interestingly, the gene expression changes observed in fibroblasts from Hutchinson–Guilford progeria syndrome patients show almost no similarity to gene expression changes observed in fibroblasts from aged donors, nor do they correspond to age-related changes in tissues from mice (Prolla, 2005).

### SAGE PROFILING OF GENE EXPRESSION IN AGING

Microarrays are not the only technology available for high-throughput analysis of gene expression. Serial analysis of gene expression (SAGE) is a technique that involves converting a mixture of cDNA into a linear concatemer of short sequence tags followed by DNA sequencing of the concatemer library (Velculescu *et al.*, 1995). The frequency at which each tag is present in the library represents the abundance of the mRNA transcript from which the tag was derived. SAGE is more technically difficult than microarray analysis and requires a large DNA sequencing capability, but has the advantage that it can detect an entire transcriptome (rather than only genes corresponding to the probes on a microarray chip) as well as changes in the frequency of different splice variants.

SAGE has been used only rarely in aging-related research. In *C. elegans*, gene expression of long-lived dauer animals relative to controls has been examined by SAGE (Jones *et al.*, 2001), and, more recently, a comparison of gene expression in *daf-2* mutants as a function of age has been reported (Halaschek-Wiener *et al.*, 2005). The latter study, in particular, is of interest because a comparison between the SAGE data and analogous microarray data (McElwee *et al.*, 2003; Murphy *et al.*, 2003) has identified a set of six genes, *hsp-12.6*, *vit-2*, *vit-5*, *fat-3*, *nid-1*, and *mtl-1*, that show reproducibly altered expression. SAGE has also been used along with microarray in a comparative analysis of age-correlated changes in muscle gene expression between humans and mice (Welle *et al.*, 2001) and to examine the age-correlated transcriptional changes in the mouse cerebellum (Popesco *et al.*, 2004).

### High-Throughput Approaches to Measuring Life Span in Simple Eukaryotes

Simple eukaryotic models, such as yeast, worms, and flies, have had a significant impact on aging-related research, largely due to their short life span and genetic tractability (see Chapters 17–25). Nearly all model-based studies of aging have been driven either by candidate gene approaches, where a particular gene is studied based on its known or assumed function related to aging, or by genetic screens for secondary phenotypes correlated with longevity. These approaches, while often fruitful, are inherently biased. The development of true high-throughput

life span assays, where longevity can be measured for thousands of individuals simultaneously, provides the opportunity to identify genetic and environmental regulators of aging in an unbiased, genome-wide manner.

### ALTERNATIVES TO STANDARD LIFE-SPAN ASSAYS

Even in simple eukaryotes, such as yeast, worms, and flies, the length of time that it takes to measure life span can be a rate-limiting step in high-throughput longevity phenotyping. New approaches are being developed that decrease the time and effort necessary to predict whether a particular mutation or environmental intervention is likely to alter aging rate. For example, in *C. elegans* a high-throughput method has been developed that combines automated worm-handling technology with a fluorescent dye exclusion phenotype to screen for small molecules that impact oxidative stress resistance and aging (Gill *et al.*, 2003). While the utility of this method has yet to be proven, the approach appears promising.

A new method has been proposed that shortens the length of time required to carry out life-span analysis in flies by 80% (Bauer *et al.*, 2004). By coupling the expression of a lethal toxin to expression of a putative age-dependent biomarker, flies are prematurely killed. In theory, any intervention that alters the rate of aging should similarly alter the rate of toxin expression and, hence, life span of the toxin-expressing animals. The authors do a good job of validating their system by showing that several examples known to increase longevity in wild-type flies also increase life span in the toxin-expressing strain. Whether expression of the biomarker correlates with aging rate in every situation has yet to be determined, and it will be important to validate any putative longevity-altering intervention discovered with this system using a standard life span assay.

In yeast, where replicative life span is measured by the number of daughter cells produced by each mother cell (see Chapter 18: Longevity and Aging in the Budding Yeast), methods have also been developed to screen for increased replicative life span. In one case, a strain has been constructed such that an essential gene is produced in mother cells but fails to be expressed in daughter cells (Jarolim *et al.*, 2004). In theory, only mother cells should be able to divide under these conditions, greatly simplifying and accelerating measurement of replicative life span. Although this system, as described in the initial report, fails to recapitulate the standard life-span assay, this represents a first step toward a workable high-throughput replicative life-span assay.

Another variation on high-throughput screening for long-lived yeast strains has been developed in which the number of chitin bud scars, a surface marker of replicative age, is quantified fluorescently by FACS (Chen *et al.*, 2003). This study reported that expression of human ferritin light chain in yeast increases the number of cells with elevated bud scar counts. The authors failed to

## 10. Application of High-Throughput Technologies to Aging-Related Research

confirm their findings using a standard replicative life-span assay, however, and no further validation of this method has been published to date. These examples illustrate, yet again, that high-throughput approaches, while potentially useful for screening, should never be used as a surrogate for life-span analysis under standard conditions. Any “hits” identified from a high-throughput screen must be validated using traditional methods to avoid false positive identifications.

### HIGH-THROUGHPUT LONGEVITY PHENOTYPING

Alternatives to standard life-span assays that accelerate the normal aging process can be useful tools for rapidly screening genes and compounds for effects on longevity. These methods suffer, however, from the fact that they are not true aging assays and putative aging effects must be verified in each case. A more satisfying, but also more difficult approach, is the development of automated, high-throughput methods for standard life-span measurements.

The system most amenable to high-throughput longevity phenotyping is the chronological life-span assay in budding yeast. “Chronological life span” refers to the length of time a yeast cell is capable of maintaining viability in a nondividing, quiescent state (see Chapter 18: Longevity and Aging in the Budding Yeast). Traditionally, chronological life span has been measured by culturing cells in 5–50 mL volumes and periodically plating onto rich media and counting colonies (Fabrizio and Longo, 2003). A semiautomated method for chronological life-span determination has recently been developed that allows for the aging of cells in a 96-well format using submilliliter volumes (Kaeberlein, 2004). Viability as a function of age is determined by transferring a small volume of cells (~1  $\mu$ L) into rich media, allowing outgrowth for a fixed period of time, and measuring the optical density at 660 nm. This method allows for the simultaneous determination of chronological life span for several thousand strains.

The first true genome-wide longevity screen to be described is an RNAi-based screen for genes that increase life span when knocked down in *C. elegans* (Lee *et al.*, 2003). A library of *E. coli* strains carrying double-stranded RNAi constructs corresponding to nearly 17,000 unique genes (~85% of *C. elegans* predicted ORFs) has been partially screened, with several genes identified that increase life span when knocked down. By far, the largest class of genes that increase life span when knocked down are genes that play a role in proper mitochondrial function, suggesting that decreased mitochondrial function increases life span in worms, perhaps due to decreased production of oxidative damage. The genome-wide RNAi approach is limited, however, by the fact that only genes that function to promote aging (genes that increase life span when knocked down) can be identified with reliability from such a screen. Efficiency of

gene knock-down by RNAi is also variable from gene to gene, and the use of double-stranded mRNA for RNAi may result in the knock-down of genes with homology to the target gene. A newly developed *C. elegans* RNAi library using hairpin siRNA technology may circumvent some of these limitations (Rual *et al.*, 2004), and the development of high-throughput methods for making transgenic worms would allow screening for genes that function to promote longevity.

### Targeted Screens for Small Molecules that Slow Aging

The identification of small molecules that impact human aging is of obvious value. A true antiaging compound would be expected to not only increase life span but delay the onset of most age-associated diseases. With the development of high-throughput life-span assays in model systems (see High-Throughput Approaches to Measuring Life Span in Simple Eukaryotes), the ability to carry out small molecule screens for compounds that slow aging has become reality. This type of unbiased screening is likely to result in a plethora of small molecules that increase the life span of simple eukaryotic models such as yeast, worms, and flies, which can then be tested in mammalian systems.

Traditional gene-specific approaches are also being taken to identify small molecules that impact aging or age-associated disease, through the development of high-throughput screening methods to identify specific inhibitors or activators of putative aging genes.

For example, resveratrol, a polyphenolic molecule found in red wine, has received much attention as a possible antiaging drug and CR mimetic based on this type of approach. The link between resveratrol and aging came out of a screen for small molecules that activate SirT1, a human protein orthologous to yeast Sir2 (Howitz *et al.*, 2003). Sir2-family proteins (Sirtuins) have been reported to increase life span in yeast (Kaeberlein *et al.*, 1999), worms (Tissenbaum and Guarente, 2001), and flies (Rogina and Helfand, 2004) when overexpressed, suggesting that Sirtuin activators might also slow aging.

A high-throughput screening method (Fluor-de-Lys) was developed to identify small molecule activators of Sirtuins (Howitz *et al.*, 2003). Sirtuins are NAD-dependent protein deacetylases (Imai *et al.*, 2000; Landry *et al.*, 2000; Tanner *et al.*, 2000), and the Fluor-de-Lys method monitors deacetylation of a peptide substrate that has been covalently linked to a fluorescent moiety. Resveratrol and several related compounds were isolated from this screen as activators of SirT1. Resveratrol treatment was reported to increase life span in yeast, worms, and flies (Howitz *et al.*, 2003; Wood *et al.*, 2004), apparently confirming its antiaging properties, at least in simple eukaryotes. More recently, however, two reports have independently determined that activation of Sirtuins

by resveratrol is an *in vitro* artifact caused by the Fluoride-Lys substrate (Borra *et al.*, 2005; Kaeberlein *et al.*, 2005a). The fluorophore inhibits interaction of enzyme with substrate, an effect “suppressed” by resveratrol, and resveratrol has no effect on *in vitro* deacetylation of a native peptide lacking the fluorescent moiety. Further, one study finds no detectable *in vivo* activation of Sir2 (Kaeberlein *et al.*, 2005a). This example points out a potential flaw in high-throughput methods that alter the fundamental properties of the standard low-throughput assay system. Novel “hits” from a high-throughput screen must always be validated using well-characterized methods.

In addition to Sirtuins, several other genes have been identified that play a role in determining aging rate in multiple eukaryotic models. For example, stress and nutrient responsive kinases, including TOR and Akt homologs increase life span in several different organisms when function is decreased (Fabrizio *et al.*, 2001; Kaeberlein *et al.*, 2005b; Kapahi *et al.*, 2004; Vellai *et al.*, 2003), and are likely to represent viable small molecule targets. Indeed, inhibitors of TOR, such as rapamycin and rapamycin analogues, are currently in clinical trials as anticancer agents. In general, genes that function to promote aging (increase longevity when function is reduced) are likely to make better candidates for high-throughput small molecule screening, as it is much easier to identify protein inhibitors rather than activators.

## Genome-wide Screens for Human Aging Genes

One of the primary goals of aging-related research is to identify genes that modify human aging and susceptibility to age-associated disease. Model systems have been particularly useful for providing candidate aging genes, by identifying mutations that significantly increase life span in lower eukaryotes. The relatively long life spans enjoyed by most people make analogous studies in humans impossible. Therefore, researchers are using several different indirect approaches to understand the genetic and environmental factors that affect aging in humans. High-throughput methods that employ new technologies for DNA sequence analysis are likely to prove particularly fruitful in this regard.

One approach toward identifying genes that modify human aging is to restrict the search space to individuals that demonstrate an extreme longevity trait, such as centenarians. Puca and colleagues have carried out a genome-wide linkage screen to identify loci that correlate with extreme longevity in centenarian sibships (Puca *et al.*, 2001). From this screen, a locus on chromosome 4 was identified and was subsequently mapped to microsomal transfer protein. Alleles of microsomal transfer protein have been associated with abetalipoproteinemia in humans (Geesaman *et al.*, 2003), and it is likely that

**Figure 10.2** Hypothetical change in allele frequency for a human aging gene. If many individuals from a variety of ages are genotyped and the allele frequency is plotted as a function of donor age, the relative frequency of the allele that promotes longevity (Allele B) will increase as homozygous carriers of the allele that does not confer a longevity benefit (Allele A) die early, and only homozygous carriers of the beneficial allele achieve extremely old age.

the role this gene plays in determining human longevity is related to the ability of centenarians to escape cardiovascular disease.

Another method for identifying polymorphisms correlated with longevity is a high-throughput SNP-typing approach, where allele frequencies are determined for a large number of SNPs from individuals of many different ages. Under this design, alleles that result in disease susceptibility are expected to decrease in frequency with donor age, while alleles that are important for longevity should increase in frequency (Figure 10.2).

An isoleucine-to-valine polymorphism in the protein kinase A-anchoring protein AKAP2 was found to correlate with decreased longevity and cardiac disease in one study of this type (Kammerer *et al.*, 2003). Unfortunately, no large-scale search for age-related changes in SNP frequencies has yet been reported.

Both approaches described above have the advantage of being unbiased, in the sense that no assumptions about the identity of the putative longevity gene are required. It is possible, however, that these types of unbiased approaches will be unable to detect polymorphisms that influence aging if disease alleles, particularly alleles protective for heart disease and cancer, give a more robust signal than allelic variation in genes that affect the aging process at a more fundamental level. In order to get around this potential limitation, researchers are beginning to look for polymorphisms that alter the function of conserved aging genes identified from simple eukaryotes. For example, an allelic variant in the human SIRT3 gene, resulting in decreased expression of the protein *in vitro*, has been reported to correlate with

## 10. Application of High-Throughput Technologies to Aging-Related Research

failure to attain extreme longevity (Bellizzi *et al.*, 2005). SIRT3 was chosen as a candidate human aging gene based on reports that increased expression of SIRT3 homologs increases life span in yeast (Kaeberlein *et al.*, 1999), worms (Tissenbaum and Guarente, 2001), and flies (Rogina and Helfand, 2004). The insulin/IGF-1 signaling pathway is another highly conserved longevity-determining pathway that has been screened for longevity-associated polymorphisms in people (van Heemst *et al.*, 2005). As additional conserved aging genes are identified, further studies of this type will shed light on the role of specific genetic variation in human aging.

### Other High-Throughput Approaches

New technologies continue to be developed for biomedical research, and application of these methods to aging-related problems will be an important force for advancing our understanding of the aging process. High-throughput proteomic (see Chapter 9 on proteomics) and metabolomic methods, in particular, offer the opportunity to dissect age-associated changes that go beyond mRNA. Protein microarrays, for example, may allow for genome-scale determination of protein levels (rather than mRNA) as a function of age and aging rate. Other high-throughput methods can detect macromolecular damage and modifications, such as glycation, that might play an important role in cellular aging (Schoneich, 2003). A particularly exciting prospect is the development of a noninvasive test for mammalian aging rate (perhaps serum based) that relies on protein or metabolite markers to determine whether a particular intervention alters aging in individual animals or people. The value of such a diagnostic method, both for disease treatment and aging research, would be immense.

### Conclusion

The application and development of high-throughput technologies in aging-related research have the potential to dramatically enhance our understanding of human aging. Microarray studies are beginning to identify conserved age-associated transcriptional changes across model systems, and the identification of *bona fide* gene expression biomarkers will be essential for testing putative antiaging therapies in people.

Accelerated assays for measuring life span in simple eukaryotes will provide additional candidates for longevity studies in mammals. Genome-wide attempts to identify genetic polymorphisms associated with human longevity have already uncovered important age-associated disease alleles, and will perhaps result in candidate aging genes in people.

Indeed, there is reason to be optimistic that continued application of these new technologies will enhance our understanding of the molecular biology of aging and, ultimately, our ability to treat age-associated disease.

### Recommended Resources

The institute for genomics research (TIGR) microarray resources: <http://www.tigr.org/tdb/microarray/>. A nice compilation of microarray-related information and links. TIGR also provides free software for processing, analyzing, and presenting array data. <http://www.tigr.org/software/#m>

Stanford microarray resources: <http://genome-www5.stanford.edu/resources/>. Another good collection of array resources and software.

Eisen lab software: <http://rana.lbl.gov/EisenSoftware.htm>. The classic Cluster and Treeview software along with additional software for array analysis and data presentation.

Significance analysis of microarrays (SAM): <http://www-stat.stanford.edu/~tibs/SAM/>. Statistical software for detecting significant changes in gene expression from microarray data. Can be used as a Microsoft Excel plug-in.

Bioconductor: <http://www.bioconductor.org/>. Open source software for bioinformatic analyses. More powerful than most of the other free software, but requires R, a software environment for statistical computing and graphics.

BASE BioArray Software Environment: <http://base.thep.lu.se/index.phtml>. An open-source database system for storage, retrieval, and analysis of microarray data.

GeneX-Lite: <http://www.ncgr.org/genex/>. Relational database system for managing, analyzing, and visualizing array data.

Gene Expression Omnibus: <http://www.ncbi.nlm.nih.gov/geo/>. NCBI database for depositing and retrieving microarray data.

ArrayExpress: <http://www.ebi.ac.uk/arrayexpress/>. European bioinformatics institute database for depositing and retrieving microarray data.

# Models of Alzheimer's Disease

Harry LeVine III and Lary C. Walker

*The concepts that drive disease modeling are presented in the context of animal models for Alzheimer's disease (AD). A number of the best-characterized natural and transgenic animal models for AD are described along with the caveats that each presents for studying mechanisms of disease and for testing of potential therapeutic strategies.*

## Introduction

Animal models do not now exist that recapitulate all of the behavioral, physiological, and biochemical facets of Alzheimer's disease (AD). In the last dozen years, transgenic mouse models have been developed that display many of the hallmark neuropathological structures as well as some of the behavioral consequences predicted by the Amyloid Hypothesis. They have been useful for testing hypotheses for root causes, defining interactions, and in investigating therapeutic strategies for this most prevalent chronic neurodegenerative condition. A brief description of AD is provided that points out the key features of the disease and the evolution of the models that have been used to probe mechanisms and to search for therapeutics. Rationales for development of different kinds of disease models and the limits of their utility are explained. The bulk of the chapter summarizes models that have been the most thoroughly investigated or that have made seminal contributions to the understanding of AD. It is not intended to be a comprehensive review of AD animal models, and the authors apologize to those investigators whose work or animals were not included due to limits on scope.

## Characteristics of AD

Alzheimer's disease (AD) is a progressive neurodegenerative disorder that is characterized by the relentless decline of cognitive function, judgment, perception and personality, and ultimately the loss of the distinctive and shared qualities that define an individual's existence (Cummings, 2004). For unknown reasons, the full behavioral and neurodegenerative phenotype of AD is unique to humans, a characteristic that has hindered the

development of representative AD models. However, in recent years substantial progress has been made in the development of animal models of behavioral and pathological components of AD.

Histopathologically, AD is characterized primarily by the presence of senile plaques and neurofibrillary tangles (NFTs) in specific brain regions (Figure 11.1) (see Hauw and Duyckaerts, 2001; Hardy and Selkoe, 2002 for review). Senile plaques are intricate lesions centered about a core of aggregated, fibrillar amyloid- $\beta$  ( $A\beta$ ) peptide; neurofibrillary tangles are intracellular inclusions comprised of aberrant, microtubule-associated protein *tau*. A variety of additional pathologic changes accompany plaques and tangles in AD, including cerebral  $\beta$ -amyloid angiopathy (CAA; Figure 11.1B), granulovacuolar degeneration, inflammation, and loss of specific neurons and synapses (Hauw and Duyckaerts, 2001) (Cummings, 2004). NFTs occur in over 20 brain disorders besides AD, and mutations in the gene for tau on chromosome 17 have been linked to hereditary CNS tauopathies (FTDP-17) (Lee *et al.*, 2001, 2005). Despite some similarities, the genetic tauopathies differ in important ways from AD, one being the critical role that  $A\beta$  plays in Alzheimer pathogenesis.

Alzheimer's disease afflicts primarily the higher order processing regions of the cerebral cortex and associated subcortical nuclei. The pathogenic process begins stereotypically in the allocortex of the medial temporal lobe and progresses inexorably to other brain regions over the course of many years (Braak *et al.*, 1997). Structures that are heavily involved in the end-stages of the disease are the neocortex, hippocampus, and amygdala, whereas some regions (such as the cerebellum) remain relatively spared (Hauw and Duyckaerts, 2001). Within affected areas, certain neurons are selectively vulnerable, in particular long projection neurons and/or neurons that use glutamate, acetylcholine, gamma-amino butyric acid (GABA), dopamine, or norepinephrine as neurotransmitters.

Paradoxically, in spite of evidence that  $A\beta$  plays a primary role in the causation of AD (below), the atypical, intraneuronal accumulation of tau is the first lesion to appear in aging humans (Braak *et al.*, 1997). Tau protein, which normally stabilizes cellular microtubules, begins to polymerize separately in affected cells,

**Figure 11.1** The Canonical Pathology of Alzheimer's Disease. (A) Gallyas silver-stained section showing neurofibrillary tangles (arrows) and senile plaques (arrowheads) in the hippocampal formation of an AD patient (10X objective). (B) Aβ-immunostained section showing senile plaques (arrowhead) and CAA (grey arrow) in the neocortex (antibody 10D5; 20X objective).

**Figure 11.2** Familial AD Mutations in βAPP. The amino acid sequence of the region of the Amyloid Precursor Protein that contains the Aβ peptide is shown with the different secretase sites (α-, β-, γ-) marked. The sequence numbering for the Aβ peptide is above the sequence while the βAPP sequence numbering is below the sequence. Positions and amino acid changes of the various familial mutations in βAPP are indicated.

eventually forming neurofibrillary tangles, neuropil threads, and vacuolar granules (granulovacuolar degeneration). Tauopathy is first apparent in the entorhinal region, which receives heavy input from the sensory association areas of the neocortex, and then spreads progressively into other limbic structures, the neocortex, and specific subcortical neuronal groups. Senile plaques generally arise after the first tau lesions, and they do not consistently colocalize with neurofibrillary tangles, although there is evidence that they occur in terminal fields of tangle-bearing projection neurons (Schonheit *et al.*, 2004). The stereotypical localization of plaques and tangles suggests the importance of local biochemical conditions and neuronal interconnections in the instigation and spread of the lesions.

While neurofibrillary tangles become evident prior to senile plaques in aging humans, there is growing evidence that the anomalous aggregation of Aβ is a seminal event in AD pathogenesis (Hardy and Selkoe, 2002; Walker and LeVine, 2002) and that the corruption of tau occurs in response to initial abnormalities of Aβ (Walker and LeVine, 2002; Oddo *et al.*, 2004). Three compelling arguments support the primacy of Aβ in the

Alzheimer's disease cascade: (1) The large quantity of Aβ deposits in the AD brain implicates the peptide in pathogenesis; (2) the most common autosomal dominant forms of AD all involve mutations either in the β-amyloid precursor protein (βAPP) (Figure 11.2) (Revesz *et al.*, 2003) or in the presenilins (PS1 and PS2), which form the probable catalytic subunit of the gamma-secretase complex that liberates Aβ at its C-terminus (Marjaux *et al.*, 2004); and (3) all known genetic and environmental risk factors for AD increase the production of Aβ and/or its tendency to aggregate (Hardy and Selkoe, 2002).

According to the Aβ-cascade hypothesis, the abnormal accumulation of multimeric Aβ triggers a progression of events leading to amyloid plaques, neurofibrillary tangles, inflammation, neuron- and synapse loss, and dementia. *In vitro* and *in vivo* studies are beginning to implicate a prefibrillar, oligomeric form of Aβ in this cascade (Kayed *et al.*, 2003). Indeed, the major genetic risk factor for AD (accounting for over 50% of the risk) is the inheritance of the ε4 allele of apolipoprotein-E (ApoE); ApoEε4 is associated with increased Aβ(1–42) while decreasing the age of disease onset (Poirier, 1994).

### NORMAL AGING OR DISEASE?

A key issue for AD model development is whether AD is a pathological process or whether it is part of the normal sequence of aging. It is not as easy to decide this as it might seem. Sporadic AD is a condition of advanced age; average onset in the general population is 80–85 years. In fact, advancing age is the single most important risk factor for AD. Some of the symptoms and many of the lesions of AD are observed in normal persons as they age, a significant number of whom never develop dementia. Would all of them develop dementia if they were to live long enough? This issue remains unresolved, although it is clear at least that the initiation and trajectory of AD pathogenesis vary widely among aging persons.

Advanced age is not a requirement for AD pathology. Familial (genetic) forms of AD clearly fit the criteria for a disease, as the pathology occurs decades earlier than for the sporadic form of AD. One mutation (presenilin-1, P117L) causes disease onset as early as the 20s (Wisniewski *et al.*, 1998). Early onset AD is not a progeric disorder, as other signs of advanced age are not observed. The difference between a disease and aging blurs when the processes involved overlap.

In terms of therapeutics, the prospects for blocking an aberrant process are significantly greater than for discovering a fountain-of-youth agent that halts aging. Disease models based on current hypotheses of what is driving AD pathology address the former condition while general aging models concentrate on the latter. The two approaches are not exclusive. Aging provides a substrate for the pathological processes in AD. Much can be learned from both types of models, and from considering how they interact and overlap.

### Characteristics of an Animal Model: Modeling Pathology or Function?

Animal models of human disease are seldom comprehensive. Rarely does a single system recapitulate all aspects of the human pathological process. Defining the key characteristics of a disease to be reproduced requires some knowledge of the driving force for the pathology and the symptoms. Secondary co-morbid characteristics that may be observed in the disease, but that are not critical for disease progression, would clearly be poor choices for modeling. It is not always easy to tell the difference. Before the development of molecular targets and mechanism-based approaches, pharmaceutical research and drug discovery were heavily based on animal models that reproduced symptoms seen in humans. Animals with high blood pressure or hyperglycemia were treated to determine which compounds best normalized the condition. The success of such models in predicting efficacious agents in humans depended greatly on whether the mechanisms were similar.

This approach had been relatively successful for another chronic neurodegenerative disease, Parkinson's disease. Remarkable improvement was achieved with dopaminergic neurotransmitter replacement therapy (L-dopa). The first AD models and therapeutics were based on a similar principle of symptomatic relief, alleviating the functional deficits of cholinergic systems early in the disease. Cholinergic therapies for AD were significantly less effective than was L-dopa for Parkinson's disease, and clinical evidence indicates that supplementation of cholinergic function can slow, but fails to halt, the progression of AD. The lack of effect of L-dopa on disease progression also was recognized for Parkinson's disease, suggesting that the prime mover in both diseases remained to be addressed.

Symptom-based models gave way to pathology-based models as molecular knowledge of AD expanded, and the interplay of genetic factors and the metabolism of the precursor protein to the  $A\beta$  peptide found in the amyloid plaques were understood. The models based on this insight produced  $A\beta$  plaques or tau filaments in the brains of transgenic mice overexpressing  $\beta$ APP or tau, respectively, but failed to develop robust neuronal cell death or atrophy that resemble these events in AD. Neurophysiological and behavioral deficits were observed in young  $\beta$ APP-overexpressing animals; however, they were not linked to histologically demonstrable deposits of  $A\beta$ , which usually developed later.

### PURPOSES OF MODELS

Since only humans develop AD, there are no “natural” models that display all of the pathological, physiological, and symptomatic features of the human disease. The same is true for genetically engineered models, as each model has both advantages and weaknesses in recapitulating the AD phenotype. It is thus important when choosing a model for study to consider how well it is suited to answering the specific questions being asked about AD.

#### *Development of therapeutics*

Testing of potential therapeutics was the motivation for developing a number of the early models of AD. A symptomatic approach was adopted similar to the one that produced effective therapy for Parkinson's disease, where the targeted deficit was in the nigrostriatal dopaminergic system and the control of movement was monitored. Cognitive deficits in AD were modeled by subjecting hippocampally deficient mice or aged monkeys to memory tests of different sorts. Reversal of pharmacologically or lesion-induced cholinergic dysfunction in behavioral tasks by test agents was another approach.

Cholinergic therapeutics—specifically inhibitors of acetylcholinesterase—have proven to provide some benefit to patients for a limited period of time. However, this first generation of cholinergic therapeutics failed to cure or halt AD, prompting the development of models based on other pathogenic mechanisms, such as

the “A $\beta$ -cascade” (Hardy and Selkoe, 2002). Such models could be used for monitoring the effects of therapeutics targeting such elements of the pathogenic cascade as plaque deposition, A $\beta$  peptide levels, glial responses, and secondary pathology. These animal models lack the profound neurodegeneration of AD, and thus they are incomplete models of AD. Combining dominant transgenes for  $\beta$ APP, PS1, and even tau had surprisingly little effect on neurodegeneration, the substrate for dementia. Nevertheless, these models, when judiciously chosen, are useful for developing possible therapeutic agents targeting key components of the pathogenic process, but the efficacy of such disease-modifying treatments in humans remains to be validated.

#### *Probing mechanisms of AD neurodegeneration*

The cell-selective neurodegeneration in AD and other chronic neurodegenerative diseases and the failure to produce models with comparable neuronal cell death are unexplained. The partial models of AD pathology have been useful for teasing out mechanistic details that may apply to AD. The human disease, or cohort of diseases as some believe, is a morass of overlapping pathologies where it is difficult to determine which one(s) drive(s) the disease process, and when, during the estimated forty years of (mostly silent) progression the key players act. Modeling individual components of the multifactorial process, assessing their impact, and then combining them in different ways provide information on how they might interact in a disease state. Incorporation into a single model with the correct temporal and spatial sequencing of events would be the Holy Grail of AD.

#### *Optimizing clinical trials*

A model that rapidly predicts the efficacy of an agent in producing the desired therapeutic effect, even if it is unknown whether that intervention will ultimately influence the disease, would invigorate clinical trials. The double unknown of pharmacologic efficacy and impact on the disease is discouraging. Another area in which models can contribute is in identifying potential side-effects or toxicities and to establish safe dosage ranges. Gamma secretase inhibitors have the potential to interfere with important signaling molecules, such as Notch in hematopoiesis, and this is assessed in the models.

The current models do not anticipate all possible side-effects. An A $\beta$  immunization trial designed to lower A $\beta$  levels (AN-1792, Elan) was halted by unexpected immune encephalopathy in 6% of the immunized patients. In addition, the patients who mounted an antibody response to A $\beta$ -immunization, despite weak evidence for clinical improvement, paradoxically showed an augmented shrinkage of the brain substance. A search for models capable of detecting these serious side effects is underway.

## MAMMALIAN VS NONMAMMALIAN SYSTEMS

A debate rages over the relevance of nonmammalian animal models to what is a uniquely human disease. Much has been learned about the basic biology of AD mechanisms from nonmammalian systems. Biochemical processes tend to follow general precepts that are comparable in simple and complex organisms. The yeast *Saccharomyces cerevisiae* allows the use of powerful classical and molecular genetic tools, although this organism lacks a nervous system. The roundworm *Caenorhabditis elegans* and the fruit fly *Drosophila melanogaster* are well-studied animals that are also genetically accessible. Both feature relatively simple, stereotyped nervous systems to analyze biochemical pathways and cell function. *C. elegans* (Rankin, 2004) and *Drosophila* (Rohrbough *et al.*, 2003) display certain aspects of learning behavior that have been dissected genetically. The genomes of all these organisms have been sequenced, so mammalian and human gene homologs can be readily identified. Short generation times shrink the timescale of experiments with these organisms, even for elderly individuals.

While possessing a number of advantages for studying specific instances of biochemical pathways, mechanisms, or physiological subsystems, there remain significant differences in complexity and organization between invertebrate and mammalian nervous systems that limit the simpler organisms as AD models. Although these organisms have been used as models of aging, and there are certain similarities, questions remain about the equivalence of two months of life in fruit flies to 80 years in humans.

#### *Nonmammalian organism models*

*Drosophila* and *C. elegans* provide both powerful genetic tools and a sufficiently complex behavioral repertoire to be able to detect alterations in brain function (Driscoll and Gerstbrein, 2003). They possess homologs to the human genes that are linked to familial AD. Unfortunately, neither the fly nor worm  $\beta$ APP contains the amyloidogenic sequence, and thus natural AD  $\beta$ -amyloid models are not available. The fly, in particular, has been useful for studies in AD, in Huntington's disease (HD), and in Parkinson's disease (PD) when the human familial disease transgenes are expressed leading to neurodegeneration. By a judicious choice of promoters, the mutant gene is directed to an easily observed neural tissue, the compound eye, in which neurodegeneration can be easily monitored.

In *C. elegans* expression of human A $\beta$ (1–42) in muscle leads to toxic effects (Fonte *et al.*, 2002). By searching for suppressor genes for the toxic phenotype in both flies and worms, potential pathways for countering the neurodegeneration have been identified. An example is the hsp70 chaperone protein, which reduces the accumulation of misfolded proteins. Mutation of negative

## 11. Models of Alzheimer's Disease

regulators of hsp70 activity also suppresses the toxic phenotype. Toxicity of misfolded proteins linked to AD, PD, and HD in these organisms is ameliorated by increased hsp70 activity. However, implementing a therapeutic strategy of increased hsp70 levels is likely to be fraught with difficulties due to the multiple roles of hsp70 in cell biology and the consequences of a sustained stress response.

### *Ex-vivo models*

In this category we include both isolated cell culture and tissue slice organotypic culture systems that approximate various aspects of AD. *Ex vivo* models are a step up in complexity—and hopefully disease relevance—from *in vitro* assays of biochemical components and biophysical processes. A variety of cell lines have been used via transfection of appropriate genes to study  $\beta$ APP metabolism and to work out the consequences of the familial AD mutations in  $\beta$ APP and the presenilins. Under the premise that many of the events are similar in all cells, even ones not thought to be altered in AD, these systems have been used to probe the cell biology of the amyloid cascade. Overall correspondence of results with those from neuronally derived cell lines is cited as evidence for the validity of these models. Indeed, the link between mutant presenilins and the increased production of  $A\beta$  in familial AD was accurately predicted from cell culture models.

Major caveats to blanket acceptance of the isolated cell systems as models of AD are that they are mostly transformed, relatively undifferentiated cells, often of nonneuronal origin or mixed neuronal–glial origin. Those cell lines of neuronal origin are frequently derived from the peripheral nervous system, which is spared in AD. Cultured cells also do not manifest the multiple connections or the extreme polarity and long-distance transport requirements of central neurons that are most affected in AD. Neurons cultured from embryonic or fetal brain regions are more representative of differentiated neurons, although they are mixtures of different kinds of neurons, in early stages of differentiation, that are removed from the surroundings in which they developed. There is much discussion about how similar these neurons are to *in situ* neurons because of the selection pressures *in vitro*. Fetal neurons from some brain regions survive to various degrees, while fully differentiated neurons from postnatal animals rarely are successfully cultured.

Organotypic brain-slice cultures are routinely used for neurotransmitter electrophysiology studies. The connectivity of various regions is more or less intact, depending on how the slices are made. Advantages are that the cells maintain their local contacts and are more highly differentiated than are embryonic cultures. Disadvantages are that they are labor- and resource-intensive, generally not long-term, and are difficult to prepare successfully from older animals. These systems have been useful for distinguishing neuronal toxicity of

soluble monomeric, oligomeric and fibrillar  $\beta$ -amyloid species (Lacor *et al.*, 2004) and the effects of  $A\beta$  on electrophysiology, such as blocking LTP but not LTD (Walsh and Selkoe, 2004).

Cerebrovascular smooth muscle cells cultured from human, canine, and  $\beta$ APP-transgenic mouse (Tg2576) leptomeninges actively produce  $A\beta$  peptides, secreting them into the medium and depositing them intracellularly and extracellularly (Frackowiak *et al.*, 2003; Frackowiak *et al.*, 2005). This is the only cell system that deposits  $A\beta$  in culture. The smooth muscle cells are susceptible to  $A\beta$  toxicity, particularly to a mutant peptide,  $A\beta$  E22Q, that produces a selective cerebrovascular smooth muscle amyloidosis with little parenchymal involvement in humans and in mouse models. This is a highly relevant system since these cells are involved in cerebral  $\beta$ -amyloid angiopathy (CAA), which is seen in virtually all AD patients and can lead to intracerebral hemorrhages.

### BEHAVIORAL MODELS AND THE CHOLINERGIC HYPOTHESIS

The symptomatic approach to treating AD involves maintaining or restoring the neuronal pathways that become deficient during the course of the disease. In early AD, a prominent deficit occurs in cholinergic pathways, particularly in the basal forebrain cholinergic system, whose afferents project widely to the hippocampus, amygdala and neocortical areas. The Cholinergic Hypothesis for AD held that the deficiency of presynaptic neurotransmitter was a central etiologic factor. The drugs currently on the market for treatment of AD are designed to boost presynaptic levels of acetylcholine, usually by inhibition of the breakdown of acetylcholine by cholinesterases. These cholinesterase inhibitors were developed through the use of mice or rats whose cholinergic function had been impaired by genetics (hippocampally-deficient mice), reversal of acetylcholinergic antagonist drugs, or lesioning. The animals were then assessed for behavioral improvement in the presence of the test agent. The compounds developed had the expected pharmacological properties, but they do not alter the course of the disease in a major way.

### MODELING OTHER BEHAVIORAL CONDITIONS

AD is characterized by a number of behavioral disturbances beyond cognitive function, particularly in the mid- to late stages of the disease. These include sleep disturbances, depression, wandering, and aggressiveness, which are frequently the cause of nursing home placement. These are conditions that also occur in the absence of AD symptoms. There is some question as to whether they are different in the presence and absence of dementia. This is an area in which better therapeutics could make a significant impact on quality of life for the patient and the caregivers. These behavioral problems are currently addressed by add-on medications, but the

effects are somewhat different than in nondemented subjects. This topic is outside the scope of this review.

## Pathology Models: Natural vs Engineered

AD symptoms are dominated by the progressive loss of cognitive function, although other modalities are affected, particularly in the later stages of the disease. Dementia, however, can result from multiple etiologies such as tumors, drugs, toxic agents, multiple cerebral infarcts, Lewy body disease, prionoses, and tauopathies, to name a few. Each disease generally presents a clinical picture that is distinct from the others, although areas of overlap are a persistent challenge for clinical diagnosis. The defining characteristic of AD is that the dementia develops in the context of the accumulation of  $\beta$ -amyloid peptide in plaque structures and the development of neurofibrillary tangles. In the absence of these lesions, in particular the amyloid deposition, the dementia is not considered to be of the Alzheimer's type.

### "NATURAL" MODELS OF ALZHEIMER-LIKE PATHOLOGY

Several animal species naturally develop senile plaques, cerebral amyloid angiopathy (CAA), and (to a limited degree) tauopathy with age. The most comprehensively studied nonhuman animals have been primates and canines. These animals are well-suited for modeling AD neuropathology for the following reasons: (1) They have the human-like  $A\beta$  sequence and develop senile plaques and CAA with age; (2) tau abnormalities (but not fully developed tangles) occur naturally with age in some primates and dogs; (3) the behavioral complexity of monkeys and dogs enables in-depth analysis of cognitive, social and motoric components of neurodegeneration; (4) both groups manifest age-associated decline of certain behavioral capacities; and (5) their large brains allow detailed *in vivo* imaging (Walker and Cork, 1999; Bussiere *et al.*, 2002; Voytko and Tinkler, 2004).

#### *Aging canine*

Cerebral amyloid deposition was first noted in a non-human species in the 1950s by von Braunnmuhl, who described senile plaques in elderly dogs. Since then, the characteristics of the deposits and the natural history of their emergence have been well established, as has their possible relationship to age-associated cognitive decline. In dogs, as in primates, the  $A\beta$  peptide is identical in sequence to human  $A\beta$ . Normal rats and mice differ in three amino acids from humans. The deposits that arise in the parenchyma of the aged canine brain are usually diffuse in nature; i.e., fully developed, dense-cored senile plaques are relatively rare. However, cerebral amyloid angiopathy (CAA) is common in older dogs (Wegiel *et al.*, 1995). CAA in canines, as in humans, primates, and transgenic mice, is associated with an increased incidence

of intracerebral hemorrhage and possibly white matter lesions as well (Torp *et al.*, 2000).

$A\beta$  accumulation correlates with behavioral impairments in aged dogs (Colle *et al.*, 2000), and with a regional loss of brain substance (particularly in the frontal lobes) beginning around 8 years of age (Tapp *et al.*, 2004). As in all affected species, there is substantial variation in age-associated changes among animals of comparable age; in addition, controlled comparative studies of the development and composition of lesions in different breeds of dogs are lacking. The age-related cognitive decline in aged dogs can be ameliorated by a diet rich in antioxidants and mitochondrial co-factors, as well as by behavioral enrichment (Milgram *et al.*, 2005; Siwak *et al.*, 2005), and there is evidence that drugs used to treat cognitive decline in humans can be usefully tested in aged canines (Studzinski *et al.*, 2005).

#### *Aging primate*

Information on the neurobiology of aging in nonhuman primates has grown steadily over the past four decades (Hof *et al.*, 2002). By far the most thoroughly investigated species are the rhesus monkey (*Macaca mulatta*) and the squirrel monkey (*Saimiri* spp), although there is a burgeoning literature on other nonhuman primate species, including great apes, marmosets (*Saguinus jacchus*), cynomolgus monkeys (*Macaca fascicularis*), green monkeys (*Chlorocebus aethiops*), baboons (*Papio hamadryas*), and mouse lemurs (*Microcebus murinus*). We will focus here primarily on rhesus monkeys and squirrel monkeys as natural primate models of Alzheimer-like pathology.

**Rhesus monkeys.** Rhesus monkeys are Old World monkeys with a maximum life span of approximately 40 years; they reach puberty at 3–4 years of age, and females go through menopause at approximately 25 years of age (Walker, 1995). Age-related cognitive decline is well-documented in rhesus monkeys, but a dementia-like state has not been reported. Rhesus monkeys develop senile plaques with age, usually in their early-mid 20's (Walker and Cork, 1999). These lesions are cytologically and biochemically similar to human plaques, except that the abnormal neurites that surround the core are devoid of tau filaments. Indeed, although primates can manifest tau abnormalities in brain, fully formed neurofibrillary tangles have not yet been detected in any nonhuman primate, including the apes.

**Squirrel monkeys.** In addition to widely varying phenotypes and lifespans, nonhuman primates show species-specific patterns of age-associated lesion development in brain. Squirrel monkeys are small, New World primates with a maximum lifespan of approximately 30 years (Walker and Cork, 1999). They begin to form  $A\beta$  deposits in the brain by the age of 13 years (around the age of menopause in females), and such lesions can be plentiful by 21 years. Unlike in rhesus monkeys, the  $A\beta$ -proteopathy in squirrel monkeys is predominantly

## 11. Models of Alzheimer's Disease

in the walls of cerebral blood vessels. Senile plaques also are present in squirrel monkeys, but they are less common than is CAA. Infrequent neurons are immunoreactive for hyperphosphorylated tau, but as in all nonhuman primates studied to date there are no fully developed neurofibrillary tangles.

Apolipoprotein E (ApoE) is heterogeneous in humans, and one form (ApoE4) is linked to an increased risk of AD and CAA. Intriguingly, *all* nonhuman primates are homozygous for apoE4; that is, their apoE resembles human apoE4 with arginines at positions 112 and 158. However, in nonhuman primates, threonine replaces arginine at position 61 of the human apoE sequence, which causes simian apoE to interact with lipoproteins similarly to human apoE3. Thus, neither  $\beta$ APP mutations nor apoE type account for the species-related variation in A $\beta$ -pathology, at least in *nonhuman* primates.

In summary, nonhuman primates and canines have been invaluable in illuminating the biochemistry, cytology and genetics of senile plaques, amyloid angiopathy and tau pathology in the aging brain, and they remain useful for testing emerging therapies for neurodegenerative diseases (Studzinski *et al.*, 2005; Walker *et al.*, 2005). However, for a variety of reasons, a major component of which is their longevity, research with these species is limited in scope. The emergence of genetically engineered rodent models has greatly accelerated the investigation of AD-like pathogenesis *in vivo*.

### Engineered Pathology Models

Although aged dogs and primates provide some insight into spontaneous AD and can be invaluable in testing the safety and efficacy of diagnostic and therapeutic agents, they are long-lived and do not reproduce all of the pathological features of the human disease. Engineered models attempt to combine knowledge gained from the familial forms of AD with transgenic technology to individually reconstruct the major components of the pathology. In order for such an approach to completely succeed, either the prime mover in the disease process has to be addressed or the complex pathology has to be an approximately linear combination of two or more pathologies, such as plaques and tangles. In the case of overlapping pathologies, each transgene should be able to induce key characteristics of AD pathology. Finally, the organism must be capable of reflecting the impact of the pathology in a recognizable way, preferably with behavioral signs and symptoms similar to those in humans with AD.

### AMYLOID HYPOTHESIS AND A $\beta$ AMYLOIDOSIS

The characteristic pathological signature of AD noted by Alzheimer is the presence of deposits of A $\beta$  peptide in extracellular plaques accompanied by tau deposits in intracellular tangles. The weight of the genetic evidence from familial forms of AD supports the A $\beta$  peptide as a

prime mover in the etiology of the disease (Hardy and Selkoe, 2002). While it is clear that mutations in  $\beta$ APP *can* cause AD in the genetic cases, sporadic AD must involve other factors. If it is true that multimeric A $\beta$  is either an initiating factor and/or a chronic stressor, strategies to alleviate these effects should alter the course of the disease.

### SEEKING THE PRIME MOVER IN ANIMAL MODELS

The human sequence of the A $\beta$  peptide is particularly prone to aggregation *in vitro* and is required for deposition *in vivo*. The murine sequence contains three amino acid substitutions, F4G, Y10F, H13R, all in the hydrophilic N-terminus of the peptide (Figure 11.2), resulting in greatly reduced fibril-forming activity, which may explain why rats and mice don't spontaneously develop plaques. Initial attempts at modeling amyloid deposition involved infusion of the human sequence peptide or plaque cores into the brains of recipient animals. In rat models, the infused peptide itself can form deposits in brain, but these lesions lack many features of bona fide plaques, and, unlike AD, the deposition is not sustained by endogenous processes. In a monkey model of synthetic A $\beta$  fibril infusion (Geula *et al.*, 1998), some neurodegeneration at the site of injection was observed, but amyloid plaque pathology did not develop. Similar results were obtained in rodent brain (Frautschy *et al.*, 1996).

A $\beta$  amyloid pathology has been successfully induced in animals by taking a lead from the prion field, where mouse models to study infectious prions were created in which the species barrier had been circumvented by overexpressing the cognate normal prion protein in mice. Seeding of new  $\beta$ -amyloid plaques in the parenchyma and the walls of the cerebrovasculature was engineered in Tg2576 animals with high interstitial fluid levels of A $\beta$  by a single injection of dilute AD brain extract (Walker *et al.*, 2002). A $\beta$  proteopathy was not inducible in age-matched, nontransgenic mice, and the injection of brain extracts from young subjects was ineffective. To date, injections of pure, synthetic A $\beta$ (1–40) and A $\beta$ (1–42) have failed to instigate  $\beta$ -amyloidogenesis in the same way as brain extracts, suggesting that there is something special about the A $\beta$  in the extract that is not found in the synthetic material. Identifying the properties of the brain extracts that promote  $\beta$ -amyloidogenesis will yield important information about the events that initiate this process *in vivo*.

#### *Transgenic expression models*

Success in obtaining plaque deposition in transgenic mice initially required overexpression of the human  $\beta$ APP relative to the endogenous mouse protein. Transgenic animals with human  $\beta$ APP-overexpression under the control of neuron-selective or neuron-specific promoters deposit A $\beta$  peptides in parenchymal plaques in many of the same areas as in the AD brain as well as around

cerebral and leptomeningeal blood vessels. Deposition is age- and protein level-dependent, usually beginning at 6–10 months in the absence of accelerating mutations. Dystrophic neurites develop around condensed senile plaques, as do reactive microgliosis and astrogliosis. While phosphorylated tau epitopes become prominent in dystrophic neurites, true neurofibrillary tangles never develop, and large-scale neuronal cell death has not been documented. A number of  $\beta$ APP transgenic models have been produced that employ a variety of promoters, expression levels, and  $\beta$ APP splicing variants. The upshot is that human  $\beta$ APP overexpression in mice reproduces CNS  $\beta$ -amyloidosis and (to a variable degree) amyloid angiopathy in specific brain regions, but the mice do not develop the full histopathology of AD.  $\beta$ APP overexpression also produces deficits in synaptic physiology (particularly in long-term potentiation [LTP]) and in several behavioral paradigms thought to reflect memory function in humans well before  $A\beta$  deposits are histologically demonstrable. While potentially due to the overexpression of  $\beta$ APP, which is believed to mediate cell–cell contact and signaling, these same effects can be induced by application of soluble oligomeric forms of  $A\beta$ , and the deficits are abolished by antibodies to  $A\beta$  peptide. Only some of the most widely used or most informative models are discussed here.

**Caveats.** In evaluating the histopathologic effects of murine transgene expression, it is important to recognize the presence of nonspecific lesions that develop with age in various strains of mice. Specifically, clusters of inclusions emerge most prominently in the hippocampus but to a lesser degree also in the cerebellum and other areas (Jucker *et al.*, 1992). These inclusions (sometimes referred to as *Jucker Bodies*) occur within astrocytes and do not closely resemble any known human lesions. The inclusions can react nonspecifically with many antibodies, particularly polyclonal antibodies, and their presence is governed by a variety of factors, including the age, strain, and possibly sex of the mice. It is imperative to distinguish these inclusions from transgene-related neuropathology.

It is also important to recognize that the gender of the mice can influence the degree of  $A\beta$  pathology. In Tg2576  $\beta$ APP-transgenic mice, amyloid deposition is significantly greater in females than in males (Callahan *et al.*, 2001).

**PDAPP.** The first compelling report of a transgenic mouse that deposited  $A\beta$  plaques used  $\beta$ APP V717F familial AD mutation minigene construct containing some intronic sequences under the control of the platelet-derived growth factor- $\beta$  (PDGF- $\beta$ ) promoter (Games *et al.*, 1995). The V717F mutation, which is near the gamma-secretase cleavage site, promotes the selective production of the highly amyloidogenic  $A\beta_{42}$  peptide. Plaque deposition is noticeable around 6 months of age. Between 6 and 12 months plaque deposition increases, and virtually all plaques up through this age

are neuritic and Thioflavine S-positive. After 12 months,  $A\beta$ -deposition increases precipitously, much of which is diffuse and Thioflavine S-negative. The dentate gyrus and entorhinal cortex are heavily invested (Reilly *et al.*, 2003). There is no change in hippocampal volume from 3 to 22 months in the transgenic animals compared to nontransgenic littermates. Four to five months before plaque deposition there are significant differences in electrophysiology and behavior in the transgenic animals. This model has been a workhorse driving anti- $A\beta$ -based therapeutic development for Elan (Athena) and Lilly, but PDAPP mice were not made generally available to the research community. At Elan, they were used for the studies that first demonstrated that immunization with the  $A\beta$  peptide would prevent or clear brain  $A\beta$  deposits, currently a promising therapeutic strategy for AD and an area of active research.

**Tg2576 – Hsiao mouse.** The human  $\beta$ APP695 amino acid protein with a Swedish K670N/M671L mutation coupled to a mouse prion promoter was designed to express the human protein in neuronal cells (Hsiao *et al.*, 1996), although this promoter seems to be active in other cell types such as vascular smooth muscle cells. A five- to six-fold overexpression was achieved in this early model, which is sufficient to drive deposition by 9 months of age, increasing dramatically up to 30 months. The Swedish mutation increases only  $\beta$ -site cleavage; as a result, there is a higher ratio of  $A\beta_{40}$ : $A\beta_{42}$  produced, and the plaques are a mixture of diffuse Thioflavin S-negative and neuritic Thioflavin S-positive deposits. Neuritic plaques are associated with abnormal, tau-immunoreactive neurites and with a glial inflammatory response. An electrophysiological and behavioral phenotype that is typical of the  $\beta$ APP overexpressing mouse models is present in these animals. These deficits are established before plaque deposition is apparent. Maintenance on a SJL/BL6 hybrid strain background and  $\beta$ APP heterozygosity are required because of  $\beta$ APP toxicity and of the site of insertion of the transgene array, respectively. These mice were made available both to industry and academia, and as a result, Tg2576 has become the most thoroughly studied of the murine  $\beta$ APP models. They are now commercially available from Taconic.

**Caveat.** Several inbred mouse strains, including SJL, carry the *rd* (retinal degeneration) mutation, a recessive, null mutation in the  $\beta$ -subunit of rod-specific cyclic GMP phosphodiesterase. Homozygous *rd* animals lose their rod cells between postnatal days 8 and 20, followed by a more gradual disappearance of the cone cells, such that by 4 weeks of age, the retina is devoid of photoreceptors. Obviously, this condition can profoundly influence performance on vision-dependent behavioral tasks.

**APP23 mice.** These mice express  $\beta$ APP751 with a Swedish K670N/M671L mutation under control of the neuron-specific Thy 1 promoter. The 751 isoform of  $\beta$ APP is not normally expressed in neurons, which

## 11. Models of Alzheimer's Disease

produce mostly  $\beta$ APP695. Plaque deposition begins around 6 months of age (0.3% of the cortical area) rising to 9% area at 22 months. Electrophysiological and behavioral deficits are noted before the onset of deposition, and condensed plaques induce inflammatory responses in the surrounding glial elements. Phospho-tau epitope induction is documented in neurites, but as in other  $\beta$ APP-transgenics, there are no neurofibrillary tangles. Some neurodegeneration is also reported, which is unusual in  $\beta$ APP models, but neocortical synapses are not depleted even when amyloid load is high (Boncristiano *et al.*, 2005). APP23 mice have a particularly strong propensity to develop  $A\beta$  accumulation in the vascular wall, and thus are a useful model of cerebral amyloid angiopathy (CAA) (Vloeberghs *et al.*, 2004).

**CRND8 mouse.** The double  $\beta$ APP695 Swedish K670N/M671L–Indiana V717F mutant under control of the hamster prion protein promoter produces a massive amount of  $A\beta$  and a particularly virulent  $\beta$ -amyloidosis. The Swedish mutation increases the total amount of peptide produced by altering the  $\beta$ APP sequence immediately N-terminal to the  $\beta$ -secretase cleavage site, making it a much better substrate for BACE. The Indiana mutation alters the  $\beta$ APP sequence immediately C-terminal to the  $\gamma$ -secretase cleavage site causing more  $A\beta(1-42)$  than  $A\beta(1-40)$  to be present after 8 weeks of age. The CRND8 mouse attains significant Thioflavine S-positive  $A\beta$  deposition at 3 months of age in 100% of the animals, and both diffuse and neuritic plaques are apparent by 6 months. Neurofibrillary tangles are not present, but studies of the phospho-tau epitopes in neurites, which are seen in all other  $\beta$ APP models, have not been published. The lack of neuronal cell death with the high level of  $\beta$ APP expression achieved in these animals is unusual. A possible explanation for this is the C3H genetic background, which is resistant to  $\beta$ APP toxicity. Behavioral and electrophysiological effects are noted early and can be reversed by immunization with anti- $A\beta$  antibodies.

**Hereditary cerebral  $A\beta$  angiopathy.** Several  $\beta$ APP familial mutations are associated with pathologies other than pure AD.  $\beta$ APP mutations that change specific amino acids within  $A\beta$  (at positions 21–23) cause rare, autosomal dominant  $A\beta$ -proteopathies characterized by profuse CAA (Revesz *et al.*, 2003). The  $A\beta(1-40)$  peptide is the main deposited species in these mutants; as deposition progresses, the smooth muscle cells of the tunica media are lost, and the vessel walls lose their elasticity and become susceptible to rupture. While hereditary CAA is rare, wild-type  $A\beta$  is deposited in the cerebrovasculature of nearly all AD subjects as well as Down Syndrome patients, increasing the probability of hemorrhage.

Until recently, CAA has been difficult to model in mice bearing the human familial mutations. Mice transgenic for  $\beta$ APP770 Swedish K670N/M671L + Dutch E22Q and

Iowa D23N under control of the Thy 1.2 promoter express very low levels of  $\beta$ APP770, less than the endogenous mouse  $\beta$ APP (Davis *et al.*, 2004). Nevertheless, the mice develop significant accumulations of mostly fibrillar vascular and perivascular  $A\beta$  by 3 months of age. After 6 months, about 50% of vessels have deposits, and diffuse plaques appear in brain forebrain parenchyma. By one year of age there is robust deposition of  $A\beta$  in microvessels and within the brain parenchyma. Part of the reason for the accumulation of the (Dutch, Iowa)  $A\beta(1-40)$  is that, at physiologic concentration, the mutant peptides are 10-fold less readily cleared than the wild-type peptide.

In another model of CAA, neuronal overexpression of Dutch mutant E693Q h $\beta$ APP driven by the Thy-1 promoter produced a phenotype characterized predominantly by CAA, whereas overexpression of wild-type  $\beta$ APP caused mainly parenchymal (plaque) amyloidosis (Herzig *et al.*, 2004). Interestingly, when the Dutch mutant mice are made doubly transgenic by crossing with mutant presenilin-1-transgenic mice, the most abundant form of brain  $A\beta$  is changed from  $A\beta40$  to  $A\beta42$ , and the amyloid pathology is shifted from the vasculature to the brain parenchyma.

### Double transgenics

In an effort to produce animals that more rapidly develop plaque pathology and a more severe phenotype, presenilin (PS) mutants were crossed with h $\beta$ APP-expressing animals.  $A\beta$  deposition requires the presence of the human  $A\beta$  peptide, as transgenic mice expressing only mutant PS fail to develop plaque pathology or CAA. A number of different PS1 mutant double transgenics reproduce the pattern of elevated  $A\beta42/40$  ratios seen in the human familial AD cases (Borchelt *et al.*, 1996; Duff *et al.*, 1996; Citron *et al.*, 1997). Plaque formation in the transgenic animals mimics the aggressiveness of the familial disease as judged by the age of onset and rate of progression of the human cognitive symptoms. Plaques are detected as early as three months of age in the double mutants. There are some differences depending on which PS1 mutant is used.

**$\beta$ APPSWE  $\times$  PS1(M146L) (Duff mouse).** This mouse was constructed by crossing the human  $\beta$ APPSWE Tg2576 (Hsiao mouse section) with human PS1 (A246E) mutant mice (Holcomb *et al.*, 1998). Since the transgenes are both under the control of the mouse prion protein promoter, they are expressed in the same cells.

**$\beta$ APPSWE  $\times$  PS1(A246E) (Borchelt Mouse).** These mice overexpress murine  $\beta$ APP695 in which the mouse  $\beta$ APP  $A\beta$  region is replaced with the human  $A\beta$  sequence with the Swedish K670N/M671L mutation (Borchelt *et al.*, 1997). The mice were crossed with human PS1 (A246E) mutant mice, and both transgenes are under control of the mouse prion promoter. A 50% increase in the ratio of  $A\beta42/A\beta40$  is observed in the brains of

these animals.  $A\beta$  accumulation is accelerated by several months, although the eventual degree of deposition is similar in the APPSWE and the APPSWE/PS1 animals.

**Caveat.** While useful in screening for agents that will prevent amyloid deposition, transgenic mice expressing mutant PS1 come with complications for studying mechanisms of neurodegeneration. The sporadic form of AD does not involve PS1 mutations or  $\beta$ APP mutations. PS1 is thought to be the catalytic component of the intramembrane  $\gamma$ -secretase complex, which includes a number of proteins of unknown function. Mutations in PS1 alter the processing of other  $\gamma$ -secretase substrates besides  $\beta$ APP, such as Notch as well as unknown substrates. There is one PS1 mutant (out of over 150 different mutations) that demonstrates frontotemporal dementia-like neurodegeneration in the absence of changes in  $\beta$ APP metabolism (Dermaut *et al.*, 2004). Thus, mutations in PS1 could have effects on cellular physiology beyond  $\beta$ APP.

Even with both transgenes present, the amount of neurodegeneration observed in  $\beta$ APP/PS1 animals is disappointingly meager compared to that occurring in AD brain. The reason for the lack of extensive neuronal death is unknown. Possible explanations include an incomplete inflammatory response resulting from a deficiency in complement components in many mouse strains, augmented metabolism or sequestration of intracellular  $A\beta$ , or a missing linkage between PKR and JNK/p38 stress kinase systems in mice (Peel and Bredesen, 2003).

#### *Non-overexpressing transgenic models*

Early experiences in trying to create mice that would produce  $A\beta$  plaques appeared to dictate that levels of  $\beta$ APP 5–6 times the endogenous mouse  $\beta$ APP were required for deposition. Several laboratories produced models that were expected to be more like the sporadic AD situation, making do with less expression and leaving the  $\beta$ APP gene in its normal chromosomal context.

**$\beta$ APP Knock-in mice.** Murine  $\beta$ APP was modified by inserting the Swedish mutation immediately N-terminal to the  $\beta$ -secretase cleavage site and humanizing the three residues in the mouse  $A\beta$  sequence that differ from those in humans (H:M=R5G, Y10F, H13R) (Siman *et al.*, 2000). The hybrid full-length  $\beta$ APP was under the control of the endogenous mouse promoter and retained the native mouse introns and splicing signals. In these animals humanized  $\beta$ APP is produced in the absence of the mouse peptide in homozygotes at a normal level. The Swedish mutation causes a 9-fold increase in the amount of  $A\beta$  present as a result of its enhancement of  $\beta$ -secretase cleavage. These mice produce human sequence  $A\beta$  in the absence of the mouse sequence protein and develop plaques around 20 months of age. Other characteristics of the pathology are the same as in the overexpressors.

**YAC mice.** Another approach designed to maintain appropriate promoter control and splice variant production employed inserting the genomic sequence for the entire human  $\beta$ APP gene, including introns and exons for the 770 residue protein (~400 kb) plus flanking sequences (~250 kb) in a yeast artificial chromosome construct (Lamb *et al.*, 1999). Expression levels are modest, 2–3 times the endogenous mouse protein, and the tissue-specific ratios of splice variants are retained. The Swedish mutation (K670N, M671L) increases the amount of  $A\beta$  peptides produced while (V717I) increases the proportion of  $A\beta(x-42)$ . The Swedish mutation animals produce plaques at 14 months but with a different anatomical distribution than the Tg2576 cDNA-equivalent overexpressing mice. Most transgenic  $\beta$ APP models employ neuron-specific/selective promoters. The results with the native  $\beta$ APP promoter and introns suggest that  $\beta$ APP splicing to produce isoforms and/or promoter activity in different brain regions or cell types such as glia can influence the development of pathology. This is a particularly important concept to consider when employing transgenic models to study mechanisms.

## THE TAU HYPOTHESIS AND TAU PATHOLOGY

Since neurofibrillary pathology is the first lesion observed in most AD cases (see Characteristics of AD), often preceding amyloid plaques, and deranged tau function can be mechanistically related to impaired microtubular function, a logical hypothesis was that altered tau was the primary etiologic agent in AD, with  $A\beta$  as a secondary factor. The two competing dogmas attracted supporters and detractors, the “Tau-ists” and the “ $\beta$ AP-tists.” Although the sequence of histopathological changes supported the preeminence of tau, the genetics of the familial, early-onset forms of AD highlighted the importance of  $A\beta$ .

#### *Tau transgenics*

The discovery of mutations in the tau gene in frontotemporal dementia-17 (FTDP-17) familial tauopathy opened up the possibility that similar advantage could be taken of tau mutants to model pathology as had been so useful with  $\beta$ APP. There was also the chance to settle the long-standing debate over the primary insult in AD. Although familial forms of various tauopathies were mapped to the tau gene, no tau mutations have been linked to AD, despite ample tau deposition in neurofibrillary tangles in AD. Tau is expressed as multiple splice variants in humans such that up to six forms are produced in developmental-, tissue-, and cell-specific patterns. Abnormal polymerization of tau is caused by mutations in coding or intronic regions of the tau gene, each somehow resulting in a characteristic tangle morphology causing a recognizable clinical phenotype resulting in different diseases such as Pick’s disease, progressive supranuclear palsy, and multiple system tauopathy. Both the fibril morphology and dementia

## 11. Models of Alzheimer's Disease

profile differ from those found in AD. A $\beta$  usually is not deposited in these diseases.

Unlike the case for mouse models of  $\beta$ -amyloidosis, generating murine neurofibrillary tangles that mimic those in humans has been more challenging. Unlike humans, which express 3- and 4-repeat tau, mice produce only the four-repeat form. Overexpression of a number of proteins such as tau kinases increases the phosphorylation and accumulation of tau in axons, but the phenotype seldom resembles that seen in AD (Tesseur *et al.*, 2000; Bian *et al.*, 2002). Transgenic mice expressing human tau protein produce tangle-like structures in the CNS (Lewis *et al.*, 2000; Gotz *et al.*, 2004). When co-expressed with mutant human  $\beta$ APP transgenes (Lewis *et al.*, 2001; Oddo *et al.*, 2003a; Oddo *et al.*, 2003b), tangle-like pathology is exacerbated in these mice.

The fibril morphologies in tau-transgenic mice resemble human tauopathy in the disease from which the mutant tau was derived, not the twisted organization of true NFTs that are common in AD. In most instances, tau in transgenic mice is expressed and deposited in areas where it is not seen in AD and yet is missing from areas in which it is found in AD (Lewis *et al.*, 2001). Major pathology in these models occurs in the spinal cord and brain stem, with much less in cortical areas where the pathology is prominent in humans. Relative amounts of expression of the different splice variants seem to be part of the explanation. No A $\beta$  deposits have been detected in tau-only transgenic models. The current state of tauopathy models is summarized by Lee *et al.* (2005).

### *Combined A $\beta$ and tau pathology*

Critical evidence consistent with a role for A $\beta$  as a driving force in AD was obtained with mice doubly transgenic for  $\beta$ APP and for P301L tau (Lewis *et al.*, 2001). Tg 2576 mice were crossed with JNPL3 mice carrying a four-repeat form of tau without the N-terminal repeats under control of the mouse prion promoter. Tau expression does not significantly alter regional A $\beta$  deposition patterns, while  $\beta$ APP expression results in tau deposition in AD-relevant areas where the tau is not deposited in the single tau transgenic animals. The morphology of the tau fibrils is not PHF-like, resembling, instead, the tauopathy from which the mutant tau had been derived. These observations and microinjection studies of A $\beta$ (1–42) fibrils into P301L tau-expressing mice (Gotz *et al.*, 2001) indicate that A $\beta$ , and not tauopathy, is the primary insult in AD. Tissue culture models are being used to tease apart the complex biochemical network that connects the two pathologies (Gotz *et al.*, 2004).

**Triple transgenics (APP, PS1, P301L tau).** Human  $\beta$ APP Swedish mutant K670N/M671L and human tau 4R P301L cloned separately behind neuron-specific Thy1.2 promoters were co-injected into the pronucleus of oocytes of homozygous PS1 M146V knock-in mice in which the human sequence I145V and human mutation M146V had been engineered into the mouse gene behind its natural

promoter (Oddo *et al.*, 2003a; Oddo *et al.*, 2003b). The  $\beta$ APP and tau genes both incorporate at the same locus, greatly simplifying the breeding by ensuring that they are co-inherited. These animals develop synaptic dysfunction before plaques or tangles appear, and the deficits in LTP correlate with the accumulation of intraneuronal A $\beta$ . The patterns and relative timing of A $\beta$  and tau deposition, which are distinct, closely resemble those in AD brain. While closer to AD-like tangle morphology, the tau deposits have not been definitively characterized as NFTs. Interestingly, A $\beta$  immunotherapy in these animals results in the clearance of amyloid plaques and of early, but not established, tau pathology (Oddo *et al.*, 2004).

## Models Omitted

It is not possible in the space of this chapter to consider models of other important aspects of AD. These include recapitulation of brain inflammation, oxidative stress, and apolipoprotein E isotype effects, along with the role of cholesterol. Reviews on mouse models of these subjects in relation to AD are available (Eikelenboom *et al.*, 2002; Mattson, 2002; DeMattos, 2004).

## Conclusions

The modeling of AD, much like the modeling of many other human diseases, has been partially successful, but is in need of further refinement. Many, but not all, of the aspects of the AD phenotype have been reproduced in animal models. It is too early to know whether the models will be predictive of therapeutic efficacy in humans of the different agents currently being tested. That is a hurdle that all models for testing interventions must clear. The models have already proven extremely valuable for hypothesis testing and exploration of molecular mechanisms of disease.

## PROGRESS IN RECAPITULATING ALZHEIMER'S DISEASE

The original models for AD attempted to mimic the neurochemical deficits, mainly in the cholinergic pathways. With a better understanding of the neuropathological lesions at a molecular level, transgenic models were devised that recapitulated a surprising degree of AD pathology. These include reasonably faithful age dependence, brain region specificity, and appropriate behavioral effects. There is evidence of neuroinflammation in microglial activation, even though many of the mouse strains are deficient in the inflammatory response (Schwab *et al.*, 2004). There is also evidence of oxidative stress, and some of the neurochemical changes are similar to those in AD. Some of the behavioral changes in the  $\beta$ APP overexpressing mice also resemble facets of early AD dementia.

## DEFICIENCIES OF AD MODELS

The missing link in current animal models for AD is the lack of the profound neurodegeneration of AD. In the context of animal models of other diseases, as mentioned earlier, this is common. Often, different species model particular aspects of the human disease, but not others, so multiple models are used for each disease. A compounding factor for AD is that it is a disease of aging, and extreme age at that. Mice may simply not live long enough to produce the decrements in neuronal structure and function. Longer lived models, on the order of the human lifespan, that recapitulated the disease would be of academic and mechanistic interest, but not practical for testing therapeutic interventions. It is possible that critical pathways that couple insults such as A $\beta$  aggregation to toxicity and neurodegeneration are deficient in mice, or that there is a compensating pathway. Processes that magnify the toxic effects of A $\beta$ , such as inflammation, may be attenuated in mice. Compounding this could be an intrinsic difference in the plaque structure (Klunk *et al.*, 2004) or composition compared to the AD brain.

## FUTURE OUTLOOK

Mouse models are likely to remain the workhorses for the *in vivo* modeling of AD pathogenesis. The advantages of speed, economy, and reasonably compelling lesion development are likely to improve as new models are developed and refined. There remains a disconnect between current models and the profound neurodegeneration that is prominent in AD. Filling this gap is the most important mechanistic need. Present models are sufficient for testing many of the current therapeutic avenues being explored. However, if time is an essential and immutable element in the ultimate manifestation of AD, and many years are required for the full phenotype to emerge, then the expression of AD-related transgenes in longer-lived species, such as nonhuman primates, could provide an important bridge between mouse models and the human disease. To this end, the expression of disease-related transgenes in adult animals via viral vectors, which has produced a remarkably Parkinsonian phenotype in nonhuman primates (Kirik *et al.*, 2003), has potential for more faithfully recapitulating the full neuropathological phenotype of AD. At the other end of the taxonomic spectrum, advances in modeling AD pathology in lower organisms such as fruit flies and worms will be a boon to testing mechanistic hypotheses at the cellular and molecular levels.

Since AD is a uniquely human disorder, the thoughtful integration of experimental information from cellular, nonmammalian and mammalian models will be needed to achieve a comprehensive view of the natural history of the Alzheimer's disease process.

# Age-Related Hippocampal Dysfunction: Early Alzheimer's Disease vs. Normal Aging

Scott A. Small

*As we age, all of us will experience an inexorable slide into forgetfulness. Age-related memory decline localizes, in part, to the hippocampal formation, a brain circuit made up of separate but interconnected hippocampal subregions. Human studies have established that Alzheimer's disease targets the hippocampal circuit early in its course, and since Alzheimer's disease affects older individuals it is one cause of age-related hippocampal dysfunction. Animal studies, however, have established that the aging process itself targets the hippocampal circuit, contributing to age-related hippocampal dysfunction observed in all mammalian species. These independent observations have led to a continued debate among investigators of the aging human brain, summarized by the following questions: Is age-related hippocampal dysfunction in humans etiologically homogeneous, or is age-related hippocampal dysfunction caused by both AD and by normal aging? If age-related hippocampal dysfunction is caused by both AD and normal aging how can they be distinguished from each other? If age-related hippocampal dysfunction is caused by both AD and normal aging what are the molecular underpinnings of each? This chapter will review a series of recent studies that rely on in vivo imaging, the results of which have begun addressing these important questions.*

## Introduction

As commonly experienced, and as neuropsychologically documented, our cognitive abilities decline with advancing aging (Zelinski and Burnight, 1997). Luckily for us, age-related cognitive decline is not diffuse, but rather aging targets select cognitive domains. The ability to consciously memorize new and complex experiences—for example, learning the name of a new acquaintance—is one cognitive domain particularly sensitive to the aging process (Small, Stern *et al.*, 1999). This cognitive ability requires the hippocampal formation (Amaral and Witter, 1989), a brain structure nestled deep in the temporal lobes (Figure 12.1).

As clinicians, we are interested in the etiology of age-related hippocampal dysfunction. One cause is undoubtedly Alzheimer's disease (AD), a gradually progressive disorder that typically manifests in later life. Anatomically, AD begins by targeting the hippocampal formation, presenting as mild forgetfulness, but ultimately sweeps throughout the neocortical mantle, devastating most cognitive abilities in its wake (Masur, Sliwinski *et al.*, 1994; Jacobs, Sano *et al.*, 1995) and leading to dementia. Within each affected area, AD progressed through different pathophysiological stages. Early on, AD causes neurons to malfunction (Selkoe, 2002), manifesting as metabolic and synaptic failure, before causing neurons to die. Accordingly, a distinction is sometimes made between the early “cell sickness” stage versus the later “cell death” stage of AD (Small, 2005).

Not every aging individual with age-related hippocampal dysfunction progresses to AD dementia, raising the possibility that the aging process itself might affect hippocampal function. A wide range of nonhuman studies support this possibility (Barnes, 1994; Gallagher and Rapp, 1997; Erickson and Barnes, 2003). All aging nonhuman mammals manifest hippocampal dysfunction, yet no species besides our own develops AD. Thus, all species develop non-AD age-related memory decline, and it would seem unlikely that humans would be spared this species-wide process. Nevertheless, the possibility still exists that in humans age-related hippocampal dysfunction uniformly reflects the early stages of AD, and that if humans live long enough all will develop full-fledged AD.

This chapter will review a combination of human and animal studies that have set out to address two interrelated questions: First, is age-related hippocampal dysfunction etiologically homogeneous—uniformly reflecting the early stages of AD—or is age-related hippocampal caused by both AD and by normal aging? Second, if age-related hippocampal dysfunction is caused by both AD and normal aging, how can they be distinguished from each other?

**Figure 12.1.** The functional organization of the hippocampal formation. The hippocampal formation is a cylindrical structure located in the medial temporal lobes (demarcated in the upper panel). The microanatomy of the hippocampal formation (bottom panel) is best appreciated by viewing a transverse slice through the body of the hippocampal formation (stippled line in the upper panel). The hippocampal formation is made up of the anatomically and molecularly distinct subregions—the entorhinal cortex (EC), the dentate gyrus (DG) and the CA1 and CA3 subfields (bottom panel). The hippocampal subregions are interconnected, giving rise to the hippocampal circuit. The circuit organization of the hippocampal formation accounts for why dysfunction in any individual hippocampal subregion will equivalently interrupt the circuit, causing overlapping memory deficits. The molecular organization of the hippocampal formation accounts for why each hippocampal subregion is differentially vulnerable to mechanisms of dysfunction.

### The Functional and Molecular Organization of the Hippocampal Formation

In theory, the microanatomy of the hippocampal formation may provide an answer to both questions. The hippocampal formation is a complex structure made up of separate but interconnected subregions (Amaral and Witter, 1989): the entorhinal cortex, the dentate gyrus, the CA1 and CA3 subfields, and the subiculum (Figure 12.1). Because the subregions are connected in a unidirectional manner, the hippocampal formation functions as a circuit. Thus, a lesion in any individual hippocampal subregion will equivalently interrupt the circuit, leading to overlapping memory deficits.

Importantly, each hippocampal subregion houses a distinct population of neurons, unique in their molecular expression profiles (Zhao, Lein *et al.*, 2001). It is this molecular uniqueness that accounts for why each hippocampal subregion is differentially vulnerable to mechanisms of dysfunction (Small, 2001). So, for example, transient hypoxemia causes memory deficits by targeting the CA1 subfield because of high expression of glutamate receptors in CA1 neurons, while, in contrast, an adrenalectomy causes overlapping memory deficits by targeting the dentate gyrus because neurons in this subregion express relatively high concentrations of corticosteroid receptors.

Based on this anatomical and molecular organization, the following hypothesis can be made: If AD and normal aging are indeed pathologically separate processes, then the odds are that they should target different hippocampal subregions (Small, 2001). Establishing whether this anatomical dissociation exists, therefore, is an effective approach for answering the first question (Is age-related hippocampal dysfunction etiologically homogeneous?); and if it does exist, then this anatomical dissociation can potentially be used in dissociating one cause from the other.

### A Classification of Brain Imaging

In order to test this hypothesis, an imaging technique is needed that fulfills two requirements. First, a technique needs to be sensitive to neuronal function—not just structure. As already mentioned, the early stages of AD are characterized by cell sickness, not cell death. Animal studies have established that insofar as aging causes memory decline, it does so by interrupting neuronal physiology—again, a form of cell sickness—with a notable absence of cell loss (Rapp and Gallagher, 1996). Second, the technique needs to have sufficient spatial resolution to interrogate the hippocampus as a circuit. Because of its circuit organization, a lesion in one hippocampal subregion will secondarily affect the function of other subregions, and will affect the circuit as a whole. Thus, in order to pinpoint the primary subregion targeted by a particular mechanism of dysfunction, a technique needs to assess each hippocampal subregion individually but also simultaneously to account for circuitwide effects.

With these goals in mind, a number of imaging approaches have been developed that have fulfilled both requirements—sensitivity to neuronal function and resolution sufficient to visualize individual hippocampal subregions (Small, 2003). As in any field, a shorthand terminology is typically used to describe different imaging approaches, and terms are often confusing or even misleading. In this regard, a brief review of the field of functional imaging is worthwhile, pinning down which aspects of the brain are actually being imaged (Figure 12.2).

## 12. Age-Related Hippocampal Dysfunction: Early Alzheimer's Disease vs. Normal Aging

**Figure 12.2.** Classification of brain imaging. Brain imaging is dichotomized into structural versus functional imaging. Brain structure is imaged using either magnetic resonance imaging (MRI) or computerized tomography (CT). Functional imaging indirectly assesses regional energy metabolism by relying on the neuronal consumption of two ingredients of ATP production—glucose and oxygen. Glucose consumption is imaged with positron emission tomography (PET). Oxygen consumption is measured by imaging its three correlates—cerebral blood volume (CBV), deoxyhemoglobin content, or cerebral blood flow (CBF). CBV and deoxyhemoglobin content can be imaged with functional magnetic resonance imaging (fMRI), and CBF can be imaged with fMRI, PET, or single photon emission tomography (SPECT). Among these, CBV and deoxyhemoglobin content imaged with fMRI are best suited for pinpointing functional defects in individual hippocampal subregions.

Historically, *in vivo* imaging has been subdivided into *structural imaging*, such as magnetic resonance imaging (MRI) or computerized axial tomography (CT) imaging, versus *functional imaging*—single photon emission tomography (SPECT), positron emission tomography (PET) or functional magnetic resonance imaging (fMRI). Of course, in principle, functional imaging techniques are more likely to be sensitive to cell sickness. What exactly is meant by the “function” in functional imaging? Since the early studies performed by Kety and Schmidt (Small, 2004), functional brain imaging has come to imply a method that detects changes in regional energy metabolism. Energy metabolism is best defined as the rate with which cells produce ATP, which in neurons requires the consumption of oxygen and glucose from the blood stream. Visualizing ATP directly is challenging, but imaging techniques have been developed that can visualize correlates of oxygen and glucose consumption. With the use of radiolabeled glucose, PET can quantify the regional rates of glucose uptake. In contrast, MRI-based techniques have typically relied on the second ingredient of ATP production, oxygen consumption, to visualize correlates of energy metabolism. Because of hemodynamic coupling, oxygen consumption is correlated with cerebral blood flow, cerebral blood volume,

and deoxyhemoglobin content, and all these correlates can be estimated with MRI.

The cell-sickness stage of any disease typically affects the basal metabolic rate of oxygen consumption, and relying on the basal state to map anatomical sites of dysfunction enhances parametric quantification and spatial resolution. Indeed, the basal changes of energy metabolism associated with disease have been detected relying on all metabolic correlates—glucose uptake, CBF, CBV, and deoxyhemoglobin content. Among these variables, however, only MRI measures of CBV and deoxyhemoglobin content can achieve the spatial resolution required to visualize individual hippocampal subregions. Indeed, studies have used MRI measures of basal CBV or deoxyhemoglobin content to investigate the hippocampal circuit in aging and AD, and these will be reviewed in the next sections.

### Human Studies Interrogating the Hippocampal Circuit in AD and Aging

By quantifying cell loss in postmortem tissue of AD patients, studies have suggested that either the entorhinal cortex or the CA1 subfield is the hippocampal

subregion most vulnerable to AD (Braak and Braak, 1996; Fukutani, Cairns *et al.*, 2000; Price, Ko *et al.*, 2001; Shoghi-Jadid, Small *et al.*, 2002; Giannakopoulos, Herrmann *et al.*, 2003; Schonheit, Zarski *et al.*, 2004). In many of these studies, the entorhinal cortex and the CA1 subfield were not assessed simultaneously, accounting in part for the reported inconsistencies. More generally, however, isolating the hippocampal subregion most vulnerable to AD is difficult relying on postmortem studies alone. Not only are postmortem series biased against the earliest and most discriminatory stages of disease, but these studies cannot assess the cell-sickness stage of AD (Selkoe, 2002).

As discussed above, variants of fMRI sensitive to basal correlates of neuronal function are well suited to aid in resolving this debate. In one study, an MRI measure sensitive to basal levels of deoxyhemoglobin was used to assess the hippocampal subregions in patients with AD dementia compared to age-matched controls (Small, Nava *et al.*, 2000). This MRI measure has proven capable to detect cell sickness in individual hippocampal subregions. Univariate analysis revealed that normalized signal intensity was reduced in all hippocampal subregions in patients compared to controls. Nevertheless, when the hippocampus was analyzed as a circuit—namely, using a multivariate model to analyze signals from all hippocampal subregions simultaneously—the entorhinal cortex was found to be the primary site of dysfunction in AD (Small, Nava *et al.*, 2000).

This study suggests that the entorhinal cortex, not the CA1 subfield, is the hippocampal subregion most vulnerable to AD—agreeing with some, though not all, postmortem studies. Nevertheless, the patients assessed in this study already had full-blown dementia, indicating that they had already progressed from the cell-sickness to the cell-death stage of AD. Furthermore, this study does not inform us about the hippocampal subregions most vulnerable to normal aging.

Both of these issues were addressed in a second study, in which 70 subjects across the age span—from 20 to 88 years of age—were imaged with the same MRI measure (Small, Tsai *et al.*, 2002). Importantly, all subjects were healthy. The older age groups in particular were carefully screened against any evidence of dementia. The starting assumption made in this study was that some of the older subjects were in the earliest stage of AD and some subjects were aging normally. The question was how to make this distinction. Remember, there is no independent indicator to determine who had early AD or not. This is true even if the hippocampal formation of all subjects could be examined postmortem, because, as mentioned, the earliest stages of AD may be invisible to the microscope. Instead, formal parametric criteria were used to distinguish a “pathological pattern” of decline (i.e., related to Alzheimer’s disease) versus a “normal pattern” of decline. Specifically, since the effect of normal aging on the brain is, by definition, a stochastic

process, the variance of signal intensity among an older age group should be equal to the variance among a younger age group, although a shift in the mean is expected. In contrast, since it is a disease, AD should affect a subgroup within an older age group, which should significantly broaden the variance of signal intensity compared to a younger age group.

Applying this and other criteria, the results of this study showed that age-related changes in the entorhinal cortex fulfilled criteria for pathological decline; in contrast, age-related changes in the dentate gyrus, and to a lesser extent in the subiculum, fulfilled criteria for normal aging (Small, Tsai *et al.*, 2002). These findings not only confirm but also extend the results of the previous study. First, the entorhinal cortex indeed appears to be the hippocampal subregion most vulnerable to AD, even during the early cell-sickness stage. Second, these findings provided the first evidence that the dentate gyrus might be the hippocampal subregion most vulnerable to normal aging.

This study had a number of limitations. First, despite the strict criteria, independent verification of which older subjects did or did not have early AD was not possible. Second, although the MRI measure used is sensitive to basal deoxyhemoglobin levels, these images are also sensitive to other, nonmetabolic, tissue constituents that are potential confounds (Small, Wu *et al.*, 2000; Small, 2003).

These potential limitations were addressed in a third study. First, a cohort of aging individuals was needed that indisputably were free of AD. Because this cohort is difficult, or even impossible, to identify in human subjects, we turned to aging nonhuman primates instead. Like all mammals, monkeys develop age-related hippocampal dysfunction, yet they do not develop the known molecular or histological hallmarks of AD. Second, because of the stated limitations of imaging techniques sensitive to deoxyhemoglobin content, we relied on MRI to generate regional measures of cerebral blood volume (CBV). Previous studies have established that CBV is a hemodynamic variable tightly correlated with brain metabolism, capable of detecting brain dysfunction in the hippocampus and other brain regions (Gonzalez, Fischman *et al.*, 1995; Harris, Lewis *et al.*, 1998; Wu, Bruening *et al.*, 1999; Bozzao, Floris *et al.*, 2001).

In the third study, the hippocampal subregions of 14 rhesus monkeys were imaged across the age span from 7 to 31 years of age (Small, Chawla *et al.*, 2004). In a remarkable parallel to the previous human study, age-related decline in CBV was observed only in the dentate gyrus, and to a lesser extent the subiculum. Notably, CBV measured from the entorhinal cortex and the CA1 subregion remained stable across the life span. Indeed, when all subregions were analyzed simultaneously—in accordance with the circuit organization of the hippocampus—the dentate gyrus was the primary subregion that declined with age. Furthermore, since all

## 12. Age-Related Hippocampal Dysfunction: Early Alzheimer's Disease vs. Normal Aging

monkeys were assessed cognitively, we found that a decline in dentate gyrus CBV was the only subregion that correlated with a decline in memory performance (Small, Chawla *et al.*, 2004).

Despite the reliance on CBV to investigate aging monkeys, this third study also had a number of limitations. The first limitation applies to all functional imaging: As derived from Fick's principle (Small, 2004), all hemodynamic variables—deoxyhemoglobin, CBV, or cerebral blood flow (CBF)—are correlates of oxygen metabolism; nevertheless, they are only *indirect* correlates. The possibility always exists that these measures are confounded by changes in vascular physiology, and not underlying neuronal physiology. Thus, we cannot exclude the possibility that there is something unique to the vascular system within the dentate gyrus that caused shrinkage of CBV, independent of dentate gyrus physiologic dysfunction. The second limitation of the monkey MRI study has to do with the cellular complexity of any brain subregion, including the dentate gyrus. Although the granule cells are the primary neurons of the dentate gyrus, the dentate gyrus contains other types of neurons as well as glial cells. Even if the CBV measure does reflect underlying cellular function, MRI cannot be relied on to isolate the cells that govern this observed effect.

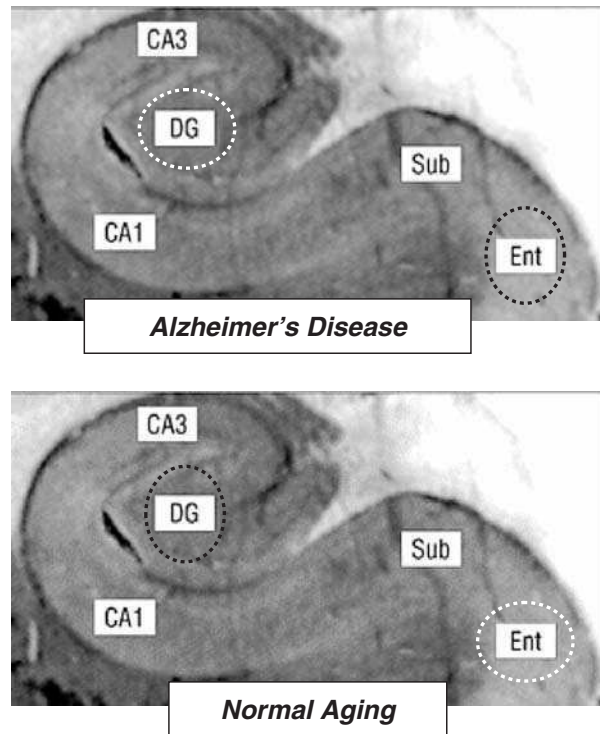

A fourth study was designed to address these concerns. Here, *in vitro* imaging was used, directly visualizing correlates of neuronal physiology. Aging rats were investigated, who like humans and monkeys develop age-related hippocampal dysfunction. Immunocytochemistry was used to visualize the behaviorally-induced expression of *Arc* in the hippocampal subregions of aging rats. *Arc* is an immediate early gene whose expression has been shown to correlate with spike activity and with long-term plasticity in hippocampal neurons (Guzowski, McNaughton *et al.*, 1999; Guzowski, Lyford *et al.*, 2000; Guzowski, Setlow *et al.*, 2001). Rats of different ages were allowed to explore a novel place and sacrificed and processed for *Arc* staining. *Arc* expression was quantified in the granule cells of the dentate gyrus and in the pyramidal neurons of the CA1 and CA3 subregions. The dentate gyrus was the only hippocampal subregion whose neurons were found to have a significant age-related decline in *Arc* expression (Small, Chawla *et al.*, 2004). Thus, this study confirms and extends the prior studies, showing that it is in fact neuronal, not vascular, physiology that underlies the aging effect. Moreover, this study established that aging primarily targets the granule cells of the dentate gyrus.

To summarize, by using different imaging techniques across three different mammalian species (Small, Tsai *et al.*, 2002; Small, Pierce *et al.*, 2003), a consensus has emerged from these complementary studies: That the dentate gyrus is the hippocampal subregion differentially vulnerable to the aging process, and that it is the primary subregion underlying age-related hippocampal dysfunction and memory decline.

## Conclusions

By interrogating the functional integrity of the hippocampal circuit in humans and animals, a double anatomical dissociation has emerged distinguishing early AD from normal aging. During its earliest stages, AD targets the entorhinal cortex and spares the dentate gyrus, while, in contrast, normal aging spares the entorhinal cortex but targets the dentate gyrus (Figure 12.3).

This anatomical profiling has three important implications. First, the anatomical dissociation establishes that AD and normal aging are pathogenically separate processes, forevermore putting an end to the possibility that age-related memory decline might solely represent AD. Second, the anatomical dissociation, and the ability to visualize this dissociation in living subjects, can be exploited as a diagnostic tool. Although we currently do not have effective treatments for AD, on theoretical

**Figure 12.3.** A double-anatomical dissociation distinguishes early Alzheimer's disease from normal aging. Alzheimer's disease targets the neurons of the entorhinal cortex with relative sparing of the neurons of the dentate gyrus. In contrast, normal aging targets the neurons of the dentate gyrus with relative sparing of the neurons of the entorhinal cortex. This dissociation establishes that Alzheimer's disease and normal aging are separate processes, and that both contribute to age-related hippocampal dysfunction. Furthermore, this dissociation, and the ability to visualize dysfunction in individual hippocampal subregions in living subjects, provide a method for distinguishing the early stages of Alzheimer's disease from normal age-related hippocampal dysfunction. Finally, this dissociation sets the stage for uncovering the molecular underpinnings of both Alzheimer's disease and normal age-related memory decline.

grounds arresting or even reversing the cell-sickness stage of AD is more likely than treating the cell-death stage of AD. Currently, relying on cognitive measures alone, we cannot accurately diagnose AD during its early cell-sickness stage because it cognitively overlaps with normal aging. Imaging techniques that can assess the functional integrity of the hippocampal subregions—in particular, the entorhinal cortex and the dentate gyrus—are well suited to achieve this diagnostic goal. Testing the diagnostic capabilities of any technique requires large-scale, epidemiologically rigorous, prospective studies. One such study is currently underway, testing whether the imaging approaches discussed in this chapter can be used to diagnose AD during its earliest stages.

Finally, pinpointing the hippocampal neurons most vulnerable to AD and to aging is a required first step for uncovering the molecular causes of each process. By isolating the molecular defects that underlie the rare autosomal-dominant form of AD, and by expressing these molecules in cell culture and in transgenic mice, tremendous strides have been made uncovering the molecular biology of AD. Nevertheless, the primary molecules whose defects underlie autosomal-dominant AD are normal in sporadic AD, the common form that accounts for over 95% of all cases. Thus, the primary molecular defects of the vast majority of AD remain unknown. Pinpointing the entorhinal cortex as the site of greatest vulnerability provides an anatomical handle with which to tackle this problem. Specifically, comparing the molecular profiles of the entorhinal cortex of affected and unaffected brains, at the mRNA or protein level, holds great promise for uncovering heretofore unidentified pathogenic molecules underlying sporadic AD. In a similar fashion, mapping age-related changes in the molecular profiles of the dentate gyrus, among healthy brains, may lead to insights into the molecular causes of memory decline associated with normal aging.

Age-related hippocampal dysfunction has emerged as a serious societal problem. As life expectancy is expanding, most of us do not simply want to live longer, but rather we would like to age with cognitive grace, remaining intellectually engaged in our information-rich environments. As discussed in this chapter, and in accordance with fundamental principles of clinical neuroscience, pinpointing the population of neurons differentially vulnerable to aging and to AD is an important first step towards developing effective diagnostics and, one day, even ameliorating the age-related slide into forgetfulness.

# Epidemiology in Aging Research

Hermann Brenner and Volker Arndt

*In this chapter, we outline the definition of epidemiology and its historical development as a scientific discipline. Various conceptual approaches to epidemiology in aging research are introduced and discussed. We present the major epidemiological study designs and epidemiological measures, with a particular emphasis on peculiarities of their application in aging research. We review major fields of application of epidemiology in aging research, and we give examples of past and current contributions of epidemiology to those fields. We outline the specific challenges, difficulties and opportunities encountered by epidemiologists in aging research. We end up with an outlook on major challenges and opportunities for further development of epidemiology in aging research.*

## Introduction

It has long been known that the complex and intertwined causes and consequences of aging of populations demand an interdisciplinary approach including the application of epidemiological skills. Nevertheless, epidemiology has only recently emerged as a substantial contributor and as an integrating activity within aging research, drawing upon the clinical sciences, biology and genetics, social science, demography, economics and policy/planning methods and using numeric and biostatistical and experimental techniques. Epidemiologic research provides answers to questions on how much age-related burden of disease and functional impairment there is within various populations, who is affected, and what specific factors put individuals at risk.

The term *epidemiology* was originally used almost exclusively to mean the study of epidemics of infectious diseases, but the definition has broadened during the past 80 years due to the marked change of patterns of morbidity and mortality in developed countries. It is now generally understood as comparing all phenomena related to health in populations and is defined as “the study of the distribution and determinants of health-related states in specific populations, and the application of this study to control of health problems” (Last, 2001).

## Key Concepts of Epidemiology

In the most basic classification of epidemiological study designs, two major fields are to be distinguished: descriptive

epidemiology and analytical epidemiology. Occasionally, a third category—experimental or interventional epidemiology—is added to this list. A common feature of all these studies is that they focus on populations rather than on individuals, cells or molecules. Figure 13.1 illustrates how descriptive, analytical and experimental epidemiology are interrelated and how observational studies contribute to the development of public health interventions.

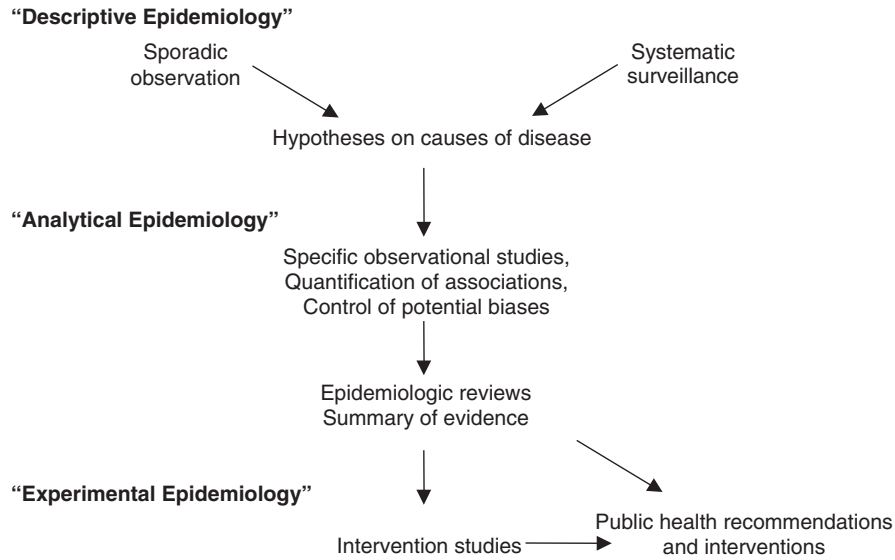

## DESCRIPTIVE EPIDEMIOLOGY

### *Data sources*

As expressed in the title, descriptive epidemiology deals with the description of the occurrence of diseases or functional impairments in the population without regard to causal or other hypotheses. Depending on the legal regulations, various sources may provide data for descriptive morbidity statistics (a more detailed description can be found in Lilienfeld and Stolley, 1994):

- Disease control programs such as disease reporting systems in case of communicable disease or case registries for cancer, cardiovascular, and other diseases
- Tax-financed public-assistance programs (public aid to the disabled, department of veterans affairs, ...)
- Records of industrial absenteeism and periodic physical examination in industry
- Data from medical care plans, public or private health insurance plans, state disability insurance plans, data from retirement boards, hospital discharge data
- Morbidity surveys on population samples

However, one has to have in mind that most sources of morbidity statistics provide information only on special population groups, such as the group covered by a particular health insurance plan. Also, the underlying population served by a facility, such as a hospital, is not well defined. Permanent population-based registries may provide valuable epidemiologic data for some specific disease, but completeness is crucial and makes it necessary to collect information from many sources. Mortality data are also of direct interest to the epidemiologist, as they may serve as proxies for morbidity information about a population. Nationwide or statewide death registration

**Figure 13.1.** Cascade from observational studies to public health intervention.

based on standardized death certificates has been legally mandated in many developed countries. The cause of death, in fact the underlying cause, is classified according to the International Classification of Disease (ICD). Revisions of the ICD, which are implemented about every 8 to 10 years, have to be considered in analysis of mortality trends. Further specific methodological issues, such as the accuracy of the cause of death statements on the certificate and problems with the use of a single cause of death have to be considered and are further discussed in standard textbooks (e.g., Lilienfeld and Stolley, 1994). In countries where a National Death Index has been established, computerized mortality data may be linked to other databases through some common identifier such as the Social Security Number. Mortality data for descriptive statistics also may be obtained in some countries from other sources such as autopsy, hospital, occupational, and financial records (e.g., insurance, pension funds), but these data sources may not represent the general population.

*Measures*

Basic measures of descriptive epidemiology include the incidence (which quantifies the occurrence of new diseases or functional impairments among persons at risk), the mortality (the occurrence of deaths), and the prevalence (the proportion of people with a certain disease or a certain functional impairment at a given point or at some point during a given period of time). The terms “risk” and “rate” are sometimes used synonymously, but strictly speaking they represent two different measures. Risk describes the probability that a person will develop a disease or die within a given time frame, and is usually derived from the proportion of those who develop the

disease among a large group of people. Although the concept of risk is easily understood, it is almost impossible to measure risk over any appreciable time interval as some people inevitably either will be withdrawn from the study population due to competing risks such as dying from causes other than the outcome under study, or will be lost to follow-up. To overcome the problem of competing risks, a different measure of disease occurrence—the incidence (or mortality) *rate*—has been introduced and is widely used in epidemiology. A rate is calculated as the number of cases that occur in a study population, over the person time experienced by the population followed. Unlike risk, the rate measures not the proportion of the population that is affected, but rather the ratio of the number of cases to the time at risk for disease.

In addition, there are a large number of more complex measures derived from these basic measures, such as the (healthy) life expectancy, defined as the average length of (healthy) life from birth or from a given age, the years of life lost (with or without “quality adjustment”), the maximum lifespan, defined as the average maximum length of time people can be expected to survive, and so on.

For many chronic diseases and functional impairments, incidence, mortality and prevalence strongly increase with age, and they often vary by sex even within the same age groups. Therefore, it is often crucial that these measures are reported by age and sex, as so-called age and sex specific measures. However, in analyses of time trends or comparisons between populations, it is often desirable to come up with a single summary measure of disease (or functional impairment) frequency rather than a whole bunch of age- and sex-specific

### 13. Epidemiology in Aging Research

measures. On the other hand, it is essential that such comparisons are not biased by possible changes in the age structure of the population over time or between various populations to be compared. In such instances, calculation of age-standardized measures of incidence, mortality and prevalence may often be reasonable. With this procedure, the respective measures for the populations to be compared are recalculated assuming a common fixed age structure of some “standard population.” Depending on the kind of study, the world population, or some regional or national population, may be used as standard.

#### ANALYTICAL EPIDEMIOLOGY

The aim of analytical epidemiology is to identify risk factors or protective factors for diseases and functional impairments, and to quantify their impact on disease (or functional impairment) occurrence by measures such as the relative risk, the risk difference or more recently developed measures which may be particularly relevant for aging research, such as risk advancement periods (Brenner *et al.*, 1993).

In the simplest case of a binary exposure and a binary outcome (disease), the data collected in an epidemiologic study can be tabulated in the form of a fourfold table (see Table 13.1). Basically, two prototypes of study designs, case-control studies and cohort (longitudinal) studies, can be distinguished. The choice of study design primarily depends on the frequency of the risk factors and the diseases (or impairments) under study.

##### *Case-control studies*

For rare health outcomes, such as certain rare cancers, a case-control approach is often used, in which the cases (people with newly acquired disease or functional impairment) are compared with the controls (people without this outcome) with respect to the frequency of certain potential risk factors or preventive factors. In such

studies, utmost care has to be taken that the controls are selected in such a way that they can be assumed to be representative of the population base from which the cases are recruited. This is often best done in a population-based study. For example, one might decide to recruit all cases diagnosed with a certain disease within some time window in a state, and to select a control group of comparable age and sex by some stratified random sampling from the general population of the same state. Case-control studies usually comprise more cases with age-related diseases than the current cohort studies. Several hundreds of cases and a similar (or an up to four times larger) number of controls are typically included, but even much larger studies are needed for the assessment of specific questions, such as the interaction of certain environmental and genetic factors in the development of chronic diseases.

##### *Cohort studies*

In cohort studies, participants are classified with respect to potential risk factors or protective factors in the first place, and they are then followed over time with respect to the occurrence of certain health outcomes. Unlike case-control studies, this study design allows for the assessment of etiologic factors of multiple health outcomes (all of which may be ascertained during follow-up), but it may be inefficient for rare health outcomes. Given that the frequency of multimorbidity strongly increases with age, the former argument strongly favors the use of cohort studies in epidemiologic aging research in many instances. Also, the quality of data on risk factors or protective factors is often superior in cohort studies, where this information is prospectively collected, compared to case-control studies, where such information has to be collected retrospectively, often over many decades. The cohort approach also provides more unequivocal evidence regarding the temporal relation between the occurrence of putative risk or preventive factors and the health outcome, and is therefore more suitable for establishing causal effects. Cohort studies do have their drawbacks, though, as conduction of large-scale cohort studies poses major challenges in terms of costs and logistics. Typical cohort studies include thousands (sometimes even tens of thousands and occasionally even hundreds of thousands) of participants who are followed over many years.

Prominent examples of cohort studies in aging research include the Baltimore Longitudinal Study on Aging, the Longitudinal Aging Study Amsterdam, the Rotterdam Study, the Health and Retirement Study (USA), and many others. A comprehensive overview of longitudinal studies on aging has been prepared by Health Canada and can be accessed online (Health Canada, 2002).

##### *Cross-sectional studies*

Somewhere in-between cohort studies and case-control studies are cross-sectional studies, in which the prevalence

TABLE 13.1  
The distinction between cohort and case-control study

		Case-control study ↓	
		Diseased group (cases)	Nondiseased group (controls)
Cohort Study →	Exposure (Risk factor) Present (exposed)	a	b
	Absent (not exposed)	c	d

Relative risk (cohort studies only):  $(a/(a+b))/(c/(c+d))$   
 Risk difference (cohort studies only):  $(a/(a+b)) - (c/(c+d))$   
 Odds ratio (cohort and case-control studies):  $ad/bc$

of certain health outcomes is assessed in relation with the prevalence of certain putative risk factors or protective factors at a given point of time. This approach is often less challenging in terms of costs and logistics, particularly in comparison with cohort studies, but is more prone to certain biases, which may be particularly relevant at old age. For example, the association between physical inactivity and presence of a certain disease, such as cardiovascular disease, may be difficult to interpret in a cross-sectional study, as temporality and causality of the association may be ambiguous.

### INTERVENTIONAL STUDIES, EXPERIMENTAL STUDY DESIGNS

Once risk factors have been identified by observational studies, the impact of their reduction or elimination on health outcomes may be assessed in randomized trials, and positive results of such studies are commonly regarded as the definitive (and sometimes necessary) proof of causality of epidemiological associations. Well-known examples include reduction of cardiovascular disease endpoints by lipid lowering or antihypertensive medication in randomized trials after hyperlipidemia and hypertension had been identified as major risk factors in observational epidemiologic studies (e.g., Hebert *et al.*, 1997; Psaty *et al.*, 1997) or randomized clinical trials to prevent falls in elderly patients as summarized by Tinetti (2003).

Such intervention studies, which may address measures of primary, secondary or tertiary prevention, are sometimes summarized under the heading of “experimental epidemiology.”

### DERIVING CAUSAL INFERENCES FROM EPIDEMIOLOGICAL STUDIES

Much of epidemiologic research is aimed at uncovering the causes of disease and identifying potential risk or protective factors. The demonstration of a statistical association between a disease and a potential risk factor does not necessarily imply a causal relationship; chance, confounding or other forms of bias have to be carefully discussed as further explanations for any observed statistical association.

Even if chance and bias can be ruled out, further careful evaluation is warranted. A well-known and widely used framework for deriving causal inference has been proposed by Hill (1965) and provides a helpful orientation for causal inference (see Table 13.2). However, it should not be considered as a checklist as it does not allow clearly distinguishing causal from noncausal relations. For a more in-depth discussion of the Hill criteria and some encountered problems, we refer to some standard textbooks (e.g., Rothman and Greenland, 1998; Rothman, 2002).

TABLE 13.2  
Causal criteria proposed by Hill (1965)

### GENERAL METHODOLOGICAL CONSIDERATIONS OF OBSERVATIONAL STUDIES

With the exception of experimental studies, epidemiologic research is based on observational studies, and as such, in theory prone to bias by “confounding.” Confounders are “extraneous factors” that may lead to an apparent (or conceal a true) association between putative risk factors (or protective factors) and disease, due to their own association with both the former and the latter. For example, various lifestyle factors, such as dietary habits, physical activity, smoking and alcohol consumption, which are clearly related to a variety of health outcomes at old age, are often also interrelated. Therefore, when the impact of one of these factors on some health outcome is assessed, it is crucial that the other factors, as well as additional relevant factors, such as age or gender, are carefully measured and controlled for in the analysis. Control for confounding is typically done by means of multivariable analysis, such as multiple logistic regression or the Cox proportional hazards model (Hosmer and Lemeshow, 1999 and 2000). But even if this caveat is taken into account, one can rarely rule out confounding from still other, unmeasured factors. The only design to guarantee absence of this possibility is large-scale randomized trials. Obviously, for ethical reasons, such trials cannot be conducted to experimentally assess the impact of putative risk factors on health outcomes in humans. Therefore, carefully conducted observational studies will always be in the center of etiologic epidemiologic research.

Besides confounding, selection bias and information bias represent other sources of systematic errors and have to be carefully addressed in planning, conducting and interpreting epidemiologic research. In addition, random variability and the role of chance due to a finite number of observations have to be considered. Whereas random variability has an effect on the precision

of the study result, systematic errors compromise the validity of a study.

*Selection bias* occurs when the association between exposure and disease differs for those who participate and those who do not participate in the study and it is mainly due to systematic differences in characteristics between participants and nonparticipants. For example, a hospital-based study on cases with myocardial infarction will exclude those cases who die before admission to hospital, and such a selection may invalidate conclusions and generalizations.

*Information bias* arises if the information collected about or from the study participants is less than perfect. It can apply to either exposure or disease status or both. Imperfect measurement is often referred to as misclassification if the variable is measured on a categorical scale.

Misclassification of subjects can be either differential or nondifferential. The distinction between these two terms refers to the question of whether misclassification of exposure (disease) relates to disease (exposure) status. A more thorough discussion about sources and consequences of information bias and misclassification can be found in standard textbooks (e.g., Rothman and Greenland, 1998).

#### **Specific Challenges of Epidemiology in Aging Research**

When looking at the epidemiologic literature, it is surprising to see how limited evidence from epidemiologic studies is available on health outcomes for the elderly. Similar to the situation in clinical studies, older people have often been excluded from epidemiologic studies, and evidence from studies conducted among younger age groups have often been generalized without adequate attention to the limited age range studied. There may be multiple reasons why epidemiologic findings for the elderly are so limited.

#### **DIFFICULTIES OF INCLUDING ELDERLY STUDY PARTICIPANTS IN EPIDEMIOLOGIC STUDIES**

A primary prerequisite for any epidemiological study is informed consent of study participants. Among the elderly, this may often be a difficult matter given the higher prevalence of cognitive and functional impairment compared to younger populations. Often, extensive data collections needed in many epidemiological studies may also be too exhausting for potential study participants with reduced general health status. In case of major cognitive impairment or dependence on nursing care, additional persons (relatives, professional care providers) have to be involved, which poses additional challenges with regard to legal issues, cooperation and validity of data.

#### **DIFFICULTIES OF CONSIDERING LONG TIME SPANS**

There is increasing evidence that many chronic diseases at old age have their roots quite early in life, which requires a life course approach in analytical epidemiologic research. While prospective longitudinal studies from the prenatal period to the oldest age, which is a reasonable option in laboratory research with short-living animals, will probably never play a relevant role in epidemiological studies among humans for obvious reasons, obtaining high-quality data on early life exposures retrospectively collected in epidemiologic studies is a major challenge, given that imperfect or incomplete memory, lack of pertinent records and so on are the rule rather than the exception. Another difficulty related to aging studies lies in “cohort” or “generation” effects in which variation in health status arises from different causal factors to which each birth cohort in the population is exposed as the environment and society change.

#### **SELECTIVE SURVIVAL**

Due to their lower costs and shorter duration, cross-sectional studies have remained a common epidemiologic study design even among the elderly. In these studies, the role of risk factors potentially associated with lower odds of surviving up to old age needs to be interpreted with particular caution, however. For example, the decrease in prevalence of major cardiovascular risk factors at higher ages, such as hypertension, hyperlipidemia or smoking, or even of certain chronic diseases, may reflect selective survival in addition to rather than changes of risk factors over time which have to be studied longitudinally (Corti *et al.*, 1996).

#### **MULTIMORBIDITY**

In the past, most epidemiologic studies have focused on single health outcomes, depending on the clinical specialty of the principal investigator. Also, many epidemiological measures and methods have been primarily developed for single health endpoints. An obvious example is studies on cause-specific mortality which typically relied on single causes of death. Such approaches may be inadequate for studies among the elderly who often suffer from multiple diseases and functional impairments which may share etiologic factors and influence each other. For example, depressive illness may lead to reduced activity and consequent muscle weakness, which then may lead to increased joint pain and a diagnosis of osteoarthritis (Ebrahim, 1996). Comorbidity may also lead to treatment or changes in behavior (e.g., eating habits) that modify risk factors or the natural history of the disease (or functional impairment) under study. Also comorbidity itself may alter risk factors under study and bias the results of epidemiologic studies unless such

patterns are carefully taken into account in the analysis (e.g., a previous myocardial infarction may lower the blood pressure and attenuate the association between blood pressure and risk of stroke).

## Epidemiology of Common Major Diseases Among Older Adults

### CARDIOVASCULAR DISEASE

Despite some reduction in recent decades, cardiovascular disease continues to be the most common cause of death, accounting for up to 50% of deaths in developed countries. Incidence and mortality strongly increase with age. In the following, the epidemiology of three major clinical manifestations of cardiovascular disease, coronary heart disease, stroke and heart failure (which to a large extent have common etiologies), will be addressed.

Despite a major decline in mortality by more than 50% in the second half of the 20th century, coronary heart disease (CHD) remains the single largest killer, accounting for 20% of all deaths in developed countries such as the United States, where mean age of manifestation of a first heart attack is 65–70 years (American Heart Association, 2005). The major risk factors for CHD, which include hypertension, hyperlipidemia, smoking and diabetes, are well established, and 80–90% of all CHD patients have prior exposure to at least one of these risk factors (Khot *et al.*, 2003). In the United States, about 700,000 patients have a new heart attack each year. In recent years, the proportion of affected people surviving the acute stage of a heart attack has substantially increased, but the survivors have a risk of another heart attack, stroke and heart failure that is substantially higher than that of the general population (Hurst, 2002). Although there is evidence that much of the subsequent disease burden could be prevented by cardiac rehabilitation, this opportunity appears to be largely underused. For example, only a minority (32%) of patients aged 70 or older participate in cardiac rehabilitation in the United States (Witt *et al.*, 2004).

Although stroke also accounts for a large share of mortality in developed countries (e.g., about 160,000 deaths annually in the United States [American Heart Association, 2005]), it has an even larger impact as a disabling disease, accounting for a large share of disability among the elderly. For example, in Germany, stroke is responsible for about 15 percent of cases of dependency on permanent nursing care (Ramroth *et al.*, 2005). Mortality has been declining worldwide in the last decades (American Heart Association, 2005), mainly due to improved clinical management, whereas trends for incidence have been less consistent. International comparative studies have found major variation of incidence between countries. For example, within Europe, incidence was found to be threefold higher in some populations from Northern Europe than in populations from

middle and Southern Europe (Thorvaldsen *et al.*, 1995). Incidence rates are higher for men than for women, but women generally have a higher stroke prevalence, because they have a longer life expectancy and are more likely to survive a stroke (Sacco, 1997).

Regarding etiology and risk factors, three major types of stroke have to be distinguished: ischemic stroke (IS), intracerebral hemorrhage (ICH), and subarachnoid hemorrhage (SAH), accounting for about 88%, 9%, and 3% of all strokes, respectively (American Heart Association, 2005). Major modifiable risk factors for IS identified in large-scale epidemiologic case-control and cohort studies include hypertension, diabetes, lack of physical activity, smoking and coronary artery disease (Boden-Albala and Sacco, 2004). Hypertension is clearly the most important modifiable risk factor for IS, but other factors, including heavy alcohol consumption, anti-coagulant therapy and potentially low cholesterol levels may also play a role. For SAH, smoking appears to be a particularly strong risk factor (Longstreth *et al.*, 1992).

Whereas age-adjusted death rates of coronary heart disease and stroke decreased within the past decades, there have been significant increases in the prevalence of chronic heart failure (HF) as well as in associated morbidity and mortality. The lifetime risk of developing HF is now 1 in 5 for both men and women, and it is considerably higher among victims of a myocardial infarction. The prevalence of HF strongly increases with age, and 50% of patients are older than 65 years. Mortality is as high as 50% in 24 months in symptomatic men. In the United States, HF has become the most common hospital discharge diagnosis in patients >65 years of age and the primary cause of readmission within 60 days of discharge (Young, 2004; American Heart Association, 2005). Major risk factors include hypertension, coronary heart disease, diabetes and overweight. With the rise of the diabetes and overweight epidemic in many countries, the burden of disease is expected to rise further in the years to come in many countries.

### CANCER

Cancer is a major health problem in developing countries, in many of which it is the second most common cause of death behind cardiovascular disease for all ages combined, and it will become of increasing importance in developing countries in the future as well. All of the major malignancies primarily affect the elderly, and the incidence of most common cancer types as well as of all tumors combined sharply increases with age.

The incidence of cancer at different sites shows extreme variations between populations and also strongly varies over time within populations. Furthermore, migrant studies have shown that migrants adopt cancer rates of the countries they are going to. Taken together, these patterns strongly support a major role of environmental, cultural and behavioral factors for the occurrence of different types of cancer. Although genetic factors

### 13. Epidemiology in Aging Research

undoubtedly also play a role, hereditary forms of cancer often account for small fractions of cancers only.

Prognosis of cancer patients strongly varies by cancer site, with 5-year survival rates ranging from almost 0% for patients with pancreatic cancer to almost 100%, for example, for patients with thyroid and prostate cancer, in some developed countries (Brenner, 2002; Brenner and Arndt, 2005). However, even for cancers of the same site, there is often strong variation of prognosis according to stage at diagnosis. For example, 5-year survival for patients with colorectal cancer nowadays exceeds 80% for patients with localized cancer, whereas it remains as low as 10% for patients with distant tumor spread. For that reason, there is much hope that the cancer burden can be strongly reduced by effective early detection programs. For some forms of cancer, such as cancer of the uterine cervix, early detection programs have been shown to be very effective indeed in lowering mortality. For other forms of cancer, such as colorectal cancer and breast cancer, the effectiveness of early detection measures has been demonstrated or is currently being assessed in large-scale clinical trials, and their implementation is likely to contribute to major reductions in mortality.

At the same time, progress in therapy will also continue to reduce cancer mortality. It certainly has contributed to major increases in survival of patients with a variety of cancers, including cancers of the breast, colon and rectum, testis and thyroid. Unfortunately, however, improvements have often been less pronounced for older adults, so that the age gradient in survival, which exists for many forms of cancer, has further increased in recent years (Brenner and Arndt, 2004). This is not too surprising, though, since older age groups, despite accounting for the majority of cancer patients, have often been and continue to be excluded from clinical trials evaluating new therapies (Hutchins *et al.*, 1999), and older patients less often receive effective therapy (Bouchardy *et al.*, 2003). With increasing expectations of survival, quality of life will become more and more important as an outcome measure for patients with cancer (Arndt *et al.*, 2004 and 2005).

Probably the most powerful tool for reducing the cancer burden in the elderly would be primary prevention. For example, it is well established by large-scale epidemiologic studies that at least 20% of all cancers and more than 90% of lung cancers are attributable to smoking and could be prevented by reducing or eliminating this most harmful habit in the population. There also seems to be a large potential to reduce the cancer burden by a diet that is rich in vegetables and fruits. Although these facts have been well known for a long time, progress in primary prevention is slow and even absent in many countries of the world. Given the long latency period between tumor initiation and clinical cancer manifestation, primary prevention measures need to start early in life; many cancers in the elderly could

be best prevented by primary prevention in childhood, adolescence and early and middle adulthood.

#### NEUROLOGIC DISORDERS

Neurologic disorders are much less common as causes of death than cardiovascular disease and cancer, but account for a tremendous share of morbidity, disability, and dependence on nursing care in the elderly. This particularly applies to cognitive decline and dementia, the epidemiology of which we will focus on in this section.

The prevalence of dementia has been found to increase exponentially with age, with prevalence doubling every five years. Overall prevalence has been estimated to be about 2% between ages 65 and 74 and reaching 30% for ages 85 and over (Borenstein Graves, 2004). Age-specific overall prevalences of dementia appear to be quite similar in different countries.

Two major forms of dementia are commonly distinguished: Alzheimer's disease (AD) and vascular dementia. In most studies, the majority of cases of dementia have been classified as AD, but there have been substantial variation in estimates of the relative frequency of both disorders between studies from different populations. Furthermore, there is considerable overlap between both disorders: Between 18% and 46% of dementia cases share both Alzheimer and vascular lesions, and this overlap increases with age. Recent epidemiologic studies have consistently found cardiovascular risk factors to be related to both forms of dementia, suggesting they may share a common etiology (Launer, 2002).

Although analytical epidemiologic studies on dementia are facing particular logistic challenges (e.g., the need to rely on proxy respondents in case-control studies), a number of risk factors have now been quite consistently established in more recent large-scale prospective cohort studies. Genetic factors undoubtedly play some role, particularly among early onset cases, with the ApoE- $\epsilon$ 4 alleles being the best established single markers. The ApoE- $\epsilon$ 4 allele is also an established risk factor for cardiovascular disease (CVD). Other risk factors of CVD linked to the occurrence of dementia include diabetes, hypertension, hyperlipidemia, and high levels of plasma homocysteine. As is the case for CVD, moderate alcohol consumption as well as intake of nonsteroidal anti-inflammatory drugs seem to be protective (Borenstein Graves, 2004).

#### MUSCULOSKELETAL DISORDERS

Musculoskeletal disorders represent another group of diseases whose incidence steeply increases with age and which are rarely fatal by themselves, but which account for a major share of detriments in quality of life, disability and costs for medical and nursing care among older adults. Up to 10% of cases of severe disability are mainly caused by these disorders (Ramroth *et al.*, 2005). The most important disabling musculoskeletal disorders include osteoporosis and osteoarthritis. The former is

the main reason for the strong increase in the incidence of fractures with age, particularly among women. Osteoarthritis (OA) affects a variety of joints, with OA of the hip and knee accounting for the largest share in morbidity, disability and costs. Causes and risk factors are still rather incompletely understood. Apart from congenital malformations and injury, “systemic” factors, such as overweight and related metabolic disorders, may play a major role, and their reduction may provide possibilities of primary prevention (Stürmer *et al.*, 1998, 2000).

## Conclusion and Outlook

Epidemiology has been well established as an indispensable component of the disciplinary spectrum for aging research in recent years. Its contributions to aging research will continue to grow in the decades to come, mainly due to the contributions from recently and newly setup large-scale longitudinal studies. The largest benefits are to be expected from interdisciplinary approaches which keep determinants of health throughout the life span in mind. The unique contributions of this discipline to aging research may become even more fruitful, however, by taking the following aspects into account:

### 1. Strengthening interdisciplinarity

Given the high prevalence of multimorbidity at old age, the horizon of single clinical specialties, which are mostly focused on a single (group of) diagnosis, may often be much too narrow for epidemiological studies among the elderly. Simply addressing multiple different health outcomes separately does not overcome the problem. What is needed are integrative approaches with a particular emphasis on functional impairments. Also, development of new methods is required to adequately deal with multiple, complexly inter-related health outcomes. The rapidly emerging fields of molecular aging research and molecular genetics provide new opportunities for interdisciplinary cooperation in epidemiologic studies in which biological materials (such as blood samples) are collected and stored.

### 2. From epidemiology among the elderly to epidemiology in aging research

The etiology of chronic diseases and impairments among the elderly cannot be studied by restricting the focus to health outcomes and their determinants at old age. Major efforts are needed to incorporate measures of relevant determinants throughout the life span, starting from the genetic predisposition and intrauterine growth, and including factors that may act in childhood, adolescence or various parts of adulthood. Achievements to

this end may again best be made by integrating expertise from such diverse fields as human genetics, prenatal and neonatal care, pediatrics, internal and family medicine, and developmental psychology (Kuh *et al.*, 2003).

### 3. Large-scale longitudinal studies

Most of the study questions in epidemiologic aging research can best be answered by large-scale longitudinal (cohort) studies, on either a regional, national or international level. Although investments in such studies in terms of time and funds are comparably large in the beginning, this investment is often more than paid off after a few years of follow-up. International studies are confronted with more difficult logistics (e.g., for standardization and validation of instruments), but may often benefit from a wider range of possible health determinants and outcomes. A number of well-planned large-scale cohort studies have meanwhile been set up among older adults in different parts of the world. While they steadily provide a wealth of data, their contribution to aging research will further increase with each additional year of follow-up.

### 4. Epidemiology of medical and nursing care

Apart from studying health outcomes, epidemiologic methods can also be used and should be more widely used to study patterns of medical and nursing care and their determinants (e.g., Kliebsch *et al.*, 1998; Ramroth *et al.*, 2005). The epidemiology of medical and nursing care might prove particularly useful in the process of modernization of health and nursing care systems that is required to meet the challenges imposed by demographic aging and that is now ongoing in many countries around the world.

### 5. Translating epidemiologic study results into the practice of prevention

In the last 50 years, epidemiologic research has identified a large number of risk factors and preventive factors of multiple chronic diseases, yet the transfer of these findings into applied disease prevention has often remained unsatisfactory. For example, half a century after the deleterious health effects of smoking have been disclosed by carefully conducted epidemiologic studies, the global number of smokers and prevalence of smoking keep rising. A similar development appears to be seen for physical inactivity, which is likewise related to a large number of severe chronic diseases. Therefore, further development of epidemiology in aging research has to go along with research on how to more effectively translate epidemiologic study results into the practice of prevention. Preventive efforts again have to keep the entire life span in mind.

# Statistical Issues for Longevity Studies in Animal Models

Chenxi Wang, Scott W. Keith, Kevin R. Fontaine, and David B. Allison

*In this chapter we provide an overview of basic statistical concepts and procedures that are germane to researchers interested in aging. We include discussions of hypothesis testing, research design, statistical power, data collection, statistical significance, parametric and nonparametric statistical methods, and choosing an appropriate statistical test. We also provide brief introductions to the different types of data (categorical versus continuous), summary statistics, and a selection of parametric and nonparametric statistical tests including t-tests, analysis of variance, ordinary least squares regression, logistic regression, and survival analysis. We place special emphasis on statistics for maximum lifespan using the example of animal research on caloric restriction. We also include discussions of the major methods of significance testing for statistics of maximum lifespan. We conclude the chapter by offering a series of recommendations that will greatly increase the chances of conducting a valid statistical analysis.*

## Introduction

Although findings from animal experiments cannot be directly applied to humans, well-designed animal studies remain powerful tools for advancing scientific knowledge, especially in biomedical fields including aging research. Most applied researchers share the idea with statisticians that statistics is an essential component for successful scientific research. This appreciation is not always clearly reflected in appropriate analysis and interpretation of results in published studies (Olsen, 2003; Williams *et al.*, 1997; Murphy, 2004). Therefore, a brief review of basic statistical concepts and considerations is important not only for the completeness of this comprehensive book but also for quality of research practice. In this chapter, we review some basic statistical concepts, summary statistics, hypothesis testing, and study design considerations. We then discuss statistical methods to test differences in maximum lifespan. Finally, using a maximum lifespan example, we illustrate how to choose an appropriate design and statistical methods.

Our goal is to provide applied researchers on aging with a better understanding of basic statistical concepts to help them communicate more effectively with the statistical support staff who actually conduct the analyses. Therefore, the primary task of this chapter is to provide a general overview of statistical concepts and issues, not to provide a detailed and exhaustive discussion. We will focus on statistical hypothesis testing and statistical methods useful for animal experiments in which, typically, the researcher can control factors that affect the outcomes, but not have to face issues that are common in human clinical trials such as loss to follow-up, missing data, and noncompliance to treatment. Motivated readers looking for more extensive discussions are referred to some excellent texts (Daniel, 1998; Alterman, 1999; Fisher and van Belle, 1993).

## Brief Review of Statistical Concepts

Biomedical researchers try to find answers for questions pertaining to populations of interest. A hypothesis is a formal statement of or prediction for the scientific question of interest. In other words, most research activities are designed to test a given hypothesis in one or more populations. Hypothesis testing involves a number of steps (Daniel, 1998): (A) developing a formal hypothesis; (B) designing a study that tests the hypothesis; (C) collecting data from a sample of the target population; and (D) calculating the test statistics from the data and drawing conclusions as to whether the hypothesis is supported.

Each of these steps is summarized below.

### A. DEVELOPING A FORMAL HYPOTHESIS

In the planning stage of research, the researcher should generate a formal hypothesis or set of hypotheses based on previous research and/or theories that have yet to be formally tested. The hypothesis is usually a statement or prediction that the researcher seeks to evaluate with a study. For example, suppose a researcher wants to test the hypothesis that the average lifespan of mouse line A is longer than the average lifespan of mouse line B. Implicit in this hypothesis are two distinct possibilities

represented individually by the null hypothesis, denoted  $H_0$ , and the alternative hypothesis, denoted  $H_a$ . The null and alternative hypotheses can be expressed as follows:

$H_0$ : there is no difference in average lifespan between mouse line A and mouse line B ( $\mu_A = \mu_B$ );

$H_a$ : the average lifespan of mouse line A is longer than mouse line B ( $\mu_A > \mu_B$ ).

This is an example of a one-sided hypothesis (i.e., the researcher expects mouse line B to live longer, on average.)

If the researcher has no particular reason to believe that the average lifespan of mouse line A will be longer than the average lifespan of mouse line B, or vice versa, he or she will need to test a two-sided hypothesis. The null and alternative hypotheses would then be as follows:

$H_0$ : there is no difference in average lifespan between line A and line B ( $\mu_A = \mu_B$ );

$H_a$ : there is a difference in average lifespan between line A and line B ( $\mu_A \neq \mu_B$ ).

Depending on the form of the hypotheses, the researcher uses either a two-sided or one-sided statistical test to determine the statistical significance of any observed difference in average lifespan before either accepting  $H_0$  or rejecting  $H_0$  in favor of  $H_a$ . Most statistical analysis software will calculate both one-sided and two-sided tests at the same time, and the researcher simply needs to pick the proper one based on the nature of their hypothesis.

## B. DESIGNING A STUDY

In the design stage, one needs to select a test statistic, significance level, desired power, and the sample size required to adequately test the hypothesis.

### 1. Statistical test

A simple approach is to choose a statistical test according to the type of data to be collected. We will discuss this in greater detail in the next section. In short, to compare the lifespans of two mouse lines from our example an independent  $t$ -test is appropriate if the lifespans of both mouse lines are approximately normally distributed or can be transformed to produce a normal distribution and the sample variances for the two lines are approximately equal.

### 2. Significance level

An investigator always runs the risk of observing significant-looking results by chance alone. The significance level reflects the investigator's tolerance for committing a type I error, which occurs when a true null hypothesis is rejected by chance resulting in a false positive test. That chance is expressed in terms of probability and is conventionally preset at 0.05 or 0.01. In other words, the researcher has sufficient control over

other aspects of the study in order to set the significance level (sometimes called alpha ( $\alpha$ ) level) to 0.05 or 0.01.

It is also possible to accept the null hypothesis when the alternative is true. This is known as a type II error or false negative. The probability of committing a type II error is called the beta ( $\beta$ ) level. One minus  $\beta$  is the power of a statistical test, which represents the probability of finding a true difference when the alternative hypothesis is true (i.e., finding a true difference when there actually is one). In general, with all other factors held constant, the smaller  $\alpha$  is, the higher the power is; and the larger  $\alpha$  is, the lower the power is.

Sometimes the true type I error rate of certain statistical tests may not be equal to the preset  $\alpha$  level. When it is smaller than the preset  $\alpha$  level, we say that the statistical test is conservative, and, as a result, the type II error rate increases and the power of the test decreases. When the type I error rate is larger than the  $\alpha$  level, which may be due to a violation of the test assumptions, we may consider the statistical test to be invalid. Readers can find further discussion of these issues in *Statistics for Maximum Lifespan*.

### 3. Sample size calculation and power analysis

Sample size calculation is a procedure for calculating the sample size required to achieve a desirable degree of statistical power. The calculation is based upon a selected statistical test, an estimate of the variation in the population, an established significance level, and an expected effect size. Power analysis estimates the power of a study given the sample size used, the selected statistical test, the significance level, the variance of the outcome variables, and the effect size. If the researcher has limited resources or has any other reason to conduct research with a fixed number of subjects, the researcher will need to conduct a power analysis to determine whether the study would be adequately powered. If it is determined that the study would have low power (typically  $\beta < 0.80$ ) the researcher may decide to alter the significance level and/or the expected effect size to increase the power.

In practice, we usually calculate sample size instead. When we calculate the sample size, the statistical power is chosen arbitrarily anywhere between 0.8 and 0.95 and the type I error rate is set at 0.05 (or 0.01). Sometimes, deciding on the effect size to be detected is challenging. For example, holding all other factors constant, a test with very good power to detect a 20% difference in mean lifespan between mouse lines A and B may have very low power to detect a 10% difference using the same sample size. A practical guideline is to choose the effect size according to biological or clinical importance. If the researcher thinks a 10% difference in average lifespan is not important or does not care if the study cannot detect the 10% difference, a smaller sample size can be used to detect a larger difference. If a 10% difference is biologically or clinically meaningful, the sample size has to be recalculated according to the 10% effect size.

## 14. Statistical Issues for Longevity Studies in Animal Models

As previously stated, in order to calculate sample size, a researcher will need to have reasonable variance estimates for the outcome variables of interest. While they may be based on pilot studies or other sources, such estimates can be highly inaccurate and can thus result in underpowered studies. Suppose, for example, that a group of researchers have underestimated the population variance at the outset of their study. Consequently, they would then be apt to underestimate the sample size required to detect the difference for which they are looking. Suppose further that there truly was a difference, yet the results of their underpowered study yielded  $p$ -values close to, but still greater than, the significance level. As a result of their insufficient sample, the researchers were not successful in detecting the true difference. Therefore, it may be necessary, in general, to adjust the sample size during and/or at the proposed end of a study using information from the observed sample.

Researchers can recalculate the sample size based on conditional power. This method uses the power of the proposed statistical tests, calculated conditionally on the data from the current sample, to suggest the extension of the study to collect a larger and/or more comprehensive sample. The original data can then be combined with the new data to retest the hypothesis.

Under certain circumstances, more advanced sampling methods can be useful and cost-effective. Some studies require the use of expensive animals, such as nonhuman primates, and investigators may not have the resources to recruit the entire sample at one time. Other studies are longitudinal, and data will be collected two or more times on each subject followed over time. In cases such as these, it is a common practice to do interim data analysis or group sequential power analysis to determine if the study may be terminated early due to obtaining enough evidence either to accept or reject the null hypothesis.

It is important to note that both conditional power analysis and group sequential analysis are complicated methods in which one must control for the inflated type I error rate resulting from the multiple comparisons. Motivated readers are referred to texts by Proschan and Hunsberger (1995); Brannath and Bauer (2004); DeMets and Lan (1994); and Jennison and Turnbull (1999).

Bootstrapping—a resampling with replacement procedure—can be a useful approach to studying the properties (e.g., variance) of estimates and test statistics. In the bootstrap approach, a sample of size  $m$  is drawn with replacement from the observed sample of size  $n$  drawn originally from the population of interest. This sample may then be combined with the original sample, and the  $m + n$  observations may be analyzed together. If this resampling procedure is reiterated a sufficient number of times, one can obtain empirical estimates of the power of proposed tests based on samples of size  $m + n$  from the population while controlling for type I errors. For more information and instruction on bootstrapping, the interested reader is referred to Mooney and Duval (1993).

Many formulas, tables, nomograms (for example, Machin *et al.*, 1987; Schoenfeld and Richter, 1982) and software packages are available for power and sample size calculations. For example, when the type I error rate is  $\alpha$  and expected power is  $1 - \beta$ , the sample size needed for each group in order to detect a difference in average lifespan of size,  $\delta$ , between two groups with equal sample size,  $n$ , and equal standard deviation,  $s$ , can be calculated as

$$n = 2s^2 \left( \frac{t_{\alpha/2} + t_{\beta}}{\delta} \right)^2$$

where  $t_{\alpha/2}$  and  $t_{\beta}$  are critical values from the  $t$ -distribution. Some of these equations are self-explanatory, while some of them are not so straightforward. Applied researchers are encouraged to consult with statisticians when necessary.

### C. COLLECTING DATA

The third step in hypothesis testing is to collect the study data. A population is defined as the entire set of individuals of interest. In our example, all the mice of line A and all the mice of line B are the populations of interest. Most of the time, it is impossible and unnecessary to collect data from the entire population in order to test a hypothesis. In practice, researchers usually collect data from a subset of the population and generalize the finding from this subset to the original population. This subset is called a sample. Ideally, the sample used for a study is a random sample, which implies that every individual in the population has an equal probability of being selected. This ensures that the sample represents the population well with respect to the variation within the population. Sampling is a complex issue that is beyond the scope of this chapter. The interested reader is referred to Thompson (2002).

### D. CALCULATING STATISTICS AND DRAWING CONCLUSIONS

Finally, one needs to use the data to calculate test statistics and the associated  $p$ -values which provide the basis for testing hypotheses and drawing conclusions. Statistical testing is analogous to finding the signal-to-noise ratio (Carlin and Doyle, 2001). In our mice example, when sample means are compared, the signal is the difference between the means of the two mice lines and the noise is the standard error, a measurement of variability. The test statistic would be a ratio of these two quantities, and the general formula for a test statistic can be expressed as (Carlin and Doyle, 2001)

$$\text{Test statistic} \propto \frac{\text{signal}}{\text{variation}/\sqrt{n}} \quad (1)$$

where  $n$  is the sample size.

A  $p$ -value is the probability of obtaining a test statistic as extreme as or more extreme than the test statistic observed from the sample given that the null

hypothesis is true. In other words, large negative or large positive values for the ratio in Equation (1) will result in small  $p$ -values. When the  $p$ -value for a test is equal to or smaller than the significance level (often set at 0.05 or 0.01), one rejects the null hypothesis in favor of the alternative hypothesis. Note that, as shown in Equation (1), the test statistic and therefore the  $p$ -value, are functions of the sample size,  $n$ . This implies that even a small difference between means can become statistically significant given a sufficiently large sample size.

## Choosing the Proper Statistical Test

### TYPE OF DATA

Loosely speaking, there are two types of data: categorical data and continuous data. The categorical data can be further divided into nominal data and ordinal data.

The possible values for continuous data typically will form a whole interval or range. For example, data collected from measuring the body weight of adult mice in line A could range from very low, say 150 grams, to very high, say 450 grams. The body weight of a randomly selected member of this population could assume any value in this range. For instance, a random sample of  $n=5$  subjects from this population could have the following set of weight measurements: {177, 283, 222, 155, 399}.

Categorical data are a collection of observations that can be categorized by classification or on an ordered scale. Nominal data are based on classifications. Suppose that, as a researcher, you are interested in collecting information on the distribution of body weight throughout a given mouse line according to the breeders from which they were bred. Each subject would be measured for body weight and then classified by the breeder. The body weights of mice could also be categorized according to relative size. For instance, mice with body weight less than the 25th percentile may be categorized as “lean”; mice with body weight between the 25th and 75th percentile may be categorized as “normal weight”; and those over the 75th percentile may be categorized as “overweight.” These categories have a natural order or scale to them, and this type of data is called ordinal. The information on the scale of ordinal data can be used to the advantage of the researcher by way of testing for trends that would not be possible were the data treated as nominal.

The distinctions between these data types are not always clear. One must look beyond the measurements themselves and examine the quantities or qualities being measured before giving meaning to the numbers in a dataset. Continuous data may be divided into categories that can be treated as being either ordinal or nominal. Although there may also be many justifiable reasons for doing this, such as nonlinear relationships between factors under study, continuous data may be categorized

simply to ease the interpretation of the results of an experiment. In our previous example, we showed how the mice could be categorized according to preset cut points into either lean, normal weight, or overweight classifications by their body weights. In this case, researchers may prefer the ordinal categorization in order to make statements about the relationship between some factor(s) and being normal weight or overweight rather than trying to relate the continuous measure of body weight with the factor(s). Another example is that we can categorize animals into those with hypertension and those with normal blood pressures based on their systolic blood pressure. In this case, we transform a continuous variable into a nominal one. The ease in interpretation from such analyses does come at a cost. Categorizing continuous data will strip it of some portion, perhaps a very significant portion, of the information on the relationship the researcher is investigating.

### SUMMARY STATISTICS

Every experiment will produce a set of data. We denote the original data without any statistical process as raw data. Summary statistical analysis is always the first step of statistical treatment that will give a systemic overview of the features of the data and can guide further presentation and analysis of the data. Moreover, it is often the case that producing both graphical and numerical summaries of a set of data can provide the investigator with important insights that could inform subsequent hypothesis testing (Altman, 1999). An initial summary of the data determines whether parametric or nonparametric statistical methods are most appropriate when one seeks to address issues of inference (see Section “Statistical Inference Methods,” below).

In general, investigators will want to summarize the data as simply as possible so that they can acquire a general sense of what the data look like. For example, nominal variables such as sex and years of education can be summarized by tabulating the frequency of responses in a given category (i.e., the number of males and the number of respondents with a high school education) or by converting these frequencies into percentages (i.e., the number of males divided by the total number of respondents). These summary data can be presented in a table or bar diagram.

For ordinal or continuous data, it is important to derive point estimates of the center of the distribution, as well as the spread or dispersion of the distribution. The former numerical summary is often called a measure of central tendency, while the latter is called a measure of variability. The most common measures of central tendency are the arithmetic mean (i.e., the sum of all of the observations divided by the number of observations), the median (i.e., the value that comes half way when the data are ranked in order) and the mode (i.e., the most common value observed).

## 14. Statistical Issues for Longevity Studies in Animal Models

The mean is by far the most common measure of central tendency because it ties in well with most approaches to inferential statistical analysis (Fisher and van Belle, 1993). However, because the mean is sensitive to extreme values in the distribution (sometimes called outliers), it is often the case that the median provides the “best” estimate of the center of a distribution.

With regard to summarizing the variability of data, the most common measures are the range (i.e., the smallest value subtracted from the largest), quartiles (i.e., an estimate of the four quarters of the distribution), the interquartile range (i.e., the difference between the third and first quartile), and percentiles (i.e., the value below which a given percentage of values occur). In general these measures of dispersion are useful in getting a general sense of the data, but their mathematical properties do not lend themselves to inferential statistical techniques.

Another way to quantify variability is to calculate and standardize the average distance of each value for the mean of the distribution. This summary measure, the standard deviation, is a point estimate of the variability of values in a given distribution.

Both the mean and standard deviation of a given set of ordinal or continuous data provide the cornerstone for parametric methods of statistical inference. Once an investigator derives a general sense of the data and calculates the appropriate summary measures, he or she is well placed to begin to use these data to test a given hypothesis.

### STATISTICAL INFERENCE METHODS

We will now discuss the differences between parametric and nonparametric methods, then describe some of the most common and effective statistical methods being used in the field. For a comprehensive listing of tests based on these methods see Table 14.1, and for a listing of the underlying assumptions for each test see Table 14.2.

#### 1. Parametric vs. nonparametric methods

Before applying a particular statistical test of a hypothesis, the analyst must verify that the data being tested meets the requirements (assumptions) for that test (see Table 14.1). In particular, when the hypothesis compares the measures of central tendency of two groups, the researcher has the option of using either parametric or nonparametric methods (see Table 14.2). A parametric method is used for testing hypotheses about parameters in a population described by a specified distributional form such as the normal distribution. Alternatively, a nonparametric method is useful for testing hypotheses using information based on a function of the sample observations (often the ranks) whose probability distribution does not depend on a complete specification of the probability distribution of the population from which the sample was drawn, as is generally the case with parametric methods. Hence, a nonparametric method

will be valid under relatively general assumptions about the underlying population.

Parametric methods, on the other hand, are valid only under certain distributional conditions. Most parametric methods, such as the *t*-test described in more detail below, require that observations be approximately normally distributed, and both groups should have equal sample variances. Implicit in these requirements is that the data should be continuous, although ordinal data may be suitable as well, especially when the sample size is large.

Nonparametric methods ignore many of the distributional aspects of the data in favor of having the flexibility to handle nominal data as well as continuous and ordinal data for which we either (a) have insufficient information about the distribution or (b) know that the distributional requirements for parametric methods have not been adequately satisfied. The nonparametric methods offer a suitable alternative under these conditions, but they are not as powerful and efficient as the analogous parametric methods when the data do not violate the distributional assumptions.

With either method, the data must be from a random sample of the population of interest. In addition to generating samples that adequately represent the population as we have already mentioned, random sampling also gives a sample the desirable property of having independent observations. Independence between observations is a critical assumption for virtually every common statistical test. For more information and in-depth discussion of nonparametric methods we suggest that the reader refer to Conover (1999).

#### 2. Analysis of continuous data

The *t*-test is a parametric statistical method used for testing the difference in a mean from a hypothesized value or the difference in means between two normally distributed populations with equal variances.

Analysis of Variance (ANOVA) is another parametric statistical method. One-way ANOVA is a popular tool for comparing the means from several samples. For example, Weindruch *et al.* (1986) collected data from mice on the relationship between caloric intake and life expectancy. They randomly assigned female mice to feeding regimen groups where scientists regulated the caloric intake as well as the composition and quality of the nutrition in the diets of the mice. In this situation, comparisons of mean life expectancy between feeding groups can be made by using ANOVA. Keep in mind, however, that ANOVA is a parametric method and the validity of the assumptions underlying this method must be verified prior to performing this analysis.

Ordinary least squares regression (OLS) is a parametric method that is used to test for a linear relationship between a continuous dependent response variable and a set of independent predictor variables that can be either continuous or categorical. The parameters

TABLE 14.1.  
Statistical methods and their assumptions

Assumption <sup>b</sup> Test <sup>a</sup>	Independent observations <sup>c</sup>	Equal standard deviations <sup>d</sup>	Normal distribution <sup>e</sup>	Adequate model fit <sup>f</sup>	Typical Hypothesis Tested

<sup>a</sup> Textbook references we suggest for these statistical tests include the following: for basic statistical methods try Ramsey and Schafer (2002) or Ott (1993); for regression try Montgomery *et al.* (2001); for categorical methods try Agresti (1996); for nonparametric methods try Conover (1999); for time-to-event (survival) analysis try Lee and Wang (2003).

<sup>b</sup> The statistical and graphical methods used to verify these assumptions are beyond the scope of this chapter. Most of these methods are detailed in the text by Ramsey and Schafer (2002). A reference for categorical data methods is the text by Agresti (1996).

<sup>c</sup> Observations must be free of cluster and serial effects. Random sampling from the population of interest implies that the observations will be independent of one another.

<sup>d</sup> Standard deviation must be the same between groups being compared, and the variance of a dependent variable should be homogeneous over the range of the independent variable(s) being considered.

<sup>e</sup> This assumption may be ignored if the sample sizes involved are large enough. How large depends on how far from normality the data seem to stray.

<sup>f</sup> Adequate model fit typically requires that the dependent response varies as a linear function of the independent predictors and no insignificant (nuisance) parameters are allowed to remain in the model.

<sup>g</sup> Both variables must be from random samples.

<sup>h</sup> Loess local regression is a nonparametric technique for describing bivariate relationships where the functional form is not known in advance.

<sup>i</sup> This method has underlying distributional requirements but not necessarily that of normality.

<sup>j</sup> Censored observations are typically assumed to be censored at random.

<sup>k</sup> Assumes that the hazard functions of different individuals are proportional and independent of time.

TABLE 14.2.  
Appropriate statistical method according to the type of data

Dependent variable		Independent variables		
		Continuous	Categorical	Combined
Continuous	Parametric	Linear regression Correlation coefficient ( $r$ )	$t$ -test ANOVA	Linear regression ANCOVA

	Nonparametric	Cox proportional hazards regression	Cox–Mantel test Log rank test	Cox proportional hazards regression

estimated by this method describe the expected change in response per unit increase in each continuous predictor, independently. When the predictor variable is categorical, the associated parameters represent the expected change in response for each particular category relative to a chosen reference category. For more information and in-depth discussion, the interested reader is referred to Ramsey and Schafer (2002); Ott (1993) and Montgomery *et al.* (2001).

### 3. Analysis of categorical data

The chi-squared ( $\chi^2$ ) test is typically applied when an investigator needs to tell if the categories of one variable occur independently of the categories of another variable. The  $\chi^2$  test also may be utilized for the purpose of testing the goodness of fit of a more complicated statistical model.

Logistic regression is a parametric method used for examining the relationship between a binary response variable (one that is categorical having only two categories) and a set of independent predictor variables that can be either continuous or categorical. Unlike OLS, the natural exponent of an estimated parameter represents the contribution to the odds of response occurring, where we can think of the response as being the more interesting event of the two possible outcomes. For continuous predictor variables, the natural exponent of the estimated parameter represents the contribution to the odds of response per unit increase in the predictor variable. In cases where a predictor is a categorical variable, the natural exponent of the parameter represents the contribution to the odds of the response occurring for that category relative to a reference category chosen by the investigator. For more information and in-depth discussion of these categorical statistical methods see Agresti (1996).

### 4. Analysis of time-to-event data

In aging studies, researchers may be interested in not only the occurrence of a certain event but also in the timing of the event. This type of data is called time-to-event data. Statistical methods applicable to this type of data are generally known as survival analysis. Time-to-event data have two distinguishing features: censoring and time-dependent covariates (Allison, 1995). For example, suppose that a young investigator gets a one-year pilot grant to follow the effect of a new anti-hypertension agent on the occurrence of heart attack in a certain rodent model. By the end of the one-year period, both the treatment group and the control group have some subjects that had the event (the heart attack) and some had not. The status of animals without events is censored. In this context, censored means that we cannot know whether, much less when, they would have a heart attack after the follow-up period. As another example of censoring data, we may wish to study lifespan and mortality rate by conducting an aging study. For some animal models

with a relatively long lifespan, such as nonhuman primates, it is difficult or impractical to follow the animals until death. By the end of the study, one can expect that there will be some subjects with unknown life expectancy (i.e., censored). Moreover, during the follow-up period, the values of some covariates, such as blood pressure and heart function, may also change over time. Conventional statistical methods such as logistic regression and linear regression cannot model the event and the timing of event simultaneously, nor can they incorporate changes in covariates over time. Modern survival analysis methods are capable of handling these complexities inherent in longitudinal time-to-event data analysis (Singer and Willett, 2003).

Survival analysis techniques model the event and timing of the event simultaneously by estimating the hazard function or the survivor function. The hazard function,  $h(t)$  is the rate, not the probability, of an event (failure) in a very short time interval. The survivor function,  $S(t)$ , is the probability that the time to event is greater than  $t$ . The hazard function, survivor function, and probability density function of the event time,  $T$ , are equivalent. That is, we can derive all of these three functions if we know any one of them (Allison, 1995). Some widely used nonparametric, semiparametric, and parametric survival analysis methods, their assumptions, and the survivor and hazard functions to be estimated are listed in Table 14.3. In summary, the proportional hazards model (Cox, 1972) is the most popular model because, as a semiparametric method, it is the most robust. The nonparametric methods such as Kaplan–Meier and life-table methods are useful for comparing survival curves and evaluating model fit for regression methods (Allison, 1995).

Given the unique features of survival analysis, there are some specific considerations for sample size calculation for studies using time-to-event data. For example, in addition to the information needed for sample size calculation using conventional methods, the researcher may also need to know the follow-up time, an estimate of the overall follow-up event rate, the underlying assumption of event time, and/or the ratio of median/mean survival time of different groups depending on the study design. The most popular approach for sample size calculation of survival analysis is based on the assumption that the survival times are random draws from an exponential distribution (Schoenfeld and Richer, 1982). Several software packages have implemented either this approach or similar approaches (Iwane *et al.*, 1997). One property of the exponential distribution is that the hazard rate is constant over time, but this is not always true in reality. Some other distributions, such as the Weibull distribution, may be more appropriate to characterize the distribution of survival time especially when the follow-up period is long and the hazard rate is accelerated with time. Heo *et al.* (1997) developed an approximate sample calculation method for the Weibull regression

TABLE 14.3.  
Comparison of widely used survival analysis methods

Method		Assumption	Survivor/hazard function to be estimated	
Nonparametric	Kaplan–Meier method	N/A	$\hat{S}(t) = \prod_{i:t_i \leq t} \left[ 1 - \frac{d_i}{n_i} \right]$	1
	Life-table method	N/A	$\hat{S}(t_i) = \prod_{j=1}^{i-1} (1 - q_j)$	2
Parametric (Accelerated failure time model)	Exponential model	Event time is a random draw from the exponential distribution	$\log h(t) = \mu + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$	3
	Weibull model	Event time is a random draw from the Weibull distribution	$\log h(t) = \mu + \alpha \log(t) + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$	3
	Gompertz model	Event time is a random draw from the Gompertz distribution	$\log h(t) = \mu + \alpha t + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$	3
Semiparametric	Proportional hazard model	Hazard ratio is constant over time	$h_i(t) = \lambda_0(t) \exp(\beta_1 X_{i1} + \beta_2 X_{i2} + \dots + \beta_k X_{ik})$	4

1.  $\hat{S}(t)$  is the survival function;  $d_i$  is the number of events at time  $t_i$ ;  $n_i$  is the number of individual at risk at time  $t_i$ .
2.  $\hat{S}(t)$  is the survival function of the  $i$ th time interval with start time  $t_i$ ;  $q_i$  is the probability of event conditional on no event at time  $t_i$ .
3.  $h(t)$  is the hazard function at time  $t$  and  $\alpha$ ,  $\mu$ , and  $\beta_1, \beta_2, \dots, \beta_k$  are parameters to be estimated.  $X_{i1}, \dots, X_{ik}$  are covariates.

method that extended the method developed by Schoenfeld and Richer (1982). Investigators can implement Heo *et al.*'s method by using existing software (Heo *et al.*, 1997). There are also other recently developed methods to calculate sample size for Weibull and proportional hazard models (Vaeth and Skovlund, 2004; Halabi and Singh, 2004).

## Statistics for Maximum Lifespan

Interesting research topics unique to aging research include comparing the "maximum lifespan" for different populations or the examination of the effects of different treatments on lifespan. As mentioned previously, it is generally impractical or impossible to collect data from all of the individuals in the population of interest. As such, we collect data on samples taken from the population and attempt to generalize our sample-specific findings to the larger population. As a result, one can only observe the maximum lifespan of a sample which is sensitive to sample size (David and Nagaraja, 2003). Therefore, in practice, the phrase "maximum lifespan" is used to refer to upper percentiles, for example, the 90th percentile (Speakman *et al.*, 2002). Seeking and evaluating interventions that can extend maximum lifespan is an exciting and active field in aging research. For instance, evidence that caloric restriction (CR) increases both the maximum and mean lifespan of many species has been accumulating (Weindruch and Walford, 1988). In this context, the null hypothesis is that there is no difference in maximum lifespan between two independent groups, say one experiencing CR and one not. What is a little surprising is that many studies, including some recent, well-known studies (Hochschild, 1973; Flurkey *et al.*, 2001; and Anisimov *et al.*, 1998) did not conduct any formal statistical hypothesis testing to compare maximum lifespan between treatment groups. Moreover, there is no statistical test accepted as being the "best" for testing the difference in lifespan.

## COMPARE MEANS

Because lifespan is a continuous variable, it is straightforward to apply a *t*-test to compare the maximum lifespan between two groups, or to apply ANOVA to compare maximum lifespan among multiple groups. We call this the conditional *t*-test (CTT) approach. It can be easily generalized to compare means across multiple groups by conditional ANOVA (Goodrick *et al.*, 1990). If the lifespan of the sample is normally distributed, it is apparent that the distribution of the lifespan in the upper percentile has a truncated normal distribution, not a symmetric distribution. We already know that the *t*-test is a parametric method and that one of its assumptions is that the data are derived randomly from a normally distributed population. Therefore, in this instance, the application of the CTT is questionable. In fact, in a simulation study, Wang *et al.* (2004) showed that the CTT

does have an inflated type I error rate and is invalid for comparing maximum lifespan.

## COMPARE PERCENTILES

An alternative approach is to compare percentiles or quantiles across groups. Quantile regression is such an approach (Koenker and Bassett, 1978). It is used to estimate conditional quantile functions by minimizing the weighted sum function. Redden *et al.* (2004) recently developed a simplified quantile regression method using logistic regression which has an appropriate type I error rate and good power. For comparing maximum lifespan, one needs to first find the 90th percentile for all animals combined. Then the animals are categorized into two categories (i.e., constituting a binary variable): lifespan longer than the 90th percentile versus lifespan shorter than the 90th percentile. This binary variable can then be regressed on the predictors including the group assignment by logistic regression to test for differences in maximum lifespan. Although Redden *et al.*'s method performs very well when the sample size is reasonably large, this approach is not informative when there is a cell count of zero or near zero in the two-by-two contingency table, which is often likely given the sample sizes in animal experiments.

It should be noted that Redden *et al.*'s approach represents a form of categorical data analysis. The methods suitable for contingency tables with small sample sizes, such as Fisher's exact test, may be a better choice in this context. As shown by Wang *et al.* (2004), apart from Fisher's exact test, an ordinary chi-squared test, Boschloo's test, or a score test could also be used to test for significance. Mehrotra *et al.* (2003) thoroughly studied the properties of these four methods and found that when the sample size is small, the ordinary chi-squared test inflates the type I error rate; the Fisher's exact test is conservative but has good power; and the Boschloo's test and score test have relatively appropriate type I error rate and good power even when the sample sizes are as small as 50 per group (i.e., only 10 subjects in two groups having a lifespan equal to or longer than the 90th percentile). In summary, Fisher's exact test, Boschloo's test, and the score test are valid and suitable when testing for significant differences in maximum lifespan and they each possess reasonably good power. Wang *et al.*'s (2004) simulation study also provides practical guidelines for choosing the appropriate sample size for the given effect size and type I error rate.

## FUTURE STUDY

In addition to the methods discussed, some other nonparametric methods may also be applicable to test for differences in maximum lifespan. These include the Wilcoxon rank-sum test (or the Mann-Whitney U-test) for two independent samples and the Kruskal-Wallis one-way ANOVA for multiple groups. Indeed, the Wilcoxon rank-sum test and Mann-Whitney U-test are analogous

to the *t*-test and can be appropriately used to test for the difference in median between two independent groups by using the ranks of the raw data. In general, nonparametric methods are more robust when the assumptions of parametric methods are not satisfied and/or when the sample size is small. Of course, there is a trade-off in that nonparametric methods are less powerful than parametric methods when the distributional requirements have been met. Further statistical evaluations are required to confirm the validity of these approaches when applied to maximum life span studies.

### Practical Recommendations

Many excellent statistical software packages available commercially (e.g. SAS<sup>®</sup>, SPSS<sup>®</sup>, S-Plus<sup>®</sup>) can perform the statistical procedures outlined in this chapter. Some of these software packages, such as SPSS, are very user friendly. In addition to procedures for data analysis, some software, such as SAS, can be used to assist in developing a study design. With the help of such software, we can perform statistical tasks much more efficiently and with greater power than ever before. Indeed, statistical procedures that once took months to calculate can now be performed in less than 5 seconds. Although this is a blessing, it can also become problematic. That is, in the wrong hands these powerful statistical software packages can produce misleading if not downright false results.

One must exercise great care and use caution when conducting complex statistical analyses. As such, to increase the chances of producing a valid analysis, we offer the following recommendations: (1) Whenever possible, and ideally at the study design stage, consult with a statistician regarding the best statistical approach to addressing a given research question. (2) Begin with graphical and/or tabular displays of the data to develop a sense of what the data look like and to assess possible errors in data input and processing. (3) Carefully examine your data to assess whether the assumptions required for the use of parametric methods are adequately met (sometimes a simple data transformation can transform skewed data into a normal distribution, thereby meeting a parametric assumption). (4) Always opt for the simplest statistical analysis possible to test a given hypothesis.

### Conclusions

Statistics are important and powerful tools for conducting sound scientific research. Statistical methods can affect the validation of such research at almost every stage beginning with the design of the study through to the interpretation of the results and statements of the conclusions. To be valid, a study must have a testable hypothesis, a properly chosen statistical method to test that hypothesis with a suitable type I error rate, and a sufficient number of study subjects in order to achieve the degree of statistical power necessary for detecting

a meaningful difference or effect. Descriptive statistics can help to summarize the data, check assumptions, and guide further analysis. While many statistical software packages are powerful tools for data analysis, applied researchers should understand the statistical basis of the procedures they use and avoid careless operation of such software.

Many topics are not included in this chapter, and aging researchers are collecting data with increasing levels of complexity, such as microarray and other high-dimension biological data. We strongly suggest that the applied researchers seek assistance from statisticians when necessary. The basic concepts and considerations discussed in this chapter will be helpful for communication between applied researchers and statisticians.

# Models for the Study of Infection in Populations

John R. Williams

*This chapter provides an overview of the modeling of transmission dynamics of infectious diseases, with particular focus on the use of compartmental differential equation models, the most commonly used for such work. An introduction including a brief description of historical antecedents is followed by a section putting such modeling in its ecological context. The next section discusses some of the characteristics of infection in populations that are determinants of the observed population dynamics of infection. This is followed by a brief section considering the scope and limitations of dynamic models, followed by a section summarizing some of the key concepts relevant to this type of modeling work. Simple ordinary differential equation models are introduced in the next section. Demography and the relevance of population age structure to infection transmission dynamics, and partial differential equation models incorporating age structure and age-related processes of infection and disease, are explored in the following two sections. The section after this considers three examples of infections in which age-related processes are important. Next there is a brief look at alternative approaches to modeling, and the penultimate section introduces further uses for dynamic models in health economic analysis, immune system dynamics, and exploring the impact of strain variation in infections. The concluding section is followed by a short appendix on the solution of differential equation system models.*

## Introduction

Infectious agents are no respecters of age. The population as a whole is their natural habitat, so a focus on the population therefore does not preclude, but rather facilitates, investigation of how aging and life span influence and are influenced by the public health impact of infections. Thus the population in any given epidemiological setting is the sensible unit to consider when using mathematical models to address issues relating to aging and infectious diseases.

The first attempts to model infections in populations appear to have been undertaken by Bernoulli in 1760

in relation to smallpox. A few instances occur also in the 19th century, but the true origins of today's mathematical modeling of infection transmission in populations can be found in the work of Hamer and of Ross in the early years of the 20th century on malaria. Further developed in the 1920s by Soper, and Kermack and McKendrick, this has led to a rapidly expanding literature on the dynamics of infection transmission in populations (see Anderson and May (1991) for an overview and a comprehensive introduction to the field). In essence, infectious disease transmission dynamics consists of the ebb and flow of infection within populations, as mediated by the distribution of immunity in the population and patterns of contacts leading to exposure. While a substantial proportion of the relevant literature is largely theoretical and to be found in mathematical journals, increasingly work involving transmission dynamics modeling is concerned with questions involving real data, future trends, and what may be expected from specific control interventions. Such work may be found with increasing frequency in journals with an orientation towards public health.

This chapter largely focuses on the use of a particular class of mathematical models to investigate the transmission dynamics of infectious diseases. Mathematical modeling, in general, is a very wide field from which many new approaches to the modeling of infection transmission have arisen, but the class of model considered here is one of the most generally useful. These models are known as deterministic compartmental differential equation models. In simple terms, differential equations describe the relationship between the value of a variable (e.g., number of infected individuals at a particular point in time) and the way in which that variable changes (e.g., how the rate of change increases or decreases as the number of infected individuals changes); if they are deterministic, their results are completely determined by the initial model parameters and initial conditions (i.e., there are no stochastic or random processes included in these models), and the models are described as compartmental because the population

under consideration is divided between compartments representing different states of susceptibility, infection and disease. This chapter will describe how this initially simple approach can usefully be expanded to take into account, among other things, demographics, age-related processes of infection and immunity, patterns of contact and risk behaviors, and public health interventions. First, however, it may be helpful to say something about the ecological context in which such models operate, as many useful developments and insights from the field of modeling population ecology have found their way into that of modeling infections in human populations. Infectious agents are, after all, simply organisms which operate in a particular and specialized environment.

### The Ecological Context of Infection

As with other biological organisms, infectious agents have evolved through natural selection to fill a particular niche in the global ecosystem, but in this case the organism is a parasite (Begon *et al.*, 1996) having the “body” of another organism as the environment in which to grow or reproduce and from which to disseminate in order to colonize other suitable environments. Here we are, of course, interested in infections of humans, but it is useful to bear in mind that infection is a widespread phenomenon across the biosphere, including bacteriophages infecting bacteria, viral infections of plants, bacterial infections of insects and nematodes, and so forth.

Numerous strategies have evolved allowing infections to continue to reproduce and disseminate (Mims *et al.*, 2001; Davies *et al.*, 1999). Rapid reproduction facilitates dissemination before the host’s immune system can suppress it; alternatively a very slow rate of reproduction may allow the infection to establish and persist “below the radar” of the immune system. A highly virulent infection may kill the host before it has had the opportunity to disseminate (although in some cases consumption of the dead host by another potential host may be a potential route for further dissemination, as in hydatid disease); in some cases an infection may be highly virulent only when infecting a species not its usual host (e.g., arenaviruses causing hemorrhagic fevers or meningitis in humans, but little apparent disease in rodent reservoirs). Alternatively the infection may evolve with reduced virulence, providing a longer time window within which to spread to a new host. The duration of immunity evoked by infection is a significant determinant of observed infection behavior; for example, if immunity from measles infection were of only short duration, it would no longer simply be classifiable as an infection of childhood, whereas the long duration of immunity that it does produce necessitates a continual supply of newly susceptible infants.

The size of the infectious organism is also a factor in its reproductive strategy; the fact that single-cell organisms

invest fewer resources in development than multicellular ones means that rapid reproduction and dissemination are easier to accomplish, whereas for multicellular organisms a longer lifespan is desirable to allow an adequate return on investment in development, which in turn implies more resources being invested also in defenses against the host’s immune response. Broadly speaking, human infectious agents (and those of other animals) can usefully be divided into microparasites and macroparasites (Anderson and May, 1991; Thomas and Weber, 2001), although the distinction between the two is pragmatic rather than absolute. Microparasites are those organisms which reproduce directly in the host with relatively short generation times. They do so in such large numbers that it is impracticable to make a count of the numbers of the organism; in general upon recovery from infection there tends to be a period of immunity against reinfection. Viruses and bacteria are typical microparasites. Macroparasites, on the other hand, are generally larger organisms, as the name implies, which do not in general complete their reproductive cycle in a single host; their life cycles can be quite complex, with perhaps another animal species forming an intermediate host, or a free-living stage in the environment before maturity is reached in the definitive host. Infections with macroparasites result in many fewer organisms than with microparasites, and numbers of individuals in each individual stage in the life cycle can often be measured to provide a quantitative indicator of intensity of infection, typically correlating with the severity of disease experienced (but see page 178). Macroparasite infections tend to be of relatively long duration—a significant proportion of the host life time—and a degree of immune tolerance is usually evoked; if infection should be eliminated, for example as a result of treatment, immunity against further infection tends to be short-lived, so that repeated infections tend to be the norm. For reasons of space, the remainder of this chapter will concentrate on modeling microparasitic infections, with the modeling of macroparasite infections (a topic in itself) only briefly being discussed.

### Infections in Human Populations

There are many clinical characteristics of human infections that are relevant to modeling of infection transmission dynamics in populations (Thomas and Weber, 2001) and that determine whether they are endemic (i.e., sustained at similar levels over a long period) or epidemic (i.e., with a substantial excess of cases over and above the norm). The time spent in each stage of infection is particularly important, bearing in mind that the “goal” of an infectious agent is to reproduce and disseminate itself through the population. Thus the length of the period of infectivity and its intensity (generally related to the probability of infecting a contact) are clearly important to establish. However the latent period, the period between being infected and becoming infectious, is also a factor

## 15. Models for the Study of Infection in Populations

to be considered as this also affects how rapidly an infection may spread in the population. One more factor which may or may not be significant is the length of the prepatient period, the time between infection and symptoms becoming apparent, as the onset of symptoms may result in relative isolation from the rest of the population. Some infections, such as herpes simplex or hepatitis B (HBV), may be symptomatic in some individuals but to a greater or lesser degree asymptomatic in others with corresponding differences shown in infectivity, and the tendency to symptomatic vs. asymptomatic infection may vary according to age, as is shown very strongly in the case of hepatitis B (Medley *et al.*, 2001). HBV is also a good example of an infection that may manifest itself as an initial asymptomatic infection or an acute primary infection (in this case lasting a few weeks) leading to recovery or to a persistent chronic infection which for HBV may last several decades or be effectively lifelong. The existence and duration of immunity following infection, ranging for different infections from several months to more or less lifelong immunity, is a further strong determinant of an infection's transmission dynamics in the population. The case fatality rate may or may not be another important determinant. For example, the extremely rapid virulence of the Ebola virus is probably the reason why it has so far failed to propagate itself beyond its local environment; on the other hand, the substantial mortality arising from HBV infection over the long term does not significantly impede its transmission. All these factors may also vary according to the age of infected individuals, so that the age distribution of infection is one further determinant of transmission dynamics (Anderson and May, 1991).

The route or routes of transmission characteristic of an infection also determine the population dynamics of an infection. The means by which the infection leaves its host, the means by which it is transported from one host to another, and the means by which it enters the new host are topics in themselves, but for the purposes of transmission dynamics modeling routes can be classified as horizontal transmission through direct or very close contact between hosts (e.g., measles, rubella), vertical transmission from mother to child at or around birth (e.g., HBV, toxoplasmosis), sexual transmission between sexual partners (often considered to be in a separate category from horizontal transmission) (e.g., gonorrhoea, syphilis), environmental transmission in which the infective agent is disseminated in the air, water, food or soil (e.g., Legionnaire's disease, hepatitis A, hookworm), and vector transmission in which the agent is transported, usually by an arthropod, from one host to another (e.g., malaria, river blindness, dengue fever). Additionally some infections make use of more than one host species to complete their transmission cycle (e.g., snail-human for schistosome flukes). As well as the transmission dynamics themselves, these transmission routes determine the structure of the models to be used to investigate the

dynamics; the intensity of these different modes of transmission is also often age-dependent, with such age-dependencies forming another determinant of the epidemiological dynamics (Anderson and May, 1991).

### Philosophy Underlying Modeling of Infection

Before proceeding further, it is perhaps useful to emphasize what transmission dynamics models can do and what they cannot. In order for a model to be useful, many assumptions and generalizations need to be made if its behavior is not to become so complex that it is impossible to interpret the results or to understand how the various processes interact in the model. Unless we understand why a model produces the results it does we cannot sensibly interpret the results, nor answer the questions we wish to ask (and nor can we identify when an error has crept into the design or implementation of the model!). The value of the results is directly related to the skill with which the complexity of the real-world system is simplified while still retaining the essential features of the epidemiology. When undertaking modeling work, and when reviewing the results of other peoples' models, it should always be borne closely in mind that the results of such work can never be predictions of the future course of an epidemic with the precision that the term "prediction" implies. What such models can do is to make qualitative projections of possible future trends under specific scenarios allowing such questions to be addressed as follows: How should we interpret the epidemiological trends in infection that are being observed, and what might be the underlying processes involved? What data do we need to gather to gain a better understanding of these trends and processes? If a specific infection is introduced into a population, is there the potential for an epidemic, and how many people might be infected? How best might we optimize the design of control programs? What might be the relative advantages and disadvantages of one health intervention versus another?

### Key Concepts in Mathematical Modeling of Infection

Before proceeding to look at some simple models, we should first consider some of the key concepts which underpin this approach to modeling the transmission dynamics of infectious disease.

#### SUSTAINABILITY OF INFECTION IN A POPULATION

The ability of an infection to transmit from an infectious individual to another who is susceptible to that infection depends on many factors, but an essential component is that there should be a point of contact between the two which is either direct—such as through droplets, skin to

skin contacts, or sexual transmission, and so on—or indirect, such as via insect vectors or through ingestion or other contact with infective particles which have been disseminated into the environment, for example, through food or water, or contaminated objects. No matter how the infective contact is made, if on average each infection in an individual is only able to newly infect, directly or indirectly, less than one other individual, the infection itself will inevitably die out in this population; the operation of chance effects may result in shorter or longer chains of infection, but in the longer term the infection will be unable to sustain itself. Thus, in order to persist in a population, each infection must, on average, result in the infection of at least one further individual, that is, the infection must reproduce itself at least once.

### THE EFFECTIVE REPRODUCTIVE NUMBER

The effective reproductive number,  $R$ , is a measure of how many new infections on average result from each existing infection (Anderson and May, 1991);  $R$  is also known as the effective reproductive ratio or, incorrectly, as it is not strictly a rate, the effective reproductive rate. When  $R=1$ , on average each infection produces only one further infected individual. If there are sufficient numbers of infections in the population to ensure that it does not die out simply through chance effects, the infection will be at equilibrium in the population and if this equilibrium is self-sustaining the infection will be endemic; where on the other hand  $R$  is significantly greater than one, a growing number of infections, i.e., an epidemic, will result. Although  $R$  is a useful measure of the speed with which an infection in a population is spreading, it changes over time as infection spreads through the population and does not give an indication of the potential rate of increase of infection in other populations because the value of  $R$  is governed not only by the characteristics of the infection itself but also by the proportion of the population which is immune through past infection or otherwise.

### THE BASIC REPRODUCTIVE NUMBER

The basic reproductive number,  $R_0$  (also known as the basic reproductive ratio or, again incorrectly, rate), is the measure used to characterize the potential for an infectious organism to spread through a population in which there is no prior immunity and thus gives a measure of the maximum potential rate of spread in a given population (though differing social, economic, demographic and health characteristics of populations may provide widely differing opportunities for an infectious organism to disseminate) (Anderson and May, 1991). Clearly when everyone in a population is susceptible to infection  $R$  and  $R_0$  will have the same value, but assuming some degree of immunity is produced, however short term,  $R$  will decrease as the infection spreads whereas  $R_0$  by definition remains constant.

When an infection is at equilibrium,  $R=1.0$ , as noted above. If  $R_0$  is greater than  $R$  ( $R_0 > R$ ), a proportion of the potential transmission events implied by  $R_0$  will fail because a proportion of potential contacts are already immune to infection in these circumstances, and only effective contacts with susceptible individuals will result in transmission. The symbol  $X$  is often used to represent the number of susceptible individuals in a population of  $N$  individuals, and  $x$  ( $=X/N$ ) to represent the proportion of susceptible individuals in the population. In a theoretically uniformly homogeneous population, if  $x^*$  represents the proportion of susceptible individuals when the infection is at equilibrium,  $x^*$  can be used to estimate  $R_0$  as  $R_0x^*=R=1.0$ . Anderson and May (1991) quote from their earlier work a range of values for  $R_0$  for different infections and different epidemiological settings; that for measles, for example, varying from 5 to 6 in post-World War I Kansas, USA to 16 to 18 in post-World War II England and Wales. Although in theory when  $R_0=1$  an infection has the capacity to spread in a wholly susceptible population, in practice it needs to exceed this value by a sufficient amount to ensure that the chain of infection is not terminated purely through chance events.

### FORCE OF INFECTION

The incidence (total yearly number of new cases or yearly proportion of the population newly infected) and prevalence of an infection (proportion of the population with current infection) in a population are basic and essential epidemiological measures, and are in principle directly observable or deducible, given an adequate surveillance system, clear case definition, and either unambiguous clinical symptoms or suitable laboratory techniques for confirmation. However, incidence and prevalence cannot be used directly as inputs to a model because these measures are a reflection, among other things, of both the capacity of the infectious agent to spread and also the distribution of prior immunity in the population. What is needed is a measure of the intrinsic ability of the infectious agent to spread from an infected individual to a susceptible individual in the population. The *force of infection* (FOI, often assigned the Greek letter lambda,  $\lambda$ ) is the measure that is needed and plays an integral role in the operation of transmission dynamic models. This measure corresponds to the yearly incidence of infection per capita among those individuals who are susceptible to infection, that is, those who are not immune as a result of past infection, the presence of maternal antibody, or effective immunization, or those who are currently infected with the same infectious agent (it will be seen that there are parallels here with  $R_0$ , the basic reproductive number; see Anderson and May (1991) for a detailed exposition of the relationship between the two). In fact the FOI is a composite of (a) the rate of contacts with other individuals in the population, whether infectious or not; (b) the risk of infection actually

## 15. Models for the Study of Infection in Populations

being transmitted to another individual given a suitable contact; and (c) the proportion of contacts who are in fact infectious. Depending on the complexity of the model, many simplifying assumptions need to be made if these components of the FOI are to be measured. However, it is also possible for the FOI to be inferred from serological data (prior to introduction of any vaccination) if infection results in long-lasting immunity to further infection and case mortality is relatively small (Farrington, 1990). An additional requirement for this approach is that the infection, to a rough approximation, can be considered to be more or less at equilibrium in the population over the longer term so that the distribution of immunity by age does not change significantly over time. Such stability in the age profile of immunity over time means that measurement at a given time (i.e., cross-sectional measurement) of the age distribution of exposure to infection in a population (i.e., the proportion at each age with the appropriate antibody) may be taken to correspond to a longitudinal measurement over time of exposure to infection of any birth cohort of the population. This cumulative risk can be analyzed in the same way as other cumulative risks by using survival analysis (Farrington, 1990) and making the assumption that everyone entering the population at birth is either susceptible to infection or becomes so following the loss of maternal antibody. The “failure rate” resulting from this analysis is the FOI which may be either independent of age or, if the data is sufficiently detailed to warrant it, age-dependent. An alternative to estimation of the FOI in such a population is to make use of case notifications, but the potential weakness of this latter approach lies in the common problem of failures and biases intrinsic to reporting systems; the use of sentinel surveys is likely to prove the more reliable approach. If an infection is newly introduced into a previously unexposed population, which therefore has no immunity, a useful estimate of the FOI can also be derived from  $R_0$ , which in turn can be estimated from the time taken for the number of cases of the newly introduced infection to double (Anderson *et al.*, 1986; Anderson and May, 1991). When there are no long-lasting markers of infection, mortality is high, infection is not at equilibrium, or there are substantial heterogeneities in patterns of infection in different subgroups of the population, this last method is particularly useful for estimating the FOI. The case of HIV/AIDS is a notable example where this latter technique has been used in the initial stages of an epidemic (Anderson *et al.*, 1986).

### HERD IMMUNITY

Herd immunity is essentially a simple concept describing the totality of naturally acquired and vaccine-based immunity to a given infectious agent as a proportion of the whole population. While the individual objective of vaccination is clearly to prevent or reduce the risk of infection for the individual concerned, the public health

objective of vaccination is to increase the level of herd immunity to that required for control or elimination of the infection from the population, and in the longer term on a regional or global scale to eradicate the infection altogether. (Note the distinction between *elimination* where an infectious agent is no longer present in a particular population and *eradication* in which the agent is eliminated world- or region-wide; the smallpox virus remains, at the time of writing, the only infection for which global eradication has been achieved.) The term *herd immunity* is occasionally used to describe the level of population immunity that will result in elimination of a specific infection from a population, but here *herd immunity for elimination* would be more appropriate. This level of herd immunity for elimination is that at which an infection cannot propagate effectively in the population; at this level of immunity there may be some secondary cases or even short chains of infection, but these chains are sooner or later broken and prove insufficient to prevent the infection from dying out. In other words, the effective reproduction number,  $R$ , in these circumstances is less than 1.0. Herd immunity is obviously dynamic, as natural or vaccine-based immunity is lost over time through waning of immunological memory or deaths of immune individuals, and newly susceptible individuals arrive through births or migration. Thus to maintain the effectiveness of vaccination programs, vaccine coverage and herd immunity need to be monitored at regular intervals and if necessary a strategy planned, informed by dynamic modeling, of supplementary vaccination programs introduced to boost herd immunity to the necessary level (Nokes and Anderson, 1988).

### CONTACT MATRICES

The various patterns of contacts between individuals, which are necessary for transmission of infection to occur, clearly are not dependent on the presence of a particular infection (although it is true that the presence of infection may lead to changes in patterns of behavior that might result in contacts being made). As prevalence and perhaps intensity or duration of an infection will vary between age groups and between the various subgroups that make up a population, the patterns of contact between these may be important determinants of the dynamics of the infection in the population and the age distribution of infection and hence of the burden of disease. It is therefore advantageous to be able to include a representation of such contact patterns when modeling the transmission dynamics of infection. Although such a representation cannot hope to reproduce the full richness of patterns of contact found in everyday life, nevertheless there are greatly simplified ways of representing such patterns, which nonetheless allow some of the essence of these patterns to be usefully captured. In the compartmental models described in this chapter, this is typically achieved by the use of a matrix specifying the

proportion of contacts made by each group with every other group represented in the model (i.e., contacts which would result in transmission of infection if made with an infectious individual). Typically, for infections such as measles which may be acquired simply through close proximity to an infective case, the contact matrix is presented in the form of a “Who Acquires Infection from Whom” (WAIFW) matrix (Anderson and May, 1985; Anderson and Grenfell, 1986; Anderson and May, 1991) in which the individual elements of the matrix represent the probability per unit of time that a susceptible individual in one subgroup (often an age group) may be infected by an infective individual from the same or one of the other subgroups. There is not normally sufficient data to be able to specify the elements of the WAIFW matrix directly, so estimates of the force of infection for each group may be used in combination with estimates of the proportion of the precontrol population in the infective state to estimate the matrix indirectly (there are also strong constraints on the form which the WAIFW matrix may take using this procedure) (Anderson and May, 1991). In the case of sexually transmitted infections (STIs) the contact matrix might simply describe the proportion of its sexual partnerships (or sexual acts) that each subgroup has with each of the other subgroups; then the numbers of partners and/or acts per unit time for individuals in each subgroup together with the probability of transmission per partnership (or per act) are specified as separate parameters (Anderson and May, 1991; Williams and Anderson, 1994).

#### AVERAGE AGE AT INFECTION ( $A$ )

Average age at infection ( $A$ ) is a useful summary measure indicating the arithmetic mean age at infection of all cases over some (often unspecified) period of time. For a childhood infection such as measles, it also provides an approximate indication of how narrow is the age window for vaccination which public health programs should aim for between the loss of passive immunity from maternal antibodies and the age at which the majority of children will already have been infected. The average age at infection will also provide some indication of the likely disease burden from an infection in which processes of morbidity or mortality are age-related. For infections provoking long-lasting immunity the average age at infection will change according to the evolution of the age profile of herd immunity in the population, so that it is likely to be higher when an infection is introduced into the population for the first time and lower as the infection becomes endemic in the population and many older individuals are immune following recovery from infection; the infectious agent is then primarily reliant on births to supply new susceptible individuals to the population. If an infection is characterized by epidemics repeated at longer intervals of time, the average age at infection will rise and fall accordingly. Note that the introduction of a vaccination program,

through its impact on the age distribution of immunity, will itself change the average age at infection, and as infection becomes more rare as a result of a successful vaccination program, those who have not been vaccinated will themselves be less at risk of infection (herd immunity effect). If these individuals do eventually become infected it is likely to be at an older age than would otherwise have been the case in the absence of vaccination. Should morbidity increase with age it is therefore theoretically possible, dependent on circumstances, for vaccination to result in an increased burden of disease (Williams and Manfredi, 2004). Rubella infection constitutes a prime example of such a risk, being a mild infection in childhood, but should the average age at infection be delayed there is likely to be an increase in risk of infection for women in their fertile years, with a resulting risk of congenital rubella if infection occurs in the first trimester of pregnancy (Edmunds *et al.*, 2000). Processes of demographic change whether a result of increase or reduction in the population growth rate or the onset of population decline, by changing the population age structure (and indirectly therefore the age profile of susceptibility), may also change the average age at infection (Williams and Manfredi, 2004). The arithmetic mean, of course, tells us little about the variance in ages at infection which may itself be important—if there is substantial variance in ages at infection, a substantial proportion of cases may occur in younger or older (perhaps much older) ages, so that when considering how changes in the age distribution of infection may affect age-dependent morbidity or mortality, median and percentile measures also become important.

#### MODEL VALIDATION AND SENSITIVITY AND UNCERTAINTY ANALYSIS

An essential aspect of the use of mathematical models in infectious disease epidemiology is validation of model results against real data, validation here referring simply to the ability to satisfy oneself that the model results are consistent with the available data relating to the population which is being modeled (or in its absence, data from a population sharing similar characteristics). It is not necessary for this process to be one of fitting, in the statistical sense, as we are dealing with model results which are qualitative rather than quantitative, and it is usually therefore more important that the model can reproduce the change in shape over time of the data being used for validation rather than absolute values. Thus the process is more one of inspection and fitting by eye rather than statistical fitting. Given that we can establish the validity of the model results in this way, it is important to know how sensitive these results are to the values of the model parameters. Depending upon the structure of the model and the role played by each parameter in the model, very small changes in the values of some parameters can lead to large variations in model results; for other parameters the situation may be reversed and

## 15. Models for the Study of Infection in Populations

relatively large changes in values may have little impact on the results. It is the role of sensitivity analysis to establish how variation in parameter values might impact on model outputs; if the model should prove to be too sensitive, the results will be useless. This can either be done simply by varying the values of each parameter in turn and observing what effect each has, or more systematically by the use of “Latin hypercube” sampling (cf. Latin square), which involves specifying a distribution for the values of each parameter (which could simply be a uniform distribution if the true distribution is not known) and sampling at random and without replacement parameter values from the combined set of distributions (Seaholm *et al.*, 1988). Once the sensitivity of the model to its parameters has been established, it is necessary to consider how much uncertainty there is in our knowledge about the true values of each parameter in relation to the population being considered. In uncertainty analysis we are considering what the plausible range of values for each parameter might be, and exploring the variation in model results which arises when parameter values are varied within this set of ranges; the variation in model outputs then provides an indication of uncertainty about the likely way in which, for example, prevalence or incidence of an infection may change over time in the population being studied.

### Simple Compartmental Models

#### FLOW DIAGRAMS

A key stage in the design and definition of a transmission dynamics model is preparation of a flow diagram. This comprises (1) a set of compartments representing that part of the population found in each of the various states of susceptibility, infection or disease to be included in the model and (2) the transitions or flows of population from one state to another upon initial infection, progression of disease, recovery etc. Such diagrams may often appear simple in the extreme (Figure 15.1), but they provide an invaluable aid to thinking about the epidemiological system being modeled by ensuring that the modeler specifies very precisely which stages of infection will be

**Figure 15.1.** A simple flow diagram. The diagram shows the compartments representing the susceptible (S), infected (I) and recovered (R) proportions of the population and arrows representing the flows or transitions between compartments upon infection, at rate  $\lambda$  (the force of infection) per capita, and recovery from infection at the per capita rate  $\sigma$ ; arrows representing births into the population and deaths leaving the population may also be included if desired or useful. This is often referred to as an S-I-R model, although the letters X, Y and Z are commonly used in place, respectively, of S, I and R.

incorporated in the model (and what, precisely, is the meaning of each stage), and also how each stage is entered and how it is left; this should be done bearing in mind that simplicity will facilitate understanding and that unnecessary complexity will have the opposite result.

#### MODEL EQUATIONS

The design of the flow diagram also specifies the structure of the system of differential equations that constitutes the compartmental model. There is a direct correspondence between the flow diagram compartments and the model’s state variables (representing the proportion or numbers in the population in each stage), and between the flows in the diagram and how the rates of change in the equations are specified. (The model equations may also incorporate subsidiary population structure such as different age groups or different behavioral groups which might not be included in the flow diagram.) The simplest example of a differential equation is the exponential growth curve in which the rate of increase over time of, say, a population  $N$  depends only on a constant per capita growth rate parameter  $r$ , and on the size of  $N$  (known as the equation’s state variable).

$$\frac{dN}{dt} = rN$$

Here  $dN/dt$  is the rate at which the value of  $N$  changes with time and is equivalent to the slope of the curve of  $N$  at any point in time. This example, of course, assumes no deaths. A more realistic simple example incorporating also infection and recovery to permanent immunity would be the equation system corresponding to the flow diagram of Figure 15.1.

$$\frac{dX}{dt} = \mu N - (\lambda + \mu)X$$

$$\frac{dY}{dt} = \lambda X - (\sigma + \mu)Y$$

$$\frac{dZ}{dt} = \sigma Y - \mu Z$$

$$N = X + Y + Z$$

(NB: Addition of the equations will give the rate of change of the whole population ( $dN/dt$ ) so that, if population size is constant, the sum of the equations will be zero, a useful check for errors in specifying the equations.)

In this set of equations,  $X$  (the susceptible population),  $Y$  (the infected population), and  $Z$  (the recovered population) are the “state variables” corresponding to the compartments in the flow diagram, and the various terms in the equations represent the different flows into and out of the compartments in the form of the product of the values of the state variables at that moment in time and the values of the parameters determining the rates of flow. (Here  $\lambda$  represents the force of infection,  $\sigma$  the rate of recovery from infection and  $\mu$  the per capita

death rate and also, for convenience in order to ensure constant population size, the per capita birth rate.) Note that the model is expressed as rates of change of each of the state variables. In simple cases, the values of the state variables at any point in time (an analytic solution) can be found through a mathematical solution of the equation system (see Appendix). In many cases, however, it is necessary to rely on a numerical solution of the equations using either computer modeling tools, or in the more complex cases involving partial differential equations (see below) computer programs written *ad hoc*. Various types of intervention can also be incorporated into such models, perhaps by explicitly adding further compartments/variables (e.g., for individuals who are vaccinated and thus at reduced risk of infection, or for those receiving some therapeutic intervention speeding recovery or reducing infectiousness) together with a corresponding further flow from the appropriate compartment (e.g., from the susceptible compartment in the case of prophylactic intervention or from an infection compartment for a therapeutic intervention). In the case of vaccination at or shortly after birth, the entry flow into the population could be divided into those entering as susceptible and those entering as immune through vaccination (in other cases intervention might be included implicitly by assuming that only a proportion of the population might be susceptible to infection) (Figures 15.2, 15.3, and 15.4) (Anderson and May, 1991).

The model population can also be stratified into different behavioral or other relevant subgroups (it may not be necessary to represent this stratification in the flow diagram), and contact matrices specifying contacts between the subgroups can then become a component of the force of infection. A simple example of the latter is for sexually transmitted infections in which the force of infection term experienced by individuals in subgroup  $i$  ( $\lambda_i$ ) is composed of a term describing probability of infection,  $\beta$ , as a result of a sexual contact with an

infected individual, the contact matrix itself,  $\rho_{ij}$ , specifying the proportion of sexual contacts that an individual in group  $i$  might have with an individual in group  $j$ , and the number of sexual contacts per year,  $c_i$ , by individuals in group  $i$ :

$$\lambda_i = c_i \beta \rho_{ij}$$

**PARAMETER VALUES**

Values for some model parameter values, such as birth or death rates, may be easily available from data; in other cases, such as vaccination rates, it may be appropriate to investigate a range of plausible values to see how they affect the model results. Often the most important and at the same time most difficult to estimate will be the value of the force of infection (see above).

**Figure 15.2.** A flow diagram with vaccination. As Figure 15.1 but with the addition of a latent stage following infection prior to becoming infective at the per capita rate  $\sigma_1$ , with recovery at rate  $\sigma_2$ , and a compartment representing vaccination with permanent immunity of susceptible individuals at a per capita rate  $\nu$ . Note that, with the possible exception of lambda,  $\lambda$ , representing the force of infection, there are no rules about which symbol should be used to label transitions in the model (equivalent to parameters in the equations).

**Figure 15.3.** Influence of latent period of infection on dynamics. Outputs from simple model shown in Figure 15.2 showing epidemic peaks in prevalence of infection (compartment Y) in absence of vaccination but with different durations for the period of latent infection prior to becoming infectious. It can be seen that increasing the latent period (here from 0.5 month (thin line) to 1 month (thick line)) increases the time interval between epidemic peaks.

**Figure 15.4.** Influence of vaccination on dynamics. More outputs from the simple model of Figure 15.2 showing the impact of vaccination in this model. Though the model is over simplistic, the results do show the increase in period between epidemics when a moderate level of vaccination is introduced (thick line) compared with a scenario with no vaccination (thin line) (doubling the rate of vaccination leads to immediate elimination of the infection).

## The Role of Demography

### AGE DISTRIBUTIONS AND FERTILITY

The three basic processes of fertility, mortality and migration determine observed population age profiles. Grossly simplified age profiles that are stable over time are often used as convenient caricatures of real-world populations (Figure 15.5): (1) an exponentially declining age distribution curve for exponentially growing populations in the Less Developed Countries (LDC) in the developing world, and (2) a uniform age distribution for the Industrialized Developed Countries (IDC); for a number of older industrialized economies, however (3) a more appropriate age distribution is one in which the proportion of older individuals exceeds that of the younger as fertility is below the level necessary for replacing deaths.

Clearly the first of these is unsustainable over the longer term as it would lead to infinite population size and (3), with fertility below replacement level, would lead to population extinction unless supplemented by immigration. More realistically fertility, mortality, and migration evolve over time in response to influences such as better health care, socio-economic factors, and people's expectations about the future (e.g., basic fertility may increase as a result of better health care, but individuals, for a wide range of reasons, may also have, or choose to have, fewer children, the latter trend, in general, appearing to dominate over the long term). Also important is the time lag between birth and reproduction; an increase or decrease in births will lead to an increase or decrease in individuals of reproductive age some two decades later so that the changes observed now in numbers of births will, as those born now reach their reproductive years, be

**Figure 15.5.** Stylized population age profiles. Two simple population age profiles often employed in modeling: (1) an exponentially declining age profile corresponding to an exponentially growing population (dotted line); (2) a uniform age distribution for a population of constant size (dashed line); and (3) a less simple, theoretical stable age distribution corresponding to a declining population size (solid line).

echoed by increases or decreases in birth numbers two or three decades hence. Thus to reverse the decline of an aging population (i.e., one with an age distribution increasingly skewed towards older ages) simply by means of an increasing per capita birth rate becomes increasingly difficult over the short term (i.e., less than several decades). In these circumstances inward migration becomes the major defense against a declining workforce, which, as migrants may well have had different previous experiences of infection to that of the host population, in turn may bring changes to the age distributions of susceptibility and immunity in the combined population and have implications for epidemiology and the design of control programs.

### CHANGING DEMOGRAPHY AND ITS IMPACT

The age distribution of infection is governed by the intrinsic transmissibility of the infection, by contact patterns between age groups, and by the age distribution of immunity from past infection. Thus, changes in age distribution of the population itself will impact upon the transmission dynamics of infection, perhaps in complex ways, and these in turn will impact upon the future age distribution of infection and disease and of susceptibility and immunity; the “echoes” of such perturbations in the dynamics of infection have the potential therefore to persist for a number of years (Williams and Manfredi, 2004). The processes of infection and disease are often strongly age related, so that changes in age at infection may have important consequences for the number of deaths or cases of serious disease. Well-known examples are rubella, mumps, and poliomyelitis in which infection of young children is likely to have few long-term consequences, but infection of young adults may have severe consequences, such as congenital rubella when infection occurs in the first trimester of pregnancy; meningitis or encephalitis, and orchitis in males, in the case of mumps; paralysis in the case of poliomyelitis (Mims *et al.*, 2001). Age-related phenomena are found in many infections, affecting how the infection manifests itself in terms of symptoms, course, duration or outcome, and patterns of contact which vary by age also determine the likelihood of infection. In particular a number of infections manifest increasing severity with increasing age, so that in aging populations in which individuals may have not had the “opportunity” to be exposed to infection as a result of partial control (e.g., vaccination without elimination) they may run a greater risk of experiencing significant morbidity (Williams and Manfredi, 2004). Another zexample of age-related phenomena is responsiveness to immunization; for example, older individuals are less likely to generate a satisfactory immune response to hepatitis B vaccine. Such age-related processes can have substantial implications for the epidemiology of infectious disease, but often ones which are difficult to intuit (Medley *et al.*, 2001). Modeling can help to elucidate the ways in which these processes may interact. Although

simple compartmental models can be used to model in a simple way the population size effects of basic demographic processes of fertility, mortality and migration, to consider impacts of age-related processes of infection, models explicitly incorporating age structure and age-related processes are desirable. These are considered in the next section.

### Age-Structured Models

Simple compartmental models (i.e., ODE models), as described above, in effect represent populations in which the risk of mortality and infection processes does not change with age, which as a result would have an age distribution that is exponentially declining with increasing age. The mean age at death for such a population is  $1/\mu$ , where  $\mu$  is the per capita death rate. However, with a mean age at death of 75, this distribution would imply a substantial proportion of the population would be over 100 years old and some would be very much older—several hundreds of years with the oldest tending to infinite age. Nevertheless, despite this lack of realism in terms of age distribution, such models are extremely useful for preliminary investigations of transmission dynamics.

Simple representations of age can be introduced into ODE models by the straightforward means of adding further series of compartments, such as for children, young adults and older adults (Figure 15.6), with flows representing aging between, for example, compartments for children and young adults and between young adults and older adults; by this means some age-related infection processes can be incorporated, so that risk of infection, rate of recovery, mortality etc. can vary according to the subset of compartments representing a particular age grouping; also contact patterns between the different age groupings can be specified using a contact or mixing matrix.

**Figure 15.6.** Simple model with different ages. A development of the simple model in Figure 15.1 representing three successive age groups, e.g., children ( $X_1, Y_1, Z_1$ ), young adults ( $X_2, Y_2, Z_2$ ) and older adults ( $X_3, Y_3, Z_3$ ) and the rate of aging  $\alpha_1$  and  $\alpha_2$  from each age group to the next. In this instance the value of the force of infection is shown to differ from age group to age group ( $\lambda_1, \lambda_2, \lambda_3$ ) although the rate of recovery from infection,  $\sigma$ , does not change.

There is no restriction on the number of compartments that can be added in this way, but the model will become increasingly cumbersome, and it needs to be borne in mind that in each “age grouping” so created there will effectively be an exponential distribution of ages, so that, for example, although the average time spent in a compartment representing the first 5 years of life may be 5 years (corresponding to a rate of 0.2 per year = 1/5 years), as with a single compartment representing all age groups, a proportion of this exponentially distributed population will be far older with no limit on maximum age. (A further drawback of this scheme is that the rate of flow from one compartment to another in the same age group, say, upon infection or upon recovery from infection, corresponds to an exponentially distributed waiting time in the first compartment. For a flow, for example, from the susceptible children compartment via infected and recovered children’s compartments to that of recovered adolescents, the overall mean time to reach adolescence is greater than that for a flow from susceptible children to susceptible adolescent—the mean time to reach the oldest age group represented is not the same for all routes through the system.)

A great improvement on this strategy is achieved by the use of a more complex class of models using partial differential equations (PDE). In essence, while ODE models describe how the state variables change over time, PDE models describe how they change both with time and with age; that is, whereas ODE models can be visualized as epidemiology evolving in one dimension along the arrow of time, PDE models incorporating age structure can be thought of as epidemiology evolving two-dimensionally through both time and by age. (NB: Such PDE models are a special case of PDE because population age and time advance in step at the same rate as in Figure 15.7; this greatly facilitates approaches to solution of the equations.)

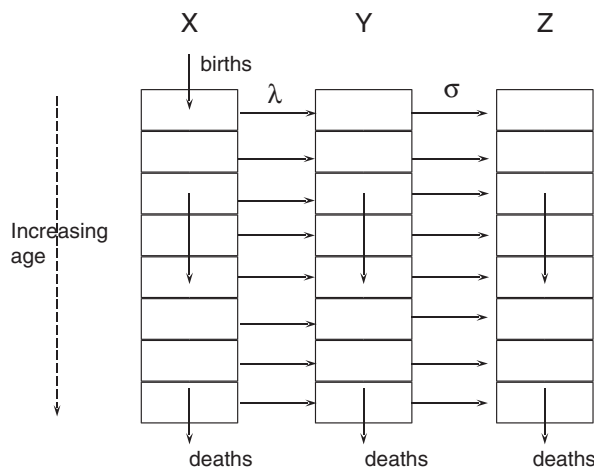

When using PDE models, in addition to specifying how entries into the population at birth (i.e., at age = 0) are distributed between the various states of susceptibility, infection and immunity, the initial age distribution (i.e., at time = 0) must also be specified (these are known as the boundary conditions) as inputs to the model. Using PDE models allows achievement of much more realistic age distributions through the use of age-related mortality and fertility rates. An age-structured version of the simple ODE model of Figure 15.1 might be

$$\frac{\partial X}{\partial t} + \frac{\partial X}{\partial a} = -[\lambda(a) + \mu(a)]X(a)$$

$$\frac{\partial Y}{\partial t} + \frac{\partial Y}{\partial a} = \lambda(a)X(a) - [\sigma(a) + \mu(a)]Y(a)$$

$$\frac{\partial Z}{\partial t} + \frac{\partial Z}{\partial a} = \sigma(a)Y(a) - \mu(a)Z(a)$$

Here the differential on the left-hand side of the equation represents the rate of change of the state

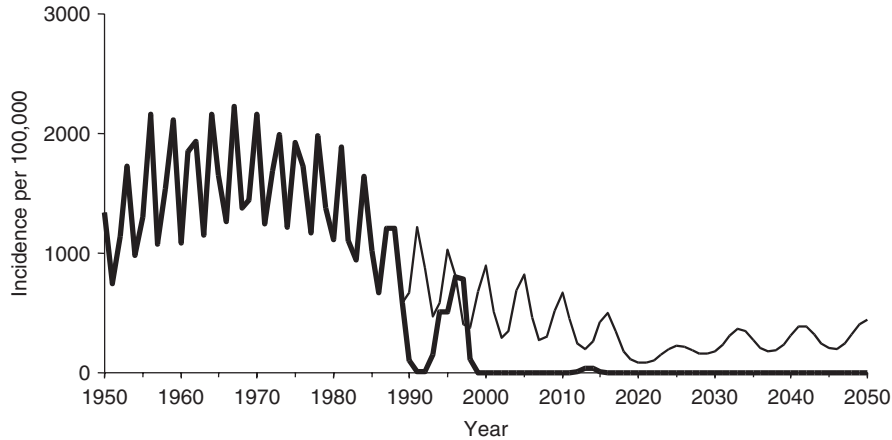

**Figure 15.7.** Schematic diagram of an age-structured model. A schematic diagram of a partial differential equation (PDE) model with full age structure. As before, X, Y and Z represent susceptibles, infecteds and recovered, with horizontal arrows representing infection and recovery; however, with each time step individuals also increase in age by one age step (typically time steps and age steps are of equal duration), thus gradually progressing vertically downwards until reaching maximum age, when death occurs.

variable with age,  $a$ , and time,  $t$ , and the parameters all vary with age. Typically, however, when modeling growing populations in developing countries, mortality rates may be kept constant over age and time (commonly referred as Type II mortality, a usage adopted by epidemiological modelers from demography and ecology). This results in an exponentially decreasing age distribution, but, to avoid unrealistically high ages, it is truncated at a predetermined maximum age (e.g., 75 years) so that when reaching this age all die. For populations in the so-called developed world an alternative scheme is often adopted in which it is assumed that no one dies until the limiting maximum age is reached so that the age distribution, in the absence of disease induced mortality, is completely uniform (referred to as Type I mortality). Use of these distributions providing a stable age distribution makes it easier to understand the transmission dynamics of a system than it is with one in which the age distribution is changing over time at the same time as processes of infection and disease and behaviors may also be changing with age. However, in the real world, of course, age distributions do indeed change with time, and once a good understanding of the nature of the dynamics has been achieved through the use of theoretical rates, it is relatively simple to incorporate age-specific mortality rates derived from data. In a similar way, age-specific fertility rates can be incorporated into the model so that a much better representation of demography may be obtained. It should be borne in mind, however, that it is necessary also to specify the initial age distribution of the population. Clearly, if the majority of the population is in the fertile age range, the shape of the age distribution of

the population will, over the short and medium term, evolve in a different way to that observed if the majority of the adult population have passed their fertile years. Provided that the per capita age-related fertility and mortality rates are constant over time, the final equilibrium age distribution is determined simply by the rates specified. This will, however, be attained only over a generational time scale. It should also be borne in mind that even though a stable age distribution may be achieved, this does not necessarily mean that population size itself is at equilibrium. A declining population may have attained a stable age distribution skewed towards upper ages (Figure 15.5) but, in the absence of migration, population numbers will continue to decline as fewer individuals are entering the population through births than are leaving it through deaths. Age-specific migration also may be incorporated into the model through additional terms in the state variable equations, but this does increase the challenge of interpreting model results and of maintaining a suitable age distribution. In theoretical terms, also, this adds a further layer of difficulty in terms of gaining theoretical insight into the PDE equation system, although in practice PDE models are solved numerically using a computer so that migrational flows into and out of the model population can be dealt with in a relatively straightforward way. For practical considerations, much epidemiological modeling has been and remains concerned with populations at demographic equilibrium. With the prospect of substantial demographic change occurring in many parts of the world, however, often leading to a significantly older population age distribution, it becomes desirable to consider possible epidemiological scenarios under such conditions of change, as there may be the potential for these demographic changes to drive epidemiological dynamics in unexpected ways (Figures 15.8 and 15.9) (Williams and Manfredi, 2004).

Often the population in PDE (and ODE) models is not divided between the two sexes—although in many instances this is not of great significance particularly if we are concerned solely with population levels of infection and disease, as control or treatment issues that relate to males or females can be simply considered by assuming a 50:50 split. Even in the case, for example, of congenital rubella in which the concern is the proportion of females reaching fertile age ranges without prior exposure or immunization, the impact of a given universal vaccination strategy can usefully be assessed without specific representation of males and females, as the age at infection remains the same for both. In some circumstances, however, it will be useful to explicitly divide the population into male and female. Examples are health provisions specifically directed at males or females, and cases of significant differences in epidemiology between males and females. One instance might be the modeling of sexually transmitted infections (STI) in heterosexual populations in which transmission risks or proportions

**Figure 15.8.** Examples of age-structured model outputs for measles incidence under two regimes of measles vaccination in an aging population. Outputs from fully age-structured (PDE) model with realistic demography. For a population with declining birth rate leading to an increasingly aging population the incidence of measles infection over time is shown under two scenarios: (i) from 1976 onwards moderate continuous infant vaccination coverage insufficient to achieve elimination (thin line) and (ii) the same level of vaccination but with additional vaccination campaigns every 4 years from 1989 onwards, which achieves elimination (thick line), albeit after a significant epidemic in 1995 and a miniscule one in 2015. (Williams and Manfredi, 2004)

**Figure 15.9.** Examples of age-structured model outputs showing the influence of suboptimal measles vaccination on age at infection in an aging population. Further outputs from the same PDE model as shown in Figure 15.8. These show for a population with declining birth rate leading to an increasingly aging population how the median and upper and lower quartiles of the distribution of the age at infection change through time under a scenario of moderate vaccination coverage insufficient to achieve elimination. This scenario highlights the potential for a substantial proportion of cases of ostensibly childhood infection to occur among older individuals. (Williams and Manfredi, 2004)

of asymptomatic (and hence probably untreated) infection may differ between males and females. In the case of heterosexual transmission of HIV/AIDS in sub-Saharan Africa while the risk of transmission from an infectious partner for women may be significantly higher, males in general may tend to have more partners and so may be more likely to have sex with an infectious partner. The interaction between the two effects is difficult to tease out without incorporating both sexes in the model. Note that when a model population is explicitly divided into males and females for modeling STI epidemiology, it is necessary to ensure that the numbers of partnerships experienced by females with males corresponds to the

number of partnerships that females have with males; where numbers in male or female populations change at different rates, a mechanism must be included in the model to allow the balance in the numbers of partnerships to be maintained over time.

#### AGE-RELATED PROCESSES

The age structure of PDE models facilitates the inclusion of parameters representing age-related processes of infection and disease (Anderson and May, 1991). These can be processes related to exposure, such as patterns of behavior and of contacts (including sexual contacts), or to the initial establishment and

## 15. Models for the Study of Infection in Populations

subsequent course of infection or to the transmission of infection from an infected individual as some function of processes of maturation or aging. Patterns of exposure will be determined by the changing intensity and patterns of social and familial contacts (and whether families are nuclear or extended) that an individual has through his or her lifetime, or by more specific patterns such as sexual partner choice and sexual lifestyles. Nursery and primary schools are prime points of contact for exchange of viruses for young children, though in different regions children may enter these institutions at different ages. Young adults may be more likely to have many sexual partners, or to have, for the first time, significant contacts with those from other parts of the country or the world during higher education, military service or travel (illustrative examples are, in Italy, a peak in measles cases in males at military age or, in the UK, recent outbreaks of mumps among university students). Older people are more likely to spend significant time in hospitals or nursing homes and be exposed to the particular range of infections which may have found a niche there among the frail and the sick. Examples of age-determined factors relating to establishment of disease are, for the very young, the degree of protection remaining from passive (i.e., maternal) antibody, or, for older individuals, the possibly decreasing degree of protection from acquired active immunity arising from past infection or from vaccination many years previously, or diminished lung function or reduced effectiveness of the mucous membranes leading to easier establishment of infections. Disease processes in many infections are age-determined; for example, for hepatitis B the age at infection is a very strong determinant of the risk of persistent infection—neonates and the very young being at very much greater risk than older children and adults even less so, although older individuals are significantly less responsive to HBV vaccine. In the case of varicella zoster (chicken pox virus), its secondary manifestation as shingles or zoster is essentially a disease of older ages (probably a result of reactivation following a diminution of immune function perhaps following ill health or simply as a result of loss of immune function with age) (Brisson *et al.*, 2003).

Control measures also may be distributed according to age. For example often vaccination may be targeted at people of a specific age (e.g., young children for measles or the elderly for influenza) or a specific group (e.g., those with many sexual partners for hepatitis B). In such cases vaccination in the model can be effected by specifying a transition at a particular age to a vaccinated compartment for age cohort vaccination, or by specifying that those in a particular compartment are continuously vaccinated at a specified rate. Vaccination campaigns may also be simply effected in the computer program, providing the numerical solution to a model through the device of switching vaccination on and

off at specified time points (Figure 15.8) (Manfredi *et al.*, 2005).

### Examples of Infections in Which Population Dynamics Is Governed by Age-Related Processes

#### MEASLES

A great deal of modeling work has focused upon the population dynamics of measles infection (see Anderson and May, 1991). In part this is because there are good data sets resulting from a long history of case notifications against which model performance may be judged; in some cases, there are data also from serological surveys carried out prior to the introduction of vaccination. However, it is also in part because measles provides the classic example of an infection with strong epidemic cycles: in the case of England and Wales, for example, with numbers of cases oscillating over a 2-year period, whereas in others the period of oscillation is greater (Anderson *et al.*, 1984; Manfredi *et al.*, 2005). From a global public health perspective, however, the prime interest is the fact that until recently up to 1 million children each year are believed to have died as a result of measles infection. Even now, with safe and effective vaccination widely available, substantial numbers of deaths and serious disease occur in the developing world. Measles case mortality rates decline sharply with age in the first few months and early years of life, but then increase again towards adult years so that by early adulthood the risk is of a similar order to that seen in infants only a few months old, and case mortality rates appear to continue to increase towards old age. Thus although the majority of older individuals will have experienced measles infection in childhood and, because of the particular patterns of contact between age groups, may in any event be at reduced risk of infection, those who do become infected in later life may be at greatly enhanced risk of death or disease. As noted above, interventions in the form of vaccination and demographic change can result in increases in the average age at infection with a resulting skewing of the distribution of infection towards older age groups, so that there is the potential for these processes to bring about an increase in disease burden at older ages (Figure 15.9) (Williams and Manfredi, 2004). In such circumstances, the modeling of plausible scenarios of vaccination and demographic change can help (1) to indicate which age groups are more at risk, (2) to quantify the broad range of the increase in disease burden, (3) to identify to what extent this is a function of a transient change in demography or a side effect of gradual elimination of the infection from the population and to what extent it is a more long lasting phenomenon, and (4) to inform design of vaccination strategies. An approach of this type can be applied to any infection where case fatality rates or case morbidity rates change with age.

## HEPATITIS B

Age-related processes play a very important role in the population dynamics of hepatitis B virus (HBV) (Medley *et al.*, 2001). This infection has similarly been estimated to result in 1 million deaths each year, but mainly in adulthood as a result of liver cancer and cirrhosis; as with measles, however, there is a safe and effective vaccine. In contrast to measles, infection with HBV can result in persistent infection over a period of decades, and additionally the probability of persistent infection is much greater if infection occurs in early childhood. The modes of transmission of HBV are similar to those of HIV (though HBV is very much more infectious), such as through sexual contacts, health interventions, intravenous drug use (IVU) or at birth from mother to child (Edmunds *et al.*, 1996; Williams *et al.*, 1996). These processes all have a strongly age-related or age-determined component. Also, in general, the endpoint of many persistent HBV infections, such as liver cancer or cirrhosis, is not reached for several decades, so that persistent HBV infection arising in childhood (e.g., through maternal transmission) or in young adulthood (perhaps through sexual contacts or IVU) often becomes a cause of severe disease or death in middle-aged or older adults. This long time span of infection means that the population dynamics of HBV is quite different from that of measles, showing no regular oscillations and, in the absence of sharp changes in behavioral trends, prevalence of infection will change only over a period of decades. In these circumstances even a program vaccinating all susceptibles in every age with 100% efficacy will take decades before persistent infection can be eliminated, and over this extended period the reservoir of persistent infection and associated disease would be found increasingly in older age groups.

## MACROPARASITE INFECTIONS

For macroparasite infections, disease tends to be associated with past or present intensity of infection, that is, the numbers of parasites infecting the human host. Intensity of exposure and host genetics are components contributing to intensity of infection. However, as macroparasites may live for many years in the human host, the duration of exposure to infection is also a determinant of infection intensity and, in general, duration of exposure correlates with age and with behaviors associated with particular age and sex factors (e.g., being exposed while working in fields, fishing or watering cattle), so that older individuals may be expected to have higher burdens of disease from macroparasite infections and perhaps also higher mortality. An additional factor to consider is the degree to which immune tolerance develops towards the macroparasite infection, so that a high parasite worm burden may be acquired with little accompanying disease, although when such immunotolerance breaks down the host's immune reaction

may exacerbate pathology—disease is a result of the immune response to macroparasite infection rather than due to the infection itself. (In some circumstances there may be a reduction in level of disease with increasing age, although some changes may be irreversible such as the corneal opacities giving rise to river blindness which are generated by the immune response to certain parasite stages dying in the eye (Maizels and Lawrence, 1991).) Because intensity of infection is the main determinant of disease rather than infection itself (low-intensity infections causing little if any disease), the modeling of these infections concentrates on the distribution of intensity of infection in the exposed population rather than simply prevalence of infection, and age-structured models are necessary to capture observed age profiles of infection and disease. Often a vector or other secondary host may play an essential role in the transmission of such infections, such as simuliid flies as vectors of onchocerciasis, or snails as intermediate hosts in schistosomiasis and these, in addition to direct treatment of the human host, may also be subjected to measures aimed at controlling infection spread; in these circumstances it becomes most important to consider how to incorporate these stages into the modeling framework. There is insufficient space here to do more than mention the importance of such considerations in relation to modeling, but there are good examples in the literature devoted to this topic. Useful and instructive examples of modeling macroparasite infections and the associated complexities may be found in Anderson and May (1991), Anderson and Medley (1985), Basanez and Ricardez-Esquinca (2001), Brown and Grenfell (2001), Chan *et al.* (1995), and Medley and Bundy (1996).

## Alternative Approaches

The type of model described here, compartmental and deterministic, is one of the most widely adopted for investigating the transmission dynamics of infections in populations. As noted earlier, the results from these models are completely determined by their structure, the values specified for the parameters, and the initial values of the state variables. One drawback of this is that when an infection is first introduced into a population, when it is fading out, when it is very rare, or when the population is very small, the effects of chance can be an important determinant of whether the infection is able to continue to propagate itself through the population. In such cases a model incorporating random or stochastic elements into the transmission dynamics process can help to determine the distribution of possible outcomes (Bailey (1975) provides a useful introduction to this approach); in a sense, a deterministic model provides information about the mean of such a possible distribution of outcomes (they are sometimes called “mean field” models). In the limited space available it would not be possible to discuss adequately the full range of types of

## 15. Models for the Study of Infection in Populations

models used in infectious disease epidemiology including, among others, individual-based models and network models; for this purpose the reader is referred to the references quoted in the Resources section.

### Going Further

#### OTHER APPLICATIONS FOR TRANSMISSION DYNAMICS MODELS

There are several other areas in which dynamic compartmental models can provide useful insights into aspects of the understanding, treatment and control of human infections. Some examples are as follows:

#### ECONOMIC ANALYSES

The outputs of models which incorporate some kind of intervention, say, treatment or vaccination, can provide useful inputs to economic analyses. In many cases health economics analyses ignore the importance of herd immunity effects in the control of infections. Dynamics models allow these nonlinear effects to be taken into account in the analysis (Brisson and Edmunds, 2003). By running a model both with and without intervention, the numbers of prevented cases of infection or disease can be calculated. Likewise the number of treatments or vaccinations can be output so that an indication of the number of cases prevented by the program per individual intervention may be calculated, and similarly comparisons between levels of intervention or between different interventions may be undertaken.

#### WITHIN HOST/IMMUNE SYSTEM MODELS

The compartmental differential equation models described earlier are also adaptable to the study of the dynamics of the immune system in response to infection. Such models can provide novel and useful insights into the observed time course of quantitative clinical measures of infection within the human host and how these might relate to the probable course which may be taken by the infection; by providing explanations for observed dynamical changes in such measures they also offer the prospect of illuminating some of the reasons why response to infection appears to differ between hosts. Useful examples of such work may be found in work on HIV by Nowak and Bangham (1996) and Nowak *et al.* (1997), and on viral hepatitis by Bocharov *et al.* (2004).

#### STRAIN VARIATION

For a number of infections, previous exposure to different strains of the infection can be an important determinant of eventual outcome of infection, whether as a result of a degree cross-immunity between closely related strains which might therefore mitigate the seriousness of disease (e.g., influenza) or, as appears to be the case for dengue virus, a degree of “antigenic enhancement” resulting in increased morbidity (e.g., dengue hemorrhagic

shock syndrome). Transmission dynamics models are eminently suitable for the investigation of the epidemiology arising from such phenomena, and there are a number of examples in the literature (e.g., Koella and Antia, 2003; Turner and Garnett, 2002), although as the possible number of co-circulating strains of an infection increases, the complexity of such models increases greatly and the difficulty in providing satisfactory estimates for the increasing number of parameters greatly increases. Another aspect of strain variation which can usefully be tackled using these types of models relates to the evolution of resistance to control measures in some strains but not in others. Here modeling can provide insights in a number of ways, such as how long it might take for the less controlled or uncontrolled strain to predominate or how best control measures might be designed to counter the danger of emergence of new strains (Wilson *et al.*, 2000).

#### ISSUES RELATING TO AGE

Age-related processes can be introduced into the types of models described in this section in a number of ways. Examples of this might be, for economic analyses, the targeting of interventions at those in a particular age group or efficacy that varies with age; for immune system dynamics, factors relating to the effectiveness of the immune response; or for strain variation, levels of past exposure to the different strains of infection that are a function of age.

### Conclusion

Transmission dynamics models are capable of providing a valuable tool with which to investigate the epidemiology of infectious diseases. The process of simplification of the real world inherent in the design and implementation of such a model is of itself an important step in achieving epidemiological understanding; indeed, in contrast to so-called black box models in which the relative importance of interactions giving rise to results remains obscure, it has often been said that mathematical models are tools for thinking about epidemiology in a precise way and are, in a sense, thought experiments.

The ability of the modeling framework to include population age structure and age-specific parameters allows exploration of many facets of infection in the context of age and aging. An appreciation of the theoretical abilities of such models, however, should not distract from the fundamental importance of having sufficient good data with which to parameterize the models and against which to measure model performance. The modeling process itself can help to highlight what data are needed to further epidemiological understanding and to assess prospects for control, but a lack of reliable data inevitably limits in turn the reliability of further modeling work, although sensitivity and uncertainty analysis are useful tools for assessing

how much faith may be placed in the results being produced.

Among the areas where good data are often lacking are the quantification of risk of infection per contact, the nature of contact patterns, and how these change over time. A further challenge lies in establishing and understanding the importance of heterogeneity in behaviors and contact patterns. In the field of sexually transmitted infections, behavioral data are vital but particularly difficult to acquire and validate. Insights from the field of genetics have the potential to greatly increase our understanding of variation in responses to infection and differing patterns of disease, but also to increase the complexity and to bring new challenges for modelers. Infections with multiple strains, reassortment of genetic material between strains, and significant cross-immunity between strains pose yet another challenge. Changing demography, including migrational trends, has the potential to profoundly influence the epidemiology of many infections but also to substantially increase the difficulty of the task of specifying and acquiring the necessary data for modeling.

As far as the techniques and approaches used in infectious disease modeling are concerned, historically these have been adapted from uses in other fields, primarily the physical sciences, and the introduction of new techniques often occurs when those entering infectious disease modeling from another field bring with them new insights and approaches to modeling from that field. With continually increasing computing power and no lack of potentially useful modeling techniques, given sufficient suitable and reliable data, the major challenge remains that of achieving a satisfactory balance between simplicity and explanatory power and that of understanding and interpreting model results.

## Appendix: Solution of Ordinary and Partial Differential Equation Systems

### SOLUTION OF ODE MODELS

The solution at epidemic equilibrium of the simple set of equations on page 171 be arrived at analytically by noting that under equilibrium the values of the state variables remain constant so that therefore the rates of change of these variables (the differentials) become zero. From this fact we have

$$\frac{dX}{dt} = \mu N - (\lambda + \mu)X = 0$$

$$\frac{dY}{dt} = \lambda X - (\sigma + \mu)Y = 0$$

$$\frac{dZ}{dt} = \sigma Y - \mu Z = 0$$

$$N = X + Y + Z$$

Thus at equilibrium

$$\mu N = (\lambda + \mu)X$$

$$\lambda X = (\sigma + \mu)Y$$

$$\sigma Y = \mu Z$$

and from this set of equations expressions can be derived for the values for the state variables at equilibrium in terms of the parameters:

$$X = \frac{\mu}{(\lambda + \mu)}N$$

$$Y = \frac{\lambda\mu}{(\sigma + \mu)(\lambda + \mu)}N$$

$$Z = \frac{\lambda\sigma}{(\sigma + \mu)(\lambda + \mu)}N$$

Further examples of the analytic solutions of transmission dynamics models, both at equilibrium and during the dynamic stages prior to equilibrium, are provided by Anderson and May (1991), to which reference should be made if more detailed exposition is sought.

A number of easy-to-use computer-based tools are available to facilitate the task of solving ODE models, including Berkeley Madonna, ModelMaker, and Stella (see Recommended Resources).

### SOLUTION OF PDE MODELS

While some aspects of PDE models may be amenable to an analytic approach, or, in very straightforward cases, solution, in general it is necessary to resort to numerical approaches to solution. Although good computer modeling tools are available for the solution of ODE models, the picture is different for PDE models for which the usual approach is for computer programs to be written ad hoc in a high-level programming language such as C, C++ or Fortran; although often tedious, this approach is usually relatively straightforward. Suitable algorithms for numerical solutions can be found in reference works such as Numerical Recipes series (see Recommended Resources). Essentially the procedure is for a set of arrays, or one multidimensional array to be used to represent the proportion of the population in each compartment of the model with consecutive locations in the arrays representing consecutive age steps. As before, at each time step the appropriate transitions occur between the different epidemiological compartments; but also at each time step, starting from the oldest age step, the contents of adjacent age steps are moved to the next (i.e., older) age step (the contents of oldest age step being discarded on the assumption that for this age step death is the next step). As a rule of thumb the time step used should, for convenience, be of the same duration as the age step and, to avoid numerical errors, preferably be about an order of magnitude less than the mean duration corresponding to the fastest transition rate in the equation system; that is, if the time from infection to the

development of symptoms is 10 days and is the shortest period represented in the model, the time and age steps should be around 1 day.

## Recommended Resources

### BOOKS

1. *Infectious Diseases of Humans. Dynamics and Control* by Roy M. Anderson and Robert M. May. Oxford University Press (1991) Oxford. A unique and comprehensive reference giving an in-depth exposition of transmission dynamics modeling considering both deterministic and stochastic models but largely focusing on the former. The book provides much mathematical detail for those who would like it, but for those who do not wish to immerse themselves in the mathematics, a great deal can be gained from simply reading the text and skimming over the mathematical details.
2. *Parasitic and Infectious Diseases: Epidemiology and Ecology* by Marilyn E. Scott and Gary Smith. Academic Press; 1st ed. (1994). An easily accessible introduction to modeling infectious disease transmission, which introduces the mathematics in a clear and easily understandable fashion.
3. *Modern Infectious Disease Epidemiology* by Johan Giesecke. Arnold Publication; 2nd ed. (2001). An excellent and easily accessible initial introduction to current ideas in infectious disease epidemiology including dynamic modeling.
4. *Epidemiologic Methods for the Study of Infectious Diseases* by J.C. Thomas and D.J. Weber (eds). Oxford University Press (2001): New York. Not a modeling book but an excellent introduction to many of the concepts used in infectious disease modeling as well as to infectious disease epidemiology in general.
5. *Mathematical Epidemiology of Infectious Diseases: Model Building, Analysis and Interpretation* (Wiley Series in Mathematical and Computational Biology) by O. Diekmann and J.A.P. Heesterbeek. John Wiley Sons; New Ed edition (2000). A thorough, more mathematical treatment aimed at theoretical biologists, epidemiologists and applied mathematicians, which covers both deterministic and stochastic approaches to epidemiological modeling and includes exercises for the reader throughout.
6. *The Mathematical Theory of Infectious Diseases* by Norman T.J. B. Griffin; 2nd ed London. A very comprehensive coverage of stochastic infectious disease modeling, currently out of print but it is very much worth trying to locate a copy in specialist bookstores or libraries.

13. *Numerical Recipes in Fortran: The Art of Scientific Computing* by William H. Press *et al.* Cambridge University Press. 2nd ed. (1992). A very useful series of source books of methods for tackling numerical tasks arising when creating *ad hoc* computer programs to solve ODE or PDE models; included in each section are algorithms set out in computer code which implement these methods.

### MODELING SOFTWARE

Among the software packages available for constructing and solving ordinary differential equation models, good examples are the following which are also straightforward to use:

---

Berkeley Madonna, Robert I. Macey and George F. Oster	<a href="http://www.berkeleymadonna.com/">http://www.berkeleymadonna.com/</a>
ModelMaker, FamilyGenetix Ltd	<a href="http://www.modelkinetix.com/">http://www.modelkinetix.com/</a>
Stella, ISEE Systems, Inc	<a href="http://www.iseesystems.com/">http://www.iseesystems.com/</a>

---

Flow diagrams can also be designed with these packages and then automatically transformed into systems of ODEs.

# Estimation of the Rate of Production of Oxygen Radicals by Mitochondria

Alberto Sanz and Gustavo Barja

*Oxygen radical production by mitochondria seems to be implicated in various degenerative diseases and aging. In order to estimate the rate of generation of reactive oxygen species, it is necessary to use adequate methods. In this article we describe a fluorometric method appropriate to measure the rate of generation of H<sub>2</sub>O<sub>2</sub> in isolated functional mitochondria. The method is specific for H<sub>2</sub>O<sub>2</sub> and is sensitive enough to assay mitochondrial H<sub>2</sub>O<sub>2</sub> generation in the presence of respiratory substrates without the presence of inhibitors of the respiratory chain. Just after isolating functional mitochondria from fresh tissues, rates of generation of H<sub>2</sub>O<sub>2</sub> are measured by fluorometry in the presence of homovanillic acid and horseradish peroxidase. Simultaneous measurement of mitochondrial oxygen consumption allows calculation of the percent of electrons out of sequence, which reduce oxygen to oxygen radicals along the mitochondrial respiratory chain instead of reducing oxygen to water at the terminal cytochrome oxidase. This is known as the free radical leak. This method is also appropriate to study the effect of different inhibitors and modulators on the rate of mitochondrial oxygen radical production, allowing the localization of the sites of generation in the respiratory chain where reactive oxygen species are specifically formed.*

## Abbreviations

ETC	Electron transport chain

O <sub>2</sub> <sup>•-</sup>	Superoxide
ROS	Reactive oxygen species
SOD	Superoxide dismutase

## Introduction

Since Denham Harman published his Free Radical Theory of Aging in 1956, there has been growing evidence that reactive oxygen species (ROS) of biological origin are implicated in pathological processes. Free radicals

damage cellular macromolecules including carbohydrates, lipids, proteins, and most importantly, the nucleic acids of nuclear and mitochondrial DNA. In addition, ROS are continuously generated by aerobic tissues. These two properties make ROS potentially responsible in part for degenerative processes like diabetes, cancer, Parkinson's or Alzheimer's diseases, as well as aging (Barja, 2004; Sohal *et al.*, 2002).

Mitochondria are the main generator of ROS in healthy cells. The mitochondrial electron transport chain (ETC) is responsible for more than 90% of cellular oxygen consumption. During the flow of electrons in the ETC, a small percent of them incompletely reduce oxygen to superoxide and hydrogen peroxide. The first reactive species produced in the ETC is superoxide radical (O<sub>2</sub><sup>•-</sup>), resulting from the univalent reduction of oxygen. O<sub>2</sub><sup>•-</sup> dismutates to hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), which can diffuse out of mitochondria to their surrounding medium. In submitochondrial particles O<sub>2</sub><sup>•-</sup> is directly secreted outside. For this reason ROS generation is measured as O<sub>2</sub><sup>•-</sup> in submitochondrial particles and as H<sub>2</sub>O<sub>2</sub> in intact mitochondria. Although submitochondrial particles are adequate for various particular reasons including the possibility of using NADH directly as a substrate, assays in intact functional mitochondria are closer to the real physiological situation. The ideal situation would be to measure mitochondria ROS production *in vivo* in the whole animal, but techniques allowing this are still not available.

In the present paper we describe a reliable method for measuring H<sub>2</sub>O<sub>2</sub> production in isolated functional mitochondria. This method was originally designed to measure H<sub>2</sub>O<sub>2</sub> in macrophages and neutrophils (Ruch *et al.*, 1983), and it was afterwards adapted to isolated mitochondria (Barja, 1999; Barja, 2002). We described the method in detail, including the latest improvements.

## Characteristics of Different Mitochondrial ROS Production Assays

ROS production can be measured with different techniques including chemiluminescence, electron spin

resonance (ESR), spectrophotometry, and fluorometry. These techniques have been used to estimate ROS levels in submitochondrial particles, mitochondria and whole cells. Any appropriate method for estimating ROS production must be highly sensitive since the amount of ROS produced by intact mitochondria in the absence of inhibitors is small. In many physiological comparisons (e.g., related to aging) it is essential to be able to measure basal ROS production without inhibitors. Chemiluminescent methods are highly sensitive (Chance and Gao, 1994), but unfortunately have low chemical specificity. This is why they are seldom used to assay mitochondrial ROS production. On the other hand, spin-trap ESR techniques can have enough sensitivity and specificity, and their main advantage is their capacity to detect free radicals directly. These methods have been employed to measure ROS levels in brain mitochondria (Dykens, 1994), heart submitochondrial particles (Giulivi *et al.*, 1995), cultured vascular cells (Inoguchi *et al.*, 2000), or liver mitoplasts (Han *et al.*, 2001). However, ESR techniques require expensive equipment not frequently present in biochemistry laboratories, and in many occasions need the use of spin trap intermediates.

The two more classical methods of estimating free radical production in mitochondria use spectrophotometry and fluorometry. The measurement of  $\text{O}_2^{\cdot -}$  production by spectrophotometry in mitochondrial preparations has been commonly performed by kinetic assays of superoxide dismutase-sensitive epinephrine reduction to adrenochrome or reduction of acetylated or succinylated cytochrome *c* (Boveris *et al.*, 1976; Takeshige and Minakami, 1979; Lass and Sohal, 2000). They have been also applied to submitochondrial particles or to isolated complexes (Takeshige and Minakami, 1979; Cadenas *et al.*, 1977). However, the detection of ROS production in functional mitochondria needs methods which measure  $\text{H}_2\text{O}_2$  rather than  $\text{O}_2^{\cdot -}$ . Chance and co-workers developed a method for measuring the rate of mitochondrial  $\text{H}_2\text{O}_2$  production (Boveris and Chance, 1973). They used double wavelength spectrophotometry to follow the enzyme-substrate complex between  $\text{H}_2\text{O}_2$  and cytochrome *c* peroxidase. However cytochrome *c* peroxidase is not commercially available, and it must be prepared from yeast or other sources, which complicates routine assays (Prat *et al.*, 1991). Although substitution of cytochrome *c* peroxidase by horseradish is possible (Turrens *et al.*, 1985), it further decreases the intrinsically low sensitivity of spectrophotometric techniques.

Fluorometric techniques have the advantage that they are more sensitive. One of the earliest fluorometric methods developed for evaluating  $\text{H}_2\text{O}_2$  production (Loschen *et al.*, 1971) was scopoletin (6-methyl-7-hydroxy-1,2-benzopyrone), and sometimes it is still employed (Mattiasson, 2004). During the assay, fluorescent scopoletin is oxidized by  $\text{H}_2\text{O}_2$  to a nonfluorescent substance in the presence of horseradish peroxidase. This assay is specific, but it has the inconvenience that

it is a negative method because it is based on the disappearance of fluorescence. It requires the use of graded quantities of scopoletin in order to get the best range for measurements (Loschen *et al.*, 1971).

There are other fluorescent probes available for the measurement of ROS production in mitochondria: diacetyldichlorofluorescein, *p*-hydroxyphenylacetate, homovanillic acid (4-hydroxy-3-methoxy-phenylacetic acid) and Amplex Red (10-acetyl-3,7-dihydroxyphenoxazine), all of them specific for  $\text{H}_2\text{O}_2$  due to the presence of horseradish peroxidase. Nowadays, the last two probes are the ones most frequently used. The general principle is similar for all these substances (Tarpey *et al.*, 2004): in the presence of  $\text{H}_2\text{O}_2$ , hydrogen donors (AH<sub>2</sub>) are oxidized by horseradish-peroxidase (HRP) generating a fluorescent compound:

In the assay described here, homovanillic acid is used since it is less expensive than Amplex Red and does not spontaneously generate fluorescence in the absence of  $\text{H}_2\text{O}_2$ . Amplex Red can have interferences with NADH or reduced glutathione (Votyakova and Reynolds, 2004; Towne *et al.*, 2004). However, Amplex Red is being frequently used (Zhou *et al.*, 1997) and can produce interesting results (Muller *et al.*, 2004) when properly handled. Homovanillic has been used to specifically detect  $\text{H}_2\text{O}_2$  production in isolated mitochondria from a wide variety of tissues and animal species (Drew *et al.*, 2003; Gredilla *et al.*, 2001; Hagopian *et al.*, 2005). The method, which is described in detail below, is useful to (1) quantify basal ROS production, (2) localize the main sites of oxygen radical generation in the respiratory chain, (3) determine the free radical leak (see below), and (4) study the effect of different compounds on mitochondrial ROS production.

## Isolation of Mitochondria and Measurement of Oxygen Consumption

$\text{H}_2\text{O}_2$  production must be measured always in functional mitochondria obtained from fresh tissue, and never from frozen tissue samples. The measurement of  $\text{H}_2\text{O}_2$  in functional intact mitochondria requires the use of appropriate protocols of isolation. There are methods specifically designed to obtain functional mitochondria from different tissues. Possible choices are those of Mela and Seitz (1979) for heart mitochondria, the method of Lai and Clark (1979) for brain mitochondria (which uses Ficoll gradients specially useful in this tissue), and the protocol described by López-Torres *et al.* (2002) for liver mitochondria. Using these methods, well-coupled mitochondria can be isolated in a few hours. During all the steps, including homogenization, centrifugation and resuspensions, the mitochondrial preparations must

## 16. Estimation of the Rate of Production of Oxygen Radicals by Mitochondria

be maintained at 4°C. Between isolation and measurements the tube containing the mitochondria must be kept over ice, and the concentration of mitochondria must be high. This helps avoid loss of mitochondrial functional properties during a few hours.

Just after this isolation, the mitochondrial protein concentration must be measured. Immediately after isolation is finished, oxygen consumption and H<sub>2</sub>O<sub>2</sub> production are assayed at the same temperature (37°C), using the same buffer and with the same concentrations of substrates and inhibitors. This allows calculating the percent free radical leak (see below).

Oxygen consumption is measured with a Clark-type electrode calculating the respiratory control index (RCI), which is the ratio state 3/state 4 respiration. State 3 is the mitochondrial oxygen consumption in the presence of saturating ADP (phosphorylating state), and state 4 is the mitochondrial oxygen consumption without ADP (nonphosphorylating state). The RCI indicates the degree of coupling and metabolic activity of the mitochondrial preparations. A RCI of 1 or less indicates damaged non-functional mitochondria. The appropriate RCI must be substantially higher than 1, with values varying depending on the tissue and the substrate used.

### Fluorescent Assay of Mitochondrial H<sub>2</sub>O<sub>2</sub>

#### PRACTICAL PROCEDURE

H<sub>2</sub>O<sub>2</sub> produced by mitochondria is measured by reacting it with homovanillic acid in the presence of horseradish peroxidase (see above). This reaction produces a fluorescent dimer at 312 nm excitation and 420 nm emission.

The incubation medium contains 145 mM KCl, 30 mM Hepes, 5 mM KH<sub>2</sub>PO<sub>4</sub>, 3 mM MgCl<sub>2</sub>, 0.1 mM EGTA, and 0.1% fatty-acid free albumin at pH 7.4. The pH of the medium must be adjusted at the same temperature used during the assay (37°C). Solutions of substrates, ADP and enzymes are prepared in this medium without albumin at the following (initial) concentrations: 70 Units/ml of high purity horseradish peroxidase, 4 mM homovanillic acid, pyruvate/malate (125 mM or 250 mM depending on the tissue) and succinate neutralized to pH 7.4 (250 mM in heart and liver; 500 mM in brain).

The different components of the assay are added to tubes in the following order after adding a large volume of incubation medium: (1) mitochondria, (2) horseradish peroxidase, (3) homovanillic acid, (4) superoxide dismutase, and (5) the substrates (pyruvate/malate, glutamate/malate or succinate+rotenone) to start the reaction. The volume of incubation medium added should be around 85% of the total reaction volume (e.g., 1.5 ml of total reaction volume). The volumes added of the rest of the reactants are those needed to reach the following final concentrations: 0.25 mg of mitochondrial protein per ml in heart and liver, 0.4 mg of mitochondrial protein per ml in brain, 6 U/ml of horseradish peroxidase, 0.1 mM

homovanillic acid, 50 U/ml of SOD, 5 mM succinate + 2 μM rotenone, 2.5 mM pyruvate/2.5 mM malate or 2.5 mM glutamate/2.5 mM malate in heart and liver. However, in brain, it is advisable to increase the concentration of substrate to 10 mM for succinate (+ 2 μM rotenone) and to 5 mM for pyruvate. At those concentrations H<sub>2</sub>O<sub>2</sub> production is not substrate-dependent. To localize the place where ROS are produced inside the electron transport, chain inhibitors must be employed. Rotenone (2 μM final concentration) is used to inhibit at complex I, thenoyltrifluoroacetone (TTFA, 11 μM final concentration) for complex II, and antimycin A (10 μM final concentration) for complex III. Solutions of inhibitors are prepared in pure high-grade ethanol. The reaction is performed during 15 minutes with constant agitation in a temperature-controlled water bath at 37°C. After 15 minutes of incubation, the reaction is stopped, the samples are transferred to an ice-cold bath, 0.5 ml of the stop buffer (2 M glycine, 2.2 M NaOH, 50 mM EDTA) is added (per each 1.5 ml of reaction volume), and the fluorescence (312 nm excitation, 420 nm emission) is measured. With the addition of the glycine-NaOH-EDTA the final pH is around 12.4, which increases the sensitivity and makes the final fluorescence essentially pH-independent. This procedure highly decreases the variability of results compared to measuring the fluorescence at neutral pH at which it is strongly pH dependent.

In the absence of SOD, the rates represent H<sub>2</sub>O<sub>2</sub> production. SOD added in excess converts O<sub>2</sub><sup>•-</sup> produced (if any) to H<sub>2</sub>O<sub>2</sub>. Thus, in the presence of SOD, the assay estimates the mitochondrial production of O<sub>2</sub><sup>•-</sup> plus H<sub>2</sub>O<sub>2</sub>. Since the respiratory chain univalently reduces oxygen to O<sub>2</sub><sup>•-</sup> which then dismutates to H<sub>2</sub>O<sub>2</sub>, the measurement of mitochondrial H<sub>2</sub>O<sub>2</sub> production represents the rate of oxygen radical generation. Moreover, the addition of SOD can prevent the underestimation of the rate of H<sub>2</sub>O<sub>2</sub> production due to reaction of O<sub>2</sub><sup>•-</sup> with HRP or HRP-Compound I (Muller *et al.*, 2004).

#### BLANKS

Appropriate blanks are also run during the assay to correct for the positive fluorescence of the mitochondria themselves. These blanks have mitochondria and all the reaction components but do not contain substrate. Values are obtained by subtracting the fluorescence of the blanks from the fluorescence of the samples and dividing the results by the 15 minutes of incubation. Special blanks (also without substrate) must be included to correct for the fluorescence of antimycin A when this mitochondrial respiratory inhibitor is included in the reaction.

#### STANDARDS

The arbitrary fluorescence units must be converted to amounts of H<sub>2</sub>O<sub>2</sub>. There are different possibilities to do this. One of them is to use H<sub>2</sub>O<sub>2</sub> standards. However, μM H<sub>2</sub>O<sub>2</sub> solutions are unstable, and they should be prepared just before use from stable mM H<sub>2</sub>O<sub>2</sub> solutions.

An alternative is to use a glucose–glucose oxidase system as standard. In the presence of excess glucose, this couple generates  $H_2O_2$  at a rate that depends on the amount of glucose oxidase added. For this purpose the following is added to standard tubes: incubation medium, 6 Units/ml of horseradish peroxidase, 0.1 mM homovanillic acid, glucose oxidase, and 14 mM glucose (total volume 1.5 ml). Another advantage of this procedure is that the standards are incubated in parallel in the same conditions as the samples (15 min at 37°C, transfer to the ice-cold bath, and addition of 0.5 ml of 2 M glycine, 2.2 M NaOH, 50 mM EDTA). Glucose oxidase is added in amounts generating 1 nanomol of  $H_2O_2$ /min, and the fluorescence of samples and standards is compared. This is used to calculate the final mitochondrial production of oxygen radicals, which is expressed in nanomoles of  $H_2O_2$ /min. mg of protein. When using this kind of standard, care should be taken that no limiting losses of activity have occurred during transport to or storage of glucose oxidase and horseradish peroxidase at the laboratory.

### SPECIFICITY

The horseradish peroxidase enzyme gives the assay specificity for  $H_2O_2$ . Furthermore,  $H_2O_2$  secreted to the outside of mitochondria reacts only with the  $H_2O_2$  detection system, since there are no antioxidants in the incubation medium. On the other hand, addition of catalase to the incubation buffer prevents the increase in fluorescence elicited by  $H_2O_2$ , whereas addition of external pulses of  $H_2O_2$  during a kinetic assay shows that the response of the detection system to the peroxide is instantaneous.

### VALIDITY

Any useful assay of ROS production should not interfere with mitochondrial function. This can be checked by measuring mitochondrial respiration in the presence of the molecular probes constituting the chemical detection system. Addition of horseradish peroxidase and homovanillic acid, at the same final concentration used in the fluorometric  $H_2O_2$  assay, does not change the rates of mitochondrial state 4 or state 3 respiration or the RCI. High purity horseradish peroxidase and superoxide dismutase should be used. Commercial solution of these two enzymes stabilized with agents capable of altering mitochondria should be avoided. The appropriateness of the particular commercial reactants used can be easily checked in pilot experiments measuring mitochondrial respiration in their absence and in their presence.

### STABILITY AND REPRODUCIBILITY

The final fluorescence of the samples does not vary significantly during at least 2 hours. Variations between duplicated samples of the same preparation of mitochondria assayed on the same day are less than 4%.

## RECOMMENDATIONS

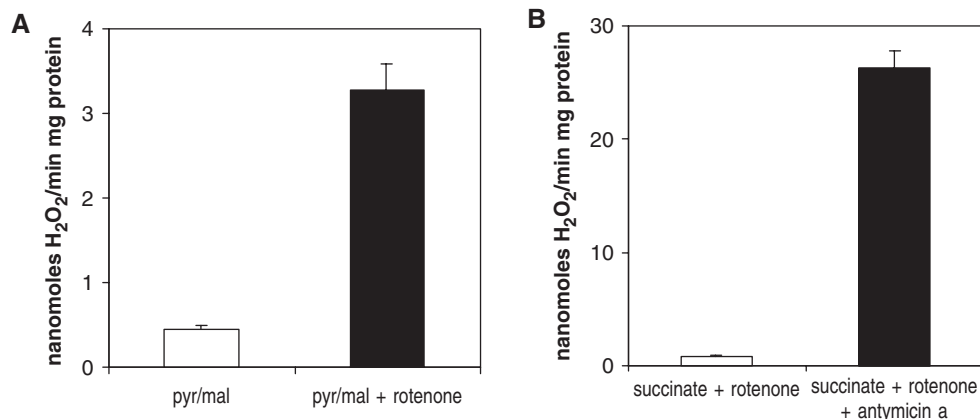

The following recommendations can help to obtain better measurements:

1. The use of highly purified ion-free water is recommended for preparation of all solutions.
2. The pH of the incubation buffer (7.4) should be carefully checked, and it should be readjusted if needed, since ROS production can be affected by this parameter.
3. Excessive mitochondrial concentration during the incubation at 37°C can cause decreases in fluorescence and should be avoided.
4. A chemical (in the absence of mitochondria)  $H_2O_2$  pulse experiment can be easily performed each day before starting the measurements with mitochondria, or even before sacrificing the animal to isolate them. This reaction can be very useful to check the quality of the horseradish peroxidase and homovanillic acid reactants, in order to avoid erroneously attributing an absence or very low rate of ROS production to the mitochondrial preparations if a recently received or stored reactant is not in good condition or has lost enzymatic activity. For this purpose  $H_2O_2$  is added from a standard  $H_2O_2$  solution to the homovanillic-HRP detection system, and the occurrence of the corresponding increase in fluorescence is checked.
5. The use of soap to clean the materials (glassware, etc.) that will be in direct contact with the mitochondria should be avoided.
6. Tubes with isolated mitochondria must be kept on ice and at high mitochondrial concentrations. The mitochondria must be used between 2 and 3 hours after isolation. If longer time periods are needed, it is necessary to check again the functionality of the mitochondria (RCI) after the assays.

## Mitochondrial Free Radical Leak

It is frequently assumed that mitochondrial ROS production is a direct function of mitochondrial  $O_2$  consumption. While this is sometimes true (Ku *et al.*, 1993), in other situations, including comparisons between birds and mammals or caloric restriction (Barja, 2004), this is not the case. A well-known example is the transition from state 4 to state 3, during which mitochondrial  $O_2$  consumption increases strongly but ROS production decreases or is even totally abolished. In this last case ROS production per unit oxygen consumption decreases acutely during the energy transition. In other words, during state 3 mitochondria are more efficient than in state 4, avoiding ROS generation per unit electron flow in the respiratory chain, which is clearly adaptive. This can be quantified by measuring the “free radical leak”: the fraction (%) of electrons out of sequence which reduce oxygen to ROS in the mitochondrial respiratory chain

## 16. Estimation of the Rate of Production of Oxygen Radicals by Mitochondria

**Figure 16.1.** Effects of inhibitors of the respiratory chain on the rate of H<sub>2</sub>O<sub>2</sub> generation of rat heart mitochondria. (A) Addition of rotenone (complex I inhibitor) to pyruvate/malate-supplemented rat heart mitochondria increases H<sub>2</sub>O<sub>2</sub> production. (B) Addition of antimycin A (complex III inhibitor) to succinate (+rotenone)-supplemented rat heart mitochondria increases H<sub>2</sub>O<sub>2</sub> production.

instead of reducing oxygen to water at cytochrome oxidase. If mitochondrial H<sub>2</sub>O<sub>2</sub> production and oxygen consumption are measured in parallel using the same incubation medium, temperature and concentrations of substrates and modulators in each mitochondria preparation, the free radical leak can be calculated. Since two electrons are needed to reduce one molecule of oxygen to H<sub>2</sub>O<sub>2</sub>, whereas four electrons are needed to reduce one molecule of oxygen to water, the free radical leak is easily calculated by dividing the rate of ROS production by two times the rate of oxygen consumption, the result being multiplied by 100.

### Localization of Mitochondrial Sites of H<sub>2</sub>O<sub>2</sub> Production

The method allows localizing the sites responsible for ROS production inside the electron transport chain. The sites of ROS production are identified by measuring the rate of H<sub>2</sub>O<sub>2</sub> production with different combinations of substrates and inhibitors specific for different segments of the respiratory chain. For example, pyruvate/malate and glutamate/malate are complex I-linked substrates, and succinate is a complex II-linked substrate. Rotenone inhibits specifically at complex I, TTFA at complex II and antimycin A at complex III.

It is well known that the rate of oxygen radical production increases as a function of the degree of reduction of the autoxidizable electron carrier responsible for ROS generation (Boveris and Chance, 1973). Blocking the respiratory chain with an inhibitor increases the reduction state of electron carriers on the substrate side of the inhibitor, whereas those in the oxygen (opposite) side change to a more oxidized state. Thus, an increase in oxygen radical production following the addition of an inhibitor means that the oxygen radical generator is located on the substrate side of the block. Conversely, if oxygen radical production decreases after addition of the

inhibitor, the generator must be situated on the oxygen side. Thus, the higher H<sub>2</sub>O<sub>2</sub> production observed in the presence than in the absence of rotenone in pyruvate/malate-supplemented rat mitochondria (Figure 16.1A) indicates that they produce ROS at complex I since this is the only complex situated on the substrate side of the inhibitor in this experiment.

Similarly, the classically described increase in H<sub>2</sub>O<sub>2</sub> production after addition of antimycin A to succinate(+rotenone)-supplemented rat heart mitochondria (Figure 16.1B) is due to ROS production at complex III. On the other hand, in contrast with the experiment with pyruvate/malate, addition of rotenone to mitochondria respiring with succinate decreases H<sub>2</sub>O<sub>2</sub> production, indicating that part of the ROS generated with this substrate comes from complex I (Herrero and Barja, 1997; Lambert and Brand, 2004). In this experiment rotenone blocks the reverse flow of electrons from succinate to complex I and thus its capacity for ROS production. Similar experiments can be used to localize the sites involved in changes in ROS generation induced by experimental manipulations in animals.

### Conclusions

An efficient and reliable method for measuring ROS production in intact functional mitochondria is described. The method is specific for H<sub>2</sub>O<sub>2</sub> and is sensitive enough to assay basal H<sub>2</sub>O<sub>2</sub> production in the respiratory chain. It shows high reproducibility, generates stable final fluorescence, and does not interfere with mitochondrial function. The assay system shows instantaneous response to H<sub>2</sub>O<sub>2</sub>, and is thus useful for studying the effect of inhibitors or modulators on the rate of ROS production. It also allows the calculation of the free radical leak (the percentage of electrons out of sequence which reduce O<sub>2</sub> to ROS instead of to water at the respiratory chain). While other fluorescent methods are available to measure

ROS production in isolated mitochondria, the one presented here has various advantages: it is based on increases (instead of decreases) in fluorescence, reactants are not expensive, and homovanillic acid does not spontaneously generate fluorescence. The method, similarly to the available alternatives, can be applied only to isolated mitochondria. The measurement of ROS production (independent of ROS scavenging) in intact cells or animals must wait for future technical developments.

# Telomeres and Aging in the Yeast Model System

Kurt W. Runge

*Telomeres are the physical ends of linear eukaryotic chromosomes. In many organisms, including humans and yeasts, telomeres are composed of short repeated DNA sequences and their associated proteins. These repeats are lost gradually due to incomplete DNA synthesis of the chromosome end, or by degradation from nucleases, and can be resynthesized by the enzyme telomerase. Many human somatic cells do not express sufficient telomerase activity to prevent telomere repeat loss, resulting in cell senescence or death when telomeres shorten to a critical length. This telomere length checkpoint for aging and cell growth is also seen in yeast whose genes for telomerase components have been deleted, allowing yeast to serve as a model for telomere-linked senescence and aging in human cells. Telomeres also serve as a reservoir of bound proteins that are released as the telomere DNA shortens, and work in yeast has shown that these telomere-associated proteins play important roles in yeast replicative aging. The advantages of yeast as an aging model include rapid growth and aging, a small well-defined and well-annotated genome, powerful molecular genetics for modifying this genome, simple but robust assays for the activity and location of telomeric proteins, publicly available collections of mutants in every gene, and multiple assays for replicative and chronological aging. This chapter will describe how the budding yeast *Saccharomyces cerevisiae* has contributed to our knowledge of telomeres and aging, and the emerging role of the evolutionarily divergent fission yeast *Schizosaccharomyces pombe* as another important model system. The powerful genetics of these two different yeast systems should identify central evolutionarily conserved processes that control cellular aging.*

## Telomere Replication, the Telomere Length Checkpoint and Growth without Telomerase

### TELOMERE STRUCTURE

Telomeres in the majority of model systems have the general DNA structure of a simple sequence repeat at the end of the chromosome that is adjacent to a middle-repetitive family of repeats. Experiments with

chromosome truncations in yeast and the discovery of viable chromosome truncations in humans indicate that the simple sequence repeats are all that are required to maintain a stable chromosomal telomere in mitosis and meiosis (Gottschling *et al.*, 1990; Wilkie *et al.*, 1990). In contrast, broken DNA ends lacking these repeats are highly recombinagenic, as are yeast telomeres that have lost their simple sequence repeats (Hackett *et al.*, 2001). In humans, the 3' end of the chromosome bears the repeat sequence TTAGGG while *S. cerevisiae* has the more divergent repeat (TG<sub>2-3</sub>)(TG)<sub>1-6</sub>, abbreviated as TG<sub>1-3</sub>, and *S. pombe* has a more divergent sequence with a core repeat of G<sub>n</sub>TTACA that can be interrupted by additional bases (Hiraoka and Chikashige, 2004; Smogorzewska and De Lange, 2004). The current model for telomere end structure in humans and yeast is that the 3' end extends past the 5' end by several telomere repeats (Makarov *et al.*, 1997; McElligott and Wellinger, 1997; Wellinger *et al.*, 1993).

### TELOMERASE AND TELOMERE REPLICATION

The structure of the telomere end reflects its unique mode of replication. Normally, replication of a linear DNA molecule from internal origins of replication would generate two daughter molecules, each of which has one blunt end and one end with a 3' overhang after removal of the terminal RNA primer. The current model from work in budding yeast is that at the end of S-phase, telomeres undergo a processing event in which the 5' strand (sometimes called the CA strand to reflect the predominant bases in the telomere repeats) is degraded to produce a long 3' overhang (possibly 50–100 bases in yeast) which is then partially filled-in to leave a shorter 3' overhang of ~12 bases (Figure 17.1).

The removal of the RNA primer, or the action of nucleases on the repeats, causes telomeres to shorten each time the cell divides. In the absence of a mechanism to replicate the telomere repeats, the telomeres continuously shorten. In this “mitotic clock” hypothesis (Harley and Villeponteau, 1995), the size of the telomere repeat tract is related to the number of divisions the cell has undergone. In old cells where the telomere tract becomes too short, the cell senses this state and induces a “short telomere checkpoint” that causes cell cycle arrest (discussed below).

**Figure 17.1.** Yeast telomere end structure. (A) Yeast telomere repeat tracts have 250–400 bp of the irregular sequence TG<sub>1-3</sub> at their very ends. The terminus of the chromosome has a 3' overhang in the G1 phase of the cell cycle which is 12–14 nt long (Larrivee *et al.*, 2004). The telomeres of human cells also possess 3' overhangs (McElligott and Wellinger 1997). (B) The 3' overhang is elongated in S phase in a telomerase-independent manner. At the end of S-phase after telomere replication, the overhang is expanded to greater than 50 nt and then returns to a shorter overhang which is presumed to have the G1 structure. Because this long overhang is detected in cells lacking *in vivo* telomerase activity, it is thought that the overhang is produced by a nuclease acting on replicated telomeres (Wellinger *et al.*, 1996).

In yeast and human germ cells, this arrest is prevented by the synthesis of new telomere repeats by the activity of the enzyme telomerase.

Telomerase is the name given to the core enzyme consisting of a protein (the TERT subunit for TELomerase Reverse Transcriptase) and RNA (the TER subunit for TELomerase RNA, also called TERC and TR). The RNA serves as an internal template for the synthesis of new telomere repeats (reviewed by Smogorzewska and De Lange (2004)). A number of other protein subunits that make up the telomerase holoenzyme are known in several organisms, but most conserved components are TERT and TER. While growing cultures of human and yeast cells that lack telomerase eventually senesce and/or die from loss of telomere function, cultures of cells that express telomerase activity form cultures that continuously double (Bodnar *et al.*, 1998). Consequently, the presence of telomerase can prevent the short telomere-mediated cell senescence or death of all cells in the culture.

When human and yeast cells express telomerase, the size of their telomere repeat tracts is usually kept within a certain range (as opposed to elongating continuously). A great deal of work on telomerase and the genetics of telomere length control has yielded a model in which much of the control of telomere length is due to telomeric

chromatin regulating the access of telomerase to the 3' end of the chromosome (reviewed by Smogorzewska and De Lange (2004)). The proteins that bind directly to the telomere repeats, or the co-factors that they recruit, are thought to form a structure that sequesters the chromosome end from telomerase and other cellular activities. Short telomeres are preferentially elongated over longer telomeres (Hemann *et al.*, 2001; Ouellette *et al.*, 2000; Teixeira *et al.*, 2004), and it is thought that shorter telomeres bind fewer of these proteins, which makes them more likely to be lengthened. This interplay between telomerase and the many telomere chromatin components is an area of intensive research, and a greater understanding of the intricacies of these processes is likely in the coming years.

### TELOMERE REPLICATION WITHOUT TELOMERASE

Failure to elongate very short telomeres, as occurs in cells lacking telomerase, induces a short telomere checkpoint. As this growth arrest can be bypassed in human cells by the expression of transforming genes without the re-expression of telomerase, this arrest represents a true cell cycle checkpoint (Harley and Villeponteau, 1995). In cultures of human and yeast cells, the majority of cells arrest. In yeast, this arrest appears as a prolonged delay at the G2/M boundary of the cell cycle (Enomoto *et al.*, 2002; Ijma and Greider, 2003). However, rare cells can undergo mutagenic events that allow them to grow out of these cultures. For transformed human cells, these rare cells go on to form cell lines. In yeast, these mutant cells that can grow without telomerase are often referred to as “survivors.”

At this point it is worth asking: is the senescence observed in yeast due to short telomeres a true senescence, or is it cell death? Senescence is defined as a quiescent but metabolically active state. In yeast, short telomere-induced senescence has been demonstrated by the ability to return these nongrowing cells to growth by reintroducing active telomerase. While defining the minimal portions of yeast telomerase RNA required for function, Livengood *et al.* (2002) grew cells lacking the telomerase RNA gene to the point of senescence and prepared these cells for transformation. Transforming cells with an empty vector yielded very few transformants, while transforming cells with a vector bearing a functional telomerase RNA gene gave many transformants. These data suggest that these arrested cells can be returned to the cell cycle and normal growth by taking up a new gene, transcribing and processing the RNA and assembling an active telomerase enzyme. These activities suggest that many of the senescent cells are metabolically active. A more defined set of experiments where telomere lengthening is re-established in senescent cells would provide the opportunity to analyze the reversible cellular changes associated with this growth arrest.

Yeasts lacking telomerase are constructed by deletion of the gene for a telomerase component such as yeast TERT (yTERT) or yeast TER (yTER or the *TLC1* gene). Since the haploid yeast have no copy of the telomerase component in its genome, the only way to escape senescence and death due to loss of telomere repeats is to find an alternative mechanism to maintain these repeats that does not involve telomerase. In the budding yeast *S. cerevisiae*, there are two types of survivors that can replicate telomeres, called Type I and Type II. Type I survivors are yeast that have rearranged their genomes such that each telomere contains copies of the subtelomeric repeat called Y' followed by a short stretch of TG<sub>1-3</sub>. These telomeres are thought to use nonreciprocal recombination to replicate their TG<sub>1-3</sub> repeats. The generation of Type I survivors requires a number of recombination genes including *RAD52*, *RAD51*, *RAD54* and *RAD57*. In contrast, Type II survivors contain long stretches of TG<sub>1-3</sub> at the chromosome end and require the recombination genes *RAD52*, *RAD50* and *SGS1* (Chen *et al.*, 2001; Huang *et al.*, 2001; Teng *et al.*, 2000; Teng and Zakian, 1999).

Postsenescent survivors have also been isolated in the fission yeast, *S. pombe*. Cells lacking the TERT subunit can give rise to two types of survivors: a recombination-driven mode of growth with amplification of subtelomeric sequences to give telomeres of heterogeneous lengths, and a chromosome circularization mode in which the 3 linear *S. pombe* chromosomes are converted to circular versions (Nakamura *et al.*, 1997). The *S. pombe* genome is similar in size to that of *S. cerevisiae*, but organized into 3 chromosomes instead of the 16 in budding yeast. This reduced chromosome number apparently allows shortening telomeres on the same chromosome to undergo head-to-head fusions and generate circular chromosomes that allow stable growth at a detectable frequency. In contrast, the 16 chromosomes of *S. cerevisiae* provide 32 telomeres that may compete with each other for telomere–telomere fusion events and reduce the chance of forming a cell where all of the cell's chromosomes are circularized. However, circularized chromosomes can be detected in some survivor strains of budding yeast, indicating that telomere–telomere fusions of this type are a general phenomenon (Liti and Louis, 2003).

In contrast to yeast deletion mutants, human cells that lack telomerase activity have often repressed the expression of the gene for the hTERT subunit. Cells that grow out of cultures that have bypassed senescence to form cell lines have often reactivated this gene and now express telomerase activity. Increased telomerase activity is also found in many, but not all, human tumors (Kim *et al.*, 1994). However, telomere replication in the absence of telomerase activity has also been found in human cells and some human tumors (reviewed by Henson *et al.* (2002)). This Alternative Lengthening of Telomeres, or ALT, pathway also appears to involve recombination pathways that involve copying sequences from one

telomere to another, as well as more complex recombination events (Fasching *et al.*, 2005; Londono-Vallejo *et al.*, 2004). Thus, both telomerase-mediated and telomerase-independent modes of telomere replication are conserved in yeasts and humans, strengthening the use of yeast as a model system for telomere function.

## YEAST TELOMERE PROTEIN COMPONENTS

### *Telomerase*

The core of the telomerase enzyme is the TERT and TER subunits. In budding yeast, the *EST2* gene encodes the protein subunit while the *TLC1* gene encodes the telomerase RNA (Lingner *et al.*, 1997; Singer and Gottschling, 1994). The *EST2* gene name stands for Ever Shorter Telomeres 2, because the telomere repeat tracts in these mutants that have inactivated the *EST2* gene continuously shorten until the most of the cells in the culture senesce. Four *EST* genes were isolated in the screen that identified *EST2*, yielding the additional protein-encoding genes *EST1*, *EST3* and *EST4* (*EST4* was found to be the previously characterized *CDC13* gene, and the *EST4* mutant is commonly referred to as *cdc13-2* or *cdc13<sup>est</sup>*) (Lendvay *et al.*, 1996). The mutants isolated in these genes all show the same phenotype, indicating a loss of telomerase activity *in vivo*. However, cell extracts from *est1*, *est3* or *cdc13<sup>est</sup>* mutants all yield telomerase activity *in vitro* (Lingner *et al.*, 1997). Elegant work has since demonstrated that the *EST1*, *EST3* and *CDC13* gene, products serve as adaptor proteins to help recruit the telomerase enzyme to the telomere, and the molecular dynamics of this process is under intensive study by many groups (Evans and Lundblad, 1999; Smith *et al.*, 2003; Taggart *et al.*, 2002). One *EST1* paralog has been identified in budding yeast. Two orthologs in fission yeast and three *EST1* orthologs in human cells have been identified, and some of these proteins associate with telomerase and telomerase RNA (Lundblad, 2003; Sanger\_Institute 2005; Zhou *et al.*, 2000). While *CDC13* has no ortholog beyond budding yeasts, it has a similar structure compared to the telomere end-binding factor POT1 in *S. pombe* and mammals.

### *Telomere structural proteins*

Double-stranded yeast telomere repeats are bound predominantly by Repressor Activator Protein 1 or *RAP1* protein. This protein represses transcription when bound to the yeast silent mating type cassettes (described below) and telomeres, activates the transcription of many housekeeping genes, and serves as a crucial telomere length regulator and chromatin component. *RAP1* protein contains an ~230 amino acid DNA binding domain and an ~170 amino acid C-terminal domain which serves as an interaction site for many telomere-associated proteins (Hardy *et al.*, 1992; Henry *et al.*, 1990; Konig *et al.*, 1996; Moretti *et al.*, 1994; Wotton and Shore, 1997). Thus, *RAP1* encodes a multifunctional protein whose

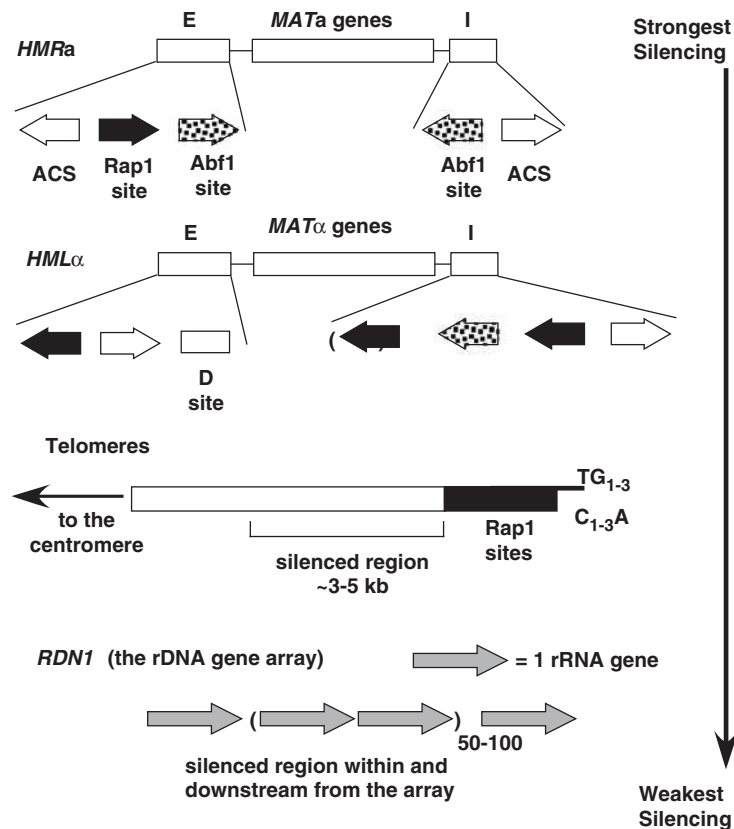

activities are dependent upon its DNA binding context. At the telomere, *RAP1* protein is known for its association with the gene-silencing proteins *SIR2*, *SIR3* and *SIR4* and the telomere length regulatory proteins encoded by *RIF1* and *RIF2*.

Gene silencing in budding yeast, a chromatin-mediated effect that prevents the transcription of genes, was first discovered in the late 1970s (Rine *et al.*, 1979). When reporter genes are placed adjacent to telomere repeats in the chromosome, their expression is repressed or silenced. Similar types of telomere-associated silencing have been reported in *S. pombe*, *Drosophila melanogaster* and humans (Baur *et al.*, 2001; Levis *et al.*, 1985; Nimmo *et al.*, 1994) in addition to other organisms. In budding yeast, silencing has been found to be effected by a number of chromatin proteins and chromatin modifying and remodeling complexes. The “classic” proteins involved are encoded by *SIR2*, *SIR3* and *SIR4*. These proteins also

act with the *SIR1* protein to silence two specialized loci, the silent mating type cassettes, and *SIR2* protein also acts with other proteins to repress RNA polymerase II transcription and recombination in the array of ribosomal RNA genes called the rDNA array (Figure 17.2).

Of *SIR2*, *SIR3* and *SIR4*, only *SIR2* has orthologs in a large number of other organisms. *SIR2* encodes an  $\text{NAD}^+$ -dependent deacetylase that is important in maintaining gene silencing and prolonging yeast lifespan (reviewed by Blander and Guarente (2004)). Many organisms encode multiple *SIR2* family members, or sirtuins, and the suggestion has been made that sirtuins may alter protein posttranslational modification to regulate responses to stress that also affect lifespan (Blander and Guarente, 2004).

In budding yeast, the *SIR* proteins are one of the first examples of telomeres serving as a reservoir of proteins that can be mobilized to move to other genetic loci.

**Figure 17.2.** Silenced loci in yeast. The 4 major silent loci are shown, which fall into 3 classes: The silent mating type cassettes *HMRa* and *HMLα*, telomeres and the tandem array of ribosomal RNA genes called the rDNA array or *RDN1* (the genetic designation of this locus). In yeast, mating type is determined by the sets of genes expressed at the MAT locus, either a and  $\alpha$ . Yeast has 3 copies of this locus, one which is expressed (MAT) and two which are strongly silenced (*HMR* and *HML*). These silent mating type cassettes contain flanking DNA elements, called E and I, which silence the MAT genes between them. The E and I sites in turn contain unidirectional binding sites for known DNA binding factors, *RAP1* protein (which binds to the Rap1 site), *ABF1* protein (which binds to the Abf1 site), and Origin Recognition Complex (which binds to the ACS element) (Laurenson and Rine 1992). The proteins encoded by *SIR1*, *SIR2*, *SIR3* and *SIR4* are required for silencing at the silent mating type cassettes. The TG<sub>1-3</sub> repeats in telomeres contain arrays of *RAP1* protein sites, which tether *SIR2*, *SIR3* and *SIR4* proteins to telomeres and silence nearby genes (Gottschling *et al.*, 1990). The rDNA array binds a different set of proteins that include *SIR2* protein and silence RNA polymerase II transcribed genes placed within these repeats (Straight *et al.*, 1999).

## 17. Telomeres and Aging in the Yeast Model System

Under a variety of mutant conditions that alter telomere chromatin structure, *SIR* proteins appeared to be released from the telomere and to relocalize at the silent mating type cassettes (Buck and Shore, 1995). Subsequently, *SIR3* protein was shown to move from telomeres to newly made double-strand breaks (Martin *et al.*, 1999; Mills *et al.*, 1999). Finally, this relocalization of *SIR* proteins from telomeres plays an important role in the replicative aging of yeast, illustrating how release of proteins from telomeres can have an impact on lifespan (see Telomeres and Yeast Replicative Aging, below).

In addition to *SIR* proteins, *RIF1* and *RIF2* proteins also interact with the C-terminus of *RAP1* protein bound at telomeres (Hardy *et al.*, 1992; Wotton and Shore, 1997). One clear function of the *RIF* proteins is in telomere length control: cells that lack the C-terminal 160 amino acids of *RAP1* protein have telomeres that grow from ~330 bp of TG<sub>1-3</sub> to 2–4 kb of TG<sub>1-3</sub>, and cells deleted for both *RIF1* and *RIF2* also have 2–4 kb TG<sub>1-3</sub> telomere tracts (Kyriou *et al.*, 1992; Wotton and Shore, 1997). Recent evidence also suggests that *RIF* proteins may interact with proteins or DNA independent of *RAP1* protein while regulating telomere length (Levy and Blackburn, 2004).

Orthologs for *RAP1* and *RIF1* proteins have been identified in *S. pombe* and in humans, and show differences from budding yeasts. While *RAP1* protein binds directly to DNA in *S. cerevisiae*, *S. pombe* and human cells have different Myb-related double-stranded telomere DNA binding proteins called *taz1*<sup>+</sup> (in fission yeast) and TRF1 and TRF2 (in human cells). The *RAP1* of fission yeast and humans lacks the DNA binding domain, and instead is tethered to telomeres by interactions with *taz1* protein or TRF2, respectively. As in *S. cerevisiae*, the *RIF1* protein ortholog also interacts with the C-terminus of the Rap1 ortholog in *S. pombe* and humans. While fission yeast *rap1* and *rif1* proteins and human Rap1 protein behave as negative regulators of telomere length (reviewed in detail by Smogorzewska and De Lange (2004)), human Rif1 protein apparently leaves telomeres to play a role in the ATM-dependent DNA damage response (Silverman *et al.*, 2004). Recruitment of the human telomere binding protein TRF2 to DSBs has also been recently reported (Bradshaw *et al.*, 2005). These properties of human Rif1 and TRF2 suggest that human telomeres may also serve as a reservoir of factors for other cellular processes such as the response to DSBs. The release of such factors could potentially be regulated by stochastic processes, e.g., a DSB activating a protein kinase cascade, or could be gradual as telomeres shorten over repeated cell divisions. A DNA damage function for the yeast Rif1 proteins has not been tested yet.

### *Telomere proteins that act at double-strand breaks*

Telomeres can be viewed as specialized double-strand breaks (DSBs). While telomeres have specific sequences and associated proteins, many of the proteins that interact

with and process telomeres also play important roles in the recognition and processing of DSBs at internal chromosomal loci. These proteins include the *S. cerevisiae* DNA damage checkpoint kinases Tel1p and Mec1p (ATM and ATR in humans), the multifunctional MRX complex (MRN in humans), and the Yku70p-Yku80p DNA-end binding heterodimer (Ku70-Ku86 in humans) (Maser and DePinho, 2004). Yeast cells lacking these proteins maintain telomeres with fewer simple sequence repeats, indicating their role in telomere replication, and have defects in responding to and processing DSBs (Lustig and Petes, 1986; Morrow *et al.*, 1995; Porter *et al.*, 1996; Ritchie *et al.*, 1999; Ritchie and Petes, 2000). The simple sequence repeats that make up telomere DNA and the combination of proteins that associate with these sequences prevent them from being processed as DSBs by the cellular machinery.

The first DSB-associated protein found to directly associate with telomeres was the Yku70/Yku80 heterodimer. This DNA end-binding protein, first found in mammalian cells, binds to DNA breaks and activates DNA-activated protein kinase catalytic subunit (DNA-PK<sub>cs</sub>), a member of the ATM family (Anderson and Lees 1992). The yeast Ku proteins were found to associate with the telomere and play a role in telomere replication by recruiting telomerase (Fisher *et al.*, 2004; Gravel *et al.*, 1998; Peterson *et al.*, 2001). Since then, Ku heterodimer association with the telomere in fission yeast and humans has also been demonstrated (Bailey *et al.*, 1999; Baumann and Cech, 2000).

Upon induction of a DSB, several proteins recognize and process this DNA lesion and signal the cell cycle machinery to pause. An elegant study investigating the choreography of these events in yeast found that the first proteins to bind are the MRX complex (composed of proteins encoded by *MRE11*, *RAD50* and *XRS2*) and *TEL1* protein, followed by recruitment of the RPA complex (Lisby *et al.*, 2004). RPA then recruits *MEC1* protein and MRX and *TEL1* protein leave the DSB. Importantly, phenotypes for mutants in each of these genes include changes in the length of the TG<sub>1-3</sub> repeats in budding yeast (Ritchie *et al.*, 1999; Schramke *et al.*, 2004; Smith *et al.*, 2000; Tsukamoto *et al.*, 2001). So what are these proteins? *TEL1* and *MEC1* are DNA damage protein kinases of the ATM family, whose orthologs are, respectively, *tell1*<sup>+</sup> and *rad3*<sup>+</sup> in *S. pombe* and ATM and ATR in humans. MRX is a multifunctional complex *in vivo* that has helicase and nuclease activity *in vitro*, whose orthologs in fission yeast and humans are called MRN complex (for Mre11-Rad50-Nbs1) (reviewed by Smogorzewska and De Lange (2004)). RPA is a conserved complex that functions in DNA synthesis and repair (reviewed by Schramke *et al.*, (2004) and Smith *et al.*, (2000)). Interestingly, cells lacking *TEL1* and *MEC1* in budding yeast, or *tell1*<sup>+</sup> and *rad3*<sup>+</sup> in fission yeast, have telomeres that gradually shorten as telomerase cannot access the telomere (Chan *et al.*, 2001; Naito *et al.*, 1998;

Ritchie *et al.*, 1999). Experiments in budding yeast have shown that *TEL1* protein associates with telomeres when they reach  $\sim 1/3$  their normal length, and *TEL1* association is a step in the pathway that allows telomere elongation by telomerase. In contrast, *MEC1* protein telomere association is observed when survivor/ALT cells arise in the culture, suggesting a role for *MEC1* protein when the telomere repeats become short enough for the telomere to lose its characteristic protection of the chromosome end (Hector *et al.*, submitted). These data indicate different roles for these checkpoint kinases in maintaining and monitoring telomere length. As all of these proteins have a role in DNA damage signaling, they most likely play some yet-to-be defined role in how the cell senses a short telomere to pause the cell cycle. This function appears to be conserved in humans, as senescing cells show increased association of ATM with telomeres.

*TEL2* protein may be another yeast telomere protein that plays a role in the cellular response to DSBs. The original *TEL2* mutation, *tel2-1*, has telomeres one-half the length of wild-type cells and appears to control telomere length through the *TEL1* pathway (Lustig and Petes, 1986). *TEL2* protein binds to double and single-stranded telomere repeats *in vitro*, suggesting a direct role at the telomere similar to *TEL1* protein (Kota and Runge 1998; Kota and Runge, 1999), and preliminary data indicate that *TEL2* protein associates with telomeres *in vivo* (R. Kota and K.W. Runge, in preparation). However, deletion of the *TEL2* gene is lethal, while deletion of the *TEL1* gene is not, suggesting that *TEL2* protein may act in another pathway as well (Runge and Zakian, 1996). Work in *Caenorhabditis elegans* suggests a role for *TEL2* protein in aging and the response to DSBs. The *C. elegans TEL2* ortholog was identified twice by mutation: once as *clk-2*, a mutation that slows the rate of aging, and once as *rad-5*, a DNA damage checkpoint mutation (Ahmed *et al.*, 2001; Benard *et al.*, 2001). The human ortholog of *TEL2* has also been cloned and overexpressed in tissue culture cells, where it localizes in the cytoplasm (Jiang *et al.*, 2003), but it is unclear if this overexpression reveals all of the normal locations for human Tel2 protein activity. Thus, while the *in vivo* functions of *TEL2* are currently obscure, the efforts in many model organisms should soon reveal its mode of action at telomeres and in aging.

#### *Chromatin remodeling complexes and telomere length*

While yeast telomeres form a nonnucleosomal complex based on micrococcal nuclease mapping (Wright *et al.*, 1992), mutations in proteins known to modify nucleosomes can alter telomere length. Every open reading frame in yeast has been deleted in a systematic fashion, and this library of strains is publicly available. A screen of each of these strains for changes in telomere length has revealed a number of unexpected gene deletions that alter telomere length. The genes identified include *RSC2* (a member of the RSC remodeling complex), *FMP26*

(which interacts with the SAGA complex) and nine members of various histone deacetylase, histone methylase and histone ubiquitination complexes (Askree *et al.*, 2004). Their effect on telomere length raises the possibility that many of these complexes may also modify telomere proteins to alter their functions or control the expression of telomere proteins. A third possibility was recently shown in *Tetrahymena*, where the placement of ordered nucleosome arrays adjacent to telomere repeats altered the length of the telomeric tract (Jacob *et al.*, 2004), raising the possibility that chromatin-modifying proteins may alter telomere length in a similar way.

#### *Unknown players in telomere metabolism*

The more telomeres are investigated, the more new processes are uncovered that require explanation. As mentioned previously, yeast telomeres have a 3' overhang of 12–14 bp during most of the cell cycle, but in late S-phase this end is resected to an overhang of  $>50$  nt in a manner that does not require telomerase activity (Wellinger *et al.*, 1996; Wellinger *et al.*, 1993) (Figure 17.1). These data suggest that a nuclease degrades the 5' strand as part of normal telomere processing each cell cycle. The identity of this nuclease (or nucleases) and how it links telomeres to DNA replication will be of great interest. The process by which the 5' strand is resected also has important implications for cell senescence and aging. When telomeres are short, degradation of the 5' strand would further reduce the number of double-stranded telomere repeats, and could convert short telomeres into structures that activate the short telomere checkpoint. Identification of the 5' telomere strand degrading nuclease may allow a direct test of this hypothesis.

## Monitoring Yeast Senescence and Identifying Important Genes

A major advantage of yeast is that one can easily generate a cell that has normal-length telomeres and completely lacks a protein essential for telomere elongation. This cell gives rise to a population of cells that lack active telomerase and whose telomeres gradually shorten until the majority of cells arrest. This shortening time course typically requires 50–70 population doublings, which provides the opportunity to generate sufficient quantities of cells for different analyses during the course of the experiment. Yeast genetics also allows one to remove telomerase from a variety of mutant backgrounds to judge the role of a gene product in the pathway to short telomere-induced senescence.

### INDUCED TELOMERASE LOSS AND BEHAVIOR OF THE RESULTING CULTURE

#### *Two ways to lose telomerase*

Telomerase loss is typically induced by deleting a gene for an essential telomerase component (usually the catalytic

## 17. Telomeres and Aging in the Yeast Model System

TERT subunit or the TER template RNA) and then maintaining that strain by providing this gene in *trans*. One common method is to construct a diploid yeast strain and then delete one copy of the gene using standard techniques. The diploid is phenotypically wild type because one active copy of the gene remains in the diploid cell. The diploid yeast can then be sporulated to produce two haploid wild-type spores and two haploid spores bearing the gene deletion (e.g., Lendvay *et al.*, 1996). Because the gene deletion is accomplished by replacing the gene with a selectable marker, the deletion spores can be identified on medium requiring the selectable marker for growth. These haploid spores are born with wild-type length telomeres that gradually shorten over repeated mitotic divisions.

A second method is to delete the gene for the telomerase component in a haploid cell, identify the correct transformant, and introduce a normal copy of the gene on a plasmid that replicates as an episome in the cell. Episomal yeast plasmids are lost at rates that vary from 1 to 50% per cell division even when grown under selection (Murray and Szostak, 1983). Since most yeast selectable markers complement auxotrophic markers, cells that have lost the plasmid continue to divide until the gene product is diluted away or degraded and then arrested due to starvation for the auxotrophy. The fraction of plasmid-free cells in a selectively grown culture can vary from 10 to 70%, depending on the type of plasmid used. These cells can grow again if plated on medium that supplements the auxotrophic requirement (Newlon, 1988). Thus, plating cells from a selectively grown culture onto complete medium and testing portions of the resulting colonies for the presence of the plasmid's selectable marker allows one to identify the colony that lacks the gene for the telomerase component. The original colony can then be grown and tested in the same way as the haploid spore generated in the method described earlier. The disadvantage of this method is that the initial transformant lacks telomerase activity, and some mutant combinations with lack of telomerase cause rapid death (e.g., haploid spores bearing deletions of a telomerase component gene and the *YKU70* gene die very rapidly (Nugent *et al.*, 1998)). While this disadvantage can be overcome using more complex yeast methods to disrupt the chromosomal copy of the gene in a cell that already bears a plasmid-borne copy of the same gene, it is probably easier for the beginner to use the diploid method described earlier.

### *Observing senescence in yeast*

Two common methods are used for different purposes in yeast. Serial streaking of individual colonies is a method used to demonstrate that senescence occurs, while serial dilution and regrowth of small cultures are used to show that the culture senesces and to isolate survivor/ALT cells whose rapid growth allows these cells to quickly overtake the slow growing cells with very short telomere tracts.

Serial streaking is streaking a colony of yeast on a plate to isolate single cells and to allow them to grow into colonies. A freshly grown colony is then restreaked on a fresh plate. A yeast colony  $\sim 2$  mm in diameter contains  $3 \times 10^5$  to  $10^6$  cells. If one approximates yeast cell growth as cell number =  $2^N$  where  $N$  is the number of cell doublings, then each yeast colony is 18–20 population doublings. Cells that have just lost a gene for a telomerase component lose 3–5 bp per cell doubling, and so give colonies for the first 3 streaks, and then show slower growth on the fourth streak (Lundblad and Szostak, 1989; Singer and Gottschling 1994). Not all cells senesce at the same time, which explains why some cells continue to grow on the fourth streak. This difference may reflect the fact that telomere tract length is not clonal and telomeres do not shorten at the same rate (e.g., Li and Lustig, 1996), and some small amount of lengthening may occur in these cells by nonreciprocal gene conversion mechanisms (Pluta and Zakian, 1989). Some cells in the colony may therefore have different telomere lengths than other cells, and so senesce after different numbers of cell divisions. Because each colony is a single cell that has grown into  $\sim 10^6$  cells, there has only been  $\sim 10^6$  cell divisions in which mutation(s) can occur to give rise to a survivor/ALT cell that can elongate its telomeres in the absence of active telomerase. Survivors can be readily identified on the fourth restreak because they grow much faster than the cells that are senescing, and form larger colonies (Teng and Zakian, 1999).

Serial dilutions of liquid cultures involve growing cells in a liquid culture, often 10 ml or so, for 24 hours. Usually, yeast grow to densities of  $\sim 10^8$  cells/ml in the first growth phase without telomerase, in the same way wild-type cells do. Cells are then diluted to a constant number (from  $10^4$  cells/ml to  $5 \times 10^5$  cells/ml, depending on the lab) in fresh medium and grown for another 24 hours for the second cycle (Le *et al.*, 1999; Teng and Zakian, 1999). Each subsequent 24-hr cycle involves diluting cells down to  $5 \times 10^5$  cells/ml and allowing regrowth; however, cells do not grow to saturation by the 4th or 5th day. Instead, they begin to show slower rates of growth as the cells in the population begin to senesce, and the number of cells/ml that grow up in 24 hours steadily decreases on days 4 to 6. By the 7th day, cells begin to grow rapidly again as survivor/ALT cells take over the culture. It should be noted that this serial dilution method selects for faster growing mutants compared to the serial restreaking method because while serial restreaking restarts from a single cell each time, serial dilution restarts from  $5 \times 10^6$  cells in a culture. Thus, any mutants that arose in an earlier dilution culture can be transferred to the new culture and undergo further selection for rapid growth. If the goal of the experiment is to isolate fast-growing survivors, the serial dilution method is superior. If the goal is to determine if the cells senesce, it is probably faster to use the serial restreaking method because more individual strains can be easily and rapidly assayed in

parallel. The serial restreaking method may also allow one to isolate suppressors that grow at different rates (Teng and Zakian, 1999).

The serial dilution method has been frequently used to monitor the requirements for cell senescence and the two types of survivor/ALT cells that form in yeast cells lacking active telomerase. By starting with cells that lack active telomerase and one DNA damage checkpoint gene, it has been shown that a subset of checkpoint genes are required for the yeast G2/M cell cycle arrest caused by short telomeres, namely, *MEC1*, *DDC2*, *MEC3* and *RAD24* (Enomoto *et al.*, 2002; Ijma and Greider, 2003). Similar experiments have used cells lacking active telomerase and one or more recombination proteins to determine the requirements for forming Type I survivors and Type II survivors (Chen *et al.*, 2001).

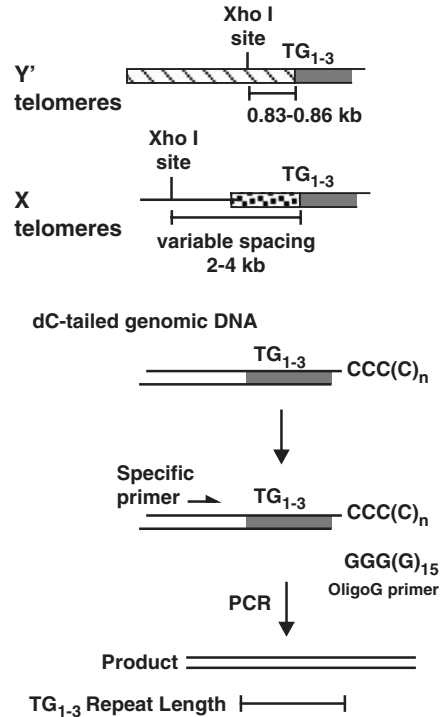

#### Monitoring telomere structure during cell senescence

The slow loss of telomere repeats in yeast cells lacking active telomerase, about 3–5 bp per generation (Lundblad and Szostak, 1989), allows the experimenter to isolate large numbers of cells at different population doublings for analysis. Examining the length of the terminal  $TG_{1-3}$  repeat tracts is necessary to ensure that the cells are behaving as predicted. Two methods are routinely used: Southern blotting and Telomere PCR. Once telomere shortening has been verified, the chromatin components of telomeres can be monitored by chromatin immunoprecipitation at different time points during the telomere shortening.

Standard Southern blotting of Xho I cut yeast DNA using  $TG_{1-3}$  or TG sequences as probes has long been used to monitor telomere length. Most lab yeast strains have two types of subtelomeric middle repetitive elements, X and Y' (reviewed by Louis 1995) (Figure 17.3).

Y' is a highly conserved family of elements that contain an Xho I site 0.83–0.86 kb from the beginning of the  $TG_{1-3}$  repeats. As more than half of the telomeres in the common lab yeast strains have Y' elements adjacent to the  $TG_{1-3}$  repeats, the 1.1–1.3 Y' telomere restriction fragment provides an indicator of the behavior of many telomeres at once. In contrast, the X family of elements is less well conserved, and the Xho I restriction site is present at varying distances from the beginning of the  $TG_{1-3}$  repeat tract. Thus, the Xho I digest provides information on individual telomeres, which run as bands in the 2–4 kb range in many strains. When telomerase activity is absent, all of these bands shorten. When Type I survivors containing many tandem Y' elements take over the culture, all of the X telomere bands disappear. When Type II survivors with heterogeneous lengths of  $TG_{1-3}$  arise, the telomere band pattern becomes highly variable (see Lundblad and Blackburn (1993); Teng and Zakian (1999)).

Telomere PCR is a more recent technique that allows one to monitor the length and sequence of the  $TG_{1-3}$  tract at the end of an individual telomere (Förstemann

**Figure 17.3.** Monitoring telomere length in budding yeast. A. The telomeres in *S. cerevisiae* end with two types of middle repetitive elements, Y' and X. The conserved Y' repeat has an Xho I site a defined distance from the  $TG_{1-3}$  repeat tract, while the less conserved X element contains upstream Xho I sites whose distance from the  $TG_{1-3}$  repeat tract is more variable. Thus, a Southern blot of Xho I digested DNA probed with  $TG_{1-3}$  or TG probe shows several telomeres at once in the Y' 1.1–1.3 kb band and individual X telomeres in the 2–4 kb size range (reviewed by Louis, 1995). B. Telomere PCR method to measure  $TG_{1-3}$  length of a unique telomere. Genomic DNA is tailed with terminal transferase, which tails telomeres and fragmented DNA. A specific primer is then used with an oligo dG primer to amplify the  $TG_{1-3}$  repeats of an individual telomere. Because the sequence of the DNA flanking the  $TG_{1-3}$  repeats is known, the size of the  $TG_{1-3}$  repeats can be easily determined by agarose gel electrophoresis.

*et al.*, 2000) (Figure 17.3). Briefly, genomic DNA is treated with terminal transferase and dCTP to add an oligo-dC tail to all free DNA ends. This mix is then PCR amplified using an oligo-dG primer and a unique primer internal to the  $TG_{1-3}$  repeats. The resulting product has  $TG_{1-3}$  repeats flanked by DNA of known sequence, so the range of  $TG_{1-3}$  lengths can be easily determined on agarose gels. In the first demonstration of this technique, a synthetic telomere constructed *in vitro* was used to replace a chromosomal telomere and thereby place unique sequences adjacent to the  $TG_{1-3}$  repeats (Förstemann *et al.*, 2000). In subsequent uses, primers that hybridize to X and Y' elements have been used to monitor telomere–telomere fusions (Mieczkowski *et al.*, 2003), and a primer that hybridizes to the unique sequences on the right telomere of chromosome VI has been used to monitor the length of that telomere (Hector *et al.*, submitted).

## 17. Telomeres and Aging in the Yeast Model System

The use of Chromatin Immunoprecipitation (ChIP) and the serial dilution method for observing cell senescence allows one to monitor the components of telomeric chromatin as the telomere shortens. If the original cell lacking a gene for a telomerase component is grown for 31 divisions, one can obtain  $\sim 2 \times 10^9$  cells, or one liter of cells at  $2 \times 10^6$  cells/ml. This number of cells is sufficient to provide DNA for multiple Southern blots and cells for a standard ChIP experiment and to seed a second one-liter culture for 5 generations of growth. In most ChIP protocols, cells are cross-linked with formaldehyde, the chromatin is isolated and fragmented, chromatin fragments are immunoprecipitated with Abs to the protein of interest, purified, de-crosslinked and amplified by PCR using primers to the region of interest (Strahl-Bolsinger *et al.*, 1997). Because of its unique sequence, the right telomere of chromosome VI has been studied by ChIP to monitor the assembly of silenced chromatin (Luo *et al.*, 2002) and the association of *TEL1* and *MEC1* proteins with shortening telomeres (Hector *et al.*, submitted).

### Telomeres and Budding Yeast Replicative Aging

As described in the discussion of Sir proteins in the Yeast Telomere Protein Components section, yeast telomeres can serve as a reservoir of proteins that can act at other chromosomal loci. One of the clearest demonstrations of this phenomenon is the role of silencing proteins in yeast replicative aging. As described in other chapters of this volume, yeast replicative aging is a measure of the number of times a cell can divide or bud before it dies. Work by Guarente, Sinclair and colleagues has illustrated how one cause of yeast aging, the production of extrachromosomal rDNA circles, is related to telomeres acting as a reservoir of silencing proteins for use in other cellular functions. Understanding this example requires understanding the basics of silencing in yeast.

#### SILENCED LOCI AND METHODS FOR MONITORING SILENCING

Yeast have 3 types of silenced loci: silent mating type cassettes, telomeres and the rDNA array (Figure 17.2). Silencing at these loci is usually monitored by examining the expression of reporter genes inserted into these loci. Strains with reporters at one of each of these silenced loci have been constructed so the effect of silencing can be monitored at each locus (e.g., Ray *et al.*, 2003) (Figure 17.4).

To be useful, the reporter constructs must be able to show both increases and decreases in silencing. Since silencing at some telomeres and in the rDNA locus occurs in only 1–10% of the cells, both increases and decreases in silencing can be readily detected. This property is not shared by the silent mating type cassettes *HMRa* and

**Figure 17.4.** Triple silencer yeast strains. To monitor silencing at the 3 types of silenced yeast loci in a single population of yeast cells, 3 different reporter genes are inserted into the silenced loci in the same strain. In order to monitor both increases and decreases in silencing, a mutant version of *HMR* can be used where the *RAP1* protein binding site in the E box (Figure 17.2 top) is deleted. Because the amount of *SIR* silencing protein in the cell appears to be limited, such strains can monitor the redistribution of silencing function. Shortening telomeres would bind less *SIR2*, *SIR3* and *SIR4* protein, and so would free up some of these proteins that could then bind to the rDNA array or mutant silent mating type cassette.

*HML $\alpha$*  as only about 1 in  $10^6$  cells expresses information from these cassettes and an increase in silencing is very difficult to detect. Mutated cassettes show weaker silencing such that reporter genes placed within the cassettes are expressed in 10% of the cells. Strains bearing these three types of reporters allow one to examine silencing at these three types of loci and determine the relative level of silencing using a simple technique called a spot test.

Spot tests are performed by diluting a freshly grown culture of cells, typically a single yeast colony, into sterile water and by making serial dilutions of this suspension, usually 10-fold dilutions. Aliquots of 3 to 5 microliters of each suspension are spotted onto different media to monitor the total number of cells that can grow and reporter gene expression (Gottschling *et al.*, 1990). Markers with both positive and negative selections are used as reporters. In one triple silencer strain (Ray *et al.*, 2003), the *hmr* locus was marked by the *TRP1* gene. The expression of *TRP1* is monitored by growth on medium lacking tryptophan, which requires the *TRP1* gene product. This assay is a *positive* selection for *TRP1* expression, so more expression leads to more growth which equals less silencing. In contrast, the telomere and rDNA array were marked, respectively, with *URA3* and *CAN1*. Expression of these two genes can be monitored on medium containing drugs (5-fluoro orotic acid and canavanine, respectively) that kill cells which express these genes. These assays are *negative* selections for gene expression, so less expression leads to more growth which equals more silencing. Understanding these

two different types of yeast reporters is essential for evaluating the silencing data, but once they are understood the assay becomes simple and extremely rapid. Six colonies can be assayed on one set of plates, allowing the screening of many different strains.

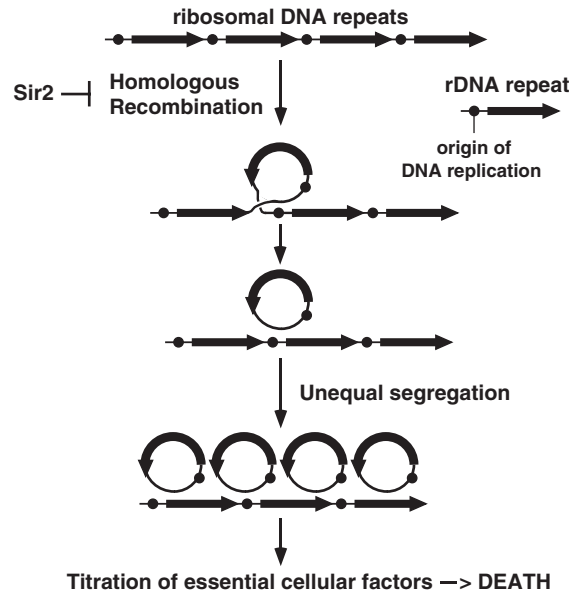

An important aspect of silencing is that the factors that accomplish it are limited. An excess of Sir proteins is toxic to the cells, and their levels are controlled (reviewed by Kahana and Gottschling (1999)). Consequently, concentrating more Sir proteins at one silenced locus can result in a decrease in silencing at another. The significance of this observation is that old yeast cells and some long-lived mutant yeast have a “silencing configuration” in which the relative level of silencing function is shifted to increase silencing at the rDNA array and decrease it at telomeres and the silent mating type cassettes.

### REPLICATIVE AGING, SILENCING AND THE ERC MODEL

A series of papers from the Guarente lab demonstrated that Sir proteins in old yeast cells (i.e., cells that had budded many times) leave silencers and telomeres and move to the nucleolus, the site of rDNA transcription (Kennedy *et al.*, 1997; Smeal *et al.*, 1996). This lab also isolated a *SIR4* mutation that truncated the C-terminus and allowed the release of other Sir proteins from telomeres and silencers in young cells (Kennedy *et al.*, 1995). These observations established the aforementioned “silencing configuration” for long-lived cells and suggested that events in the nucleolus might play some role in aging. The only known function of Sir proteins in the nucleolus at the time was suppression of rDNA recombination: direct repeats such as the rDNA array are prone to intrachromosomal and interchromosomal recombination that can lengthen and shorten the repeats, and this recombination is repressed in yeast in part by the action of the *SIR2* gene product (Gottlieb and Esposito, 1989).

Work by Sinclair and Guarente later established that extrachromosomal rDNA circles (ERCs) can cause one form of yeast aging (Sinclair and Guarente, 1997) (Figure 17.5).

ERCs are episomal plasmids that arise within yeast by means of recombination within the rDNA repeats to loop out a circular form of the repeat. Each repeat contains an origin of DNA replication, and so each circular form can replicate as an extrachromosomal plasmid. Budding yeast divides asymmetrically to produce a large mother cell and a smaller daughter cell, and extrachromosomal plasmids containing just an origin of DNA replication tend to stay with the mother cell at mitosis for unknown reasons (Murray and Szostak, 1983). Thus, once a plasmid is formed, its progeny accumulate in the mother cell quickly. Sinclair and Guarente showed that introduction of these plasmids early in life caused rapid replicative aging. Given the role of *SIR2* protein in repressing rDNA recombination, one explanation for the migration of silencing

**Figure 17.5.** The ERC model for one cause of replicative aging in yeast. As described in the text, one cause of yeast aging is the production of extrachromosomal rDNA circles (ERCs) (Sinclair and Guarente 1997). Each rDNA repeat in the head-to-tail tandem array contains an origin of DNA replication sequence. Intrachromosomal crossing over by homologous recombination can loop out one or more repeats as an extrachromosomal circle. These circles can then replicate as episomal plasmids by virtue of the origin of DNA replication. These types of plasmids do not segregate equally at mitosis, but instead stay with the larger of the two cells at division (the Mother cell in the Mother–Daughter pair). Plasmids thus build up in the Mother cell over subsequent divisions. When plasmids reach large numbers (hundreds per cell), they are thought to compete for essential proteins involved in normal transcription and DNA metabolism, resulting in gene misregulation and cell death. *SIR2* protein (Sir2) can repress homologous recombination within the rDNA repeats (Gottlieb and Esposito, 1989), so the relocation of *SIR* proteins from telomeres to the rDNA can slow this cause of yeast aging. Other causes of yeast cell aging most certainly exist, but the mechanisms by which they cause cells to age are less defined.

proteins from telomeres to the nucleolus prolonging replicative lifespan is that the *SIR2* protein released from telomeres can suppress the formation of ERCs. Subsequent work did show that increasing *SIR2* protein dosage could increase lifespan, but also indicated that suppression of rDNA recombination was not the only effect of *SIR2* protein on lifespan (Kaeberlein *et al.*, 1999). Thus, release of *SIR* proteins from telomeres may affect yeast lifespan in multiple ways.

The “silencing configuration” of long-lived cells established above provided a mechanism to search for other long-lived mutants. A mutation in the MAP kinase encoded by *SLT2* was isolated in a screen looking for mutants that have low telomere silencing and higher rDNA silencing. The *SLT2* kinase was found to phosphorylate *SIR3* protein (Ai *et al.*, 2002; Ray *et al.*, 2003). Mutation of one of the consensus *SIR3* protein phosphorylation sites to an unphosphorylatable residue

## 17. Telomeres and Aging in the Yeast Model System

(*SIR3-S275A*) caused changes in silencing and an increase in lifespan, which did not appear to occur through an ERC-related mechanism (Ray *et al.*, 2003). Because the *SLT2* kinase is activated by continuous cell growth, these results suggested a feedback loop in which rapid growth stimulates *SIR3* phosphorylation which shortens lifespan while slower growth (which usually occurs in yeast when nutrients are limiting, i.e., a state resembling caloric restriction) results in extended lifespan. However, the actual mechanism by which lifespan is changed by *SIR3* protein phosphorylation is unknown.

The *SIR3* phosphorylation story illustrates a second important point in yeast research: the genetic variation between different lab strains. While the ERC model and the *SIR3* work were done in the same strain background, subsequent work in another strain that has a longer average lifespan (S288C) found that the *SIR3-275A* mutation did not cause a significant change in lifespan (Kaeberlein *et al.*, 2005). The genetic differences between these strains are unknown, but must include modifiers of lifespan that can be corrected by mutation of *SIR3*. As individual humans are genetically diverse, the yeast case illustrates how some changes may increase the lifespan of some individuals but not others. The utility of the yeast model system might be significantly enhanced if the genomic sequences of several common lab yeast strains were known and the genetic differences, and thus potential modifier genes of aging, were identified.

### THE FISSION YEAST *S. POMBE* AS AN EMERGING MODEL SYSTEM IN AGING

As mentioned previously in the Yeast Telomere Protein Components section, fission yeast utilizes the same telomere maintenance machinery as budding yeast and humans, and in some cases contain orthologs that show more sequence similarity to the human sequences than do those of budding yeast (e.g., *pot1<sup>+</sup>* of *S. pombe* and Pot1 of humans are more similar than either protein is to *S. cerevisiae CDC13*). Fission yeast also exhibits gene silencing at telomeres, silent mating type cassettes, the rDNA, and centromeres. Thus, many of the characteristics that make budding yeast a useful model system for both short telomere-induced senescence and release of factors from telomeres are also present in fission yeast. Because these two yeasts are evolutionarily quite distant and show many physiological and genomic differences (e.g., fission yeast has fewer genes than budding yeast, and only 3/4 of the fission yeast genes have clear budding yeast orthologs (Sanger\_Institute, 2005)), analysis of fission yeast aging could reveal evolutionarily conserved mechanisms that control lifespan and guide the work in more difficult mammalian systems.

One provocative report has been published that claims that fission yeast shows replicative aging. While fission yeasts divide to produce two equally sized sister progeny, after several cell divisions an asymmetry develops such that the “older” cell becomes more round and visually

distinguishable from the “younger” sister (Barker and Walmsley, 1999). Chronological aging, the length of time cells in culture can survive in stationary phase and form colonies when transferred to fresh medium, has also been tested in *S. pombe* and provides similar results to work in budding yeast (Fabrizio and Longo, 2003) (B.-R. Chen and K.W. Runge, in preparation). Following up these results and development of high-throughput replicative and chronological aging assays will greatly enhance the utility of fission yeast as a model system for aging.

### The Universality of Yeast Aging Mechanisms and Future Outlook

The short telomere senescence phenotypes of yeast have clear parallels with human cells. Both systems utilize telomerase and ATM family members in telomere metabolism and short telomere signaling. Both systems have telomere-associated proteins that can be released to function at other sites (the *SIR* proteins in yeast and the Rif1 and TRF2 proteins in human cells). Thus, telomere shortening in both systems has the potential to release associated proteins that may play roles in lifespan regulation. While the orthologs affected in these processes may not always show an exact one-to-one correspondence, the conservation of general biological mechanisms from one system can guide the model building in the other.

The yeast strains that can replicate telomeres without telomerase have telomeres similar to those of human ALT cell lines and tumors. It therefore seems likely that some of the mechanisms that give rise to these cell types are conserved. The advantage of the yeast system is that one can test a variety of candidate genes for changes in how cells survive shortening telomeres and if this mode of survival in the absence of telomerase is susceptible to different anti-cancer drugs. One can then identify a class of protein targets and families of chemical compounds to study in human cells.

Another major advantage of yeast is the rapid phenotypic testing of candidate longevity genes. For example, the ease of gene deletion in yeast means that one can find a gene whose expression is up-regulated in a microarray experiment under one growth condition, and then delete this gene to determine if this up-regulation is actually required for this growth condition. When this experiment was done with all budding yeast genes, it was found that only 7% of yeast genes that were up-regulated were actually required for optimal growth under the test condition (Giaever *et al.*, 2002). This sobering result means that many of the genes identified by microarray approaches in organisms such as humans are probably not the most important genes affecting the aging process, and some sort of validation is required. Since such gene deletion studies and aging experiments are difficult and long in mammalian systems, budding and fission yeast will

be good first steps for identifying evolutionarily conserved processes that alter lifespan to augment the discoveries made in microarray experiments. Research in the yeast aging field is expanding rapidly, and the biggest challenge to the researcher may be sorting the future flow of information to define the biological processes that are universally conserved.

## ACKNOWLEDGMENTS

I apologize to any of my colleagues whose work was not mentioned here due to space limitations. This work was supported by NIH grants GM 50752 and AG19960.

# Longevity and Aging in Budding Yeast

Matt Kaerberlein

*This chapter presents an overview of the current understanding of how yeast ages and the genes and pathways that play a role in determining yeast chronological and replicative life span. Several genes, as well as calorie restriction, have been found to regulate aging similarly in yeast and multicellular eukaryotes, and these potentially conserved determinants of longevity are emphasized. Descriptions of the chronological and replicative life span assay are provided in enough detail to allow a researcher with common knowledge of yeast methods to carry out his or her own aging studies.*

## Introduction

The budding yeast *Saccharomyces cerevisiae* has served as an exemplary model of cellular aging for more than 50 years (Kaerberlein *et al.*, 2001). Yeast provides several advantages over other model systems, including short life span, well-characterized genetic and molecular methods, low relative cost, cell-type homogeneity, and a vast organismal information base. Two distinct types of aging have been studied in yeast: replicative and chronological (Figure 18.1).

**Figure 18.1.** Two types of yeast aging. Replicative life span is defined as the number of daughter cells produced by a given mother cell prior to senescence. Chronological life span is defined as the length of time that a yeast cell can survive during quiescence. Chronological life span is typically measured by growing cells into stationary phase, which induces a starvation response and exit from the cell cycle.

The replicative life span of a yeast cell refers to the number of daughter cells produced by a mother cell prior to senescence (Mortimer and Johnston, 1959); while chronological life span measures the time a yeast cell can survive under nonproliferative conditions (Fabrizio and Longo, 2003).

The ability to monitor both the replicative and chronological aging of a yeast cell is fortuitous, as it allows for independent analysis of the aging process in both dividing and nondividing cell types. Yeast replicative aging may serve as a suitable model for the aging of mitotically active cell types in multicellular eukaryotes, such as human stem cell populations. Chronological aging, on the other hand, models the aging process of postmitotic cell types like muscle and brain. The surprising degree of conservation, at least at the level of individual genes, between aging in yeast and aging in multicellular eukaryotes has made *S. cerevisiae* one of the premier model organisms in aging-related research.

## Replicative Aging in Yeast

The replicative life span of a yeast cell is determined by the number of daughter cells produced. Like other eukaryotic species, yeast replicative mortality follows Gompertz–Makeham kinetics, consistent with the hypothesis that similar processes underlie aging in yeast and aging in higher eukaryotes (Kaerberlein *et al.*, 2001). Several studies have demonstrated that replicative aging is under both genetic and environmental regulation, and the SAGE KE Aging Genes and Interventions Database (Kaerberlein *et al.*, 2002b) (see Chapter 8 on SAGE KE) has catalogued more than fifty genes reported to alter replicative life span in various strain backgrounds. This section describes the current understanding of the most important genetic pathways and molecular mechanisms underlying yeast replicative aging.

### EXTRACHROMOSOMAL rDNA CIRCLES: A YEAST-SPECIFIC AGING MECHANISM

Several important cellular processes have been implicated in the regulation of yeast replicative aging, including

glucose sensing, DNA damage response, stress response, mitochondrial function, and transcriptional silencing (Bitterman *et al.*, 2003; Jazwinski, 2002; Sinclair *et al.*, 1998). The roles that some of these processes play in life-span determination are beginning to be elucidated at a molecular level; however, only one molecular cause of replicative senescence has been demonstrated: the mother cell specific accumulation of extrachromosomal rDNA circles (ERCs).

ERCs are self-replicating circular DNA molecules formed through homologous recombination events at the rDNA (Sinclair and Guarente, 1997). The yeast rDNA is a tandem array of 100–200 copies of a 9.1-kb repeat unit, with each repeat unit containing all of the information needed to code for rRNA precursors. Due to the tandem nature of the rDNA array, homologous pairing and recombination can occur between adjacent repeats, resulting in the formation of ERCs containing one or more repeat units. ERCs can be observed by either 1-D or 2-D gel electrophoresis and Southern blotting with a probe for rDNA sequence, and mutations that block homologous recombination, such as deletion of *RAD52*, prevent ERC formation (Park *et al.*, 1999).

Once formed, a single ERC has the potential to undergo exponential amplification as a function of mother cell age. The age-associated accumulation of ERCs in yeast is likely due to two features: self-replication and asymmetric segregation. Each rDNA repeat unit contains an origin of replication (ARS element), but lacks a centromere-like sequence (CEN element), resulting in preferential segregation of ERCs to the mother cell during cell division (Sinclair and Guarente, 1997). Quantitation of ERCs in aged cells shows a dramatic increase in ERC levels with age, and artificial induction of a single ERC in a virgin daughter cell, through the use of a CRE recombinase system, shortens life span by about 50% (Sinclair and Guarente, 1997). Thus, ERCs accumulate in normally aging mother cells and can lead to senescence.

An important prediction of the ERC model of yeast aging is that a mutation resulting in decreased ERC formation (or accumulation) should increase life span, assuming said mutation does not also have a detrimental effect on fitness. This prediction was validated with the finding that deletion of *FOB1* both dramatically reduces ERC levels and increases mean and maximum life span by approximately 35% (Defossez *et al.*, 1999). The *Fob1* protein promotes ERC formation by binding to the rDNA and causing a recombinogenic unidirectional replication fork block (Kobayashi and Horiuchi, 1996). In the absence of *Fob1*, rDNA recombination is reduced approximately 10-fold (Defossez *et al.*, 1999).

A second protein that regulates yeast replicative life span by altering ERC levels is Sir2 (Kaeberlein *et al.*, 1999). Sir2 is an NAD<sup>+</sup>-dependent histone deacetylase (Imai *et al.*, 2000; Landry *et al.*, 2000; Smith *et al.*, 2000; Tanner *et al.*, 2000), conserved from bacteria to man (Blander and Guarente, 2004). In yeast, Sir2, along with

Sch9	✓	✓	?	?
Sir2	✓	✓	✓	?
Sod1/Sod2	✓	✓	✓	?
Tor1/Tor2	✓	✓	✓	?

**Figure 18.2.** Evolutionarily conserved determinants of longevity in yeast. CR increases life span from yeast to mammals. In addition, orthologs to the yeast-aging genes Hsf1, Rpd3, Sch9, Sir2, Sod1/Sod2, and Tor1/Tor2 similarly modify aging in at least one multicellular eukaryote.

Sir3 and Sir4, promotes transcriptional silencing near telomeres (Aparicio *et al.*, 1991) and silent mating (*HM*) loci (Ivy *et al.*, 1986; Rine and Herskowitz, 1987). Sir2, acting independently of Sir3 and Sir4, localizes to the nucleolus where it transcriptionally represses polIII transcribed genes (Bryk *et al.*, 1997; Smith and Boeke, 1997) and inhibits rDNA recombination (Gottlieb and Esposito, 1989). Deletion of *SIR2* causes an approximately 10-fold increase in rDNA recombination and shortens life span by about 50% (Kaeberlein *et al.*, 1999). Overexpression of *SIR2* in wild-type cells has the opposite effect, resulting in a 30–40% increase in life span, comparable to that observed upon deletion of *FOB1* (Kaeberlein *et al.*, 1999); however, overexpression of *SIR2* fails to further increase the life span of long-lived *fob1Δ* cells, consistent with the model that Sir2 and *Fob1* both impact aging by altering ERC levels.

Sir2 represents the first example of a conserved determinant of longevity that was initially discovered in yeast (Figure 18.2).

Following on the finding that overexpression of Sir2 increases yeast replicative life span, two groups have independently reported that overexpression of the Sir2-orthologs, Sir-2.1 and dSir2, increases life span in the nematode, *Caenorhabditis elegans*, and the fly, *Drosophila melanogaster*, respectively (Rogina and Helfand, 2004; Tissenbaum and Guarente, 2001). While it remains unclear what role, if any, Sir2-like proteins play in mammalian aging, several proteins involved in important cellular processes, including Foxo3a (Motta *et al.*, 2004), p53 (Luo *et al.*, 2001; Vaziri *et al.*, 2001), and PGC1- $\alpha$  (Nemoto *et al.*, 2005), have been suggested as targets for deacetylation by the mammalian Sir2 ortholog, SirT1.

## SIR2 AND CALORIE RESTRICTION

Calorie restriction (CR) is the only intervention demonstrated to increase life span in yeast, worms, flies, and mammals (Kaeberlein and Kennedy, 2005). CR can be accomplished in yeast by reducing the glucose concentration of the growth media, or by a number of genetic models of CR (Table 18.1) thought to mimic the physiological state of the cell under growth on low

## 18. Longevity and Aging in Budding Yeast

TABLE 18.1.

Proposed genetic models of CR in yeast. Growth on low glucose media is the commonly accepted mechanism for CR in yeast. Several mutations (CR alleles) have been described that increase life span and are thought to mimic the physiological response of yeast cells to CR.

Gene(s)	Function	CR Allele(s)
CDC25	RAS GTP/GDP exchange factor	<i>cdc25-10</i> , a temperature-sensitive hypomorphic allele
CYR1 (CDC35)	Adenylate cyclase	<i>cdc35-10</i> , a temperature-sensitive hypomorphic allele
GPA2	GTPase upstream of PKA	<i>gpa2Δ</i>
GPR1	G protein-coupled receptor coupled to GPA2	<i>gpr1Δ</i>
HXK2	Hexokinase	<i>hxk2Δ</i>
SCH9	Akt-like kinase	<i>sch9Δ</i>
TOR1	PI3-like kinase	<i>tor1Δ</i>
TPK1/TPK2/TPK3	Protein kinase A catalytic subunits	<i>tpk1Δ tpk2-63 tpk3Δ</i>

glucose (Kaeberlein *et al.*, 2005a; Lin *et al.*, 2000). CR is reported to increase replicative life span in multiple yeast strain backgrounds from 30 to 50% (e.g., see Anderson *et al.*, 2003a; Anderson *et al.*, 2003b; Kaeberlein *et al.*, 2002a; Kaeberlein *et al.*, 2004a; Kaeberlein *et al.*, 2004b; Lin *et al.*, 2000; Lin *et al.*, 2002), comparable in magnitude to the effect of CR in other organisms (Houthoofd *et al.*, 2003; Lakowski and Hekimi, 1998; Weindruch and Walford, 1988).

The mechanism(s) by which CR increases life span in yeast and other organisms remains a mystery. It was initially proposed that CR slows aging in yeast by activating Sir2 (Lin *et al.*, 2000). This idea was supported by the fact that deletion of *SIR2* prevents life span extension by growth on low glucose (Kaeberlein *et al.*, 2004a) or by genetic models of CR (Lin *et al.*, 2000). Several models have described possible molecular mechanisms by which CR might enhance Sir2 activity, including elevated NAD<sup>+</sup> (a substrate of Sir2), resulting from a metabolic shift toward respiratory growth (Lin *et al.*, 2002); decreased nicotinamide (an inhibitor of Sir2), due to transcriptional up-regulation of the gene coding for nicotinamidase, *PNCI* (Anderson *et al.*, 2003a); and decreased NADH (an inhibitor of Sir2) (Lin *et al.*, 2004).

The link between Sir2 and CR has been called into question, however, with the observation that CR slows aging even in the absence of Sir2, as long as ERC levels are kept low (Kaeberlein *et al.*, 2004b). Deletion of *FOBI* suppresses the short life span of cells lacking Sir2 and dramatically reduces ERC levels, even below that observed in wild-type cells (Kaeberlein *et al.*, 1999). In cells deleted for both *SIR2* and *FOBI*, CR increases life span to a greater extent than in wild-type cells (Kaeberlein *et al.*, 2004b), demonstrating the existence of a Sir2-independent pathway by which CR slows aging. Further support for Sir2 and CR acting in parallel pathways is provided by the observation that growth of cells

overexpressing *SIR2* on reduced glucose media results in an additive increase in life span (Kaeberlein *et al.*, 2004b). It remains to be determined whether CR acts in both a Sir2-dependent and Sir2-independent fashion, or if the longevity effects of CR are completely independent of Sir2.

### CONSERVED NUTRIENT SENSING PATHWAYS AS A MEDIATOR OF CR IN YEAST

The dissociation of Sir2 from CR in yeast has profound implications for the likelihood that downstream molecular events associated with CR are conserved across evolutionarily divergent organisms. It seems certain that ERCs are a mechanism of aging private to yeast, as there is no evidence that ERCs accumulate with age or cause senescence in the cells of multicellular eukaryotes. CR, on the other hand, slows aging in nearly every organism studied. If CR is not regulating yeast longevity by altering ERC levels through up-regulation of Sir2, this raises the possibility that the downstream effectors of CR might also be conserved (Kaeberlein and Kennedy, 2005).

Many of the pathways responsible for mediating the response of yeast cells to limited nutrients are well characterized. Among these pathways, the glucose-activated kinases protein kinase A (PKA) and Sch9 play an important role in replicative aging. Deletion of Sch9 (Fabrizio *et al.*, 2004b; Kaeberlein *et al.*, 2005a) or one of several mutations resulting in decreased PKA activity, including *gpa2Δ*, *gpr1Δ*, *cdc25-10*, and *cyr1-1* (Lin *et al.*, 2000), result in a 30–40% increase in replicative life span. CR by growth on low glucose is known to decrease both PKA and Sch9 activity (Kaeberlein *et al.*, 2005a), suggesting that mutations in these pathways are genetic mimetics of CR.

From an ongoing genome-wide study of yeast replicative aging (Kaeberlein and Kennedy, 2005), we have uncovered evidence that a third nutrient sensing pathway,

defined by the nitrogen responsive kinases Tor1 and Tor2, also plays a profound role in determining replicative life span (Kaeberlein *et al.*, 2005b). Tor1 and Tor2 regulate many of the same downstream targets as Sch9 and PKA, including genes involved in ribosome biogenesis, genes involved in autophagy, regulators of cell size and cell cycle progression, and the stress responsive transcription factors Msn2 and Msn4 (Beck and Hall, 1999). Interestingly, mutations that decrease the activity of Sch9 (Fabrizio *et al.*, 2001) or PKA (Fabrizio *et al.*, 2001) are also reported to increase chronological life span (see Nutrient Sensing and Chronological Aging). The fact that decreased activity of proteins orthologous to Sch9 or Tor1/Tor2 increases life span in worms (Vellai *et al.*, 2003) and flies (Kapahi *et al.*, 2004) indicates the evolutionary conservation of these nutrient responsive kinases as regulators of eukaryotic aging. The potential relevance of these observations is discussed further in Relationship between Replicative and Chronological Aging.

At this point it remains unclear which of the downstream targets shared by these nutrient sensing pathways are ultimately responsible for enhanced longevity in response to CR. The Msn2/Msn4-mediated stress response can be ruled out as necessary for increased replicative life span, since deletion of both *MSN2* and *MSN4* fails to prevent replicative life-span extension in response to either CR (Lin *et al.*, 2000) or deletion of Sch9 (Fabrizio *et al.*, 2004b). Decreased ribosome production or protein translation may be important for the effect of CR on replicative aging, as evidenced by the fact that deletion of individual genes coding for redundant ribosomal subunits is sufficient to confer replicative life-span extension comparable to that of CR (Kaeberlein *et al.*, 2005b). Although the molecular mechanism accounting for this effect remains poorly understood, an intriguing parallel can be drawn between yeast and flies, with the observation that mutation of S6 kinase, which functions downstream of TOR to promote ribosomal function and translation, increases life span in *D. melanogaster* (Kapahi *et al.*, 2004).

#### ADDITIONAL PATHWAYS THAT IMPACT REPLICATIVE AGING

Several additional genes have been suggested to play a role in replicative life-span determination that cannot be easily ascribed to the relatively well-characterized pathways discussed thus far. Many of these genes affect aging in a strain-specific manner, and their relevance is uncertain. This class includes *RTG1*, *RTG3*, *LAG1*, *LAG2*, and *RPD3* (Kaeberlein and Kennedy, 2005). Others, such as *SGS1*, *DNA2*, and *ATP2*, shorten life span when mutated, which could be due to accelerated aging, but this effect is most likely the result of a nonspecific reduction in fitness. Several reviews present a more comprehensive analysis of the aging phenotypes associated with these strain-specific modifiers of life

span (Bitterman *et al.*, 2003; Jazwinski, 2002; Sinclair *et al.*, 1998).

#### Chronological Aging in Yeast

The chronological life span of a yeast cell is defined as the length of time that a cell can maintain viability in a nondividing state. Chronological aging in yeast has been studied using a variety of different methods involving culturing cells into stationary phase, a quiescent state in which cells are metabolically active but nonreplicative. Compared to replicative aging, relatively few genes have been studied with respect to their effect on chronological life span; yet, some of the important pathways regulating this process have already emerged. Unlike laboratory growth conditions, the natural environment of a yeast cell is likely to consist of relatively rare periods of exponential growth followed by prolonged periods of starvation-induced quiescence. Chronological aging may, therefore, play an important part in the ecology of wild yeast populations, as well as provide insight into the aging process of nondividing cells in higher eukaryotes.

#### WHAT DO CHRONOLOGICALLY AGED CELLS DIE FROM?

The chronological life span of a yeast cell begins under conditions highly favorable for growth: low cell density, optimal temperature, high nutrient availability, and the presence of a preferred carbon source (glucose). These conditions allow cells to enter an exponential growth phase, during which cells generate ATP primarily through glycolysis and fermentation of pyruvate to ethanol. As glucose becomes depleted, yeast cells progress through the diauxic shift, a growth phase characterized by large transcriptional changes resulting in enhanced expression of many enzymes involved in the TCA cycle, mitochondrial function, and respiration. Associated with this transition to a less favorable environment is an up-regulation of many stress responsive and antioxidant genes. Eventually, as nutrients are depleted and cell density increases, a postdiauxic stationary phase is achieved in which cells exit from the cell cycle and enter into a G0-like quiescent state.

Entry of yeast cells into stationary phase is accompanied by a starvation response in which storage carbohydrates, such as glycogen and trehalose, are synthesized and maintained at high levels in the cytoplasm (Gray *et al.*, 2004). Storage carbohydrates serve as the main source of energy production during stationary phase (Fabrizio and Longo, 2003) and adequate production of storage carbohydrates is essential for long-term survival. Interestingly, some chronologically long-lived mutants show dramatically increased glycogen stores, even under logarithmic growth conditions, suggesting that depletion of reserve carbohydrates might be one factor resulting in cell death. This idea is supported by one study in which intracellular glycogen and trehalose levels were reported

## 18. Longevity and Aging in Budding Yeast

to decrease dramatically between the second and third week of chronological aging (Samokhvalov *et al.*, 2004). In contrast to this, however, Fabrizio and Longo (Fabrizio and Longo, 2003) have reported that glycogen stores are not significantly depleted even after 70% of cells have senesced during a typical chronological aging experiment. A more comprehensive analysis of reserve carbohydrate levels during chronological aging, particularly in long-lived mutants, will be necessary to definitively address this important question.

A second mechanism by which yeast cells might senesce during chronological aging is apoptosis. Mammalian cells undergo apoptosis in response to specific environmental stimuli, and it has been demonstrated that yeast cells can undergo a similar process (Madeo *et al.*, 2004). Indeed, chronologically aged cells show markers consistent with apoptotic death (Herker *et al.*, 2004). Blocking apoptosis through deletion of the gene coding for yeast caspase, *YCA1*, failed to substantially increase chronological life span, however, indicating that the apoptosis-like event may be a secondary response to the primary lethal event.

Yeast cells maintained in stationary phase generally do not reenter the cell cycle unless diluted into fresh media. On rare occasions, a yeast cell will escape from the stationary phase-induced cell cycle arrest and begin vegetative growth in the aged culture. It has recently been speculated that this “gaspings” effect is an altruistic phenomenon, whereby the majority of cells in an aging population die through a process resembling apoptosis in order to facilitate the outgrowth of a few remaining viable cells (Fabrizio *et al.*, 2004a). The probability that a cell will undergo a “gaspings” event was observed to be inversely correlated with resistance to superoxide and chronological life span, but positively correlated with mutation frequency. These findings suggest a plausible mechanism by which an apoptotic pathway might evolve in a single-celled eukaryote.

A third mechanism by which quiescent yeast cells might senesce is due to damage generated by oxidative stress. The free radical theory of aging posits that one cause of aging is the accumulation of macromolecular damage due to oxidative free radicals (Harman, 1956). There are several lines of evidence suggesting that oxidative damage plays a causal role in the chronological aging process of yeast cells. For example, loss of respiratory capacity increases with time spent in stationary phase, suggesting that mitochondrial damage accumulates during chronological aging (Fabrizio and Longo, 2003). Also consistent with the idea that oxidative damage is correlated with chronological longevity, mutation of either mitochondrial superoxide dismutase (Sod2) or cytosolic superoxide dismutase (Sod1) results in a substantial decrease in stationary phase survival (Longo *et al.*, 1996). Finally, overexpression of both Sod2 and Sod1 increases chronological life span by about 30%, suggesting that oxidative stress is one factor

limiting the survival of quiescent yeast cells (Fabrizio *et al.*, 2003).

### NUTRIENT SENSING AND CHRONOLOGICAL AGING

Based on the hypothesis that oxidative damage is one cause of chronological aging, Fabrizio and Longo carried out a screen for mutants with increased chronological life span by selecting for mutations that confer a survival advantage in the presence of paraquat, a superoxide generating agent (Fabrizio *et al.*, 2001). From this screen two genes were identified that play a central role in regulating chronological aging, *SCH9* and *CYR1*. Sch9 is a nutrient responsive kinase with homology to mammalian Akt proteins, and *CYR1* codes for adenylate cyclase, an activator of PKA. Deletion of Sch9 increases yeast chronological life span by up to 300%, while a partial loss of function allele in *CYR1*, *cyr1::mTn*, increases life span by approximately 70% (Fabrizio *et al.*, 2001). Both of these genes have also been shown to similarly regulate yeast replicative aging (discussed in Conserved nutrient sensing pathways as a mediator of CR in yeast), and RNAi knock-down of the Sch9 ortholog, Sgk-1, increases life span in worms (Hertweck *et al.*, 2004).

### CHRONOLOGICAL AGING AND RESPONSE TO STRESS

It has been proposed that aging in nondividing yeast cells is largely under the control of the transcription factors Msn2 and Msn4 (Fabrizio *et al.*, 2001). Msn2 and Msn4 bind to stress response elements (STRE) contained in the promoters of many genes coding for proteins involved in adaptation to starvation and stress, such as heat shock proteins, catalase, superoxide dismutase, and glycogen and trehalose biosynthetic enzymes (Smith *et al.*, 1998). Msn2 and Msn4 are repressed by the nutrient responsive kinases TOR, PKA, and Sch9, which promote phosphorylation and exclusion of Msn2/4 from the nucleus. Mutation of *CYR1* or deletion of *SCH9* fails to increase chronological life span in an *msn2Δ msn4Δ* double mutant, consistent with the idea the enhanced longevity seen in these mutants is due to activation of Msn2/4-dependent targets (Fabrizio *et al.*, 2001).

In many ways the function of Msn2 and Msn4 as transcriptional regulators of the yeast chronological aging program parallels the role of Daf-16 in the *C. elegans* aging process. Msn2/4 and Daf-16 are downstream targets of pathways that regulate the rate of aging in response to nutrients or growth factors, and both sets of proteins are transcriptional activators of genes involved in stress response and starvation response.

The similarity between yeast chronological aging and adult aging in the nematode is perhaps not surprising, as adult *C. elegans* are thought to be completely postmitotic (with the exception of the germ line). This similarity extends beyond transcriptional regulation in response to nutrients, as evidenced by the fact that at least some of the

downstream effectors impacting longevity are also conserved. As is the case for yeast chronological life span, Daf-16-dependent up-regulation of superoxide dismutase accounts for a portion of the life span extension seen in long-lived insulin/IGF-1 pathway mutants in *C. elegans* (Honda and Honda, 1999), and activation of the heat shock responsive transcription factor Hsf1 increases both chronological life span in yeast (Harris *et al.*, 2001) and adult life span in the nematode (Morley and Morimoto, 2004). Further studies will likely uncover additional shared longevity determinants, and it will be particularly interesting to see how highly conserved the aging process is for nondividing cells in evolutionarily divergent eukaryotes.

### Relationship between Replicative and Chronological Aging

Cells that have been maintained in stationary phase for a sufficient length of time (chronologically aged) demonstrate reduced replicative capacity (Ashrafi *et al.*, 1999), suggesting that chronological and replicative aging are linked in some way. This link appears to be unrelated to ERCs, as chronologically aged cells do not have a detectable increase in ERC levels relative to young cells (Ashrafi *et al.*, 1999). One attractive hypothesis is that accumulation of oxidatively damaged proteins during chronological aging might contribute to premature replicative senescence. It has been reported that oxidatively damaged proteins accumulate with replicative age (Reverter-Branchat *et al.*, 2004); however, thus far, no direct link between oxidative damage and replicative capacity in yeast has been demonstrated. In fact, deletion of *SOD2*, which results in sensitivity to oxidative stress and dramatically shortens chronological life span, has no effect on replicative life span (Kaeberlein *et al.*, 2005a). Thus, it seems unlikely that oxidative damage limits replicative capacity, at least under normal conditions. It may be the case, however, that in chronologically aged cells, an abnormally high level of oxidative damage is sufficient to detrimentally affect replicative capacity.

Another link between replicative and chronological aging is seen in the response of cells to CR. The same nutrient sensing pathways play an important role in determining the rate at which cells age both chronologically and replicatively, as evidenced by the fact that decreased activity of PKA or Sch9 increases both chronological and replicative life span (see Conserved Nutrient Sensing Pathways as a Mediator of CR in Yeast and Nutrient Sensing and Chronological Aging). Intriguingly, the molecular mechanisms by which nutrient depletion slows aging appear to be quite different in dividing and nondividing yeast cells.

The mechanistic divergence for replicative versus chronological life-span extension by CR is of particular interest in light of the fact that CR slows aging in both

**Figure 18.3.** Nutrient responsive pathways that promote aging in yeast. PKA, SCH9, and TOR activate overlapping downstream targets in response to environmental nutrients and limit both replicative and chronological life span. The downstream effectors, although unidentified at present, appear to be different for replicative and chronological aging.

mitotic and postmitotic cells of multicellular organisms. The yeast model provides a molecular explanation for how such a system might have evolved from a unicellular progenitor. TOR, Sch9, and PKA are known to converge on a shared set of downstream targets that impact a variety of cellular processes, including regulation of cell size, metabolic flux through many of the major biosynthetic and degradative pathways, ribosome biosynthesis and translation, and stress response (Figure 18.3).

Through modulation of specific subsets of these downstream targets, it is possible to imagine how aging can be regulated in both dividing and nondividing cells in response to similar environmental parameters, such as nutrient availability.

### Goals and Challenges for the Future

#### EMBRACING DIVERSITY: UNDERSTANDING STRAIN-SPECIFIC DIFFERENCES

As with other model systems used for aging-related research, strain-specific effects due to genetic diversity can have a large impact on longevity and other age-associated phenotypes in yeast. The importance of strain diversity for studies of aging consists of two distinct components. The first component of strain diversity is the large genetic variation between different laboratory strains commonly used in scientific research. Laboratory strains can have dramatically different life spans, ranging from an average of less than 10 generations to nearly 30 generations, for replicative life span (Kaeberlein *et al.*, 2005a). This type of diversity is analogous to that seen between different inbred strains of mice, which also can have substantially different longevity and aging

disease phenotypes. There have been no attempts to systematically characterize strain-specific effects on chronological life span, and only one attempt has been made to determine which genes are strain-specific and which are strain-independent with respect to replicative life span (Kaeberlein *et al.*, 2005a).

The second type of diversity relevant to aging-related research is the genetic divergence between “domesticated” laboratory yeast and wild isolates of *S. cerevisiae*. This type of diversity and its impact on yeast aging is almost completely unstudied. Preliminary analysis of the aging properties of a polyploid lager yeast has been reported (Maskell *et al.*, 2003; Powell *et al.*, 2000), but it is currently unknown whether the same genes and pathways that influence longevity of lab yeast will be shared among yeast obtained from other environments. The aging properties of “wild” yeast obtained from natural populations have not been examined at all. In order to begin to address this question, it will be important to determine whether ERCs accumulate and cause replicative senescence in wild yeast as well as whether CR slows aging in natural isolates.

#### AGING IN OTHER YEAST SPECIES

Given the relative ease of studying aging in *S. cerevisiae*, it is surprising that few aging-related studies have been carried out in other yeast species. The chronological aging assay, in particular, would be easily adapted to a wide variety of budding, filamentous, and fission yeast species. One study examined replicative senescence in the fission yeast *Schizosaccharomyces pombe* (Barker and Walmsley, 1999). Unlike *S. cerevisiae*, cell division in *S. pombe* is morphologically symmetric, making differentiation of mother and daughter cells problematic. By the second division, however, the progenitor mother cell (now two generations old) is both longer and thinner than the daughter cells and can be separated by microdissection from progeny cells in a manner identical to the *S. cerevisiae* replicative life-span assay (see The Replicative Life-Span Assay). Using this method, it was demonstrated that fission yeast undergoes a senescence process with mortality kinetics similar to budding yeast. Unfortunately, no additional studies of this process have been published. A system for studying aging in a yeast species that is evolutionarily divergent from *S. cerevisiae*, such as *S. pombe*, would be of great value, both for verifying the generality of findings and for potentially identifying new determinants of cellular aging.

#### DEVELOPING HIGH-THROUGHPUT METHODOLOGIES FOR LIFE-SPAN ANALYSIS

Until recently, discovery of genetic and environmental determinants of longevity in any organism has been driven largely by gene-specific studies based on prior knowledge or hypotheses. The development of new methods and technologies for moderate to high-throughput longevity phenotyping in yeast offers the promise of analyzing the replicative and chronological aging

properties of thousands of strains simultaneously (see Chapter 10: Application of High-Throughput Technologies to Aging-Related Research). Recently, a method for high-throughput chronological life-span determination carried out in a 96-well format has been developed (T. Powers, M. Kaeberlein, B. Kennedy, S. Fields, unpublished data). This approach should provide the ability to carry out both large-scale genetic screens for mutations that alter chronological life span and screens for small molecules that alter the rate of aging in nondividing cells.

The ability to measure replicative life span in a high-throughput manner has been difficult to develop due to the nature of the replicative life-span assay, which requires the separation of daughter cells from mother cells (see The Replicative Life-Span Assay). Automated microdissection of daughter cells away from mother cells has proven difficult to implement for several reasons, and other methods of enriching for aged cells (for example, see Park *et al.*, (2002)) are not sufficiently stringent to permit quantitative life-span determination. We have recently developed an iterative method that allows for moderate-throughput analysis of replicative life span for ~100 strains at one time (Kaeberlein and Kennedy, 2005). This is an improvement over past efforts; however, development of a true high-throughput method would be of immense value to the field.

The most obvious method by which high-throughput replicative life-span analysis might be accomplished is through the development of a system in which daughter cells are selectively killed. In theory, such a system could be engineered by the expression of a toxic product under the control of a daughter-specific promoter or by the expression of an essential product only in mother cells. In either case, the system would need to be inducible so that the strain can be propagated. The first system of this type to be developed uses the latter approach by expressing an essential gene, *CDC6*, under the control of the mother cell specific *HO* promoter (Jarolim *et al.*, 2004). Unfortunately, this system appears to have serious flaws, as all three mutations observed to increase mother cell survival with this method fail to increase replicative life span as measured by the standard life-span assay (Jarolim *et al.*, 2004). This may be due to a large amount of premature mother cell death, as evidenced by the fact that mother cell life span is shortened by about 70% when *CDC6* is expressed from the *HO* promoter (Jarolim *et al.*, 2004). Although not useful in its current form, this system represents a first step toward the development of a true high-throughput replicative life-span assay.

#### Methods for Measuring Life Span in Yeast

Of all the model systems used in aging-related research, yeast is perhaps the most accessible to a wide variety of scientists. Assays have been developed that allow the measurement of yeast chronological and replicative life span which require little more than a microscope and

an incubator. This section described the most common yeast life-span assays and important considerations when designing an experiment to study yeast aging.

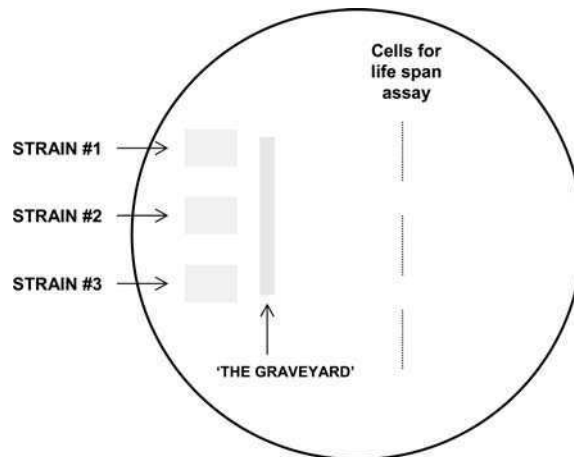

### THE REPLICATIVE LIFE-SPAN ASSAY

The goal of the replicative life-span assay is to determine how many times each mother cell buds before senescence. Cell division in yeast is an asymmetric budding process resulting in the production of a larger mother cell and a smaller daughter cell. The mother and daughter cells can be easily differentiated by an experienced researcher using a standard light microscope (total magnification 160 $\times$ ) such as the Zeiss Axioscope 40 or another comparable model. Physical separation of daughter cells from mother cells is achieved using a manual micromanipulator equipped with a fiber-optic needle (see Recommended Resources for information on obtaining needles). Currently, there is no automated method for determining replicative life span (see Developing High-Throughput Methodologies for Life-Span Analysis).

Prior to initiating the replicative life-span experiment, it is important that all strains to be analyzed are freshly removed from frozen stock and allowed to enter a logarithmic growth phase for several divisions, as growth into stationary phase is known to depress replicative life span (see The Replicative Life-Span Assay). The standard growth conditions for replicative life-span experiments are growth on solid YPD (2% bacto peptone, 1% yeast extract, 2% glucose, 1.7% agar) plates at 30°C. Replicative life-span analysis can also be carried out on synthetically defined medium; however, this is generally not recommended as growth on synthetic media shortens life span dramatically (Jiang *et al.*, 2000), complicating phenotypic analysis (Kaeberlein *et al.*, 2004b). Cells can be placed at 4–10°C overnight, or the experiment can be carried out continuously by maintaining optimal growth temperature. It has been observed in multiple wild-type backgrounds that overnight incubation at a reduced temperature has no significant effect on longevity (Kennedy *et al.*, 1994); although, it is possible that certain mutant backgrounds could be differentially affected by growth at reduced temperature.

There are a variety of similar methods that can be used to prepare cells for a replicative life-span experiment. One preferred method is to remove the strains from frozen stock and allow the formation of small colonies on YPD plates. Cells from a single colony are then patched lightly onto fresh YPD and cultured overnight. The following evening, cells are again patched lightly onto fresh YPD and allowed to grow for approximately 8–12 hours. The patches should be placed near one edge of the plate, and, depending on the number of cells to be analyzed per strain, up to 5 patches can be arranged on the same plate (Figure 18.4).

From this point on, it is essential to keep the plates wrapped in parafilm at all times, except during

**Figure 18.4.** Yeast replicative life-span assay. Strains are lightly patched onto a 100-mm diameter YPD plate and allowed to grow overnight. 40–50 cells from each strain are arrayed for life-span analysis away from the patches. Daughter cells are discarded in “the graveyard” throughout the experiment.

micromanipulation, in order to prevent moisture loss and excessive drying of the agar.

Following the overnight incubation, the cells should be growing under near optimal conditions. The next step is to position the cells away from the patches for life-span analysis. For each strain, transfer approximately 100 cells to a position on the plate distal to the patched cells using the dissecting needle. Then arrange the appropriate number of cells (generally 40–50 per strain) in a line with 1–3 needle diameters ( $\sim 100 \mu\text{m}$ ) between each cell. The cells should be allowed to go through at least one division ( $\sim 2$  hours at 30°C), at which time *daughter cells* should be selected and the mother cells discarded. This guarantees that every cell for which replicative life span is determined started as a virgin cell. From this point on, the life-span assay is an iterative process of allowing the cells to divide 1–2 generations in the incubator; dissecting daughter cells away from mother cells and counting the number of daughters produced by each mother; and discarding daughter cells by moving them to a distal portion of the plate (“the graveyard”). Once all of the mother cells have failed to divide after incubation for greater than 8 hours at 30°C, the experiment is complete. Statistical analysis of replicative life-span data is generally carried out using a Wilcoxon Rank-Sum test to determine whether a significant change in median life span has been observed.

### THE CHRONOLOGICAL AGING ASSAY

In its most general form, the chronological aging assay requires maintaining cells in a nondividing state for a prolonged period of time, while intermittently challenging a subset of the cell population for the ability to reenter the cell cycle and successfully begin vegetative growth. Several variations of this assay have been described (Fabrizio and

## 18. Longevity and Aging in Budding Yeast

Longo, 2003; MacLean *et al.*, 2001), and many others can be imagined. The most commonly utilized variation involves growing cells into stationary phase in chemically defined media with glucose as the carbon source and maintaining the cells in culture for a period of several weeks (Fabrizio and Longo, 2003). An alternative method, in which cells are grown to stationary phase in rich media and then transferred to water, has also been described. A major difference between these two methods is the metabolic state of the cells in the quiescent state; cells aged in synthetic media maintain a high metabolic rate, whereas cells transferred to water from rich media enter a so-called hypometabolic state (Fabrizio and Longo, 2003). Survival time is greatly enhanced for cells maintained in water relative to cells maintained in synthetic media. In general, it has been observed that mutations altering chronological life span in one of these assays have the same effect on life span as measured by the other assay variant; however, this has not been examined in a systematic manner.

In addition to the composition of the culture media, another important variant in the chronological aging assay is the condition under which cells are maintained during aging. Temperature and oxygenation are two of the most important environmental parameters that can alter the rate at which cells age chronologically. The importance of temperature is demonstrated by the observation that chronological longevity of cells maintained in water is substantially reduced as temperature is increased (MacLean *et al.*, 2001). Survival is also reduced as oxygenation is increased. For example, cells cultured in flasks on a rotating shaker have a chronological life span that is up to 50% shorter than cells cultured in a tube on a rotating drum, while cells maintained under low aeration (no agitation) in 96-well plates have a median life span that is extended.

In the chronological aging assay, viability is determined by the fraction of cells reintroduced to favorable growth conditions that successfully reenter the cell cycle (Figure 18.1). The most common method for assaying viability involves removing an aliquot of cells from the aging culture and determining the density of colony forming units (CFUs) by plating onto YPD media. Cells aged in SC media typically reach a saturation density of  $\sim 5 \times 10^7$  CFUs/mL by the third day in culture, which can be considered the initial viability (100%). Over time, the density of CFUs will decrease, with a rate dependent on environmental and genetic parameters, but with median survival on the order of 1–3 weeks.

In most cases, viability for each strain should be determined with time points spaced every 1–2 days. When designing a chronological aging experiment, it is important to determine whether any of the strains being examined exhibits an abnormal growth rate or stationary phase density. Extreme slow growth, in particular, should be taken into consideration when defining time points for viability measurements. Each strain should be analyzed

in triplicate, at least, with replicates grown as independent cultures, rather than measuring viability from the same culture in triplicate at each time point. Stochastic variability in culture conditions and the possibility of “gasping,” a phenomenon where a small fraction of aged cells escapes the G0-like state and takes over the culture population (see What Do Chronologically Aged Cells Die From?), make independent replication essential.

### Conclusion

As with other model organisms, the ultimate utility of yeast as a model for human aging has yet to be determined. Thus far, at least six genes and one environmental intervention (calorie restriction) have been found to increase life span in yeast and similarly impact longevity in one or more multicellular models of aging (Figure 18.2). Although it remains to be seen whether these potential conserved determinants of longevity are affecting aging through a similar mechanism in different organisms, there is reason for optimism that this is, indeed, the case. In particular, the recent findings that highly conserved nutrient responsive kinase pathways regulate aging in both dividing and nondividing yeast cells through divergent downstream components suggest a plausible mechanism by which CR might slow aging in both mitotic and postmitotic cell types of multicellular eukaryotes. Dissecting the genetic and molecular components of these nutrient responsive, longevity-determining pathways in yeast will provide direction for further study in complex systems.

# From Yeast Methuselah Genes to Evolutionary Medicine

Paola Fabrizio and Valter D. Longo

*The recent identification of many genes that regulate the life span of yeast, worms, flies, and mice has greatly enhanced our understanding of the mechanisms of aging. Saccharomyces cerevisiae has emerged as the simplest of the major model systems to study aging, thanks in part to the development of a chronological aging paradigm that has allowed a more direct comparison with higher eukaryotes. Remarkably, similar pathways regulate the chronological life span of yeast and of the other major model systems, suggesting that the “test-tube” approach to study aging and death can provide a simple but valuable contribution to the process of identification of the genes and pathways that regulate aging in humans. Furthermore, comparative studies in unicellular and higher eukaryotes can shed light on the best strategies to delay human aging and prevent age-related diseases without causing significant side-effects.*

## Introduction

Our current knowledge of the genetics of aging has relied greatly on studies in simple model systems such as *S. cerevisiae*, *Caenorhabditis elegans*, and *Drosophila melanogaster*. The recent discovery that aging, similarly to other fundamental biological processes, is regulated by a conserved set of genes has attracted many researchers interested in the basic mechanisms of human aging and diseases to the “model system” field. Yeast are particularly amenable to aging studies because of their relatively short life span, the straightforward genetic manipulation techniques available, and the high-throughput technologies recently developed specifically for this unicellular eukaryote. Yeast life span can be measured as replicative potential (replicative or budding life span) by counting the number of buds produced by individual mother cells (Mortimer, 1959) or chronologically by monitoring mean and maximum survival of populations of nondividing yeast (chronological life span). *C. elegans* represents the second simplest and perhaps the more widely studied model system for aging research. Being made up of only about 1000 somatic cells, it provides the advantages of both a multicellular organism and those

of a relatively simple genetic system. Together with *D. melanogaster*, *C. elegans* is playing a key role in elucidating both the cell autonomous and non-autonomous regulation of aging. The fourth major model system, *Mus musculus*, has the disadvantage of being much more complex and difficult to study but it is obviously an essential system because of its much closer phylogenetic relationship to humans. Thus, yeast, worms, and flies are simple systems—amenable to rapid genetic manipulation, highly characterized—and have a short life span (6 to 60 days). By contrast, the mouse has a much longer life span (30 months and more) and is much more difficult to manipulate genetically, but it is a key model system to begin to face the complexity of human aging and diseases. Given the existence of evolutionary conserved aging pathways (Kenyon, 2001; Longo and Finch, 2003), a possibility offered to the geneticists is to study simple organisms such as yeast, worms, or flies to perform genome-wide screens/selections for long-lived mutants and then test whether analogous mutations can cause similar effects in mice. In fact, some of the proteins whose modified activity was shown to extend the life span of the three simple model systems have been shown to play a similar role in mice. For example, insulin/IGF-1-like pathways have been implicated in the regulation of aging in worms, flies and mice. Notably, homologs of two of the major proteins in the insulin/IGF-1-like pathway in mice were shown to regulate the life span of *S. cerevisiae* (Figure 19.2) (Longo and Finch, 2003). Furthermore, increased antioxidant activity has been shown to cause small but significant extension of the life span of all the genetics model systems of aging (Fabrizio *et al.*, 2003; Harris *et al.*, 2003; Melov *et al.*, 2000; Orr and Sohal, 1994; Parkes *et al.*, 1998; Schriener *et al.*, 2005; Sun and Tower, 1999).

In this chapter we will provide methods to perform yeast chronological survival measurements and comprehensive genome-wide selections to isolate novel long-lived mutants. We will review the genetics of aging in yeast with particular emphasis on the genes that affect the chronological life span. We will also review

the genetics of aging in worms, flies, and mice, focusing mainly on the insulin-IGF-1 signaling and on the conserved characteristics shared by the long-lived mutants of different species.

## The Life Span of Yeast

The chronological life span is determined by measuring the survival time of populations of nondividing yeast. Alternatively, yeast life span is measured by monitoring the replicative potential of single mother cells. Each system has led to the identification of genes involved in either chronological or replicative aging (Bitterman *et al.*, 2003). The activity of the products of some of these genes (*SCH9*, *CYR1*; see The Genetics of Chronological Aging: Yeast Methuselah Genes) consistently affects both replicative and chronological life span (Fabrizio *et al.*, 2004b). Conversely, some genes encoding for stress resistance proteins (*MSN2*, *SOD1/2*) promote chronological longevity but negatively affect replicative life span, suggesting that there is only a partial overlap between the mechanisms that regulate replicative potential and survival of postmitotic yeast (Fabrizio *et al.*, 2004b). In the following section we review both paradigms with emphasis on the chronological life span.

### CHRONOLOGICAL LIFE SPAN: SURVIVAL IN THE POSTDIAUXIC AND STATIONARY PHASES

Microorganisms have evolved to survive under adverse conditions, such as starvation, that are commonly encountered in the wild. In fact, most microorganisms are estimated to survive in a low-metabolism stationary phase under nutrient-depleted conditions (Werner-Washburne *et al.*, 1996). In the wild, yeast organisms are likely to exit stationary phase only during the rare periods when all the nutrients required for growth become available. For this reason we perform most of our experiments in either a medium containing a limited amount of nutrients [synthetic dextrose complete (SDC)] or in water. Wild-type DBY746 or SP1 yeast grown in SDC medium survive 5 to 6 days while maintaining high metabolic rates for the majority of the life span (Figure 19.1).

When yeast grown in SDC are switched to water between days 1 and 5, metabolic rates decrease and survival is extended (Fabrizio *et al.*, 2004a). However, since long-lived mutants isolated by incubation in SDC also live longer when incubated in water, we believe that analogous pathways and mechanisms regulate survival in both paradigms. Yeast grown and incubated in the nutrient-rich YPD medium also survive for months in a low metabolism stationary phase. However, it is not clear whether YPD medium allows some growth to occur during the supposedly “stationary” phase (see Survival in Water/YPD).

To understand how yeast age and to identify conserved pathways that regulate longevity in many eukaryotes,

**Figure 19.1.** Chronological life-span measurement and its use for the isolation of long-lived mutants. Populations of mutagenized yeast or a pool of deletion mutants obtained from the Yeast Knock-out (YKO) collection are grown in minimal medium containing glucose (SDC). After 2–3 days, cell growth stops and ethanol accumulates in the medium. At day 3 yeast are either kept in this ethanol-rich medium or switched to water. Cell viability is measured every two days by diluting the yeast cultures and plating an appropriate number of cells onto rich medium (YPD) plates to monitor the colony forming units (CFUs). When yeast are switched to water, the cultures are washed every two days to avoid the cell division that might be caused by the accumulation of nutrients released from the dead yeast. Mutants that are still alive when the majority of the population is dead are isolated and then retested individually to monitor their mean and maximum life span.

it is of key importance to reproduce conditions similar to those under which these pathways have evolved. Although the chronological life-span paradigm may appear to be a starvation phase that does not resemble the life span of higher eukaryotes, nondividing yeast

are not starving but are slowly utilizing the nutrients stored intracellularly at the end of the growth phase. An environment that lacks nutrients may not be common for certain mammals, but it is very common for microorganisms. In some circumstances even mammals have learned how to respond to long periods of starvation. For example, black bears and turkish hamsters alternate between a high and a low metabolism hibernation phase, in which stored nutrients are utilized to survive. The longer the period turkish hamsters spend under hibernation, the longer the life span (Lyman, 1981). Similarly, yeast forced to enter the low metabolism stationary phase by incubation in water survive longer than yeast grown and incubated in SDC medium, which maintain high metabolic rates (Fabrizio *et al.*, 2004a).

In addition to the high metabolism postdiauxic life span (SDC), and the low metabolism stationary phase, under particularly severe starvation conditions, diploid *S. cerevisiae* can form haploid spores that may survive for years in a dormant state. However, most yeast diploid organisms enter and remain in stationary phase, and only a minority of diploid organisms form spores (Codon *et al.*, 1995). All of our life-span studies are performed using haploid strains that behave similarly to diploid cell under most conditions but do not sporulate. Yeast spores may be the equivalent of the worm dauer larva, which also live much longer than adult worms (Guarente, 2001; Riddle, 1988). The food supply determines whether worms grow and become metabolically active adults or exit development at the L2 larva stage to enter the low-respiration dauer larva stage. In the following sections we will describe how the ability to survive of long-lived *S. cerevisiae* and *C. elegans* mutants appears to be linked to the entry into phases with similarities to starvation-response phases such as the spore or dauer.

#### *Survival in SDC: Postdiauxic phase*

Most of our chronological life-span studies are performed by monitoring survival in the high metabolism postdiauxic phase (SDC medium). The SDC studies are started by diluting overnight cultures to an initial density of  $1\text{--}2 \times 10^6$  cells/ml ( $OD_{600}$  of 0.1–0.2) in 10–50 ml of synthetic complete medium containing 2% glucose (SDC) as well as a 4-fold excess of the supplements Trp, Leu, Ura, and His (for DBY746-derived strains). The SDC medium contains glucose, yeast nitrogen base, agar, ammonium sulfate (nitrogen source), sodium phosphate, vitamins, metals, and salts. Yeast cultures are incubated at 30°C in flasks with a volume/medium ratio of 5:1, shaking at 220 rpm. After approximately 10 hours of growth, the glucose concentration in the medium reaches very low levels, and yeast switch from a fermentation- to a respiration-based metabolism. During fermentative growth, ethanol is accumulated and released from the cells. In wild-type DBY746 and SP1 cultures the level of ethanol undergoes an age-dependent decline, suggesting that it is used as a carbon source

(VL, unpublished results). When yeast organisms are incubated in SDC, the diauxic shift is followed by a postdiauxic phase, in which growth continues slowly until approximately 48 hours, and then stops (Figure 19.1). In the postdiauxic phase metabolic rates remain high until days 4–6 (day 0 = dilution day). The final density reached at day 3 varies from strain to strain and is usually between 7 and 15 ( $OD_{600}$ ). The mean survival of wild-type strains depends on their genetic background and ranges from 6 to 7 days (DBY746 or SP1) to 15–20 days (S288C or BY4700). A diauxic-shift-like switch from fermentation to respiration may also occur after reducing the glucose concentration in the medium from 2 to 0.5%. This form of calorie restriction increases respiration rates and causes an extension of the yeast replicative life span (Lin *et al.*, 2002).

In a standard postdiauxic experiment we monitor survival by measuring the ability of an individual yeast cell/organism to form a colony (colony forming units or CFUs) within three days of plating onto YPD plates. CFUs are normally monitored until at least 99.9% of the population dies. The number of CFUs at day 3 is considered to be the initial survival (100% survival) and is used to determine the age-dependent mortality. Day 3 was selected considering that in our wild-type strains DBY746 and SP1 the population density does not normally increase after day 3, suggesting that the great majority of the cells have stopped dividing. To confirm that the loss of CFUs correlates with death, we have used a live/dead fluorescence assay to monitor the percentage of live cells over time. After staining a sample of cells with the FUN-1 dye, which confers red fluorescence to live cells and green/yellow fluorescence to dead cells, we have estimated the live/dead ratio and found a very significant correlation with the CFUs-based viability data (Fabrizio *et al.*, 2003).

The “postdiauxic phase” differs for organisms incubated in SDC and those incubated in rich YPD medium (Werner-Washburne *et al.*, 1996). In fact, incubation in YPD promotes a 6–7 day postdiauxic phase characterized by slow growth and low respiration followed by entry into a nondividing hypometabolic stationary phase in which organisms are highly resistant to multiple stresses and survive for up to 3 months. By contrast, incubation in SDC triggers the entry into an alternative postdiauxic phase in which only minimal growth occurs after 48 hours and metabolic rates remain high until the population begins to die.

#### *Survival in water/YPD: Stationary phase*

Yeast incubated in YPD or water survive much longer than yeast grown and maintained in SDC/ethanol medium (Figure 19.1). In fact, the mean life span of strains DBY746 and SP1 in water is approximately 3 times longer than in SDC (15–20 days). Our experiments are usually repeated in water to simulate an alternate environment that may be commonly encountered by

yeast in the wild and also to confirm that the extended life span of a particular mutant is not an artifact caused by regrowth. In fact, we do not monitor survival in YPD, since this rich medium may promote growth after the culture reaches the maximum density. After more than 99% of wild-type DBY746 and SP1 yeast incubated in SDC dies, in about 50% of the studies a better-adapted subpopulation is able to grow back by utilizing the nutrients released by dead cells (Fabrizio *et al.*, 2004a). A similar phenomenon called “gaspig” is observed for populations of bacteria (Zambrano and Kolter, 1996). By contrast, incubation of yeast in YPD appears to promote major increases in viability before the majority of the population has died, suggesting that some growth may occur when viability is high. Growth would create a mixed population containing both young and old organisms and possibly only young organisms, which would invalidate the survival studies.

For life-span studies in water, yeast are grown in and incubated for 3 days in SDC and are then washed with sterile distilled water and resuspended in sterile water (Figure 19.1). Viability is monitored by measuring CFUs every 2 days. The cells are washed 3 times with water every 2 days to remove all the nutrients released by dead yeast. Incubation in water and the removal of nutrients released by dead organisms minimize the chance of growth during long-term survival in stationary phase. Incubation in water decreases metabolic rates and may increase life span simply by promoting a slower rate of senescence.

### REPLICATIVE LIFE SPAN

The asymmetrical division characteristic of *S. cerevisiae* is an essential for replicative life-span measurements. Daughter cells are normally smaller than mother cells and can be easily distinguished and removed from their progenitors by micromanipulation (Mortimer, 1959). The average replicative life span is 20 divisions. “Replicative aged” cells divide more slowly, become sterile, and when cell division stops, they are considered dead, although their postreproductive survival time has never been estimated (Bitterman *et al.*, 2003). Whereas few genes are known to regulate both life spans, the relationship between replicative and chronological aging has yet to be established. Notably, yeast replicative life span is analogous to the replicative life span of mammalian fibroblasts and lymphocytes, which undergo a limited number of population doublings in culture. Thus, the “budding life span” is a model for studying aging of mitotic cells but can also provide insights on fundamental mechanisms of organismal aging.

Replicative aging can be caused by a form of genomic instability that leads to the accumulation of extrachromosomal ribosomal DNA circles (ERCs) (Sinclair and Guarente, 1997) and is delayed by increasing the activity of the silencing regulator Sir2

(Kaeberlein *et al.*, 1999). Sir2 is a NAD-dependent histone-deacetylase whose activity is required to promote chromatin silencing at the telomeres, mating type loci, and rDNA (Braunstein *et al.*, 1993; Tanny *et al.*, 1999). Increased dosage of *SIR2* delays replicative aging by inhibiting rDNA recombination and consequently the formation of ERCs (Kaeberlein *et al.*, 1999). Although this aging mechanism has not been observed in any other species, Sir2 was shown to play a conserved antiaging role in higher eukaryotes. In fact, increased dosage of the Sir2 homologs extends the life span of both *C. elegans* and *Drosophila* by up to 50%, and Sir2 activity has been associated with the longevity extension caused by calorie restriction—an intervention known to extend the life span of all model organisms (Rogina and Helfand, 2004; Tissenbaum and Guarente, 2001; Wood *et al.*, 2004). However, despite the extensive experimental effort to link the Sir2 family of proteins (sirtuins) to mammalian longevity, a conclusive role for the sirtuins in mediating life-span regulation has not been established.

Other genes implicated in the regulation of replicative aging have been identified. Among these are *RAS1/RAS2* and *LAG1/LAG2*. *RAS1* and *RAS2*, which encode for highly conserved pro-growth signaling G-protein, play opposite roles in replicative aging. The deletion of *RAS1* extends replicative life span. By contrast, lack of *RAS2* shortens replicative longevity (Sun *et al.*, 1994). Intriguingly, lack of Ras2 promotes chronological survival (see The Genetics of Chronological Aging: Yeast Methuselah Genes). Deletion of Lag1, a protein implicated in ceramides synthesis, extends replicative life span, and so does the overexpression of Lag2, a protein of unknown function (D’Mello N *et al.*, 1994).

The activation of the retrograde response also triggers replicative life-span extension. This response is activated by an intracellular signaling pathway from the mitochondrion to the nucleus and leads to the transcription of several genes encoding for metabolic enzymes (Kirchman *et al.*, 1999).

### The Genetics of Chronological Aging: Yeast Methuselah Genes

Using this aging paradigm, we have identified several mutations that promote life-span extension and resistance to both heat and oxidative stress. Among these is the deletion of the gene coding for the serine–threonine kinase Sch9. Lack of Sch9 promotes high-stress resistance and extends the life span up to 3-fold (Fabrizio *et al.*, 2001). Sch9 is part of a glucose-sensing pathway, which regulates cell division, cell size, ribosomal synthesis, and the expression of stress resistance proteins including mitochondrial superoxide dismutase (Sod2) (Fabrizio *et al.*, 2003; Jorgensen *et al.*, 2002; Jorgensen *et al.*,

2004; Toda *et al.*, 1988). Importantly, Sch9 appears to be a homolog of Akt/PKB, a component of the conserved pro-aging pathways of worms, flies and mice (see Evolutionary Conserved Pro-Aging Pathways) (Geyskens *et al.*, 2000) (Figure 19.2–19.3).

Another glucose-sensing pathway known to regulate chronological aging is the Cyr1/Ras/PKA pathway. A reduced activity of adenylate cyclase (Cyr1) promotes stress resistance and longevity, and so does the deletion of *RAS2*, (Fabrizio *et al.*, 2003; Fabrizio *et al.*, 2001). The down-regulation of the Ras/PKA pathway promotes chronological survival via the activation of stress resistance transcription factors Msn2/Msn4 (Fabrizio *et al.*, 2001), which in turn activate the expression of the detoxifying enzymes catalase and superoxide dismutase and of several heat shock proteins and promote the accumulation of reserve carbohydrate glycogen (Boy-Marcotte *et al.*, 1998; Schmitt, 1996; Smith *et al.*, 1998) (Figure 19.2). The Sch9 and Ras/PKA pathways share several gene targets although in some cases their regulation of gene expression is opposite (Roosen *et al.*, 2005). The exact relationship between these two pathways is still unclear mainly because the Sch9 pathway components upstream and downstream of Sch9 have been elusive. A recent *in vitro* study showed that the protein kinase Pkh1 can phosphorylate and activate Sch9 and that this activation is stimulated by phytosphingosine (Liu *et al.*, 2005). This is important because Pkh1 is a yeast homolog of PDK1, a protein also found in the pro-aging insulin/IGF-1 pathways of worms, flies, and mice and supports the hypothesis that the Sch9 and the insulin/IGF-1 pathways originated from a common ancestral pathway (Evolutionary Conserved Pro-Aging Pathways; Figure 19.2).

The ability to withstand oxidative stress is one of the conserved features of long-lived mutants (see Evolutionary Conserved Pro-Aging Pathways). We have shown that Sod2 functions as a mediator of longevity extension in both the Ras and Sch9 pathway and is required for chronological longevity extension (Fabrizio *et al.*, 2003). In fact, the TCA cycle enzyme aconitase is a key target of mitochondrial superoxide toxicity, and loss of aconitase activity precedes death in yeast aging chronologically (Fabrizio *et al.*, 2003; Fabrizio *et al.*, 2001).

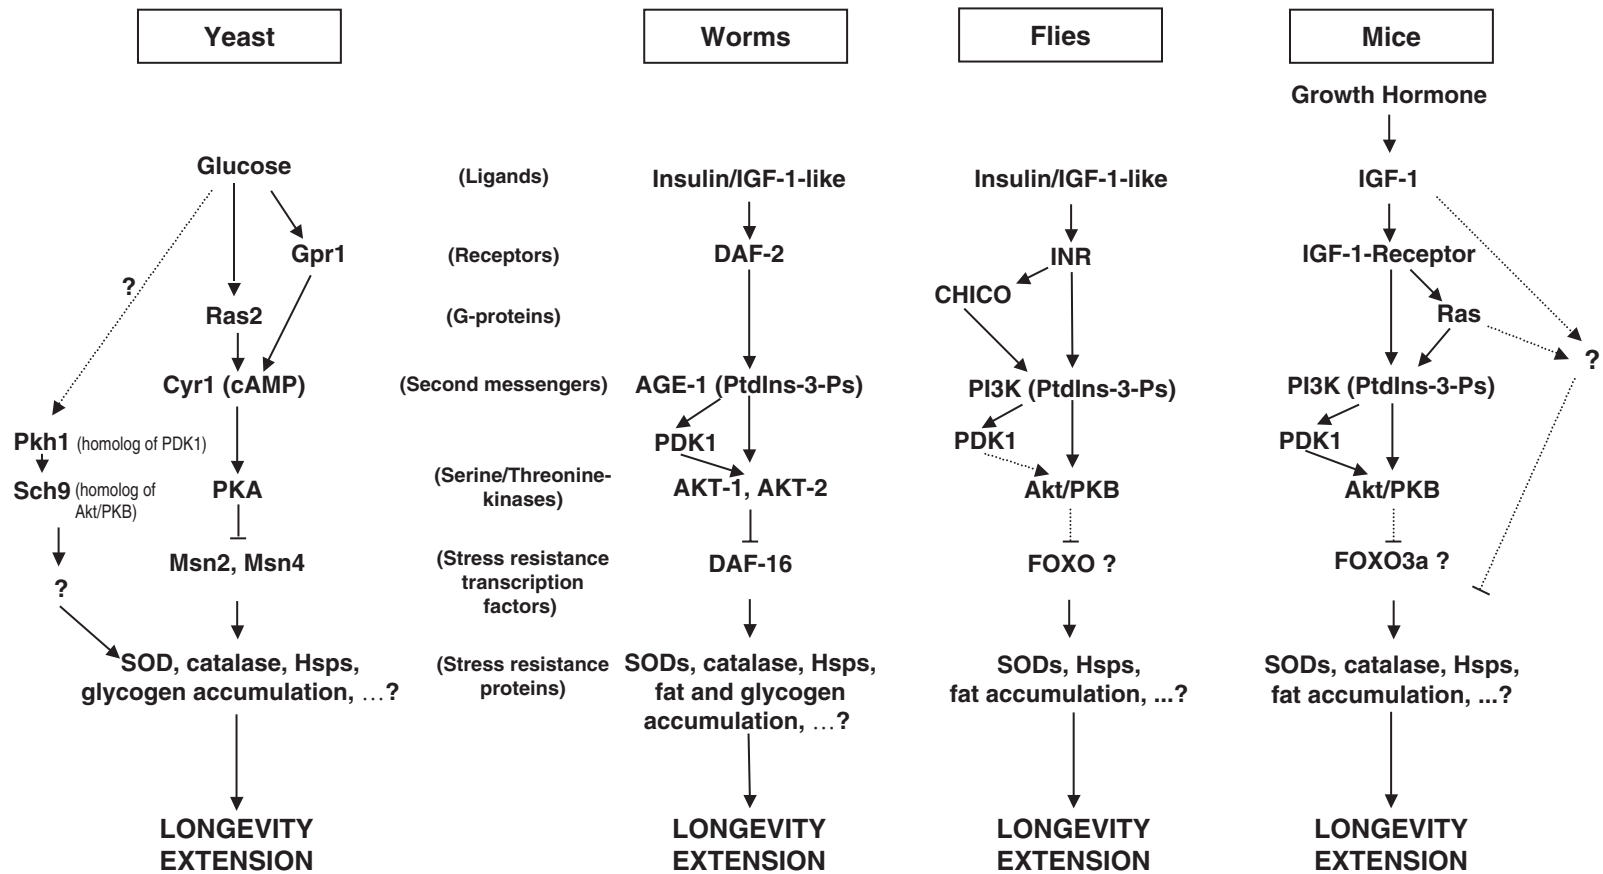

The activity of the Hsp90 chaperone also affects chronological survival. Reducing the activity of Hsp82, one of the yeast Hsp90 proteins, extends chronological life span by overactivating the heat-shock transcription factor HSF1 and consequently the heat shock response (Harris *et al.*, 2001). Further genes involved in the regulation of chronological aging are *YAPI*, *YCA1*, and *AIF1*. Overexpression of *YAPI*, which encodes for an oxygen stress response transcription factor, reduces the accumulation of reactive oxygen species during chronological aging and promotes life-span extension (Herker *et al.*, 2004). Deletion of either *YCA1*, coding

for a yeast caspase, or *AIF1*, coding for a homolog of the mammalian apoptosis-inducing factor (AIF), extends chronological survival (Madeo *et al.*, 2002; Wissing *et al.*, 2004).

### Novel Methods for the Identification of Genes that Regulate Chronological Aging

Chronological life-span experiments are conducted using yeast cultures of billions of organisms and are very well suited for the screening of long-lived mutants. In the past we used a transposon mutagenesis technique to generate a pool of yeast carrying mutations that decrease or abolish the expression of the corresponding genes. The mutagenized population was subject to either heat shock or a treatment with the superoxide generator paraquat to select for stress resistance mutants, which were subsequently tested for chronological survival in SDC. Yeast that were viable after 9–15 days were isolated and retested individually to monitor their survival (Fabrizio *et al.*, 2001). The identification of the insertions associated with life-span extension was obtained by sequencing the region adjacent to the transposon, a rather straightforward technique. The approach of preselecting the stress resistant mutants was based on the association between ability to withstand stress and life-span extension, which applies to all model organisms, and allowed us to reduce the representation of non-long lived mutants (false positives) among the day 9–15 survivors.

Recently a more sophisticated genetic tool to study how each individual gene can affect the life span of yeast has become available: the yeast knock-out (YKO) collection. Currently, the collection covers 96% of the yeast open reading frames (ORFs) and is constructed in a way that each deletion represents a complete loss of function of the gene and is uniquely tagged with two 20-nucleotide sequences (UPTAG and DNTAG) (Wach *et al.*, 1994). The abundance of specific deletion mutants in a pool can be measured quantitatively by amplifying the tag sequences and hybridizing them to a high-density oligonucleotide arrays (Affymetrix Tag3) (Giaever *et al.*, 2002). Once completed, the yeast gene-deletion collection will overcome the main limitation of the standard mutagenesis methods used for mutant screening—under-representing the yeast genome. However, with only 4% of the ORFs missing, the YKO collection already represents a remarkable genetic tool for a comprehensive genomic analysis of chronological aging. In a typical experiment, a pool generated using approximately the same number of cells for each deletion strain is (~600) grown in SDC, and viability is measured every 48 hours as described in Survival in SDC: Postdiauxic Phase. Every 48 hours samples of yeast (OD = 0.2–2) are collected and genomic DNA is extracted. 0.2  $\mu$ g of DNA is used to amplify the UPTAG and DNTAG molecular bar codes in two

**Figure 19.2.** Conserved regulation of longevity. In yeast, worms, flies, and mice the down-regulation of partially conserved glucose or insulin/ insulin-like growth factor 1 (IGF-1) pathways promotes the expression of antioxidant enzymes and heat-shock proteins, induces the accumulation of glycogen or fat, and extends life span. In yeast and worms the induction of stress resistance is required for longevity extension. In flies and mice a conclusive role for stress resistance induction in promoting life span has not been established yet. Sch9 and Pkh1 are functional homologs of Akt1 and PDK1, respectively.

**Figure 19.3.** Wild-type (left) and long-lived “dwarf” (right) yeast, flies and mice with mutations that decrease glucose or insulin/IGF-1-like signaling. Yeast *sch9* null mutants form smaller colonies (left panel). *sch9* mutants are also smaller in size, grow at a slower rate, and survive three times longer than wild-type yeast. *Chico* homozygous mutant female flies are dwarfs and exhibit an increase in life span of up to 50% (center panel) (figure provided by D. Gems). *Chico* functions in the fly insulin/IGF-1-like signaling pathway. The GHR/BP mice are dwarfs deficient in IGF-1 and exhibit a 50% increase in life span (right panel) (figure provided by A. Bartke). Other yeast and worm mutants exhibit life-span extension of more than 100% but do not have detectable growth defects. (Figure reproduced from *Science*, Vol. 299, pp. 1342–1346, 2003.)

separate PCR reactions. The UPTAG amplification uses primers B-U1 (5'biotin-GATGTCCACGAGGTCTCT) and B-U2-comp (5'biotin-GTCGACCTGCAGCGTACG); the DNTAG amplification uses B-D1 (5'biotin-CGGTGTCCGGTCTCGTAG) and B-D2-comp (5'biotin-CGAGCTCGAATTCATCG). Biotinylated amplicons are combined and used to probe high-density oligonucleotide arrays. The arrays are stained with phycoerythrin–streptavidin and scanned at an emission wavelength of 560 nm. The enrichment or depletion of any specific deletion over time is determined by monitoring the changes in TAG intensities after normalizing using day 3 arrays. Based on the relative abundance of each strain on a time course, it is possible to identify genes whose expression is required for long-term survival (the corresponding deletion mutants disappear early in the experiment), and genes whose activity reduces the life span (the corresponding deletion mutants are found in the pool after the death of the majority of the population). We expect that most deletions will have either no effect or a negative effect on life span and that only a few deletions will cause major increases in life span. However, this method should allow an accurate classification of each deletion based on its negative, positive or neutral effect on survival. After identifying the potential long-lived deletion mutants, we will test each of them individually to confirm their life-span extension phenotype. We predict that this system will allow us to identify novel long-lived deletion mutants we previously missed because of the limitations of the mutagenesis method used.

### Evolutionary Conserved Pro-Aging Pathways

Research conducted in the last decade has shown that aging is genetically regulated. More importantly, similar pro-aging pathways have been identified in all model organisms, suggesting that a strategy to regulate life span

may have appeared early during evolution (Kenyon, 2001; Longo and Finch, 2003) (Figures 19.2–19.3).

As described in *The Genetics of Chronological Aging: Yeast Methuselah Genes*, two glucose-sensing pathways are responsible for the regulation of chronological aging in yeast: the Sch9 and the Ras/PKA pathways (Figure 19.2). Down-regulating the activity of these pathways promotes life-span extension by increasing thermotolerance and oxidative stress resistance and possibly by reducing cell metabolism (Fabrizio *et al.*, 2003; Fabrizio *et al.*, 2001).

Research conducted in *C. elegans* has identified the insulin/IGF-1-like pathway as a major pro-aging pathway (Figure 19.2). The similarities between yeast and worm aging pathways are remarkable. Analogously to the yeast Ras/PKA pathway, the insulin/IGF-1-like pathway senses the presence of nutrients and regulates entry into a hypometabolic stage (dauer larva) (Kimura *et al.*, 1997). Worm life span can be extended up to three times by reducing the activity of some of the components of the insulin/IGF-1-like pathway such as the cellular receptor DAF-2 and PI-3 kinase AGE-1 (Kimura *et al.*, 1997; Morris, 1996). Importantly, AGE-1 activates kinase Akt/PKB, which was shown to be homolog of yeast Sch9 and can also be activated by PDK-1, homolog of yeast Pkh1 (Figure 19.2) (Paradis *et al.*, 1999). Life-span extension in both *daf-2* and *age-1* mutants requires the activity of stress resistance transcription factor DAF-16, which belongs to the FOXO family transcription factors, and of the heat-shock transcription factor HSF-1, a highly conserved heat-shock protein (Hsu *et al.*, 2003; Ogg *et al.*, 1997). The mediators of longevity extension downstream of DAF-16 are also partially conserved between yeast and worms and include mitochondrial superoxide dismutase, catalase, and several heat-shock proteins (Figure 19.2). Long-lived mutants of both species store carbon in the form of glycogen (yeast and worm) or fat (worm).

The insulin-IGF-1 pathway has also been linked to the regulation of aging in *Drosophila* (Figures 19.2–19.3).

Reducing the activity of this pathway by mutating the insulin receptor (*InR*) or the insulin receptor substrate (*chico*) extends the life span of fruit fly by up to 85%. This life-span extension is associated with increased levels of superoxide dismutase activity and fat accumulation (Figure 19.2) (Clancy *et al.*, 2001; Tatar *et al.*, 2001). Notably, as shown in yeast, the mitochondrial enzyme aconitase is oxidatively modified and inactivated in old flies (see The Genetics of Chronological Aging: Yeast Methuselah Genes) (Yan *et al.*, 1997). Thus, impairing mitochondrial respiration by inactivating aconitase appears to be an age-dependent phenomenon shared between species, increasing superoxide dismutase activity—a common mechanism that contributes to longevity extension. Consistently, the overexpression of *SOD1/SOD2* in yeast and flies causes a modest but significant extension of life span (Fabrizio *et al.*, 2003; Orr and Sohal, 1994; Parkes *et al.*, 1998; Sun and Tower, 1999). The life span of *Drosophila* is also extended by overexpressing dFOXO, homolog of the worm DAF-16, in the peripheral fat body (Giannakou *et al.*, 2004; Hwangbo *et al.*, 2004).

Mammals have separate receptors for IGF-1 and insulin. Research in mice has connected both receptors to life-span regulation. Dwarf mice with defective pituitary gland, consequently deficient in growth hormone (GH), IGF-1, and insulin, live up to 65% longer than the wild type and are stress resistant (Brown-Borg *et al.*, 1996; Flurkey *et al.*, 2002) (Figures 19.2–19.3). The effect of dwarf mutations on life span appears to be caused by reduction in GH and IGF-I signaling. In fact, mice lacking the GH receptor are long-lived (Coschigano *et al.*, 2000), and IGF-1 receptor heterozygous knock-out mice live 30% longer than the wild type (Holzenberger *et al.*, 2003). Furthermore, mice lacking the insulin receptor in the adipose tissue live 18% longer than the wild type (Bluher *et al.*, 2003). Stress resistance also appears to be regulated by GH and IGF-I. In fact, the activities of superoxide dismutases and catalase are decreased after exposure of murine hepatocytes to GH or IGF-1 and in transgenic mice overexpressing GH (Brown-Borg and Rakoczy, 2000; Brown-Borg *et al.*, 2002). Like the worm *daf-2* and the fly *InR* mutants, dwarf mice accumulate fat, suggesting that the accumulation of reserve carbon sources is an important and conserved portion of a maintenance mode aimed at slowing down aging and surviving through periods of starvation. Analogously, long-lived yeast mutants accumulate glycogen, their main reserve carbon source during starvation. Mammalian FOXOs transcription factors, homologs of the life-span extending DAF-16 and dFOXO transcription factors, have not been conclusively linked with life-span regulation in mammals. However, FOXO activity is associated with increased stress resistance and elevated mitochondrial superoxide dismutase activity in quiescent cells (Figure 19.2) (Kops *et al.*, 2002).

Taken together, the remarkable similarities between the life-span regulatory pathways of organisms ranging from yeast to mice suggest that they may have originated from a common ancestral pathway that regulated mechanisms of cell maintenance, protection against stress, and carbon storage in order to minimize aging during periods of starvation.

## Conclusions

Ten years ago the genes and pathways that regulate the chronological life span of eukaryotes were unknown. Since then, studies mostly performed in *S. cerevisiae*, *C. elegans*, *Drosophila*, and mice have resulted in the identification of many genes and a few conserved pathways that can be activated or inactivated to extend the life span of the organism. These pathways also regulate stress resistance, the storage of reserve carbon sources, and entry into hypometabolic starvation response phases.

Worms, flies and mice are excellent model systems to study aging because of their progressively closer relationship to humans. By contrast, the unicellular *S. cerevisiae* is a valuable model system because it is very simple and amenable to powerful techniques and technologies such as transposon mutagenesis and high-density oligonucleotide genome-wide arrays of tagged deletion mutations. The information on the function or putative function of the majority of *S. cerevisiae* proteins contributes further to making this unicellular eukaryote one of the simplest and most valuable model systems to study the fundamental mechanisms of aging. Whereas aging in *S. cerevisiae* has been studied for 50 years by measuring the number of buds generated by an individual mother cell, studies of the chronological life span of yeast populations have been mostly published in the past 10 years. These studies have indicated that yeast and higher eukaryotes use similar “molecular strategies” to regulate entry into maintenance phases that extend life span. These strategies, which include down-regulation of glucose- or IGF-I-like receptor activated signal transduction proteins, up-regulation of antioxidant enzymes and heat shock proteins, and increased storage of reserve nutrients, are likely to also extend to many additional biological processes including repair and replacement systems. We predict that we will continue to observe many similarities and some differences between the genes and pathways that regulate aging and life span in yeast and higher eukaryotes. An important aim should be to determine whether the knowledge of these conserved “antiaging” pathways can be applied to the development of drugs that cause a switch to an antidisease mode in humans. Whereas modern medicine is focused on the treatment of diseases, the identification of Methuselah genes could ignite a novel “evolutionary medicine” approach in which multiple diseases of aging including cancer, Alzheimer’s, and cardiovascular diseases are prevented pharmacologically.

# Strongyloides ratti: A Nematode with Extraordinary Plasticity in Aging

Michael P. Gardner, Mark E. Viney and David Gems

*Aging has been characterized in detail in relatively few animal species. Here we describe the aging process of a nematode with an unusual life cycle, Strongyloides ratti. This organism has distinct parasitic and free-living reproductive adult forms, which are genetically identical. S. ratti exhibits a remarkably high degree of phenotypic plasticity of aging: the maximum lifespan of parasitic adults is 80 times greater than that of free-living adults (403 and 5 days, respectively). Free-living S. ratti adults are short-lived even by terrestrial nematode standards; their lifespan is approximately only 30% of that of the short-lived free-living nematode model species C. elegans. Phenomenologically, aging appears similar in S. ratti free-living adults and C. elegans, except that it unfolds much more rapidly in S. ratti. Demographic senescence (a hallmark of aging) occurs in free-living S. ratti, with a mortality rate doubling time (MRDT) of  $0.8 \pm 0.1$  days (females), compared with  $2.0 \pm 0.3$  in C. elegans. Likewise, parasitic S. ratti undergo senescence, but have an MRDT approximately 30 times greater than that of free-living adults of S. ratti. Among nematodes, parasitic species are generally longer-lived than free-living species. This presumably reflects the evolutionary consequences of differences in levels extrinsic mortality experienced in their respective niches. Here, we describe in detail the aging process in the two adult forms of S. ratti and explore how these different lifespans might have evolved, despite sharing the same genome. In this species, an evolved and vast difference in the rate of aging appears to be determined by gene expression alone. This implies that, at least in this one species, "late-acting deleterious mutations" correspond to regulated differences in gene expression that generate a shorter lifespan. Potentially, differences in lifespan between species might evolve via similar mechanisms, involving mutationally driven alterations in gene expression.*

## Introduction

Our understanding of aging in certain model species such as the nematode *Caenorhabditis elegans*, the fruitfly *Drosophila melanogaster*, and the mouse is well advanced

(Longo and Finch, 2003). However, there are still relatively few animal species for which there are even basic descriptions of how they age. Among nematodes, patterns of aging are highly diverse, and lifespans can vary over more than a 1,000 fold range (Gems, 2001). *Strongyloides ratti*, the subject of this chapter, is a nematode that has previously been used as a model organism in parasitological studies (Grove, 1989). As a biogerontological model, it is attractive because of its unique level of phenotypic plasticity in aging and the genetics of its life cycle.

Much has been learned about the genetics of lifespan by the use of mutational studies in model organisms. In *C. elegans*, increases in lifespan of up to 7-fold have been observed in long-lived mutants (Houthoofd *et al.*, 2004). While substantial, such differences are relatively small, compared with evolved differences in lifespan between different animal species. The genetic basis of such evolved differences remains unknown. It is also unclear whether similar genes and mechanisms underlie both the altered aging in model organisms as uncovered by the analysis of mutants and the evolved differences in aging between different species. These issues may be explored via a comparative approach and through insights gained into the biology of aging from the existing diversity in evolved patterns of aging in the animal kingdom. Thus, it is worthwhile to study the basic phenomenology of aging in species with interesting life histories, such as *S. ratti*.

Many animal species show phenotypic plasticity in aging, of which there are two major types. The first is the relatively limited response to a changing environment by a given stage in the life cycle. For example, dietary restriction extends lifespan in many species, including rodents (McCay *et al.*, 1935), *Drosophila* (Nusbaum and Rose, 1999), and *C. elegans* (Lakowski and Hekimi, 1998). A more dramatic form of phenotypic plasticity in aging is associated with the development of different morphs within a given life cycle. For example, in *C. elegans* there is a facultative diapausal form of the third-stage larva, known as the dauer larva. This long-lived stress-resistant dispersal form develops when food is scarce and population density high (Golden and Riddle, 1984) and can survive for up to 3 months (Klass and Hirsh, 1976). This compares to a two- or three-week

lifespan in *C. elegans* adults (Klass, 1977). Striking differences in lifespan between adult morphs also occur in social insects (Finch, 1990), where honey bee queens survive for up to 40-times longer than genetically identical summer worker bees. Understanding the evolutionary and physiological determinants of such plasticity of aging and lifespan can provide insight into the biology of aging.

In this chapter we review what is known about *S. ratti* aging. We describe optimization of culture conditions for aging studies, environmental factors that affect lifespan, and age changes in behavior, pathology and mortality that accompany aging in this unusual nematode. In the concluding section, we consider the question of how the phenotypic plasticity in *S. ratti* may have evolved.

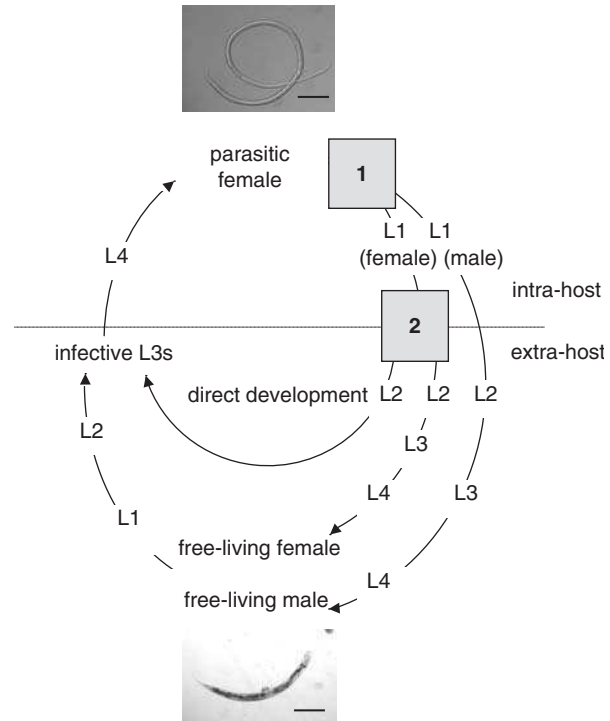

## Aging in *S. ratti*

### WHAT IS *S. RATTI*?

*Strongyloides* is a genus of parasitic nematodes that infect a wide variety of vertebrates (mammals, birds, amphibians, reptiles); two species (*S. stercoralis* and *S. fuelleborni*) infect humans (Speare, 1989). Some 50 million individuals are infected with *Strongyloides* spp. worldwide (Grove, 1989). For most individuals there are often no overt signs of infection. However, in individuals that are immunocompromised the infection can disseminate throughout the body and is fatal in the absence of anti-*Strongyloides* therapy. *S. ratti* has been used for some years as a model organism for investigating the biology of nematode parasitic infections (Viney, 1999).

*Strongyloides* spp. have an unusual and complex life cycle involving both free-living and parasitic phases (Figure 20.1).

Parasitic adult females dwell in the gut of the host (which in the case of *S. ratti*, as its name implies, is the rat). Here they burrow into the intestinal mucosa and reproduce by mitotic parthenogenesis (Viney, 1994), passing eggs via the feces into the external environment. These eggs can either moult through two larval stages into infective third-stage larvae (iL3s) or through four larval stages into free-living adult females and males (Figure 20.1). These adults mate by conventional sexual reproduction and produce progeny which (as above) can develop into iL3s (Viney *et al.*, 1993; Harvey *et al.*, 2000). Infective L3s infect new hosts by skin penetration. Experimental genetic studies found that reproduction of the parasitic females of *S. ratti* is functionally mitotic (Viney, 1994), and so the progeny of the parasitic female are genetically identical to each other and to their mother. Anecdotal observations had noted a large difference in the lifespan potential of the adult free-living and parasitic female morphs: approximately one week and one year, respectively (Viney, 1994; Gemill *et al.*, 1997).

**Figure 20.1.** Life cycle of *Strongyloides ratti* with two discrete developmental switches, shown as grey boxes: (1) a sex determination event; (2) a female-only developmental switch. Adapted from Harvey *et al.*, (2000). Also included are larval stages L1–L4. The life cycle contains both parasitic and free-living generations; an adult parasitic female (left) and free-living adult female (right). Bars = 200  $\mu$ m.

However, the role of aging in this apparent difference was unknown.

### CULTURE CONDITIONS FOR *S. RATTI*

#### *Parasitic S. ratti*

The parasitic stages of *S. ratti* are maintained in the laboratory by infecting rats. Immunologically normal animals mount an immune response against these infections, such that the infections are lost after four to six weeks (Wilkes *et al.*, 2004). However, long-term infections can be established in immunologically deficient (nude) rats (Gemill *et al.*, 1997). Feces collected from infected rats contain the eggs or first-stage larvae. These feces can be collected and used to make fecal cultures, from which all the free-living stages of the life cycle can be grown. Infective L3s obtained from such cultures are used to initiate new infections, which is done by the subcutaneous administration of iL3s to naïve rats (Gemill *et al.*, 1997; Wilkes *et al.*, 2004).

#### *Free-living S. ratti*

For the analysis of aging and lifespan, the culture conditions used for the free-living adult *S. ratti* are

## 20. *Strongyloides ratti*: A Nematode with Extraordinary Plasticity in Aging

based on those used for *C. elegans*. The latter are typically maintained on NGM agar seeded with *Escherichia coli* strain OP50 (a uracil auxotroph) as a food source (Sulston and Hodgkin, 1988). For *S. ratti*, L4 female and male worms are taken from 2-day old rat fecal cultures (19°C), cleaned by repeated washing in sterile distilled water to remove associated bacteria, and then introduced onto NGM plates under optimized culture conditions (see below). To measure lifespan, survival of the free-living stages of *S. ratti* is measured at least daily, with scoring for death as described for *C. elegans* (Klass, 1977).

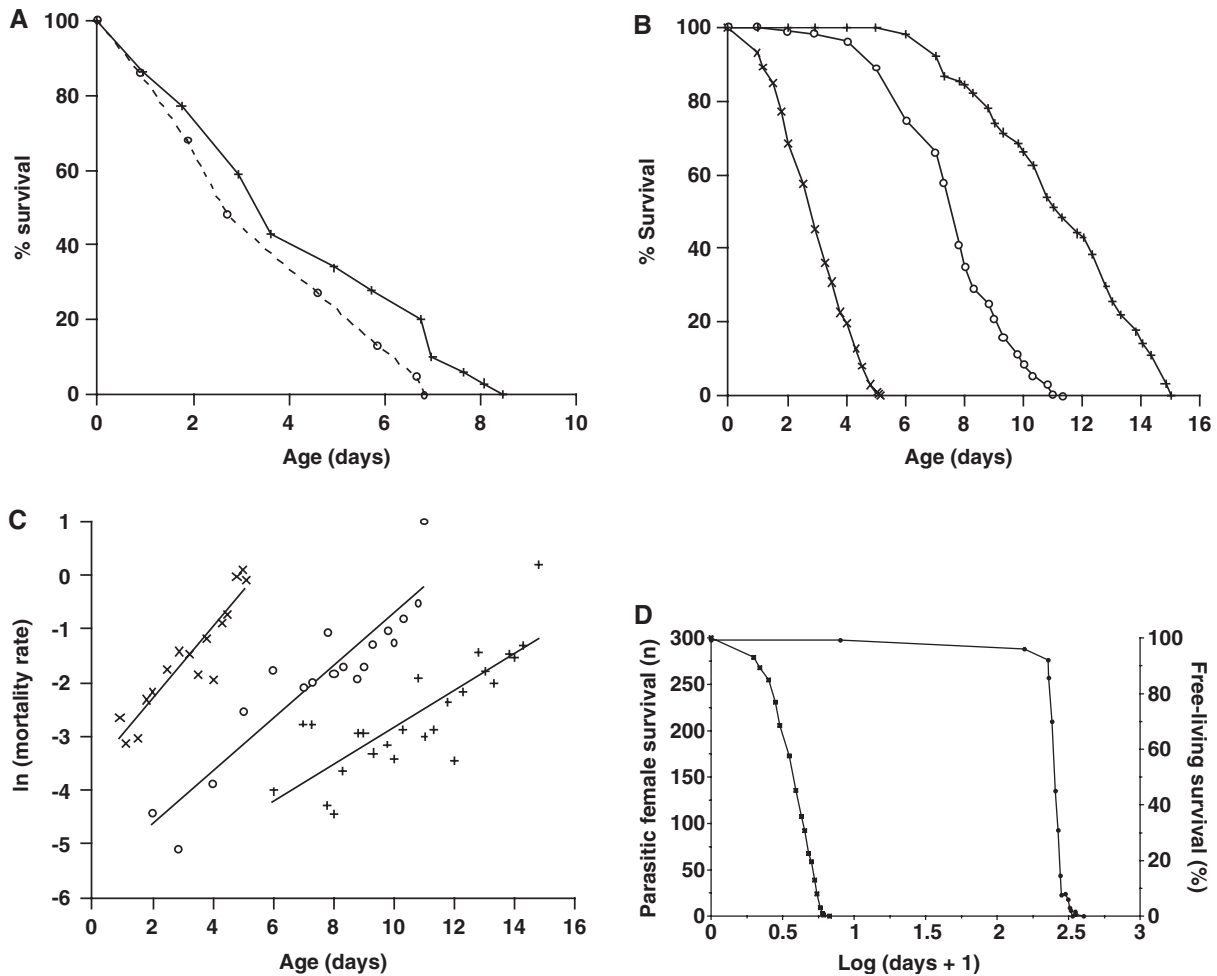

Cultures of *C. elegans* are monoxenic; that is, only the *E. coli* food source is present. In contrast, *S. ratti* larval stages derived from fecal cultures are inevitably contaminated with fecal bacteria, which may reduce their

lifespan. To minimize this problem, the agar plates on which these *S. ratti* free-living stages are cultured contain 400  $\mu\text{g/ml}$  streptomycin and are seeded with a streptomycin-resistant (SR) *E. coli* OP50 food source. Under these conditions, visible contamination by other microbes is reduced but not prevented. With these conditions the maximum mean lifespan ( $\pm$  SE) of *S. ratti* females was  $4.2 \pm 0.2$  days. This lifespan is significantly greater than that of *S. ratti* maintained without the presence of streptomycin (Gardner *et al.*, 2004; Figure 20.2A).

### MEASURING AGING IN *S. RATTI*

#### *Analysis of age-specific mortality*

One feature of aging that has been observed throughout the animal kingdom is the exponential acceleration of

**Figure 20.2.** Factors affecting *S. ratti* lifespan. (A) Survivorship of virgin free-living females under optimized culture conditions (400mg/ $\mu\text{l}$  streptomycin and *E. coli* SR) (x, —) and on *E. coli* OP50 (o, - - -). (B) Survival and (C) Plots of  $\ln(m(t))$  against age for *S. ratti* (x, —) and *C. elegans* (o, —) both in the *S. ratti*-optimized culture conditions (400mg/ $\mu\text{l}$  streptomycin and *E. coli* SR) and *C. elegans* (+, —) in monoxenic culture conditions *E. coli* OP50. (D) The estimated number of parasitic females (●) and the percent survival of free-living females (■) over time, which is shown on a log scale. Figures 20.2D, 20.3C, and 20.4C are from Gardner, Gems and Viney, submitted. Figures 20.1, 20.2A–C, 20.3A–B and 20.4A–B are reprinted from Gardner, Gems and Viney, Aging in a very short-lived nematode, *Experimental Gerontology* Volume 39, 1267–1276 (2004) with permission from Elsevier.

the mortality rate with increasing age (Finch, 1990). The pattern of age-specific mortality in many species (including humans) can be described by the Gompertz equation,  $m(t) = Ae^{\alpha t}$ , where  $m(t)$  is the mortality rate at time  $t$ ,  $A$  is the initial mortality rate (IMR) and  $\alpha$  is the Gompertz exponential function (Finch, 1990). Population cohorts may be extinguished as the result of mortality that is related or unrelated to aging; therefore, differences in lifespan *per se* do not necessarily reflect differences in the rate of aging. Limitations of lifespan by aging, as opposed to some other extrinsic cause of mortality (e.g., predation or disease), may be established by testing for the occurrence of an exponential increase in mortality rate with increasing age (Wachter and Finch, 1997). From plots of  $\ln(\text{mortality rate})$  against age, the IMR and the Gompertz exponential function can be calculated. The latter may be expressed in a form that is easier to grasp: the mortality rate doubling time (MRDT). These mortality parameters for free-living *S. ratti* females and parasitic *S. ratti* females are described below.

#### *Age-specific mortality in S. ratti free-living adult females*

The survival of free-living *S. ratti* females under optimized *S. ratti* culture conditions are shown in Figure 20.2B. This shows that its maximum lifespan is  $4.5 \pm 0.8$  days. In our studies of free-living *S. ratti* we were at pains to distinguish whether the very short lifespan resulted from rapid aging, or from some form of pathology distinct from aging. To this end, we compared age changes in *S. ratti* with those in *C. elegans*. The latter was cultured either monoxenically (i.e., with *E. coli* OP50 alone), or under the same conditions as *S. ratti* (i.e. with SR OP50 and low-level contamination with other microbes). (Figure 20.2B).

The mean lifespan of *C. elegans* hermaphrodites under either culture condition (*S. ratti* conditions:  $7.7 \pm 0.1$  days; monoxenic:  $11.2 \pm 0.1$  days) was substantially and significantly longer than that of *S. ratti* ( $3.0 \pm 0.1$  days) (Gardner *et al.*, 2004; Figure 20.2B). Unsurprisingly, *C. elegans* lifespan was greater in monoxenic culture conditions than in *S. ratti* optimized culture conditions, presumably due to the presence of contaminating microbes in the *S. ratti* culture conditions (Figure 20.2B).

In all cases, an age-specific mortality rate acceleration was observed (Figure 20.2C), consistent with the occurrence of senescence (i.e., intrinsic aging). For *S. ratti* the MRDT ( $\pm$ SE) was lower and the IMR ( $\pm$ SE) higher ( $0.8 \pm 0.1$  days;  $0.025 \pm 0.002$  days<sup>-1</sup>, respectively) than in *C. elegans* (in either culture condition). For *C. elegans* under the two culture conditions, there was no difference in the MRDT (*S. ratti*-conditions:  $1.4 \pm 0.2$  days; monoxenic conditions:  $2.0 \pm 0.3$  days), but the IMR for *C. elegans* kept under *S. ratti* culture conditions was almost twice that of monoxenically cultured populations (*S. ratti* conditions:  $0.0036 \pm 0.0003$  days<sup>-1</sup>; monoxenic:  $0.0018 \pm 0.0002$  days<sup>-1</sup>). Overall, these findings imply

that *S. ratti* is shorter lived than *C. elegans* because (a) it is more frail, as reflected by higher IMR, and (b) it ages more quickly, as reflected by a lower MRDT.

#### *Age-specific mortality in S. ratti parasitic females*

In *S. ratti* parasitic females, maximum lifespan is 403 days (Gardner, Gems and Viney, submitted; Figure 20.2D), which compares to 5 days in the free-living morph (Figure 20.2D).

The maximum lifespan of *S. ratti* parasitic females is 403 days, which is some 80 times greater than the 5-day lifespan of the free-living females. The parasitic females underwent an exponential increase in mortality rate with age, thereby showing that senescence was occurring. The IMR of the parasitic females was  $0.0056$  days<sup>-1</sup>, which is approximately 25% of that of the free-living females. The MRDT of the parasitic females was 22.7 days, which is some 30 times longer than that of the free-living females. Overall, this comparison of the parasitic and free-living females implies that free-living morphs are shorter-lived due to their increased frailty (as reflected by the greater IMR) and a faster rate of aging (as reflected by lower MRDT). *S. ratti* is the first parasitic nematode in which the occurrence of demographic senescence has been demonstrated in the laboratory.

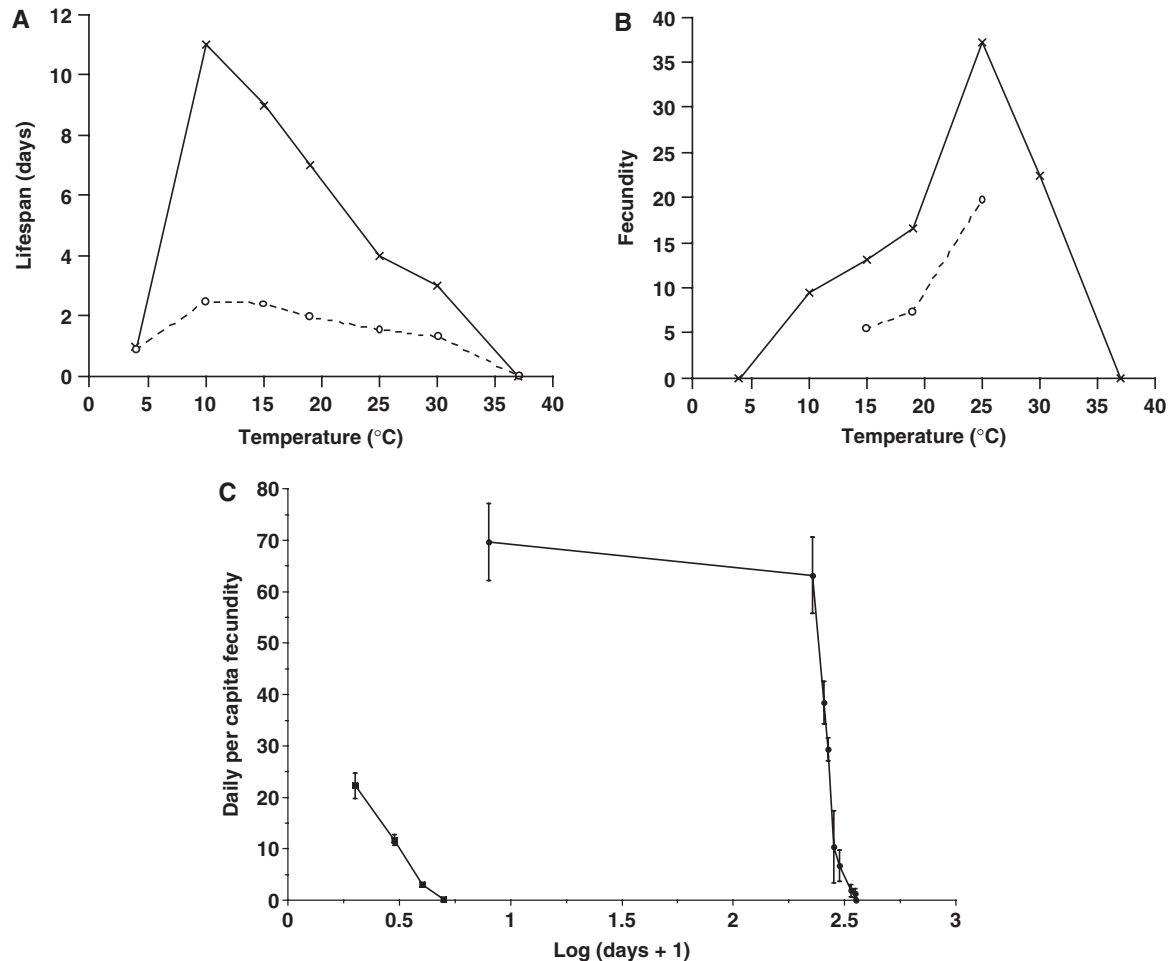

### FACTORS AFFECTING LIFESPAN IN FREE-LIVING *S. RATTI* AND *C. ELEGANS*

The lifespan of the free-living adult female *S. ratti* is really very short; in fact it is the shortest-lived nematode reported. One possibility is that this very short lifespan is not the result of aging in the usual sense. For example, mortality might result from failure to feed, or a gross anatomical defect not seen in other nematodes. To address these issues, we compared aging in free-living *S. ratti* with that in *C. elegans* in two ways. First, we tested the effect of factors known to affect aging in *C. elegans* and in *S. ratti* free-living adults. Second, we asked whether the age-associated changes in *C. elegans* behavior, morphology and appearance are also seen in *S. ratti*. Overall, our findings strongly support the view that the short lifespan in *S. ratti* free-living adults is the result of typical nematode aging, but which is happening at an unusually swift pace.

In *C. elegans*, lifespan is reduced by various factors, including the *E. coli* food source (Gems and Riddle, 2000; Garigan *et al.*, 2002), higher temperature (Klass, 1977), mating between the sexes (Gems and Riddle, 1996) and attempted mating between males (Gems and Riddle, 2000). In *S. ratti*, lifespan (Figure 20.3A) and lifetime fecundity (Figure 20.3B) were reduced by higher temperatures, as in *C. elegans* (Klass, 1977).

However, mating did not affect lifespan in *S. ratti* in the same way as it does in *C. elegans*. Thus, mating (manipulated by adjusting the male:female ratio from 0 to 4.0) had no effect on *S. ratti* free-living female lifespan,

20. *Strongyloides ratti*: A Nematode with Extraordinary Plasticity in Aging

**Figure 20.3.** (A) Effects of temperature on mean ( $\circ$ , - - -) and maximum ( $\times$ , —) lifespan of virgin free-living females. *S. ratti* adults die within 24 hours at 37°C. (B) Effect of temperature on mean per capita lifetime fecundity of *S. ratti* females, mated on day one only ( $\circ$ , - - -) or mated throughout life ( $\times$ , —). (C) The mean ( $\pm 1$  SE) daily per capita fecundity of the parasitic females ( $\bullet$ ) and of the free-living females ( $\blacksquare$ ) (mean  $\pm 1$  SE; adapted from Gardner *et al.*, 2004) over time, which is shown on a log scale.

whereas in males it actually increased lifespan. Thus lifespan in *S. ratti* and *C. elegans* is affected in the same way by some factors (temperature, food source in data not shown, proliferating bacteria) but in different ways by others (mating).

### BEHAVIORAL CHANGES ACCOMPANYING AGING IN *S. RATTI*

#### Fecundity

The daily per capita fecundity of free-living *S. ratti* females fell rapidly with age, as in *C. elegans*, but more rapidly, halving between the first and second days of adult life (Figure 20.3C). The resultant maximum lifetime fecundity was less than 40 progeny per female, compared to over 1,400 in *C. elegans* (Hodgkin and Barnes, 1991). By contrast, the daily per capita fecundity of the parasitic adult morph was  $>50$  for *c.* 250 days before it declined,

giving a lifetime fecundity of  $\sim 16,000$  (Gardner, Gems and Viney, submitted; Figure 20.3C).

#### Pharyngeal pumping rate and movement

In *C. elegans*, the rate of pharyngeal pumping (reflecting the rate of ingestion of food) declines gradually with age (Kenyon *et al.*, 1993). We observed a similar age-related decline in pharyngeal pumping rate in *S. ratti*. We also saw a similar age-related decline in movement in *S. ratti*, as in *C. elegans* (Herndon *et al.*, 2002). In each case the pattern of age-related change in *S. ratti* was similar, but more rapid than that in *C. elegans*.

### MORPHOLOGICAL CHANGES ACCOMPANYING AGING IN *S. RATTI*

#### Autofluorescence

In *C. elegans*, there is an increase in intestinal autofluorescence with age (Garigan *et al.*, 2002), similar to

accumulation of age-pigment (lipofuscin) seen during mammalian aging. There is a similar increase in autofluorescence with age in free-living *S. ratti* morphs (Gardner *et al.*, 2004). By contrast, little such autofluorescence was seen in parasitic females, even in 11-month-old individuals (Gardner, Gems and Viney, submitted). Lipofuscin accumulation reflects organismal failure to detoxify and excrete molecular waste products. The paucity of autofluorescence in *S. ratti* parasitic females suggests reduced generation, and/or increased excretion, of damaged molecular constituents. This is consistent with aging occurring in the two *S. ratti* female morphs, but at very different rates.

*Microscopic examination of aging nematodes*

The integrity of major anatomical features was compared in young and old *S. ratti* adults using differential interference contrast (DIC) and transmission electron

microscopy (TEM) (Gardner *et al.*, 2004; Gardner, Gems and Viney, submitted). Overall, the appearance of aging *S. ratti* free-living females was similar to that of aging *C. elegans* (Herndon *et al.*, 2002). The pharynxes of older free-living *S. ratti* were frequently distended and blocked with bacteria. Such pharyngeal blockage has also been observed in older *C. elegans* (Garigan *et al.*, 2002). The most striking morphological age changes in free-living *S. ratti* occurred in the intestine (Gardner *et al.*, 2004). Whilst in one-day-old animals there were large, healthy looking refractile intestinal cells (Figure 20.4A), in the majority of four-day-old animals these cells were severely atrophied and the cytoplasm had a ragged appearance (Figure 20.4B).

By contrast, older parasitic females showed no marked degenerate changes.

TEM observations of free-living females showed numerous inclusions in the intestinal cytoplasm whose

**Figure 20.4.** (A–B) *S. ratti* free-living females viewed using differential interference contrast (Nomarski) microscopy. (A): one-day-old female; (B), four-day-old adults. (A) and (B): posterior intestine. In (A), note the large, healthy refractile intestinal cells (i). In (B), the intestine is strikingly atrophied. Anus (a). Bars = 20  $\mu$ m. (C) TEM of four-day-old free-living females with electron-dense inclusions of intestinal cells indicated by \* (Bar = 2  $\mu$ m); c, cuticle; mv, microvilli; b, clump of bacteria in lumen.

number increased with age (Figure 20.4C). Most of these resembled lipid droplets (or possibly secondary lysosomes) within which have accumulated electron-opaque particles with a sooty appearance. By contrast, there were very few such inclusions in the intestines of parasitic females and their number did not change with age. These observations suggest that degeneration of the intestine, possibly associated with accumulation of fluorescent/electron opaque waste material, represents a pathology of aging that contributes to nematode pathology. This idea was previously put forward based on TEM studies of aging in *Caenorhabditis briggsae* (Epstein *et al.*, 1972). The fact that this pathology was not detected in the intestine of the parasitic *S. ratti* adult is consistent with the idea that the absence of this pathology contributes to parasitic longevity.

The parasitic and free-living females morphs of *S. ratti* are genetically identical. Therefore differences between these morphs must be due to differences in gene expression. This being so, these differences in intestinal pathology might reflect differences in regulated biochemical processes which determine longevity and aging. One intriguing and attractive possibility is that in parasitic females there is an increase in biochemical processes promoting detoxification. Recent microarray studies of long-lived insulin/IGF-1 signalling mutants of *C. elegans* have implicated a broad range of detoxification processes in longevity assurance (Murphy *et al.*, 2003; McElwee *et al.*, 2004; Gems and McElwee, 2005). These include phase 1 and phase 2 drug detoxification, as well as antioxidant enzyme and chaperonin activities. Most of these processes require energy input, and excretion of solubilized toxic metabolites by the drug detoxification system occurs via the smooth endoplasmic reticulum. Interestingly, intestinal cells of parasitic *S. ratti* adults are rich with mitochondria and smooth endoplasmic reticulum.

## Conclusion

### LEARNING ABOUT LIFESPAN EVOLUTION FROM *S. RATTI*

In this chapter we have described the uniquely high level of phenotypic plasticity in aging in *Strongyloides ratti*, corresponding to an 80-fold difference in lifespan, accompanied by a 400-fold difference in maximum fecundity. While these represent something of a comparative gerontological party trick, does it provide any real insight into the biology of aging? Arguably, the existence of plasticity of this sort has implications for the genetic mechanisms underlying lifespan evolution.

Evolutionary theory predicts that organisms in environments with a low rate of extrinsic mortality will evolve slower rates of aging than those in environments with a high rate of extrinsic mortality (Medawar, 1952; Williams, 1957). This is because high levels of extrinsic mortality reduce selection against alleles which produce deleterious

effects later in life. As a consequence, populations experiencing higher extrinsic mortality will accumulate such late-acting deleterious alleles, which cause aging. If alleles are pleiotropic, and capable of producing phenotypic effects at different time in an animal's life, there may be selection for alleles which enhance fitness due to early effects, despite later deleterious effects (antagonistic pleiotropy).

The relationship between extrinsic mortality rate and aging has been supported by numerous comparative studies. For example, bats generally live longer than rodents of a similar size, presumably since flight aids predator evasion, reducing extrinsic mortality (Wilkinson and South, 2002). Evolution results in intraspecific as well as interspecific differences in lifespan. For example, in social insect species there are intercaste differences in lifespan which may reflect the evolutionary effects of different levels of extrinsic mortality on rates of aging (Page and Peng, 2001; Chapuisat and Keller, 2002). However, the extent to which these lifespan differences are the result of differences in the rate of aging remains unclear. For example, Chapuisat and Keller (2002) compared survival in large and small worker ants, and found that the smaller workers lived significantly longer, which they hypothesized was because the larger morphs were fighting and getting killed more quickly.

Thus, here lifespan differences are not due to differences in aging but rather, just differences in extrinsic mortality rates.

Although the evolutionary theory of aging provides an explanation for how different aging rates evolve, in terms of molecular or developmental genetics, the concept of "late-acting deleterious mutations" remains frustratingly abstract. Potentially, the pattern of aging in *S. ratti* provides a clue as to the molecular genetic basis of lifespan evolution, as follows. Free-living nematodes are typically much shorter lived than parasitic nematodes, some of which have lifespans of over a decade (Gems, 2001). These evolved differences are likely to reflect differences in extrinsic mortality experienced by free-living versus parasitic species. Hence the difference in lifespan of free-living and parasitic *S. ratti* seems consistent with the evolutionary theory of aging. What is interesting about *S. ratti* is that the two adult forms have evolved such a vast difference in aging rate, despite the fact that they are the same species, sharing a common genome.

That this is possible sheds some light on the nature of "late-acting deleterious mutations." According to an evolutionary interpretation, free-living *S. ratti* have evolved a short lifespan due to high extrinsic mortality rate and accumulation of alleles with deleterious late-acting effects. However, one might expect that these alleles would be purged from the population by selection against them in the parasitic adult. The nature of *S. ratti* clearly demonstrates that this has not happened, and in this sense its evolution represents a useful experiment

of nature. What is also clear from *S. ratti* is that the evolved difference in lifespan between the two adult forms is the product of differential gene expression. This tells us that, at least in this one species, “late-acting deleterious mutations” actually reflect regulated differences in gene expression leading to shorter lifespan.

Aging is a trait which shows remarkable evolutionary plasticity and is able to evolve rapidly. For example, humans and chimpanzees have evolved a difference in maximum lifespan of some 50 years since divergence from a common ancestor only 6–7 million years ago. It has been suggested that there are “lifespan regulatory modules,” which are regulated sets of genes which control the rate of aging (Kenyon, 2005). The existence of these makes possible the observed rapid rates of evolutionary change in aging rates. Some clues to the possible nature of the genes involved in lifespan are emerging from new genetic studies of aging in model organisms.

#### BETWEEN THE GENETICS AND EVOLUTION OF LIFESPAN

Major advances have recently been made in terms of the genetics of lifespan, particularly using *C. elegans* and *D. melanogaster*. For example, the insulin/insulin-like growth factor (IGF-1) signalling pathway has been shown to be a powerful regulator of lifespan in nematodes, flies and probably rodents (Kenyon, 2005). The relationship between the lifespan-determining genes and pathways identified, and those involved in lifespan evolution, remain unclear. One possibility is that at least some of the genes and processes identified by model organism lifespan genetics are the same as those involved in lifespan evolution. In the case of *S. ratti*, insulin/IGF-1 signalling is a good candidate for a regulator of phenotypic plasticity of aging. In *C. elegans*, this pathway controls the differences in lifespan between the long-lived dauer larva and the shorter lived adult (Riddle and Albert, 1997).

In *C. elegans*, DAF-16, a FOXO-family transcription factor, controls the rate of aging in response to insulin/IGF-1 signalling. Recently, microarray studies have begun to identify the transcriptional targets of DAF-16, which are predicted to include the ultimate genetic determinants of longevity and aging in *C. elegans* (Murphy *et al.*, 2003; McElwee *et al.*, 2004). DAF-16 alters the expression of a wide range of genes, involved in many life processes, including defenses against stress,

toxins and microbial invasion. To date, these analyses of the role of IIS and DAF-16 have been based on the analysis of mutants, where lifespan differences of up to 2.5 fold can be achieved (Kenyon *et al.*, 1993). While substantial, such differences are much less than evolved, interspecific differences in lifespan, or the 80-fold differences in lifespan between the different adult morphs of *S. ratti*. Therefore, a plausible hypothesis is that *S. ratti* lifespan plasticity is determined by differential expression of the same sorts of genes and processes regulated by DAF-16 in *C. elegans*. Further, one may speculate that this is also the case for lifespan differences between species, such as that between human and chimpanzee. A graphic representation of this hypothesis is presented in Figure 20.5.

Overall, this discussion of the implications of *S. ratti* aging suggests a view of lifespan as a highly plastic, regulated trait that is consistent with the rapid evolution of interspecific differences in lifespan.

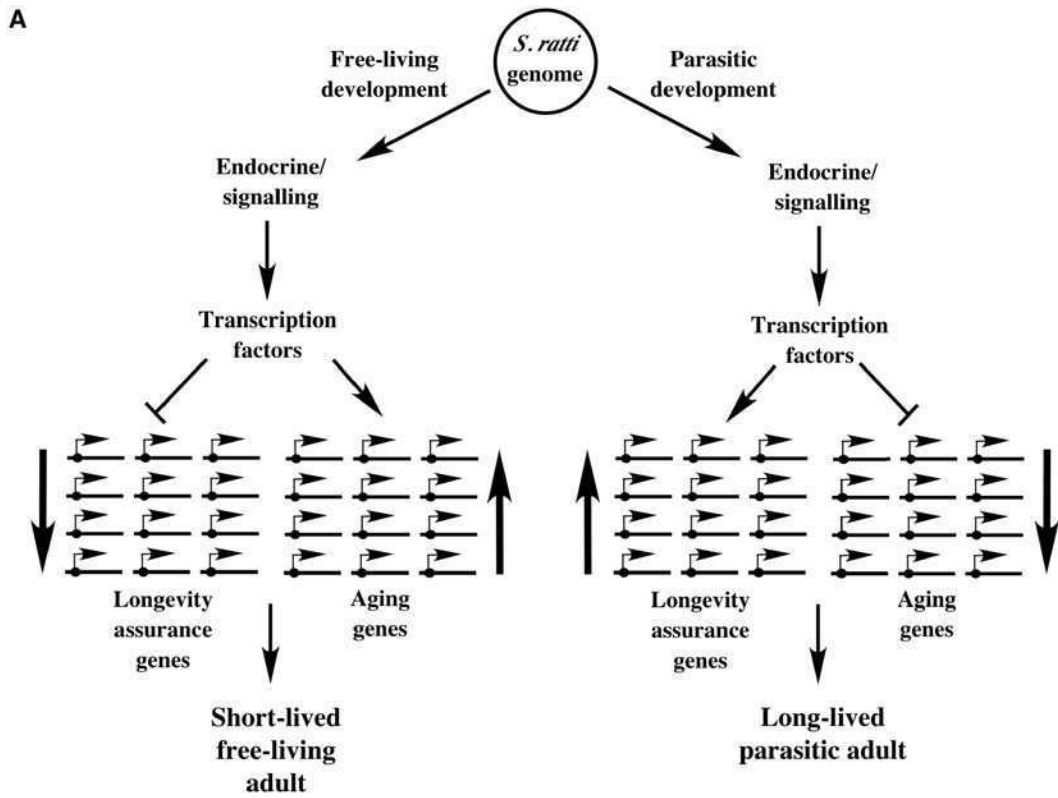

#### WHY ARE FREE-LIVING *S. RATTI* SO VERY SHORT LIVED?

One remaining oddity of *S. ratti* is that the free-living adults are really very short-lived, even by the standards of short-lived free-living nematode species. There are several possible explanations for this. First, the free-living adult phase of the life cycle is facultative (Viney, 1996). Hence when it does not occur, this may weaken selection on lifespan in the same manner as high extrinsic mortality. Second, it might result from antagonistic pleiotropy between the effects of genes on fitness in the free-living and parasitic forms. Aging may reflect action of alleles that increase early-life fitness (e.g., by increasing reproductive output) but have deleterious late-life effects (Williams, 1957). Such antagonistic pleiotropy is supported by experimental investigation (Kirkwood and Austad, 2000; Partridge and Gems, 2002). Hence, in the case of *S. ratti*, the short life of the free-living adults may result from the greater fecundity of the parasitic female, which may favor pleiotropic alleles that increase parasitic fecundity but reduce lifespan of free-living adults.

#### LEARNING ABOUT AGING FROM COMPARATIVE STUDIES

Studies concentrating on a small number of model organisms have figured strongly in recent biogerontological

**Figure 20.5.** A hypothetical scheme for the mechanism of lifespan regulation and evolution. (A) Evolved intraspecific differences in lifespan between parasitic and free-living adults are generated by differences in gene expression, regulated by endocrine and cellular signalling systems via regulated transcription factors. We propose that, as in *C. elegans* (Murphy *et al.*, 2003), parasitic adult longevity in *S. ratti* results from up-regulation of longevity assurance genes and down-regulation of genes which promote aging. A arrows = stimulation, and T bars = inhibition. (B) Potentially, differences in aging rate between species may evolve via similar mechanisms. Here, the environment of an ancestral species changes, such that the extrinsic mortality rate is lowered, and selection against deleterious late-life effects is increased. This leads to the evolution of slower aging and increased longevity, which might occur via alterations in regulation of longevity assurance and aging genes. This predicts that several types of gene are likely to be altered during lifespan evolution: those encoding endocrine, signalling proteins and transcription factors. In (B), asterisks represent alterations in the trait resulting from random mutation, and selection.

research. While this approach has been very fruitful indeed, studies of *S. ratti* aging illustrate the value of limited investigations of the biology of aging in selected animal species. Such studies in the comparative biology of aging can yield fundamental facts about the biology of aging. A good example of this is the study of *Hydra vulgaris* which revealed an apparent absence of senescence in this species (Martinez, 1998). This demonstrates that aging is not a necessary feature of adult metazoan biology. It seems likely that there are many unusual and informative patterns of aging to be discovered, particularly among lower invertebrates, which may include the absence of senescence, facultative nonsenescence and examples of phenotypic plasticity of aging even more extreme than in *S. ratti*. The possible value of organisms with exotic patterns of aging is likely to increase as the ease of genome sequencing increases and its expense falls. Comparative functional genomic approaches, using whole genome microarray analysis, applied to such organisms, have the potential to yield insights into both the biology of lifespan determination and the evolution of aging and longevity.

# Insect Models for the Study of Aging

Klaus-Günter Collatz

*The aim of the following chapter is to show that different insect species can be used to answer many questions relevant in mammalian or human aging studies. Insects share with vertebrates, including man, many basic similarities in structural components, energy metabolism, and signal transduction mechanisms. Many insects are easy and cheap to rear in mass cultures. With few exceptions they have short life and generation times. After a short survey of the principles of insect anatomy and function, biotic and abiotic factors are considered which are responsible for modifying an insect's life span. I then describe insects that we use in our own laboratory (*Phormia terraenovae*, *Gastrophysa viridula* and *Panorpa vulgaris*) and their rearing conditions, as well as those of two other flies frequently used (*Musca domestica* and *Drosophila* species). I further present various studies relevant for aging investigations, including biodemographic statistics, examples of age-dependent ultrastructural tissue changes, and different metabolic measurements. The metabolic section raises issues of caloric restriction, studies of redox systems, trade-offs between physical activities, reproduction, and longevity and chronobiological effects.*

## Introduction

Insects are a huge group of arthropods in the animal kingdom, comprising about two million described but up to 30 million estimated species. They are distributed over extremely different habitats ranging from the sea coast to high mountains. One can find them in deserts as well as in aquatic regions. Only the open sea lacks this extremely prosperous animal group.

### WHY INSECTS AS MODELS

At first sight, insects seem to be very different from vertebrates and therefore poorly qualified to act as models in our context. A closer look, however, reveals many similarities on tissue and basic metabolic levels. Aging insect tissues, for instance, are characterized by structural changes that also occur in mammalian tissues. The deposition of the age pigment lipofuscin and the more or less abundant “whorlike” structures of mitochondrial origin are examples of common signs of aging or otherwise degenerating tissues (see below). A further

peculiarity is that adult insects are composed of post-mitotic cells—except for their hemocytes and germ cells. Therefore all lifelong changes on the tissue level can easily be detected.

Most insect species are short-lived organisms. Therefore many generations can be studied in a short time. Insects can be raised in large quantities and with low costs.

The use of insects as model systems in gerontological studies has a long tradition. Loeb and Northrop (1917) were the first to use *Drosophila* in this way. They conducted experiments on metabolic rates and life span, and these early attempts can be acknowledged as the beginning of a comparative biology of aging. These *Drosophila* studies were based on results of Rubner (1908). Working with mammals, he showed that the amount of lifelong metabolic energy per gram body weight is more or less constant. These results stimulated further studies on the rate of living theory (Pearl, 1928). This old problem was then elucidated in greater detail by Sohal and coworkers using modern methods and the house fly—*Musca domestica*. The rate of living theory was then consequently redefined as follows: “The rate of ageing is directly related to the rate of unrepaired molecular damage inflicted by the by-products of oxygen metabolism and it is inversely related to the efficiency of antioxidant and repair mechanisms” (Sohal, 1986). Since that time many investigations have addressed the influence of oxidative stress, free radical damage, and repair on aging and longevity in insects. Regardless of the acceptance of the rate of living theory, these factors are generally accepted as being of central importance for the understanding of aging mechanisms.

Extensive studies on aging mechanisms are mostly restricted to dipterans. The fruit fly *Drosophila*, of course, is the most intensively studied insect even in this sense. Other dipterans more often studied are the house fly *Musca domestica* and blowflies, including our own model organism *Phormia terraenovae* (Collatz, 1997). The scorpion fly *Panorpa vulgaris* and the chrysomelid beetle *Gastrophysa viridula* attracted particular attention in our laboratory due to special questions, which are outlined in more detail below.

For the biologist interested in comparative aging studies, large differences in life-history strategies of insects

of the same genus could offer the opportunity to test phylogenetic causes of aging. In the last years special attention was given to social hymenoptera like bees, wasps, and ants with their remarkable long living queens (see below).

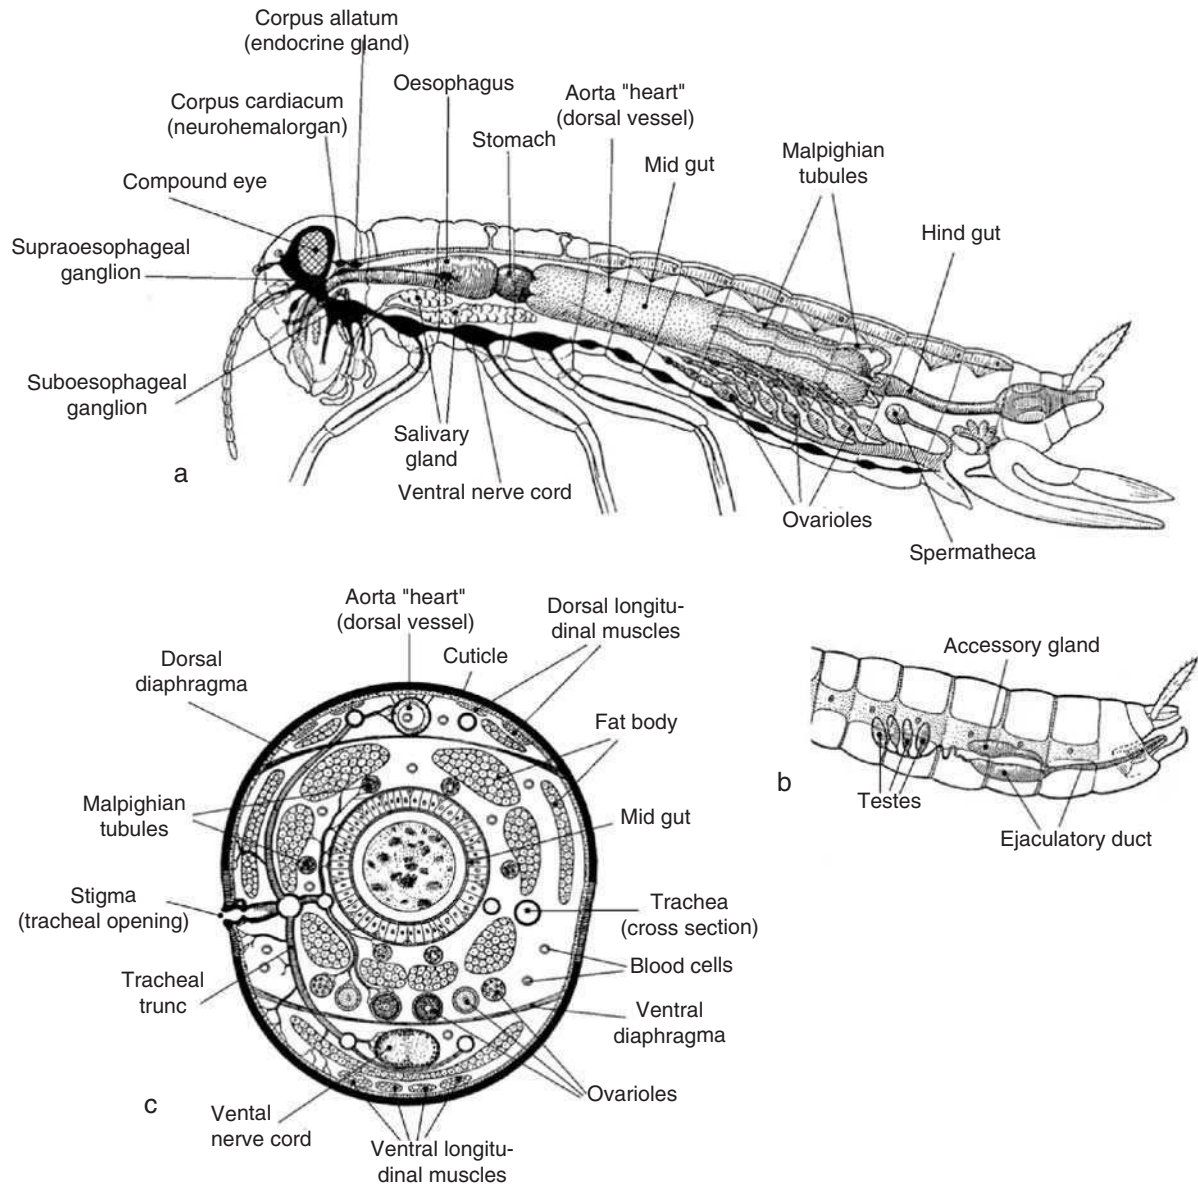

**GENERAL FEATURES OF THE INSECT BODY PLAN**

In contrast to the various life habits and life histories, the insect body plan is quite uniform with its basic body plan (see Figure 21.1).

The body is composed of three parts—head, thorax, and abdomen—and covered with a chitinous cuticle of

varying thickness. Three pairs of legs and, in winged insects, two pairs of wings, are attached to the thorax.

The central nervous system consists of a supraesophageal and a subesophageal ganglion in the head and a rope ladder-like ventral nerve cord. The supraesophageal ganglion or brain is the most complex part of the nervous system. It includes the optic center, areas of behavioral regulation and centers of integrative learning. The alimentary canal consists of three parts. It begins, behind the mouth, with an ectodermic foregut or stomodeum with pharynx and stomach, followed by the entodermic midgut or mesodeum, which is the main region of digestion. An ectodermic hind gut or

**Figure 21.1.** Basic body plan of an insect: (a) lateral view of the female insect body (fat body omitted); (b) lateral view of the male insect abdomen; (c) cross section of the female insect abdomen. (All charts modified after Weber, 1966)

proctodeum opens into the anus. The excretory system consisting of the malpighian tubules is connected to the proctodeum.

The blood circulation system of insects is an open system; their body fluid—hemolymph—is therefore comparable to a mix of extracellular fluid (“lymph”) and blood in animals with closed circulatory systems. The respiratory system is separated from the circulatory system. Tracheae that start with spiracles transport the respiratory gases. There are no respiratory proteins, and the distribution of oxygen and carbon dioxide is achieved by diffusion.

The body cavity is filled with the prominent fat body. This is not simply a storage organ like the white fat of vertebrates. It is very active metabolically, most comparable to the liver of vertebrates.

The male sex organs consist of the paired testes accompanied with glands for accessory fluids. The female ovaries are composed of a varying number of ovarioles and adjacent parts (e.g., spermatheca).

### Life-Span Characteristics and Factors Which Are Responsible for Modifying an Insect's Life Span

Although the aging pattern of insects, like that of other organisms, is doubtless under genetic control, it is extremely flexible, depending on several biotic and abiotic factors. Life span includes the longevity of all developmental stages an individual passes through during its life cycle. Individuals of insect species (as well as those of other species) experience a number of critical points in time during their life cycles, which influence the life span from eggs over larvae up to pupae and adult stages. Without knowledge of such modifying factors the life span of an insect species is unpredictable.

Insects are ectothermic organisms. The ambient temperature is therefore a key life-span modifying factor. It is easy to manipulate the metabolic rate simply by changing ambient temperature. The mentioned work of Loeb and Northrop used this regimen as an experimental tool. The light regime also acts as a prominent abiotic stimulus together with the temperature. Both factors are essential in habitats with distinctive seasons; they determine in many species whether phases of dormancy occur or not. A phase of low metabolism can be induced experimentally by changing the photoperiod from long day (16:8) to short day (8:16). This treatment evidently interrupts the aging process (see below).

All insects dealt with in the present contribution are holometabolic. Their development from egg to adult is interrupted by a metamorphosis. Preimaginal conditions are important for the adult life course. A controlled underfeeding of larvae does not terminate the development but results in dwarf adult forms. They can be used to

study the interrelationship of body size, fecundity, and longevity.

Fecundity and reproductive success are also essential for the determination of the following course of life. As we will see in the case of the blowfly *Phormia*, reproductive success depends not only on the availability of mates but equally on the presence of proteins as specific food for the development of eggs. This in turn is of great influence for longevity.

Physiological trade-offs between physical performance, reproduction, and longevity are also important and gave rise to numerous studies. We will refer to this in a later section.

As mentioned above, a particular situation is given in eusocial insects as wasps, bees, ants and termites. They live in colonies with cooperating members of different castes, sharing a high level of genetic similarity with the queen. Aging process and life span of the colony members are widely determined by extrinsic factors such as nutrition and kind of work. The remarkable longevity of the queen ranging from 4 to 8 years in wasps and up to 30 years in termites is of great interest (Page and Peng, 2001). This topic is further dealt with in Chapter 23, “Models of Aging in Honeybee Workers,” and Chapter 24, “Ants as Naturally Long-Lived Insect Models for Aging.” For a more detailed description of aging and environmental conditions in insects see Collatz (2003).

Finally, caloric restriction in general can act as a life-prolonging strategy not only in vertebrates, but also in insects. It is proposed that the basic mechanisms and effects are almost the same in such different organisms.

### Biology and Rearing Conditions of Insects Used in Our Own Laboratory (Figure 21.2)

#### PHORMIA TERRAENOVAE

The blowfly *Phormia terraenovae* (= *Protophormia terraenovae*) is a holarctic distributed calliphorid fly. It is abundant in the cooler regions and was found in Spitsbergen as well as within 550 miles of the North Pole. This synanthropic fly plays an important role as indicator in forensic biology since especially calliphorids are recognized as the first wave of the faunal succession on human cadavers.

Under free-living conditions both sexes can be found on umbels of Apiaceae. The compact body of these flies is shiny metallic blue. Their eyes and wings are well developed. The mouth parts operate as licking proboscis. Males and females are easily distinguished by the different positions of their eyes; there is a broad interspace in females and a negligible one in males. The natural food of both sexes is nectar.

*Phormia* belongs to the group of anautogenous insects in contrast to autogenous insects. The term *autogenous*, particularly used for dipterans, means that during metamorphosis larval protein is transferred into the

**Figure 21.2.** Insects used in our laboratory: (a) *Phormia*, (b) *Gastrophysa*, (c) *Panorpa*

adult. In female adults this protein is an indispensable requisite for the development of eggs. In male adults it often serves as source for the synthesis of the accessory genital gland fluids: a prerequisite for the insemination of females. Anautogenic insects such as *Phormia* rely on exogenic protein sources. Under natural conditions protein is a rare and ephemeric substrate. Time and the opportunity of acquisition influence the aging process.

#### *Rearing conditions*

We perform the stock culture of flies under a 16:8 (l:d) light regime with a temperature of 25°C and a relative humidity of 60 to 75%. The raising room is illuminated with “Lumilux-Eco Daylight” lamps (Osram). The cages are cubic with an edge length of 50 cm. This is sufficient for a population of 400 flies. The cages are covered on top and on two sides with gauze. The third side is attached with black cloth containing a sleeve. The front site is covered with a removable Plexiglas pane.

Three plastic Petri dishes with lump sugar, minced meat and water (on filter paper to avoid drowning of the flies) are placed inside the cage. If provided with meat, newly emerged flies start to lay eggs after about three days. Half a teaspoon of eggs will provide about 2500 individuals for a new generation. The eggs are placed together with meat in plastic containers (25 × 20 × 15 cm l/w/h) filled up to one-third with sawdust. The sawdust must always be moist to avoid drying of the meat and to fix the ammonia, which is produced by the maggots. The larvae hatch after about 24 hours: they need an increasing amount of meat. During the last days of larval development this amount can reach up to 500 g per day. After 7 to 10 days after hatching, the larvae stop feeding and start to pupate. The pupae are now transferred to fresh sawdust and placed into a new cage. Here the new generation of adult flies emerge after 5 to 8 days. To obtain a cohort with definite age structure, the emergence can be better synchronized by placing the cage for several hours in a cooling chamber at about 4°C.

#### *GASTROPHYSA VIRIDULA*

The chrysomelid beetle *Gastrophysa viridula* was formerly restricted to alpine regions, but now it has expanded its distribution to northern, middle, and eastern Europe. In North America this species is replaced by *G. formosa*. The oligophagous beetles are found on Polygonaceae, mostly *Rumex* plants but also on *Rheum*, and were reported to be a pest on vine in Arizona. The 4 to 6 mm long beetles are metallic green with a black ventral side. Females with eggs are easy to distinguish from males by their swollen abdomen. The eggs are deposited in batches of 20 to 45 on the underside of leaves. The emerging larvae moult two times. The developing time from egg to the adult beetle takes about 50 days (eggs: 7–10, larvae: 21–30, pupae: 6–9 days). Normally, *Gastrophysa* produces three generations per year. Adults of the autumn generation enter diapause up to the next spring.

#### *Rearing conditions*

We rear the stock culture of beetles under a 16:8 (l:d) light regime with a temperature of 20°C and a relative humidity of 50% in a climate chamber (Rubarth Apparatus 3201). Twenty to 30 beetles are placed in Petri dishes of 12 cm diameter. The dishes are covered with paper pulp, and the beetles are fed daily with fresh *Rumex* leaves. The newly

## 21. Insect Models for the Study of Aging

emerged animals start to copulate after 3 days and deposit the first eggs after 5–7 days. Larvae get *Rumex* leaves up to the end of the third stage. Thereafter they stop feeding and seek deeper places in the paper sheets. The pupae are extremely sensible against touching and they should not be disturbed.

### PANORPA VULGARIS

The over 100 species of scorpion fly *Panorpa* (Mecoptera) have a world-wide distribution. Both sexes are characterized by a snout-shaped elongated head, and the males have a tail-like grasping apparatus resembling a scorpion's tail, which is used to hold the female during copulation. During mating, the male presents a “nuptial gift” to the female, a proteinaceous bowl produced by the salivary gland. The adults are common on shrubs in shady areas. They feed on dead organisms, mostly insects. Under mid-European environmental conditions two generations per year—a spring and an autumn generation—can be produced. The last larval stage of the second generation enters an overwintering diapause.

*Panorpa* is remarkable in that it shows senescence like histological degenerations even under free-living conditions.

#### *Rearing conditions*

Adults can be maintained in the laboratory on long day (18:6 h) conditions at 23°C and 60–75% relative humidity. Cages (40 × 20 × 35 cm) for 50 individuals are covered on top and on the four sides with gauze and can be placed on paper sheets. These insects are such lazy fliers that the cages can easily be handled without special opening devices. Mealworm larvae are suited as food. Under this treatment, males and females reach a maximum life span of about 110 days, which is in accordance with free-living populations. Life expectancy at the day of emergence is 61–63 days for both males and females. After sampling egg-clusters from moist peat-soil used as egg-laying substrate, they are transferred to Petri dishes containing the same substrate. The emerging larvae are fed on pieces of mealworm larvae. Under the same conditions, the larvae hatch after 6 days, pass through 4 larval stages in 3 weeks and emerge after an additional 3 weeks. Adult males emerge 3 days after the females.

### Rearing Conditions of Other Frequently Used Insects

#### MUSCA DOMESTICA

The common house fly was often used besides *Drosophila* in early studies on aging in insects. As in *Phormia* (and other diptera), males and females can easily be distinguished by the different positions of their eyes.

The flies are easy to raise in gauze-covered boxes as used for *Phormia*.

#### *Rearing conditions*

The rearing temperature should be 27 to 28°C and the relative humidity about 60%.

The cages contain a Petri dish with humidified blotting paper. Another dish contains the larval food composed of a mixture of alfalfa flour, wheat bran, yeast and water (1:1:0, 2:5). This mixture is fermented for 3 days at 26°C. For adults, this mixture should be covered with powdered milk. Another larval food mix contains equal parts dry yeast and milk powder (10%) dissolved in 2% boiling agar solution.

After egg deposition, the food dishes are taken away and covered with gauze. After two days, the larvae are about 3 mm in length. Depending on population density, the food mixture has to be divided among additional food dishes. (About 1 kg food mixture is sufficient for breeding of 1000 maggots.) After about 6 days the larvae stop feeding and move to the dry surface of the food. They pupate after another 4 to 8 days. The dark brown pupae can be washed out with water from the food and stored in slightly wet sawdust. The adult flies emerge after 4 to 5 days. They can be fed on powdered milk, sugar and/or larval food.

### DROSOPHILA

Rearing conditions of *Drosophila* can be found in different handbooks and internet pages (see the link at the end of the References). It should therefore suffice to give only a short comment.

Breeding temperature is recommended between 18 and 25°C. Relative humidity in the breeding chamber should not be lower than 60%.

A recipe for standard medium used in our institute is given as follows:

Add together: 2.4 l water, 19.2 g agar, 192 g corn powder, 24 g soy flour (low fat), 43.2 g yeast, 180 g treacle, 90 g barley malt extract, 18 ml propionic acid and 2.5 g nipagin.

All ingredients are boiled up under constant stirring and filled in portions of about 50 ml into plastic (“*Drosophila*”) vials (10 cm height and 5 cm diameter). The indicated amount is sufficient for about 50 vials. After cooling the medium congeals. Before transferring flies on to the medium it is recommended to add some yeast on the surface. This stimulates the egg deposition and development of larvae.

### Kinds of Aging Studies

#### BIODEMOGRAPHIC STUDIES

It has been proven to be advantageous—and we recommend it—to accompany all forms of biodemographic studies with a control population. This has a simple reason. Carey (2000) emphasized how difficult it is to speak on life span in general and, in particular, in insects. In contrast to life expectancy and age specific

TABLE 21.1.  
Diagram of a mortality table

Days	$l_x$	$d_x$	$q_x$	$e_x$	$\log q_x$
1					
2					
n					

$x$ : age interval (days);  $l_x$ : survivors at the beginning of age interval;  $d_x$ : deads during the age interval (absolute death rate);  $q_x$ : age-specific death rate;  $e_x$ : life expectancy and  $a$  = number of days in the age interval

$$d_x = l_x - l_{(x+1)}$$

$$q_x = \frac{d_x}{l_x}$$

$$e_x = \frac{T_{x,a}}{L_x}$$

$$L_x = \frac{l_x + l_{(x+1)}}{2}$$

$$T_x = L_x + L_{(x+1)} + \dots + L_w = \sum_x L_x$$

mortality, which are measurable values, “life span” is weakly defined as time after which no member of a given species can survive even under the most favorable conditions. “Maximum life-span potential” is another description. It is evident therefore that maximum life span depends on the number of individuals under observation; it is higher when large numbers of individuals are observed. On the other hand, data on longevity obtained under laboratory conditions may have nothing to do with data recorded under free-living conditions. The determination of maximum life spans of ectothermic organisms as insects is even more problematical. Insects are extremely sensible to abiotic factors like temperature, humidity or light regime. It is therefore meaningless—as Carey pointed out—“to consider life-span for any species without considering environmental, ecological and evolutionary contexts.”

#### Preparing mortality data

To get survival and mortality data of *Phormia* in a longitudinal study, we start with a population of 400 individuals. Dead flies are counted daily, and mortality statistics are calculated after scaling the data to 1000. (Table 21.1; see Lamb, 1977).

Plotting the logarithm of  $q_x$  against age in days results in the Gompertz curve of mortality.

It is easy to put the single calculation steps into an Excel table, so that you only have to count the dead flies per day.

## Age-Dependent Ultrastructural Changes in Insect Tissues

As mentioned above, adult insects are composed of nondividing (postmitotic) cells. Tissue degeneration with advancing age resembles that of brain and other postmitotic tissues in mammals. The observed changes in dipterans like *Drosophila* or *Musca*, however, are not uniform, ranging from “total degeneration” to “poorly developed changes.” We use *Panorpa* as a model organism not only for comparative reasons but also because, as said above, this insect shows senescent tissue degeneration even under free-living conditions (Collatz and Collatz, 1981). Figure 21.3 shows an example of tissue degeneration in senescent *Panorpa*. It should be possible in such an organism to demonstrate protective effects of various drugs (e.g., antioxidants) on tissue degeneration.

## The Possibility of Continuously Measuring Energy Metabolism

The small body size of insects offers the opportunity of continuously monitoring the total energy metabolism of a whole population over their total life span. This results in a “metabolic picture.” One can then test the influence of different treatments (e.g., temperature, light program, drugs, mating, virginity) on the energy consumption. We performed such measurements with *Phormia* using an infrared CO<sub>2</sub> monitoring system (URAS). Due to the restriction on carbohydrates as energy-providing substrate, the CO<sub>2</sub> output equals the O<sub>2</sub> input and therefore gives a true picture of energy metabolism. Thirty-five flies were placed in a respiration chamber and fed in the usual manner with sugar and water. The relatively big volume of the chamber allows unrestricted flying and walking activity. Figure 21.4 shows an example of such a measurement.

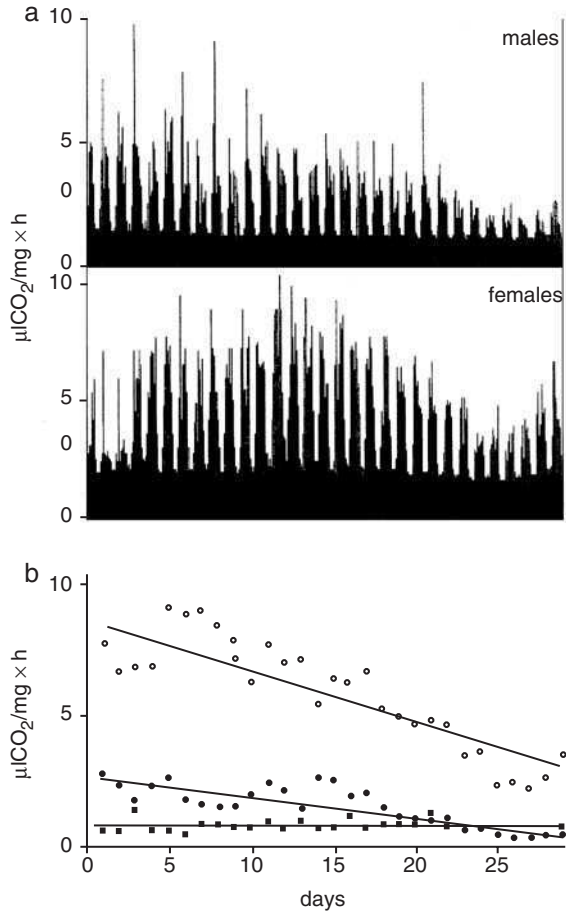

The CO<sub>2</sub> production per 30 min was calculated from the continuous monitoring. Males and females exhibit a very different energy profile. In both sexes, however, a well-developed day–night rhythm of activity could be found. With increasing age, a decline of maximum (flight) and minimum (walking) activity can be observed. The basal metabolic rate (night values) in contrast is independent from age and is constant over the life span in males.

Different light regimes influence the adult life span. At least in *Drosophila*, constant light has a life-shortening effect (Sheeba *et al.*, 2000). Under such conditions, a very high egg production rate can be observed, which might be responsible for the early death. After results from Pittendrigh (1972), the light–dark cycle under which larvae of *Drosophila* were reared had strong influence on the longevity of the adults. It is generally known that a desynchronization of endogenous rhythms affects many physiological parameters and is therefore of major

**Figure 21.3.** Example for senescent tissue degeneration in *Panorpa* ultrastructure of (a) young flight muscle, (b) flight muscle deterioration, (c) malpighian tubule with lipofuscin like inclusions and degenerated mitochondria.

influence on aging and disease. *Phormia* has proven to be a suited experimental animal to study such chronobiological aspects. After keeping the flies in non-24-h light-dark cycles or subjecting them to a jet lag, a life-shortening

**Figure 21.4.** (a) Energy profile over the life span of male and female *Phormia* flies measured as  $\text{CO}_2$  production with an infrared analyzer. (b) Decline of maximum (flight) and minimum (walking) activity and constant basal metabolic rate (night values) over the life span of males. Data taken from (a).

effect could be detected (Saint Paul, 1978). Only few attempts have been made up to now to gain more insight into the mechanisms of circadian dyschronism and aging. Aging changes in glycolytic oscillations—a basic biochemical rhythm—were described for *Phormia* by Collatz and Horning (1990) and Horning and Collatz (1990).

### Interrupting the Aging Process by Induction of a Phase of Low Metabolic Rate

Insect diapause is a particular form of prospective dormancy, comparable to adaptations like hibernation in small mammals or dauer forms in nematods. It seems reasonable to assume that the underlying mechanisms, including the signal transduction mechanisms which trigger the intrinsic metabolic rearrangements during this phase of reduced energy metabolism, are similar in different animals. The blowfly *Phormia* and *Drosophila*

could be promising models to study aging in diapause—see Tatar and Yin (2001), Stoffolano (1974), and Yin and Stoffolano (1994, 1997).

We used *Gastrophysa viridula* to show that reproductive diapause is characterized as a life period with negligible senescence (Albonetti and Becker in our laboratory).

Under experimental conditions, 75% of adult *Gastrophysa* beetles enter diapause after changing the photoperiod from long-day conditions (16:8) to short-day conditions (8:16) without lowering the normal rearing temperature of 20°C. The survival curves of diapausing and nondiapausing beetles are very different. The survival curve of beetles in diapause resembles an exponential function, which is characteristic for nonaging systems. In accordance with this, the age-specific mortality is constant over a long period. The survival curve and age-specific mortality of nondiapausing beetles follow the usual type of aging under senescence conditions. The average life span of beetles in diapause surpasses that of nondiapausing animals about fourfold (Figure 21.5).

Despite the high ambient temperature, which should enable a high activity spectrum of the beetles, the metabolic rate of diapausing animals slows down to only 20% of that of nondiapausing beetles (Figure 21.6).

**Figure 21.5.** Survival curve (d) and age-specific mortality rate (c) of *Gastrophysa* females in diapause compared to survival (a) and mortality (b) under long-day (nondiapause) conditions.

**Figure 21.6.** Metabolic rate of *Gastrophysa* females under diapause (b) and long day (nondiapause) conditions (a).

The feeding activity persists almost completely, and males and females accumulate high lipid values.

It would be interesting to study if the suppression of reproduction favors an allocation of metabolic reserves for maintenance of body integrity in the sense of the “disposable soma theory” (see Study of Trade-offs Between Physical Activities, Reproduction, and Longevity; Kirkwood and Holliday, 1979). However, the metabolic consequences that are responsible for this drastic variation in life cycle are nearly unknown.

## Caloric Restriction

Beginning with the early work of McCay and Maynard (1935) who reported a life-prolonging effect of caloric restriction in rats, numerous attempts have been made to study the underlying causes of this obviously general mechanism. It could be shown that a reduction of caloric intake of 30 to 50% prolonged the life of rodents up to 60%. The same results were obtained in young animals and in older adults which received the reduced diet later in life. The results of the studies on rodents could be confirmed in numerous studies on other vertebrates, nematodes and even protozoa (see Masoro, 2000). Evidence for enhanced survival under dietary restriction in insects was provided by studies on waterstriders (Kaitala, 1991), carabid beetles (Ernsting and Isaaks, 1991), and *Drosophila* (see chapters in this book). Long-time studies using primates started in the eighties and continue up to now, revealing exciting results (Mattison *et al.*, 2003).

The influence of dietary restriction on the organism is manifold. Obviously, the reduction of oxidative stress by reducing the accumulation of reactive oxygen molecules and the protection of the antioxidant system plays a central role.

It is often reported that a dietary restriction leads to a reduction of fertility. It was argued that the energy resources are used for the maintenance of body function instead for reproduction with the result of prolonging the life span. The evolutionary implications of such a life-history strategy were discussed by Shanley and Kirkwood (2000).

Recently the influence of dietary restriction on gene expression has attracted more and more attention. It could be shown that the expression of gluconeogenic genes was stimulated in rodents after caloric restriction (Spindler, 2001).

Regarding the change in intermediary metabolism, a gene family came into consideration which is called SIR2 (Brachman *et al.*, 1995). Studies with yeast show that the gene product of SIR2 is a NAD-dependent histone deacetylase which inactivates chromosomal regions (Guarente and Kenyon, 2000). With increasing age, a partial loss of inactivation results in errors in gene expression. This process can be delayed by high bioavailability of NAD. A reduced glycolytic flow as shown after

caloric restriction is therefore sufficient to provide the SIR2 system with more NAD.

The ultimate reasons for the evolution of the beneficial effects of caloric restriction are more speculative. Holliday (1989) considered the life prolongation as an adaptation to temporary periods with insufficient food. Animals which survive these periods due to a reduced energy metabolism and interrupted reproduction are able to reproduce when the situation becomes more favorable.

This short summary shows that a major effect of caloric restriction is visible in the glycolytic pathway and its regulation. Since *Phormia*—as pointed out—is exclusively dependent on carbohydrates as energy fuel, the fly could be a very promising subject for corresponding studies. This will be further illustrated below.

Braun in our laboratory used copulated *Phormia* flies to study the effect of caloric restriction induced by intermittent sugar feeding on mortality characteristics, fertility, and metabolic rate. Two experimental groups with starvation periods of 24 or 48 hours against a control group with ad libitum feeding were taken for the experiments. The fertility was calculated over the average number of laid eggs per day. The metabolic rate was determined by measurement of CO<sub>2</sub> production.

The specific activity of arginine phosphokinase (APK) in the thorax was measured as biomarker of muscle (flight) activity. APK represents the phosphagen cleaving enzyme in insects and other invertebrates and is comparable to creatine phosphokinase in vertebrates.

The most remarkable result was that under these experimental conditions the life expectancy and the maximum life span of males were reduced against the control group whereas that of females was increased.

Females with a starvation period of 24 hours produced significantly more eggs than the control group. After 48 hours intermittent starvation, the egg production was reduced and shifted to the last period of life. Males fed ad libitum exhibited a significantly higher metabolic rate than females. Under dietary restriction we found a reduction of metabolic rate up to 90% in the males (Figure 21.7).

In contrast, dietary restriction had no effect on metabolic rate in females. The specific activity of APK is generally higher in fully fed flies.

**Figure 21.7.** Metabolic rate of male *Phormia* flies under ad libitum feeding (a) and two days intermittent starvation (b).

In summary, caloric restriction has a sex-specific effect and does not necessarily result in a reduction of metabolic rate and fertility. In our example, the higher fertility and life span of females with caloric restriction is obviously reached at the expense of reduced activity.

## Study of Trade-offs Between Physical Activities, Reproduction, and Longevity

The comparative gerontologist often uses a theory which is assumed to explain the different longevity of organisms. This theory known as “disposable soma theory” was introduced into the studies of aging by Kirkwood (1977). The central thought is that the life history of a species in general is characterized by limited resources (constraints) of variable nature. That means that trade-offs exist between key life history variables and such trade-offs favor the allocation of energy between reproduction and maintenance of body constituents. Kirkwood argued that this universal theory should also be adaptable to humans. Together with Westendorp he had the opportunity to study the birth and death rates of about 35,000 males and females of the British aristocracy living between 740 and 1875. The main result was a negative correlation between longevity of females and the number of progeny (Westendorp and Kirkwood, 1998). Recent studies do not agree with these data (Lycett *et al.*, 2000). Accepted or not, the theory is testable with insects as models. Trade-offs between flight capability, reproduction, and longevity were indeed found in two cricket species (Tanaka and Suzuki, 1998, Zera *et al.*, 1998). In fruit flies deprived of protein as a source for egg development, the time of reproduction can be delayed with the result of a remarkable elongation of life span (Carey *et al.*, 1998). The same life-prolonging effect can be induced in *Phormia* (Wilker in our laboratory), which is an anautogenic insect as mentioned above. Feeding protein at the first time after 17 days of adult life decreases the age-specific mortality rate. This effect was particularly obvious when virgin females were used (Figure 21.8).

**Figure 21.8.** Survival curves (a,b,c) and age-specific mortality rates (d,e,f) of virgin female *Phormia* under conditions of “no protein,” “protein ad libitum,” and first protein access after 17 days (after Collatz, 2003), with permission).

## Metabolic Aging Studies

All metabolic aging studies on substrate and enzymatic level can profit by the basic similarity of the insect metabolism with that of other organisms, including man. It is therefore not surprising that many studies deal with enzyme activity or substrate changes in aging insects. Their antioxidative system garnered more attention with increasing knowledge of the role of free radicals and oxidative stress in aging and disease. Before showing some examples of such measurements, it seems advantageous to give some technical comments for the work with insects like *Phormia*.

### RECOMMENDED PREPARATION OF PHORMIA FOR ENZYME AND SUBSTRATE DETERMINATION

**Enzyme determination.** Take 5 to 10 flies total or separate thorax and abdomen after decapitation.

Homogenize in 5-fold volume of ice cold TRA-buffer, 100 mM with 10 mM EDTA at pH 7.5 with a glass homogenizer. Centrifuge 20 minutes at 4°C with 5000 g. Take the supernatant and precipitate the dissolved proteins with 80% ammonium sulphate. Dissolve the precipitant with 1 ml homogenizing buffer after centrifugation as above.

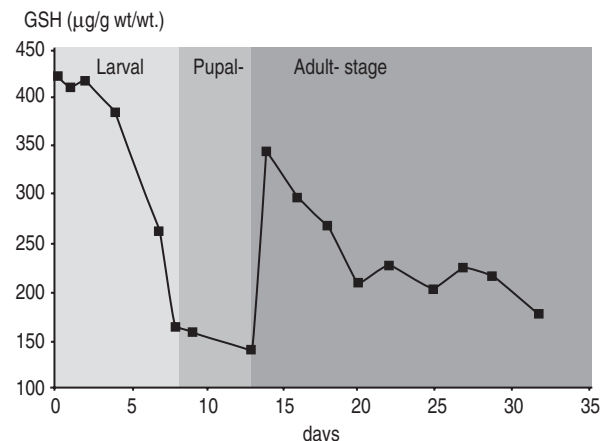

**Substrate determination.** Place 10 flies into liquid nitrogen. This separates head, thorax, abdomen and extremities. Take the desired parts and grind them in liquid nitrogen after addition of 1 ml of 0.6 N HClO<sub>4</sub>. Transfer the mixture into centrifuge tubes and centrifuge after thawing 30 min at 4°C and 5000 g. Neutralize the supernatant with solid KHCO<sub>3</sub> and store at -20°C until substrate determination.

**Isolation of mitochondria.** Put 10 thoraces (or abdomina) in 10 ml ice cold buffer (100 mM Tris/HCl, 10 mM EDTA, 320 mM sucrose, pH 7.5) and crush the material in a glass homogenizer with a Teflon pestle by raising and lowering it 20 times. Put the crude homogenate onto a nylon filter to remove chitin, myofibrils and tracheae fragments and wash it with buffer up to an end volume of 50 ml. Centrifuge 20 min at 100 g in the cold. Take the supernatant and centrifuge once more for 10 min at 3000 g and 4°C. The mitochondria are now in the precipitate and can be redissolved in 4-ml buffer.

### EXAMPLES OF METABOLIC DETERMINATIONS

#### *Redox state and influence of cell milieu on enzymatic activities*

The thiole glutathione (GSH) is the most important nonenzymatic antioxidant in organisms and exists in considerably high concentrations in all cell types. GSH can react with electrophilic compounds or free radicals. The content of GSH in aging tissues generally declines, and it is assumed that this decline reduces the capacity to

**Figure 21.9.** Glutathione content of *Phormia* flies in different life stages.

defend toxic effects of free radicals. Buthionin sulfoximine (BSO) is an irreversible inhibitor of the  $\gamma$ -glutamylcystein synthetase, which is a key enzyme for the synthesis of GSH. BSO can be used to empty the intracellular stores of GSH. This allows conclusions about the protective role of GSH.

In *Phormia* there is a strong correlation between life stage and the GSH content (Figure 21.9).

Treatment with BSO for 11 days reduces the GSH content to 10% compared with the control. After this treatment, a resynthesis of GSH is observed only in younger flies.

Similarly, *Phormia* can be used to study the age-dependent capability of xenobiotics via the GSH-S-transferase (GST) system for detoxification (Collatz and Flury, 1992). Using the analgetic drug Paracetamol, we were able to show that both a reduced GSH level and a diminished activity of GST lead to an increasing mortality of old flies after drug injection.

It is a common phenomenon that the redox state of an old organism is shifted towards the oxidized site. *Phormia* is no exception. Together with the reduced GSH content, the quotient of the NAD/NADH and NADP/NADPH redox system is responsible for the redox state of the cell (Figure 21.10).

It is important to note that a change of the redox state, and with this the cell milieu, can alter enzyme activities. Jaekel in our laboratory showed this for purified glyceraldehyde-3-phosphate dehydrogenase (GAPDH) from young and old flies (Figure 21.11).

The kinetic properties of “young” and “old” enzymes are determined by the age-appropriate *in vivo* concentrations of NAD and NADH. “Old” enzyme reacts under “young” physiological conditions with an increase of  $V_{max}$  and  $K_m$ . In contrast “young” enzyme reacts under “old” physiological conditions with a reduction of  $V_{max}$  and  $K_m$ .

## 21. Insect Models for the Study of Aging

**Figure 21.10.** NAD and NADH content and NAD/NADH-quotient over the life span of *Phormia* flies to show the shift of the redox system to more oxidized state with increasing age.

**Figure 21.11.** Influence of the cell milieu in aged *Phormia* flies on enzyme activity. Kinetics of purified GAPDH from young (8 days) and old (29 days) flies in mixture of NAD 0.4 mM/NADH 0.2 mM ("young milieu") and NAD 0.8 mM/NADH 0.1 mM ("old milieu"), after Collatz *et al.* (1993), with permission.

### Conclusion

When comparative aging studies began in the eighties of the last century, it was a frequently quoted question whether insects are appropriate as model systems for aging studies. In the meantime insects cannot be dismissed

as experimental animals for gaining insight in aging mechanisms in general. It was already addressed that the underlying chemical and cytological processes through which aging becomes visible are shared throughout the animal kingdom and, in part, even by plants.

In the last decade, several attempts have been made to unravel the similarities and differences from yeast to man that exist in signal transduction mechanisms, in particular those of the insulin/IGF-signalling pathway. According to Rincon *et al.* (2004), the disruption of the insulin/IGF-1 receptor in nematodes and flies increases life span significantly. Mammals with genetic defects in the insulin signalling pathway, however, are at risk for increased mortality. Indeed, even these contradictory results and the paradox of the insulin/IGF-1 signalling pathway in longevity were recognized only after careful examinations of invertebrate models, including flies.

# Drosophila Models of Aging

Satomi Miwa and Alan Cohen

*The fruit fly, Drosophila melanogaster, is one of the most studied organisms in a variety of biological research fields, including studies on aging. The Drosophila model has approached aging from a range of angles and contributed significantly to our understanding of aging. It has been a valuable model organism in the field and is expected to remain so. This chapter aims to introduce Drosophila as a model organism for the study of aging. First, the basic biology of Drosophila is described within the context of aging, including its life history, characteristics of aging and physiology, and factors that affect lifespan. Next, various types of experimental approaches that can be used with Drosophila are presented, such as demographic, genetic, and physiological approaches. Lastly, a review of Drosophila studies on aging is presented, with emphasis on major achievements that Drosophila studies have accomplished. They illustrate types of studies particularly suited for flies, and how to combine different experimental approaches into one integrated study. We also raise limitations and technical problems, as well as unsolved problems; such issues are discussed with possible future directions.*

## Introduction

The common fruit fly, *Drosophila melanogaster*, is one of the most studied organisms in biological research, with a history of use going back to the early 1900s. The first person known to have cultured *Drosophila* in quantity is Charles W. Woodworth, who suggested to colleagues that this organism be used for genetic work. Shortly after, *Drosophila* was introduced to Thomas Hunt Morgan, who made significant advances in genetics using this organism, leading him to win a Nobel Prize in Physiology or Medicine in 1933.

*Drosophila* is a convenient model organism in laboratories because it is easy to culture, inexpensive, available with a highly homogeneous genetic background, and has high reproductive capacity and a short lifespan. The system has traditionally been used in genetics, but more recently has become a staple in developmental biology. Furthermore, it has proven a useful model on which to study basic physiology such as circadian rhythms, learning, and memory. It even provides a genetic model for human neurodegenerative diseases including

Huntington's disease, Alzheimer's disease, and Parkinson's disease. A potential new field may be the use in nociception research (Manev and Dimitrijevic, 2005), since there are no serious ethical considerations for insects like there are for higher model organisms.

The sequencing and annotation of the entire eukaryotic component of the *Drosophila* genome (about 13,600 genes) was completed in March 2000. Humans have about twice as many genes as flies, but the extra genes rarely represent novel functions; they simply allow for more complex regulation of fundamental molecular pathways. This is one of the main reasons the *Drosophila* model has implications for biological understandings of higher organisms.

*Drosophila* has also been one of the major model organisms on which to study fundamental mechanisms of aging. Although aging has been studied in various model organisms, a unique feature the *Drosophila* model has relative to other organisms is the wealth of resources already available. Its embryonic development, physiology, and behavior have all been studied by experts in these areas, and experimental techniques including advanced genetic tools are readily accessible. Furthermore, different stocks are available from stock centers around the world, and related information is publicly available on the Internet. Thus, although there are merits to working on novel animals, working with well-characterized organisms like *Drosophila* can facilitate research immensely. In addition, there are some biological characteristics that may be useful in aging studies. First, the period of growth and development (egg, larva and pupa) is clearly distinguishable from adult phase, where aging manifests. The transition to adult phase is not always so discrete in some animals. Next, the adult fly consists of mostly postmitotic cells, except for a few cells in the gonads and gut. Thus, the changes that occur during aging in cells and tissues are readily measurable.

The purpose of this chapter is to introduce *Drosophila* as a model organism for the study of aging. It includes a description of *Drosophila* life history, *Drosophila* as an aging organism, types of studies that can be done, and a brief review of aging research on *Drosophila*. Basic fly culturing techniques are also outlined. From this, one might consider whether *Drosophila* is a suitable model for a particular question to be investigated and whether

it is feasible to culture flies in a given laboratory. Although *Drosophila* is often associated with genetic approaches, a detailed explanation of genetic techniques is beyond the scope of this chapter. More detailed laboratory protocols and experimental procedures as well as genetic technologies available are described elsewhere. See the Recommended Resources section at the end of this chapter for many excellent review articles, books and Internet resources on *Drosophila*.

## Basic Biology of *Drosophila* as It Relates to Aging Studies

### LIFE HISTORY OF *DROSOPHILA*

#### *Development and maturation*

There are three distinct morphological stages during development of *Drosophila*: egg, larva, and pupa. Approximate durations of each stage (at 25°C) are shown in Table 22.1. At 25°C, it takes around 10 days for a fertilized egg to become adult. Eggs are laid on the surface of the food medium. The egg is very small, shiny white, and ovoid (about 0.5 mm). The larva is a worm-like creature that feeds extensively. The larva molts twice, and the periods between the molts are called instars; thus the larva undergoes three stages as the first, second and third instars. It rapidly expands during molting before the new cuticle hardens (2–3 mm long at the third instar). The third instar larva eventually stops feeding and crawls out of the food medium and becomes still. After several hours a white prepupa (about 2 mm) is formed. It becomes brown within an hour, and air bubbles come out from the abdomen making it buoyant. Most pupae are stuck to the wall of the container or on the stopper. During pupation, imaginal discs develop in the tissues of the adult fly (about 3 mm).

Flies tend to eclose just before dawn. Newly eclosed adult flies have a soft cuticle and folded wings. It takes several hours for the wings to become unfolded, dry out and harden. Very young flies are light colored and have dark meconium in the gut, visible through the ventral abdominal wall. Flies do not mate for 8 hours after eclosion; this is a critical period in which virgin females can be collected. The lifespan of adult flies is dependent

TABLE 22.1  
Developmental stages and durations of *Drosophila*

Stages		Times after egg laying	Duration
Egg		–	≈1 day
Larva	1 <sup>st</sup> instar	22 hours	≈1 day
	2 <sup>nd</sup> instar	46 hours	≈1 day
	3 <sup>rd</sup> instar	70 hours	≈2 days
Pupa		120 hours	≈5 days

on strain and environment. Under standard conditions, wild-type flies live up to 2–3 months.

#### *Characteristics of aging*

Finch (1990) has identified three major patterns of aging in animals: rapid, which is typified by semelparous organisms such as Atlantic salmon and mayflies (Ephemeroptera); negligible, which is typified by colonial invertebrates and some turtles and fish; and gradual, which is found in most birds and mammals, including humans (Finch, 1990). Unlike many insects, *Drosophila* aging is gradual, an important feature for an organism serving as a model for human aging. However, unlike humans, *Drosophila* does not have a very long post-reproductive lifespan. Some examples of manifestations of senescence are shown in Table 22.2 (Rockstein and Miquel, 1973).

In general, marked degenerative changes occur in *Drosophila* tissues with advancing age. It is perhaps

TABLE 22.2  
Manifestation of aging in *Drosophila*

#### **Flight muscles**

- Formation of giant mitochondria by fusing, “swirls” in matrix
- Decrease in glycogen content, almost absent in very old individuals
- Decrease in oxidative phosphorylation enzyme activity
- Myofibrillar degeneration
- Inability to fly in very old individuals

#### **Reproductive system**

- In male testis, decreases in the number of spermatogonia and spermatocytes
- Decrease in numbers of egg production in females

#### **Digestive system**

- Accumulation of numerous large lamellated cytoplasmic inclusions in the midgut
- Increases in lipid droplets and vacuoles

#### **Fat body**

- Decrease in fat content
- Decrease in cell size and shrunken appearance
- Uneven distribution of glycogen within a cell

#### **Nervous system**

- Nerve-cell degeneration in brain
- Decrease in the amount of cytoplasm and ribosomes in neurosecretory cells
- Decrease in negative geotaxis ability

#### **Others**

- Decrease in heart rate
- Structural and functional alterations in Malpighian tubules in excretory system

due to the fact that cells in *Drosophila* are mostly postmitotic and are not replaced except for a small part of the reproductive tissues. Causes of death in *Drosophila* are not well established. Suggestions include starvation, fat body degeneration, failure of the digestive system, failure of the excretory organs, and failure of the nervous system, among others (Rockstein and Miquel, 1973).

## COMMENTS ON PHYSIOLOGY

The appearance of male and female flies is described elsewhere; see the Recommended Resources section. Like the mammals for which it often serves as a proxy, *Drosophila* has a nervous system, hormonal system, and circulatory system. However it lacks several systems present in mammals, and many shared systems function somewhat differently. First, as a poikilotherm, temperature has a direct effect on metabolic rate, and lifespan of the flies can be significantly extended when they are kept at lower temperatures (see below). Because the adult fly consists mostly of postmitotic cells, issues such as replicative senescence, cell proliferation in aging, and cancer development have not been considered in flies; however, these factors may be important in higher organisms that have many mitotic cells.

In the mammalian insulin signaling pathway, functions of growth and metabolism in mammals are regulated by different receptors, the IGF-1 and insulin receptors. In contrast, in *Drosophila*, diverse physiological functions (including growth, metabolism, and reproduction) are regulated by a single hormonal receptor in the insulin signaling pathway (Tatar, 2004). The insulin-signaling pathway influences the levels of other insect hormones including juvenile hormone and the sterol ecdysone, which themselves may affect aging (Garofalo, 2002).

The respiration of *Drosophila* is mediated by simple diffusion; oxygen uptake is achieved by diffusion through the trachea (Weis-Fogh, 1964). In flight muscles, mitochondria are located almost adjacent to tracheole. Flight muscle mitochondria in insects have an exceptionally high oxidative metabolism capacity capable of supporting around 100-fold increases in oxygen consumption on initiation of flight (Sacktor, 1974). Recently, mitochondria have been at the center of attention in aging research. First, mitochondria are implicated as a major endogenous source of reactive oxygen species that can damage surrounding molecules; second, many experimental manipulations that extend lifespan are also known to alter glucose and lipid metabolism, and logically mitochondria are thought to play an important role. Finally, mitochondria are thought to be responsible for apoptosis, at least in part. Thus, together with the fact that mitochondria undergo significant morphological alterations with age (Sohal, 1976), highly active insect flight muscle mitochondria could be an interesting research subject.

The fat body, the organ that has been implicated as playing a role in regulating lifespan (Hwangbo *et al.*, 2004; Giannakou *et al.*, 2004), is equivalent to liver and white adipose tissue in mammals. It stores fat and glycogen, and is also responsible for immune function by producing antimicrobial peptides upon infection. In contrast to mammals and many other vertebrates, insects have only an innate immune system.

## FACTORS THAT AFFECT LIFESPAN

When conducting aging studies, it is most important to control genetic and environmental factors that affect lifespan. Uncontrolled variables can lead to erroneous interpretation of the results. The information below should be used both as a guide for variables that are particularly important to control, and as a primer on lifespan-related variables for further exploration.

### *Intrinsic/genetic factors*

Genetic background plays a major role in lifespan. It is important that the effects of mutant gene actions or any experimental manipulations be studied on a standard genetic background with an appropriate control group. However, because genetic influences on longevity are described in detail in Chapter 25 of this volume, no more will be said here.

Adult survival and fecundity show significant inbreeding depression, presumably because deleterious recessive mutations present are more likely to become homozygous and have deleterious phenotypic effects on the offspring of matings between relatives. Adult survival and fecundity evolve rapidly in laboratory culture. In a typical fly lab, the newly emerged adult flies are collected into new culture bottles, allowed to lay eggs, and then discarded. When this regime is applied to flies collected from nature, there is a rapid increase in early fecundity (which is selectively favored under this culture regime) and also a large decrease in adult survivorship as a correlated response to the early fecundity (Partridge and Pletcher, 2003).

There is no evidence to suggest sex differences in lifespan; however, males and females respond differently to interventions known to extend lifespan (e.g., dietary restriction (Magwere *et al.*, 2004)). Physiological differences, for example, differences in nutrient demand, differences in resource allocation (females for egg production; males for activity and courtship), and differences in sensitivity to hormonal signaling pathways that are known to determine lifespan (such as insulin/insulin-like growth factor signaling (IIS) pathway) may be responsible.

### *Extrinsic factors*

The lifespan of *Drosophila* is also affected by factors unrelated to genetics (Table 22.3), many of which have

TABLE 22.3  
Extrinsic factors that affect lifespan in *Drosophila*

Factors	Condition	Effects
Pre-adult development	Higher larval density	Prolongs the duration of development time and extends adult lifespan; results in smaller adult size
	Lower ambient temperature	Prolongs the duration of development time and extends adult lifespan; results in larger adult size
Parental age	Older parents	Fewer viable eggs and offspring have shorter lifespan
Fecundity	Higher reproductive activity	Shortens lifespan; Virgins live longer than mated flies in both sexes, but the magnitude of increase in lifespan is greater in females
Ambient temperature	Lower ambient temperature	Extends lifespan; Flies cultured at 18°C live more than twice as long as those at 25°C
Mild stress	Heat shock, cold stress, hypergravity, low levels of radiation	Extends lifespan
Diet	Dietary restriction	Extends lifespan
Physical activity	Reduced flight activity	Extends lifespan

been used as experimental manipulations to extend lifespan in order to elucidate factors that affect longevity. However, a mechanistic explanation of these factors is still unclear (see below).

Probably the strongest environmental stimulus that affects lifespan is environmental temperature. Adult flies cultured at 18°C live more than twice as long as those cultured at 25°C. Various mild stressors, including heat shock (37°C for less than 1 hour), cold stress, hypergravity, and low levels of irradiation, have been shown to extend lifespan. It has been proposed that mild stressors may induce protective systems that will be beneficial for forthcoming events. However, the effects could be secondary in some cases, as some stressors such as irradiation have negative effects on reproduction, which alone can extend lifespan.

Dietary yeast is important in survival and reproduction in adult *Drosophila*. In the absence of yeast, *Drosophila* arrest reproduction and increase mortality in both males and females (Good and Tatar, 2001). Dietary restriction extends lifespan in a variety of organisms including *Drosophila*. The females have greater responses to dietary restriction, even in sterile or *ovaryless* females (Mair *et al.*, 2004). The maximum extension of lifespan in females is achieved at a less severe level of dietary restriction than in males (Magwere *et al.*, 2004).

Prevention of flight activity has been shown to extend lifespan in blowflies (Yan and Sohal, 2000) as well as in *Drosophila* (Tapi Magwere, personal communications). In accord with this, mutant flies that move more than normal (*shaker* mutants) have shorter lifespan (Trout and Kaplan, 1970). Thus levels of physical activity in flies appear to negatively correlate with lifespan

(see the “*Drosophila* in Aging Studies” section for further discussion).

## Types of Experimental Approaches in Aging Studies

### DEMOGRAPHIC STUDIES

In aging studies it is of course important to measure the rate of aging. However, the rate at which an individual ages is difficult to measure. There is no consensus on biomarkers of aging. Furthermore, if one were to follow the changes in a biomarker, the assay would need to be noninvasive to avoid biasing the measure, and certainly could not kill the organisms. In contrast, the measurement of the rate of aging in a population can be achieved easily by analyzing patterns of age-at-death. Age-at-death is an unambiguous and easily measurable end point. Age-specific mortality is a measure of the instantaneous hazard of death for an individual at a given age. It allows independent comparisons of vulnerability to death at different ages. The main drawback of such demographic studies is that they require very large population sizes, especially for estimates of age-specific mortality and maximum lifespan. *Drosophila* is ideally suited for demographic analyses because it is easier to culture and monitor large numbers of individuals than with other short-lived model organisms such as yeast (*Saccharomyces cerevisiae*) and nematode worms (*Caenorhabditis elegans*). One assumption of such demographic measures of aging is that physiological and functional declines correlate with increases in death rate, which might not be the case. Therefore, ideally studies should be supplemented with some physiological

measures such as the number of eggs laid and locomotive function.

The mortality rate ( $\mu_x$ ) at age  $x$  can be expressed mathematically as

$$\mu_x = -\ln(P(x)) \quad (1)$$

where  $P(x)$  is the probability of an individual alive at age  $x$  surviving to age  $x + 1$  (Carey, 1993). The data are often gathered so as to fit explicit models in order to (a) reduce complexity and day-to-day variations of mortality data, and (b) allow parametric statistical tests. The most popular model is the Gompertz model:

$$\mu_x = ae^{bx} \quad (2)$$

where the constant  $a$  is the intrinsic baseline mortality rate and  $b$  is the rate at which mortality rates accelerate with age (Promislow and Haselkorn, 2002). The natural logarithm of the Gompertz equation gives a linear function:

$$\ln(\mu_x) = a + bx \quad (3)$$

which is analogous to a straight line with slope  $b$  and intercept  $a$  on the vertical axis. The slope  $b$  represents the rate of aging (Magwere *et al.*, 2004; Mair *et al.*, 2003). In the Gompertz model, the baseline mortality rate is not independent of aging rate. It should be noted that the Gompertz model assumes a constant, exponential increase in mortality rate throughout adulthood.

However, the early and very late mortality rates do not appear to fit the model completely: the increase in mortality rates slows down at the end of the lifespan.

Using this approach, experimental manipulations to extend lifespan can be classified into two types depending on the pattern of changes in mortality trajectory: treatments that change the slope (i.e., the rate of aging) and treatments that change the intercept (i.e., the underlying baseline mortality rate is changed) (Finch, 1990). A good illustration is a study by Mair *et al.* (2003) which performed a demographic analysis of effects of dietary restriction in flies (see “*Drosophila* in aging studies” Figure 22.1).

## GENETIC APPROACHES

Genetic tools in *Drosophila* have been well developed and can be used for a variety of purposes. There are ways to explore genes that control lifespan (e.g., quantitative trait loci (QTLs), longevity screens, candidate genes), and to identify genes that change their expression patterns in response to a particular treatment and/or with age (e.g., enhancer traps, microarray analysis). There are ways in which to manipulate the cellular environment by altering gene expressions in a time-dependent and tissue-specific manner (e.g., candidate gene approach). Below is an overview of such methods; comprehensive review articles on genetic approaches

in aging studies in *Drosophila* can be found elsewhere (Partridge and Pletcher, 2003; Helfand and Rogina, 2003; Poirier and Seroude, 2005).

### *Quantitative Trait Locus (QTL) approaches*

QTL is a method for associating variation in quantitative genetic traits with specific regions of the genome. Backcrosses and intercrosses can be used to find markers on a genomic map that correlate with variation in the quantitative trait. The amount of variation in the trait that is explained by each locus can be quantified, and this information can then be used to target specific areas of the genome for further investigation. Ultimately, the utility of the QTL approach depends on a detailed genomic map and the ability to characterize the functions of genes in the regions identified, making *Drosophila* an excellent organism for this technique. Moreover, the cross-breeding and inbreeding process is facilitated in *Drosophila* by the wide variety of lineages available.

In particular, the combination of candidate gene approaches (see below) and QTL can be a powerful tool for identifying genes responsible for quantitative variation in traits such as lifespan. However, it must be cautioned that QTL results may be specific to the environment and/or genetic background under which the experiment is conducted, and care should be used in generalizing the results.

### *Phenotype (longevity) screening*

This is a method for identifying genes affecting lifespan by observing phenotypes (i.e., longevity) of flies that are generated through random gene mutations. Identification of mutated genes can be simplified by using transposition for mutagenesis: the *P*-element transposon is a commonly used mutagen. *P*-elements are transposable elements that are widely used to make mutations and manipulate the genome. Often random insertion of transposons into genes or their regulatory elements decreases gene activity (Cooley *et al.*, 1988). For example, the *methuselah* gene, which encodes G-protein-coupled receptor, was identified by this method; loss of function in this by a *P*-element transposon resulted in 40% increases in average lifespan (Lin *et al.*, 1998).

### *Enhancer Traps*

With enhancer traps, detailed gene expression patterns in specific tissues or cells can be characterized. In enhancer traps, a promoter, usually a *P*-transposable element, is inserted into the genome together with a reporter gene such as lacZ and GAL4. Enhancer regulation is expected to affect the reporter gene as well as its usual targets, so expression patterns of the reporter gene can be characterized and taken as a proxy for expression patterns of genes nearby the insertion locus. Then the region around the insertion can be identified and studied

further in order to pinpoint what nearby gene(s) may be involved in the expression pattern and may thus be relevant to the phenomenon of interest (see O’Kane, 1998 for details). The gene *Indy* (*I’m Not Dead Yet*), which is associated with extended lifespan, was originally identified with an enhancer trap (Rogina *et al.*, 2000).

#### *Microarray Analysis*

Microarray analysis is a method that makes use of gene chips to which thousands of different mRNAs can bind and be quantified. By using such chips to quantify mRNA levels in different tissues or in individuals under different treatments, tens or hundreds of specific genes which vary in relation to the tissue or treatment can be identified, aiding in a mechanistic understanding of the differences. Further work can then be conducted using candidate locus approaches (see below). In contrast to QTL, which looks at allelic variation, microarray analysis looks at gene regulation: potentially, but not necessarily, a result of allelic variation.

As with QTLs, care must be exercised not only to control for genetic background and environment, but also to limit interpretation of results to the genetic background and environment studied. Also, it must be remembered that microarray analysis is by its nature correlative, and that further study of patterns is generally necessary for clear interpretation. That said, microarray analysis remains one of the most powerful techniques for examining genetic processes underlying physiological variation.

*Drosophila* in particular are well suited to microarray analysis (a) because the genome is relatively small, meaning that most of it can be analyzed with a single microarray and that potentially important patterns are less likely to be missed, and (b) because the functions of many genes have already been studied, facilitating interpretation of results. Microarray analysis has been used in *Drosophila* to characterize gene expression changes during dietary restriction and with aging (Pletcher *et al.*, 2002).

#### *Candidate gene approaches*

The major use of candidate gene approaches is to test specific genes selected based on educated guesses as to which genes affect the process in question. The genes of interest can be deleted, overexpressed, or induced, and phenotypes of the mutant flies are observed accordingly. Mutation methods usually involve *P*-element mediated transgenes. They can be used to introduce foreign DNA into the *Drosophila* genome. However, depending on its position in the genome, the expression of an inserted transgene may vary and the insertion can have considerable effects on lifespan. Therefore, methods that allow the experimental and the control groups to have a transgenic insert in the same genomic location are desirable (Partridge and Pletcher, 2003; Helfand and

Rogina, 2003; Venken and Bellen, 2005; Poirier and Seroude, 2005).

There are techniques for “inducible” mutation that allow conditional expression of genes in a time- and tissue-specific manner. In principle, gene expression is initiated upon application of the inducer. The “flip-out” system uses a heat pulse as the inducer. However, the heat pulse can itself affect lifespan, potentially complicating the results. Two other systems, the “gene-switch” and the “tet-on” systems, use antiprogestin, RU486, and tetracycline or its analogue doxycycline respectively, to feed flies to initiate gene expression.

## PHYSIOLOGICAL AND BIOCHEMICAL APPROACHES

In order to elucidate mechanisms of aging, downstream effects of experimental manipulations that extend lifespan need to be fully characterized. For example, identification of a gene for a mutation that extends lifespan does not by itself explain how the gene achieves this. Here, physiological, biochemical, and cell biological studies become essential.

Biochemical and cell biological approaches in *Drosophila* are well developed and easy to utilize. A large number of protocols for procedures such as DNA and RNA extractions and purification of mitochondrial DNA can be found in the literature (see Recommended Resources section).

Usually most types of measurements that have been performed in other model species such as rodents can also be applied to *Drosophila*. Preparation of tissue homogenate is easy, and potential aging biomarkers such as protein, lipid and DNA oxidative damage can be measured, as well as various metabolites and enzyme activities. Mitochondria are easily prepared from the homogenates (Miwa *et al.*, 2003), and respiration rate, reactive oxygen species production, membrane potentials and mitochondrial enzyme activities can be measured.

Physiological measures are important because they can provide insight into the nature of aging processes, which may not be apparent from the “age-at-death” measure that is used in demographic studies. A number of different types of behavioral assays such as learning and memory have been established (Connolly and Tully, 1998). Also there are other measures that are relevant to aging; number of eggs laid, negative geotaxis, immune function (DeVeale *et al.*, 2004), heart function (Wessells *et al.*, 2004), and circadian rhythm (Driver, 2000). Metabolic rate can be assayed by respirometry/calorimetry (Hulbert *et al.*, 2004), and stress resistance can be tested in various forms, including hydrogen peroxide, paraquat feeding, cold, starvation, and desiccation.

## *Drosophila* in Aging Studies

*Drosophila* studies have been involved in many aging-related topics and have been instrumental in shaping our

current view of aging. The success of the *Drosophila* model is no doubt helped by the availability of the variety of experimental approaches indicated above, which have been successfully used in combination on one topic, namely, demographic and genetic approaches in combination. Contributions of *Drosophila* studies can be roughly divided into four main areas: selection experiments on the evolution of aging; tests of metabolic and oxidative damage hypotheses of aging; dietary restriction; and searches for evolutionarily conserved genetic mechanisms of lifespan regulation. Though not necessarily mutually exclusive, each of these is presented below. They illustrate practical uses of various experimental approaches and how they can be combined to perform integrative studies; in addition, problems and future directions are also discussed.

### SELECTION AND DEMOGRAPHIC EXPERIMENTS

In 1957, G.C. Williams proposed antagonistic pleiotropy as an explanation for the evolution of aging (Williams, 1957). According to the theory, the declining force of selection with age results in selection for pleiotropic genes that enhance fitness early in life but reduce it later. The accumulation of many such genes could result in a deterioration of condition with age. This hypothesis became a driving force for most evolutionary studies of aging. Current research on the topic is less explicitly genetic, referring more to “trade-offs” than “pleiotropy”: a recognition that constraints may come from physiological, developmental, or even behavioral conflicts.

Because of its short generation time, *Drosophila* is ideally suited to selection experiments testing trade-off hypotheses. In a series of seminal experiments, Rose (1984) confirmed antagonistic pleiotropy for aging in *Drosophila*, demonstrating a tight correlation between early fecundity and lifespan. Selection for early fecundity produced short lifespans; selection for late fecundity produced long lifespans. Moreover, the results were highly reproducible. Further experiments in a number of labs have examined other trade-offs with lifespan. Development time was found to not be directly associated with lifespan, disproving the developmental theory of aging (Lints, 1978), at least for *Drosophila* (Chippindale *et al.*, 1994). Stress resistance was found to correlate positively with lifespan, though this response could eventually be broken down with strong selection over many generations (Phelan *et al.*, 2003). Mating itself was found to be toxic to females, mediating the lifespan–fecundity trade-off (Chapman *et al.*, 1993).

Large population sizes in *Drosophila* have also facilitated demographic studies examining fine details of mortality rate changes with age. Late-life mortality plateaus, a common phenomenon in a number of species, has been examined in depth in *Drosophila*. Also, studies have been conducted with large populations testing antagonistic pleiotropy in contrast to simple mutation

accumulation, though the interpretation of the results is still debated (Hughes *et al.*, 2002). Both mutation accumulation and antagonistic pleiotropy predict age-specific effects of mutations on mortality; this also has been tested and found (Yampolsky *et al.*, 2000).

It is a testament to the strength of the *Drosophila* model that most of the above studies, especially the detailed demographic explorations of mortality, have been done only in *Drosophila*. However, this also produces the caveat that the results may apply only to *Drosophila*, or at least may apply less broadly than some of the genetic mechanisms of aging described below. For example, while there do appear to be trade-offs between reproduction and longevity in mammals, the correlation is much less tight than in *Drosophila* and the mechanisms may be indirect (Cohen, 2004).

### RATE OF LIVING, METABOLISM, AND OXIDATIVE DAMAGE

The first substantive biological theory of aging, the rate of living theory, was developed from studies on *Drosophila*. The early work of Loeb and Northrop (1917) demonstrated that temperature was negatively associated with lifespan in *Drosophila*. Raymond Pearl, a biostatistician who worked on population genetics, put forward this phenomenon as the “rate of living theory.” He found that the coefficient relating lifespan to ambient temperature in flies had a magnitude between two and three, which was similar to that of chemical reactions; he interpreted this as signifying that all the biochemical reactions for living processes occurred faster at higher temperatures in flies.

Thus, increased lifespan in flies at lower temperatures was originally thought to be due to slowing down of *all* biochemical processes. However, the interpretation of effects of temperature may not be so simple because not all enzyme activities are affected by temperature to the same degree. Concentration of a molecule “X” depends on its production and consumption, and if the activities of the producer and the consumer have different Q10 values (thus differently affected by temperature) the concentration of molecule “X” could go up or down, depending on the balance. Furthermore, there are certain physiological responses to cold (temperature compensation) that are independent of metabolic rate, such as changes in membrane fatty acid composition, that can affect susceptibility to oxidative damage (unpublished observation). It is not known how circadian rhythms, which are known to control various physiological functions, are affected by temperature, although a constant 12:12 hour light:dark cycle in laboratory culture conditions can force them to follow this circadian cycle. Nevertheless, the demographic study of mortality trajectories has shown that lowering temperature changes the slope, suggesting the rate of aging was slowed down (Mair *et al.*, 2003).

The rate of living theory stated that the metabolic rate of an organism is directly and causally linked to its

longevity; that is, “live fast, die young.” A mechanistic explanation of the rate of living theory was provided by the oxidative damage theory. Originally proposed by Harman (1956), its modified and refined version states that reactive oxygen species produced as byproducts by mitochondria during normal aerobic respiration can attack and damage surrounding molecules, and accumulation of such damage causes aging (Harman, 1972; Sohal and Weindruch, 1996; Beckman and Ames, 1998). It is thought that the phenomenon of increased physical activity in flies shortening lifespan is due to a higher metabolic cost in these flies, which in turn increases mitochondrial reactive oxygen species production. However, this concept is confusing because mitochondrial reactive oxygen species production will be lower, rather than higher, under state 3 respiration (active respiration state, such as during exercise, producing ATP in the presence of ADP) compared with state 4 respiration (resting state, no production of ATP). This is because mitochondrial reactive oxygen species production correlates with membrane potential, and membrane potential is lower in state 3 than state 4. Furthermore, in mammals, elevated metabolic rate by wheel running exercise (Holloszy, 1997) or cold exposure (Holloszy and Smith, 1986) in rats does not shorten lifespan, and mice with higher metabolic rates (with lower membrane potential due to more mitochondrial uncoupling) were reported to live longer than those with lower metabolic rates (Speakman *et al.*, 2004), demonstrating a dissociation of increased metabolic rate and longevity. Similarly, it has been shown that extended lifespan in *Drosophila* was not accompanied by lowered metabolic rate (van Voorhies *et al.*, 2003; Hulbert *et al.*, 2004; Khazaeli *et al.*, 2005).

Nonetheless, the elevation of respiration rates between rest and flight in *Drosophila* is much larger (~100 fold) than that seen in mammalian models, so intense oxygen uptake in flies might indeed have detrimental effects. Further investigations exploring effects of flight activity on longevity in flies are of great interest.

In addition, many *Drosophila*-based studies have tested the oxidative damage hypothesis; a popular approach has been to reduce the level of oxidative stress and see if lifespan can be extended. For example, using the candidate gene approach, attempts have been made to lower levels of oxidative stress either by overexpressing antioxidant enzymes or by lowering mitochondrial reactive oxygen species production through elevating proton conductance (Miwa *et al.*, 2004; Fridell *et al.*, 2005). Dietary antioxidant supplementation has also been performed (reviewed in Le Bourg, 2001).

However, not all studies support the hypothesis. Initial studies genetically inducing increased antioxidant defenses had technical problems: use of short-lived flies, different sized inserts between control and experimental groups, and uncontrolled position effects in transgene constructs (Tower, 2000; Partridge and Pletcher, 2003). Later work found that overexpression of Cu,Zn-SOD,

Mn-SOD, or both with the FLP/FRT system increased lifespan (Sun *et al.*, 2002; Sun *et al.*, 2004; Sun and Tower, 1999). Cu,Zn-SOD overexpression in motoneurons extended lifespan (Parkes *et al.*, 1998), but overexpression of various combinations of Cu,Zn-SOD, Mn-SOD, catalase and thioredoxin reductase did not extend lifespan (Orr *et al.*, 2003). In addition, most studies involving altering antioxidant status did not check whether damage was actually reduced.

The effects of lowered mitochondrial reactive oxygen species on lifespan have been examined using transgenic flies that have higher proton conductance. Expression of human uncoupling protein 2 (hUCP2) in nervous tissue lowered reactive oxygen species production and extended lifespan but not when it was expressed in muscles (Fridell *et al.*, 2005). Overexpression of adenine nucleotide translocase in whole fly also lowered mitochondrial membrane potential and reactive oxygen species production, but lifespan was shortened (Miwa *et al.*, 2004). Although such negative results are difficult to interpret due to potential unknown side effects, there could be tissue-specific effects of this type of manipulation on lifespan. Alternatively, it is possible that hUCP2 induction in neurons in flies extended lifespan through mechanisms which are not related to oxidative stress, for example, by impairing insulin signaling. Further examination of this issue will be enlightening.

Other studies—some of them on houseflies—have aimed to establish correlational evidence of the oxidative damage theory, as has been done in mammalian systems. Oxidative damage was found to increase with age (Sohal *et al.*, 1993; Yan *et al.*, 1997; Yan and Sohal, 1998). Mitochondrial reactive oxygen species production was found to increase with age (Sohal and Sohal, 1991; Sohal, 1993; Ross, 2000), and it was lower in long-lived lines of flies than controls (Farmer and Sohal, 1989). However, no such correlation was found when lifespan was extended by dietary restriction (Miwa *et al.*, 2004).

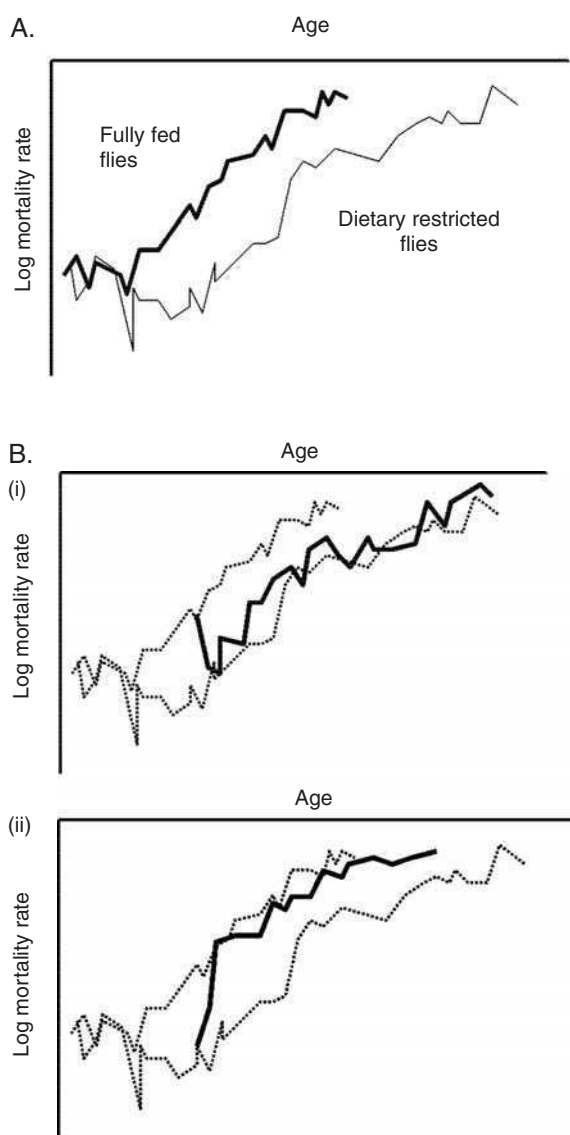

Although there is much correlative evidence to support it, confirmation of the oxidative damage theory still requires establishment of (a) which specific forms of damage (DNA, proteins or lipids) are important; (b) how the balance between ROS formation, ROS removal, and damage repair is regulated; and (c) which tissues or cell types are most critically affected. Then the appropriate direct tests should be performed accordingly. The *Drosophila* model will be a major player in this ongoing research area.

## DIETARY RESTRICTION

Dietary restriction is the only environmental manipulation that can bring robust extension of lifespan in a variety of model organisms, and is one of the most important themes in aging studies. Despite a great deal of effort, the precise mechanisms by which it works are not clear. Exploration of its mechanism has also been

attempted in *Drosophila*, and though the picture is incomplete, progress is being made.

Using demographic analyses, it has been shown that dietary restriction extends lifespan in flies by altering baseline mortality rate without altering the rate of aging (Mair *et al.*, 2003). (Figure 22.1).

**Figure 22.1.** (A) Age-specific mortality trajectories in *Drosophila* subjected to different dietary regimes. Dietary restriction lowers initial mortality rate (intercept) but does not affect the rate of increase (slope). (B) Rapid adjustment in mortality trajectories after changes in diet regime (post-switching trajectories are shown in solid lines; the trajectories in Figure 22.1-A are shown in dashed lines). (i) Switching from fully fed to dietary restriction diet; (ii) switching from dietary restriction to fully fed diet. Subsequent mortality trajectories after the diet switch are not affected by the previous dietary experiences, and only reflect the current dietary status. (Mair *et al.*, 2003). Figures re-drawn from (Mair *et al.*, 2003), with permission.

This study also suggests that dietary restriction does not affect irreversible, time-dependent accumulation of damage because the mortality was rapidly and completely reversed when the dietary restriction was removed (and vice versa). Thus, the effect of diet on mortality rate is only real-time, and not affected by past history (Mair *et al.*, 2003). Examining the reversibility of a treatment is therefore particularly informative, and it will be enlightening to conduct this type of treatment-switching experiment in other experimental models that extend lifespan. However, it is debatable whether this response is unique to flies (Partridge *et al.*, 2005). Similar demographic studies in mammals have not been performed to clarify this issue, perhaps due to a difficulty in conducting the study involving a large number of animals.

Next, microarray analysis of gene expression in response to dietary restriction showed that genes regulating cell growth, metabolism and reproduction were down regulated (Pletcher *et al.*, 2002). However, there are many other molecular, biochemical and physiological studies that can be performed on the *Drosophila* dietary restriction model, as in the case of rodent models.

#### SEARCH FOR EVOLUTIONARILY CONSERVED GENETIC MECHANISMS AFFECTING LIFESPAN

*Drosophila* has been used to identify evolutionarily conserved aging mechanisms by assessment of whether particular genes/genetic pathways that extend lifespan in other organisms such as yeast and nematodes also work in flies. Any mechanisms that are conserved across distant species are likely to have implications for humans.

Genes in the insulin/insulin-like growth factor signaling pathway have been examined based on the knowledge that homologues such as *daf-2* extend lifespan in *C. elegans*. The *Drosophila* equivalent of *daf-2* (*Inr*), *chico*, a *Drosophila* insulin receptor substrate, were also found to extend lifespan in flies when mutated, suggesting conserved mechanisms of the IIS pathway in the control of lifespan.

Another example is the role of the sirtuin family of genes. SIR2 is a NAD-dependent histone deacetylase that is involved in silencing at mating type loci in yeast. In yeast, a single extra copy of SIR2 increases lifespan, whereas its deletion shortens lifespan, and SIR2 also mediates the effect of dietary restriction. In *C. elegans*, the closest homologue is *sir-2.1*, and increased dosage extended lifespan in a *daf-2*-dependent manner. Following these findings, effects of increasing *Drosophila* Sir2 (dSir2) were examined; dSir2 was also reported to regulate lifespan in flies, and the effect was linked with that of dietary restriction (Rogina and Helfand, 2004). Again, it suggests that there is a conserved mechanism of Sir2 in the regulation of lifespan.

Phenotype screening, candidate locus approaches, and QTL mapping have resulted in discovery of a number of genes in *Drosophila* that extend lifespan. The first example of such a gene was *methuselah* (*mth*), which

codes for a G-coupled membrane receptor-like protein, reported in 1998 (Lin *et al.*, 1998) by longevity screens. Since then almost 50 additional genes have been identified. Whether these genes also affect lifespan in other species is yet to be determined, but just as *Drosophila* has served as a test species for genes identified in other organisms, others may serve to explore patterns initially found in *Drosophila*.

## ***Drosophila* in Practice**

### **BASIC FLY HANDLING**

In general, *Drosophila* are cultured at 25°C on a 12-hour light:dark cycle with 60–70% humidity. Flies may be kept in bottles or vials that have food on the bottom. Appropriately sized foam stoppers may be convenient to seal the top; however, a chunk of cotton wool may also be used. As has been mentioned, temperature has a significant effect on lifespan in flies. The minimum permissive temperature is 18°C, and the upper restrictive temperature is 29°C. If there are only a few hundred flies of a few stocks, one or two 25°C incubators are sufficient. However, if there are going to be large numbers of flies, a 25°C room will be a preferred choice.

Fly stocks can be successfully cultured by regular mass transfer to fresh food. The frequency of the transfer needs to be established depending on the fly strains, the temperature and the density of the cultures. Stocks kept at 25°C (200–300 adults per half-pint bottle) should be transferred to fresh food at least once every 2 weeks. In older stocks, mites and mold may appear and cause problems, so the stocks should be monitored from time to time regardless of the intervals. This period can be extended by keeping the stocks at a lower temperature (e.g., 18°C); however, not all strains survive well at 18°C, and mold can be a serious problem for certain strains.

To obtain healthy adults, optimum numbers of parental flies need to be established. In most cases, 300–600 flies are obtained from a bottle, in which around 100 females (and a few tens of males) are left for a day and allowed to lay eggs. All the parental flies need to be emptied afterwards. If larvae become overcrowded, baker's yeast should be added to provide additional nutrition.

There are many types of fly food used by different laboratories. Food is commercially available, but can also be cooked in laboratories (for recipes, see the "Recommended Resources" section: Roberts and Standen (1998), website for Bloomington stock center). The food may be kept at 4°C for about a month. Nipagin M (*p*-hydroxy benzoic acid methyl ester) is an antioxidant that is often included in food. *In vitro*, it is able to scavenge hydrogen peroxide production by mitochondria effectively at relatively high concentrations, although there is no report of the effects of Nipagin on lifespan.

Dietary restriction in flies has been applied by food dilution, and this method can extend lifespan in flies. However, there have been concerns about how much flies eat, since flies are cultured on food in a bottle and have access to food all the time; the flies on diluted food may eat more to make up the calories. Indeed, a recent study measuring food intake using isotope labeling reported that this is the case (Carvalho *et al.*, 2005). Further work will be needed to verify the dietary restriction effect of the dilution method if any, as well as to develop alternative methods for dietary restriction in flies.

### **ANESTHETICS**

Anesthetization of flies is required when sorting out by sex or by genotype, and also when preparing tissue homogenate. Common methods are ether and carbon dioxide, but cooling can also be used in some cases.

Although the carbon dioxide method requires setting up of some devices (see Roberts and Standen, 1998), it has a number of advantages over the ether (ethyl ether or triethylamine) method; it is much less likely to kill or sterilize *Drosophila*. Additionally it is odorless and neither flammable nor reactive. With carbon dioxide, use of the diffusion pad enables application of continuous anesthetization. Flies can be kept unconscious for up to 20 minutes under the carbon dioxide air and still recover quickly once the carbon dioxide is removed, although too strong or too long exposure to carbon dioxide can kill flies. On the other hand, the effects of ether will wear off in less than 10 minutes. Thus, carbon dioxide is a preferred choice.

While they are anesthetized, flies can be placed on a glass plate or carbon dioxide plate to be examined under the microscope. The flies are moved around using a small paintbrush on the plate, and care must be taken not to damage the wings and so forth.

### **COLLECTING VIRGIN FEMALES**

Female *Drosophila* store sperm after mating and are capable of laying fertile eggs for many days. Therefore in order to set up a cross between males and females of known genotypes, it is essential to collect virgin females. To do this, in the morning, empty all the flies from bottles that have adult flies just emerging from pupae. Then collect flies that eclose over the next 8 hours and separate into sexes. Virgins have dark meconium in the gut, visible through the ventral abdominal wall. Virgin females do lay some eggs; however, these are unfertilized and will not hatch.

## **Conclusions**

*Drosophila* is a versatile model for investigating a variety of questions. The *Drosophila* model enables researchers to perform synergetic, integrated studies in a relatively short period of time. Powerful genetic tools are available, and it has advantages for demographic

analysis and is suitable for molecular and biochemical studies. One can identify a gene of interest by phenotype screening or candidate locus approaches. The gene can be expressed, overexpressed, or deleted by genetic tools, and this can be done in a tissue- and time-specific manner. Its effect on lifespan can be monitored, and patterns of aging can be characterized by demographic analysis; downstream effects at the molecular level, as well as physiological and behavioral effects, can all be studied. Studies through gene homology will have great implications for higher organisms including humans.

However, there are some downsides to use of *Drosophila* as a model. Because *Drosophila* is small relative to mammals and birds, it is difficult to perform physiological and biochemical studies which require manual tissue isolation or dissection. *Drosophila* strains can rapidly evolve in laboratory culture; it is possible that deleterious mutations can accumulate and thus make closely related stocks genetically differentiated. This can give rise to serious confounding results, particularly when crosses are generated from these stocks.

In addition, there are theoretical considerations that should be taken into account. Aging may involve different processes in different species, and its underlying mechanisms may be different. Flies are short-lived, so they may not have evolved good longevity-promoting systems such as efficient damage-repair/defense systems. Furthermore, there are distinct biological differences between flies and mammals as indicated above. For these reasons, one cannot always translate results on *Drosophila* directly into mammals.

Nonetheless, there is no doubt that the *Drosophila* model has contributed significantly to our understanding of aging. Bearing in mind its limitations and knowing its advantages, in balance, *Drosophila* will still long continue to be an extremely useful model organism to understand basic mechanisms of aging and to give important clues for aging in the more complex mammalian systems.

# Models of Aging in Honeybee Workers

Gro V. Amdam and Olav Rueppell

*Understanding the control of senescence and lifespan constitutes one of the most intriguing but difficult goals in modern biology. Fully exploring the regulatory architectures of aging will likely require the use of a broad range of animal systems—many of which are not currently regarded as mainstream models in aging research. One such species is the honeybee (*Apis mellifera*) that is characterized by a facultative aging machinery under social control. Epigenetic regulation is responsible for the differentiation of females into workers and queens—two castes with strongly diverging lifespan potential—and a plastic pattern of worker longevity that appears to be determined by the social colony setting rather than chronological age. Compared to solitary model species, the honeybee is in a prime position to contribute to a deeper understanding of the aging phenomenology in organisms that live in complex social environments.*

## Introduction

The honeybee is a eusocial insect, which means that it is characterized by reproductive division of labor and by the presence of a facultatively sterile worker caste that engages in alloparental care behaviors such as brood care and foraging. Eusocial insect societies are found in the orders *Hymenoptera* (ants, wasps, and bees) and *Isoptera* (termites). Within these genera, the honeybee is among the most socially advanced. It is also the species with the best developed tool kit for husbandry, and constitutes, by far, the best studied social insect (reviewed by Winston, 1987).

The honeybee receives considerable attention in studies that aim to understand how complex collective patterns emerge from interactions between individuals. It is, consequently, a key research model in behavioral ecology (e.g., Calderone and Page, 1992; Huang and Robinson, 1996; Trumbo *et al.*, 1997; Pankiw and Page, 2001), neurobiology (Scheiner *et al.*, 2001; Humphries *et al.*, 2003), and systems theory (e.g., Omholt, 1987; Bonabeau, 1998; Page and Erber, 2002; Amdam and Omholt, 2003). In addition, eusocial insects can make important contributions to our understanding of aging across levels of biological complexity (Rueppell *et al.*, 2004). This is in part because of caste-specific gene expression programs, which have emerged through social insect evolution

(Evans and Wheeler, 2001). These programs may underlie trajectories of senescence and longevity regulation that show considerable variation between castes, both within and between species of the social *Hymenoptera* and *Isoptera* (for further information see Finch, 1990; Rueppell *et al.*, 2004). In this context, the honeybee worker caste also provides an additional regulatory layer of interest (Omholt and Amdam, 2004): within this caste the rate of senescence does not appear to be a function of chronological age (Amdam and Page, 2005). Rather, aging in honeybee workers is state-dependent (reviewed by Amdam, 2005), and longevity is—as a result—a function of a plastic progression through life-cycle stages with distinct behavioral and physiological profiles. This succession generates a facultative age-determination pattern of particular interest to research on aging and longevity (Omholt and Amdam, 2004; Amdam, 2005). It has therefore, been predicted that, in parallel with the development of new functional genomic tools (Beye *et al.*, 2002; Amdam *et al.*, 2003b) and the availability of the honeybee genome sequence ([www.hgsc.bcm.tmc.edu](http://www.hgsc.bcm.tmc.edu)), the bee will grow to become the most noteworthy social invertebrate model for senescence (for discussions see Rueppell *et al.*, 2004; Amdam and Page, 2005).

Rooted in these perspectives, we here provide an introductory overview aimed at researchers who are interested in using the honeybee as a gerontological model. We present a summary of the general biology of the bee, and outline the behavioral and physiological life trajectories that are specific to the different honeybee castes. The link between the plasticity of these trajectories and the dynamics of the honeybee society as a whole is emphasized. Subsequently, we present a preparative review of key handling procedures and sources of methods for studies of the bee, in which we elucidate how social integrity can be maintained under the experimental management of free-flying colonies as well as for individuals kept in a laboratory setting. We next provide examples of the use of honeybees in aging research—a section that also serves to outline the current status of the field in mechanistic and biodemographic terms. Finally, we discuss how social insects, in a wider taxonomic perspective, can contribute to the understanding of aging, and we outline future prospects for use of the honeybee as a gerontological model.

## The Honeybee Society

In contrast to the classic models of biological aging research, honeybees represent a species in an advanced state of social evolution. They live their entire lives as part of a complex society, the colony, and cannot survive or reproduce as solitary individuals. The honeybee society rivals traditional human societies in many societal parameters, such as group size, cohesiveness, information exchange, integration, and differentiation of roles (Wilson, 1980), including reproductive division of labor. Honeybees are characterized by a strong colony-level selection component, which has led to functional differentiation of colony members into separate castes and to the concept of regarding the colony as a superorganism (Moritz and Fuchs, 1998): workers fulfill the various roles of the soma (food acquisition, processing, and distribution, homeostasis, and protection), while the mature queen represents the unique germ line and stem cell (meristem), and males and young queens can be regarded as the gametes.

Typically, a honeybee colony contains one reproductive queen and tens of thousands of female workers that are functionally sterile in the presence of a reproductive queen (de Groot and Voogd, 1954). During the reproductive season, several thousand males (drones) are also found in the nest. Additionally, all stages of the developing juveniles (brood, i.e., eggs, larvae and pupae) and extensive food resources (honey and pollen) are found in the colony. The brood, honey and pollen are stored in the main nest structure, the wax combs. These combs are typically arranged in sheets. The center of the nest is filled with brood, surrounded by a sphere of pollen storage, and the outer areas of the nest are used to store honey (Winston, 1987). All demographic variables have a strong seasonal component, at least in the temperate regions where the majority of studies have been conducted (Winston, 1987). Workers are produced throughout most of the year except for the first part of winter. However, the peak in the production of new workers precedes the production of drones and new queens in the early summer when resources are abundant.

In contrast to individual honeybees, colonies are perennial and potentially immortal through the continuous replacement of their members. The queen, as the only reproducing individual, can live several years (see below), but is regularly replaced by her own daughters (reviewed by Page and Peng, 2001). As part of the regular reproductive cycle, replacement queens are raised and the old queen leaves the nest in a swarm with the majority (50–90%) of the workers present to establish a new colony. One of the new queens takes over the remaining colony, killing all other young queens and engaging in mating flights (Severson, 1984). In contrast, the male reproductive role of honeybee colonies is exerted throughout the mating season by the continuous production of drones. These seek out matings from unrelated virgin queens during mating flights (Winston, 1987). After

having been successfully mated, the young queen assumes the reproductive role in the colony, using her stored sperm (over five million) for several years of reproduction, producing up to 2000 eggs per day (Winston, 1987). During this time, the queen does not fulfill any other colony tasks and is attended by a retinue of young workers that clean and feed her.

Honeybees are haplo-diploid (drones are haploid), and their sex is determined by a single gene (Beye *et al.*, 2003). Female caste determination is nutritional: more abundant and higher quality food causes the female larva to develop into a queen, whereas less and lower quality food leads to worker development. It has been shown in cross-fostering experiments that the developmental trajectories start diverging in the bipotent third larval stage. Queens will continue to be fed royal jelly, a highly nutritional food that triggers a juvenile hormone (JH) peak that shifts global gene expression patterns compared to workers (Evans and Wheeler, 1999) and ultimately accelerates their development rate. Worker-destined larvae are reared on an inferior diet which causes them to emerge as adults with half of the body weight of queens (reviewed by Page and Peng, 2001).

## The Lifespan of Worker Bees

The lifespan of honeybee workers is extremely plastic (e.g., Sakagami and Fukuda, 1968). This plasticity emerges because the behavioral trajectories of worker bees are sensitive to changes in the intra- and extra-colonial environment (e.g., Huang and Robinson, 1996), and the phasing and layout of these trajectories translates into specific physiological signatures and patterns of lifespan (for a review see Amdam and Page, 2005).

### BEHAVIORAL SENSITIVITY IN A DYNAMIC SOCIAL CONTEXT

The worker population of a honeybee colony normally segregates into a temporal hive bee caste that performs a series of tasks inside the nest (cell cleaning, brood rearing and cell building), and a temporal forager caste that specializes in collecting nectar, pollen, water and propolis (reviewed by Winston, 1987). A worker starts out as a hive bee and subsequently switches to foraging—typically after 18–28 days. The timing of this shift, however, is elastic (7–135 days: Haydak, 1963; Free, 1965), and this plasticity is, in part, controlled by colony demography. Specifically, bees in the foraging population produce a pheromonal cue that inhibits hive bees from initiating foraging (Pankiw, 2004; Toth and Robinson, 2005). Consequently, as foragers progressively are lost from colonies they are replaced by hive bees that are not efficiently inhibited (Huang and Robinson, 1996) (but see Regulation of Aging through Social Control of Behavioral Plasticity as well for an expansion of the concept of inhibition of foraging behavior). The regulatory

## 23. Models of Aging in Honeybee Workers

mechanisms responsible for the hive bee to go on to the forager transition deserve attention in a gerontological context because the timing of the switch largely determines the overall lifespan of the worker. This is because the age at onset of foraging is normally much more variable than the length of the foraging period (for a review see Omholt and Amdam, 2004), which suggests that the duration of the hive bee phase is a dynamic entity mainly determined by the intracolony conditions, while the duration of the forager phase is more dependent on the extracolony conditions.

### *Reversion of Task-Associated Trajectories*

Worker bees can, moreover, revert from foraging duties to hive activities (Robinson *et al.*, 1992). This phenomenon constitutes an inversion of the above-mentioned behavioral progression and appears to require a substantial perturbation of colony demography: behavioral reversion can be triggered experimentally through removal of the entire hive bee population. Under this condition, a proportion of the remaining foragers initiate hive tasks such as brood rearing (Huang and Robinson, 1996). It is likely that this reversion, which withdraws bees from risky foraging tasks and causes them to engage in labor within the sheltered nest, is associated with an extension of lifespan.

### *Temporal Cessation of Behavioral Development*

As foraging opportunities decline at the onset of the unfavorable season (the winter or drought period), a third and exceedingly long-lived temporal caste emerges. This group constitutes the *diutinus* stage (formerly referred to as the “winter bee” phenotype; Omholt and Amdam, 2004), and the appearance of these workers is intimately linked to the reduction of brood rearing that precedes the onset of the unfavorable season in honeybee colonies (Maurizio, 1950). The *diutinus* workers, like hive bees, reside within the protected nest. They thermoregulate the colony and take care of the queen, and do not initiate brood rearing or foraging until the next favorable period. Shorter intervals of reduced brood rearing can, nonetheless, arise for various reasons throughout the season (e.g., when swarming, replacement, or loss of the reproductive queen results in a reduction of the number of eggs, larvae and pupae in a colony). Therefore, *diutinus* bees can emerge during the favorable period also, when workers—as a rule—segregate into the hive- and forager populations, exclusively.

## PHYSIOLOGICAL SIGNATURES AND PATTERNS OF LIFESPAN

Foragers have a high extrinsic mortality risk compared to hive bees, and the life of a forager is therefore short (typically 1–2 weeks: Neukirch, 1982) relative to the typical duration of the hive bees phase (normally 3–8 weeks: Free and Spencer-Booth, 1959) and the *diutinus*

stage (up to 280 days: reviewed by Omholt and Amdam, 2004). Consequently, the transitions among those three distinct life history states are key determinants of the lifespan of any individual worker (reviewed by Amdam and Page, 2005). Within each temporal caste, however, longevity is further conditional on physiological factors (Maurizio, 1950) (see below).

### *Metabolic Rate (MR)*

MR is one physiological factor that may underlie the temporal, caste-associated mortality rates of honeybee workers. Forager MR is significantly higher than the MR of hive bees (for a discussion see Suarez *et al.*, 1996), and the MR of a foraging bee constitutes one of the highest known mass-specific aerobic MRs among animals (approximately 3-fold higher than hummingbird flight muscle). Such intense activity is a major source of mechanical senescence in insects and causes mortality to increase as a function of age (reviewed by Finch, 1990). In accordance with their longevity, *diutinus* bees periodically exhibit low MRs compared to hive bees—and thus also relative to foragers (Crailsheim, 1986; Nerum and Buelens, 1997). The MR of *diutinus* workers can fall to half the MR of hive bees. Elevated MR causes an increase in the release of free radicals that can induce oxidative impairment (reviewed by Jazwinski, 1996), which has led to the suggestion that oxidative stress is a mediator of stage-dependent physiological frailty in honeybee workers (Amdam and Omholt, 2002).

### *Endocrine Status*

Juvenile hormone (JH) and ecdysteroids are systemic hormones that are implicated in the regulation of invertebrate lifespan by orchestrating several suites of physiological processes (Tatar *et al.*, 2003).

The JHs form a family of related sesquiterpenoid compounds secreted by the corpora allata (CA) complex, and although insects (e.g., *Lepidoptera*) may secrete a blend of JHs, JH III is the only naturally occurring JH in the honeybee (Tobe, 1985). The JH titer of worker bees increases at the onset of foraging, and a comparable rise in the JH level is associated with accelerated rates of senescence in invertebrate models like *Drosophila* spp. (Tatar and Yin, 2001). *Diutinus* workers and hive bees, however, have very low JH titres (Fluri *et al.*, 1982). In many insect species, this hormonal signature is associated with diapause, and removal of the CA complex often results in diapause-associated characteristics, e.g., low MR, reduced activity levels, regression of ovary development, and enlargement of the fat body—a storage organ analogous to the mammalian liver and white adipose tissue. Yet, removal of the CA does not trigger a diapause-like state in worker bees: workers without the CA progress through a period of hive tasks and initiate foraging (Sullivan *et al.*, 2000). Moreover, MR increases in allatectomized foragers that do not have detectable JH titers (Sullivan *et al.*, 2003). Therefore, the role of JH

in the regulation of honeybee longevity may not be directly comparable with its role in solitary insect species (see Regulation of Aging through Social Control of Behavioral Plasticity for further information).

The dominant ecdysteroid in the honeybee is Maki-sterone A (Robinson *et al.*, 1991). Steroids generally have multiple and complex regulatory effects that may affect longevity (Tatar *et al.*, 2003). Robinson *et al.* (1991), however, demonstrated that the ecdysteroid titer of adult worker bees is low (independent of age), and it is therefore unlikely that Maki-sterone A plays an important role in the regulation of adult honeybee physiology and lifespan. Yet, it has not been fully determined if ecdysteroids are involved in the control of worker reproductive maturation and oogenesis, a state that can be triggered if the queen is lost from a colony (Robinson *et al.*, 1991; Hartfelder *et al.*, 2002).

#### Nutritional State

The protein content of worker bees is low at emergence, but it increases sharply during the first 10–12 days of adult life through pollen feeding. In the broodless *diutinus* workers, protein may subsequently accumulate to extreme concentrations because nutritional resources are retained in the adult bees rather than being transferred to young larvae (Fluri *et al.*, 1977; Fluri *et al.*, 1982). This state is associated with an overall increase in longevity (Maurizio, 1950). Buildup of stored protein reserves (storage protein) is commonly linked to reduced mortality in insects. A comparable pattern to that observed in the bee is found in the ant *Camponotus festinatus*, where the presence of brood also has an inhibitory effect on the accumulation of storage proteins in workers (Martinez and Wheeler, 1994).

At the onset of foraging, protein levels in the hemolymph (blood), fat body and hypopharyngeal glands (brood food producing head glands) are significantly reduced in the bee, and a similar pattern is seen for stored lipids (Toth and Robinson, 2005). This loss of stored nutrients from individuals that perform risky exterior hive activities has parallel examples from other social *Hymenoptera*s (Porter and Jorgensen, 1981; O'Donnell and Jeanne, 1995) and has led to the proposition that foragers are stripped of nutritional resources as part of a colony-level resource-saving strategy (O'Donnell and Jeanne, 1995; Amdam and Omholt, 2002). Accordingly, foraging bees have fewer resources that can be allocated to individual somatic maintenance—a state that appears to translate into a higher level of physiological frailty.

#### Immunity

The insect immune cells, or hemocytes, are involved in defense mechanisms such as phagocytosis, encapsulation and nodule formation (reviewed by Rolff and Siva-Jothy, 2002). The immune cells also produce antibacterial peptides and contain most of the recruitable enzyme prophenoloxidase, which catalyses crucial steps in the

melanization immune response. The number of functional circulating hemocytes at any give time, therefore, reflects the organism's capacity to cope with immunogenic challenges.

Hive bees and *diutinus* workers have high numbers of functional hemocytes (5,000–12,000 immune cells per  $\mu\text{l}$  hemolymph: Fluri *et al.*, 1977; Amdam *et al.*, 2004a). JH, however, affects the number of normal hemocytes in honeybee worker hemolymph, and causes the cellular immune system of foragers to become suppressed (Rutz *et al.*, 1976). Specifically, under the influence of high JH titers, hemocytes change into inactive pycnotic forms. One effect of this loss of immunity is a complete deterioration of the nodulation response (Bedick *et al.*, 2001).

### The Lifespan of Queens and Drones

In comparison to workers, little is known about the life history of drones and queens, including the determinants of their lifespan. This is particularly true with regard to mechanistic, causative studies. The lack of research effort can be explained in part by practical considerations (only workers are abundantly available all year), but it is particularly challenging because much of the appeal of the honeybee model in aging research hinges on intraspecific comparisons.

Drone life history dramatically differs from the patterns described above for workers. These males lead a quasi-solitary life (in a social environment), as they do not actively integrate in any colony-level activities. No social influences on their life history have been demonstrated, even though some of the underlying hormonal controls (e.g., JH) may be identical to workers (Giray and Robinson, 1996). The overall mortality pattern of drones is similar to that of workers in midreproductive season (Rueppell *et al.*, 2005), and their lifespan does not significantly exceed that of workers (reviewed by Page and Peng, 2001). Due to their flight activity, the external mortality risks of drones are similar to workers: predation, misorientation, exhaustion, and other environmental hazards (e.g., rain). Mortality risk increases during their flight tenure, as in workers, probably due to wear and tear, but drones also seem to age without fulfilling any significant task before their onset of flight (Rueppell *et al.*, 2005).

No significant demographic data exist on queens for three reasons. Large data sets require a disproportionate experimental effort since only one queen exists in each colony. Moreover, queens are long-lived. Finally, the lifespan of queens may be socially controlled (reviewed by Page and Peng, 2001), and it is difficult to distinguish a swarming event from replacement of the old queen by a daughter (superseding). Longevity records demonstrate a much higher potential lifespan for queens than for either workers or drones. Their lifespan regularly exceeds one year, and maximal reported queen longevity is above

eight years (reviewed by Page and Peng, 2001). This pronounced lifespan extension in social insect queens relative to solitary insects is general and associated with low external mortality and thus favors the evolutionary theory of aging over purely mechanistic explanations (Keller and Genoud, 1997).

### Practical Aspects of Honeybee Research

There are several excellent sources for information on how to establish and maintain an apiary or a honeybee breeding program (e.g., Atkins *et al.*, 1975). Moreover, there are special resources available that describe experimental handling procedures and protocols for behavioral (Frisch, 1967; Seeley, 1995) and physiological (Snodgrass, 1956) data collection. Yet, we will provide a brief overview of tools, protocols and experimental considerations that are of specific relevance for research on aging and longevity.

#### HONEYBEE HUSBANDRY

Honeybee colonies are normally accommodated in standard commercial hive bodies, and a host of literature for laypersons and experts exists on the practical aspects of keeping honeybees (for more information see Atkins *et al.*, 1975; Laidlaw and Page, 1997). They can also easily be kept in hives or in sheltered milieus designed for specific research purposes, allowing for experimental manipulations or efficient censusing under seminatural conditions. Bees can be kept in indoor observation hives with access to the outside to facilitate behavioral observations and accurate censuses (for a discussion see Frisch, 1967). These hives can be designed to various sizes, but they require intense management. Egg-collection hives (Aase *et al.*, 2005) consist of a single-frame hive body with two aluminum frames that hold 6 Jenter frame modules (Karl Jenter, Nurtigen, Germany). This design allows the collection and introduction of eggs and larvae by simple extraction and insertion of individual cell bases. Egg-collection hives are used for *in vivo* rearing of genetically manipulated bees (Amdam *et al.*, 2003b), and is an alternative to laborious *in vitro* rearing procedures (for a discussion see Aase *et al.*, 2005). An alternative to letting the bees fly into the wild is flight cages and flight rooms. They provide a controlled environment for studies of behavioral development and mortality (Jay, 1964; van Praagh and Velthuis, 1971) but need to be designed carefully (Omholt *et al.*, 1995). Most external mortality risk factors can be excluded, and flight activity can be controlled and measured accurately (Neukirch, 1982).

#### EXPERIMENTAL PROCEDURES AND MANIPULATIONS

The transition between field and laboratory procedures is gradual in honeybee research, and often a combination of both is desirable. Honeybees prove unproblematic in both contexts, but a few points have to be kept in mind. As

members of a social group, honeybees are greatly affected by their social environment, and individuals readily adjust their life history to environmental conditions (Schulz *et al.*, 1998; Pankiw, 2003). For this reason, experimental handling and stress (including social isolation) ought to be minimized or at least carefully controlled.

Through demographic hive manipulations, introduction of comb, or brood grafting, colonies can be controlled to produce large cohorts of workers, drones, or queens (Atkins *et al.*, 1975). Artificial rearing of brood is also possible in the laboratory, but the described procedures to date are laborious and often produce individuals that do not span a normal phenotypic range. Upon emergence in a temperature- and humidity-controlled incubator, cohorts can be reliably marked for life with enamel paint, numbered color discs, or radio frequency identification tags (Streit *et al.*, 2003). Subsequently, marked bees can be introduced into a natural colony for studying their aging. Bees of older ages can also be transferred (grafted) between colonies, but special precautions have to be taken to avoid allo-recognition and rejection.

Physiological parameters such as hormone or protein titers can be investigated by taking hemolymph samples through the intersegmental membranes in the abdomen at different ages—also during larval and pupal development. Similarly, honeybees can be injected with various substances into the abdomen (e.g., JH: Muller and Hepburn, 1994) or brain (e.g., double-stranded RNA: Farooqui *et al.*, 2004) to study the physiological regulation of aging. These and other handling procedures are greatly facilitated by chilling bees to 8–12°C, keeping in mind that low temperature is a serious stressor (Jones *et al.*, 2004). Different protocols exist for investigating honeybee behavior and cognitive abilities in the laboratory (Scheiner *et al.*, 2004), and large samples, even at advanced ages, can be readily drawn from a single hive. Even though the honeybee does not compare with classic aging models for their genetic resources and versatility, some progress has been made (Robinson *et al.*, 2000; Beye *et al.*, 2002; Amdam *et al.*, 2003b; Kunieda and Kubo, 2004), and selective breeding using artificial insemination is well established (Laidlaw and Page, 1997).

### Research on Aging in Honeybee Workers

The honeybee offers a point of entry to experimental research on aging that cannot easily be addressed in any of the classic—solitary—model organisms (Rueppell *et al.*, 2004). In the following, we present a set of recent studies that exemplify how the bee is starting to contribute to our understanding of longevity.

#### REGULATION OF AGING THROUGH SOCIAL CONTROL OF BEHAVIORAL PLASTICITY

It was recently suggested (Amdam and Omholt, 2003) that the hive bee and *diutinus* worker states are governed

by an age-neutral regulatory structure that incorporates the glycolipoprotein vitellogenin. Vitellogenin is a yolk precursor that is produced by oviparous animals (for a review see Omholt and Amdam, 2004). In the honeybee worker caste, though, vitellogenin has evolved a novel function—it is utilized in the production of brood food (Amdam *et al.*, 2003a). The hypothesized regulatory link among vitellogenin, behavioral plasticity and longevity (Amdam and Omholt, 2003) has been explored in several studies with fundamental implications for our understanding of the evolvability of circuits that control the rate of aging (reviewed by Amdam, 2005). Specifically, *vitellogenin* genes are normally downstream of a female-specific regulatory cascade that has negative effects on lifespan (Murphy *et al.*, 2003). In the honeybee, however, the effect is inverted so that *vitellogenin* gene expression extends life (Seehuus *et al.*, 2005). This counterintuitive association may be caused by the novel, negative feedback regulation between vitellogenin and JH (Guidugli *et al.*, 2005).

Studies of the genetic control machinery responsible for the link among vitellogenin, behavioral plasticity and longevity in the honeybee are currently utilizing selected strains bred by Page and Fondrk (1995) that differ in JH- and vitellogenin titers in concert with dissimilar trajectories of longevity (reviewed by Amdam *et al.*, 2004b).

## IMMUNOSENESCENCE

Another study has explored the putative role of vitellogenin in the regulatory control of the decline in immunity that characterizes honeybee foragers (Amdam *et al.*, 2004c). The data from this work demonstrate that vitellogenin is the main zinc carrier in honeybee workers, and that lack of zinc induces pycnosis of honeybee hemocytes *in vitro*. The authors therefore suggested that depletion of vitellogenin, a protein that normally constitutes 30–50 % of the plasma protein pool in hive bees and *diutinus* workers but is down-regulated to undetectable levels in foragers (see Nutritional State), causes the plasma level of zinc to become so low that it triggers a loss of immunity. This phenomenon may further elucidate how natural selection works on circuits that control aging in social insect societies (reviewed by Omholt and Amdam, 2004): turning off vitellogenin synthesis in foragers can serve to economize the colony's protein household, as it prevents build-up of a storage protein that will be lost when the forager perishes in the field. Furthermore, as immune system maintenance is costly in solitary as well as social insects, the down-regulation of the honeybee forager immune system fits well into an explanatory framework where foragers constitute a disposable caste (O'Donnell and Jeanne, 1995) with an accelerated aging rate and level of physiological frailty (reviewed by Amdam, 2005).

## BIODEMOGRAPHIC RESEARCH

Honeybees provide multiple, practical advantages over other models in biodemographic research: worker cohorts are readily obtainable and maintainable in large numbers from either genetically homogeneous or heterogeneous sources (Laidlaw and Page, 1997). Honeybee workers return to their hive daily as long as they live. Thus, their activity and lifespan can be directly monitored in observation hives without disturbance and under seminatural conditions.

Due to its commercial importance and widespread public interest, the honeybee was also one of the earliest insects with a recorded lifespan (Langstroth, 1866). Early studies were based on small sample sizes or indirect estimations, but they provided the first data on the intraspecific variability and plasticity in aging that remain today one of the major reasons to study honeybee aging (Omholt and Amdam, 2004). Larger, demographic studies showed that honeybee workers have a type I (convex) survivorship curve, which is rare in insects (Sakagami and Fukuda, 1968) but common in social organisms with extended brood care, such as humans. The pattern of age-specific mortality in honeybee workers is largely due to the hive bee to forager transition, which is accompanied not only by major physiological changes, but also by a dramatic increase in external mortality risk (see above). More than 90% of all worker deaths are reported to occur outside of the colony under natural conditions (Lundie, 1925). Thus, it is difficult to identify the exact cause of death for the majority of workers (reviewed by Page and Peng, 2001), and biodemographic studies of the mortality dynamics are important for our understanding of aging and mortality in the honeybee.

The seasonality of worker lifespan is one of the most striking features of the honeybee aging model system (see Temporal Cessation of Behavioral Development). The few studies addressing seasonality from a comparative demographic perspective reveal that not only the average life expectancy, but also the variation in life expectancy (Sakagami and Fukuda, 1968) and life history trade-offs that determine life expectancy vary seasonally (Neukirch, 1982). In general, the *diutinus* phase over the winter period seems to slow aging effectively without any adverse, compensatory effects before or after this stage (Omholt and Amdam, 2004), but more work on the mechanistic and demographic aspects of this retardation of aging remains to be done.

The age at the onset of foraging activity is a major determinant of lifespan for honeybee workers, although some aging may also occur pre-foraging (honeybees that initiate flight later in life have a shorter foraging lifespan: Guzmán-Novoa *et al.*, 1994). Sharply increasing mortality dynamics indicates that foragers senesce (Sakagami and Fukuda, 1968) either as a consequence of regulatory processes (see Endocrine Status), or wear-and-tear, or expenditure of internal resources (Neukirch, 1982).

However, there is also a report of a constant mortality rate, relative to the intensity of foraging (Visscher and Dukas, 1997). Comprehensive data on larger samples are needed to resolve this issue, as well as their late-life mortality dynamics, and the quantification of genetic versus environmental influences on lifespan.

One further interesting aspect, which is unique to the honeybee model, is the connection between social structure and individual life history and aging. Isolated studies have indicated that the caregiver-to-dependent (worker-to-brood) ratio is of crucial importance to the individual longevity of the progeny (Eischen *et al.*, 1982), and possibly all other workers (Winston and Fergusson, 1985). The amount of brood and resources in a colony, and the age structure of the worker force, influence the age of foraging initiation of individual workers, and thus their lifespan (Winston, 1987). Furthermore, larger colony size confers a longevity advantage to the individuals presumably because individual workers in smaller colonies work harder, raising more offspring per adult bee (Harbo, 1986). These plastic reactions to social conditions are ultimately the result of dynamic colony-level resource allocation and optimization (Oster and Wilson, 1978). However, comprehensive quantitative models and experiments are rare because the combination of colony demography, resource flows, and individual physiology and behavior proves complex (Amdam and Omholt, 2002).

### Comparative Aspects

While we argue here that the honeybee is an emerging model organism in aging research, it has already attained the status of a model organism in several other biological disciplines and it serves as the model social insect. Social evolution has generated a wide variety of social systems with unique selection pressures and adaptations that provide many opportunities for testing ultimate theories of aging, as well as study the proximate causes of naturally evolved aging differentials. Sociality with overlapping generations, cooperative brood care, and (reproductive) division of labor, as in the honeybee, has evolved multiple times in insects, with termites, ants, wasps, and bees as prominent representatives (for other groups see Choe and Crespi, 1997).

The multiple, independent evolution of sociality offers the prospects of analyzing phylogenetic trends in a comparative context, such as the analysis of the evolution of lifespan itself (Keller and Genoud, 1997). We can study in detail the phylogenetic correlation between the degree of social evolution (such as societal complexity, colony size, or morphological queen-worker dimorphism) and the lifespan extension in reproductives. Furthermore, any lifespan-extending mechanism identified in honeybee queens can be tested for its generality and its natural evolutionary history reconstructed by studying it in related, less socially advanced species (Parker *et al.*,

2004). The broad taxonomic array of social insects with widely differing social systems and biology provides many opportunities for comparative research. Particularly valuable “wide-scale” comparisons would seem to be between flying and nonflying, predatory and herbivorous, or monogynous (groups with a single reproductive queen) and polygynous (multiple reproductive queens) groups as these life history variables seem to have some impact on longevity (Finch, 1990; Keller and Genoud, 1997). If we are to understand how social evolution has affected lifespan, it is not sufficient to compare solitary and highly social species but to study intermediates and follow plausible trends in social evolution. This can lead to insights into the ultimate factors that lead to long-lived reproductives and social evolution, as well as the reinforcement between the two (Carey, 2001; Carey and Judge, 2001). All four species of honeybees are highly social, but in their family (the Apidae) solitary species and numerous intermediates exist (Michener, 2000). One such intermediate are bumblebees whose colonies are annual and all individuals except for the newly produced (and mated) queens die at the end of the season. This life history should select for very different longevity patterns at the individual level, with an even more pronounced seasonal plasticity than in the honeybee. Another interesting feature of bumblebees is the large size variation among workers that leads to a division of labor that is not age-dependent. Therefore, we have life-long behavioral specialists with differences in external mortality and consequently predicted differences in endogenous aging rates.

Like bumblebees, some ant species also exhibit division of labor that is related to functional size divergence (Hölldobler and Wilson, 1990) and cannot be regarded as an adaptation to aging (Tofilski, 2002). However, this has been used to confirm that a higher extrinsic mortality of outside workers has led to the evolution of a shorter intrinsic lifespan, relative to workers that work inside the protected colony (Chapuisat and Keller, 2002). Other ant species follow the honeybee model of age-dependent division of labor, probably with similar mortality patterns. In general, lifespans in ants are much longer than in honeybees. This makes the evolution of their lifespan extension more extreme, and significant research efforts are geared towards elucidating mechanisms of their great queen longevity (Hartmann and Heinze, 2003; Parker *et al.*, 2004; Schrempf *et al.*, 2005), which will provide interesting comparisons to the results from honeybees. However, the much longer lifespan also makes the practical aspects of aging studies in ants more difficult than studies in the honeybee.

### Conclusion

It is now widely realized that the study of biological models can considerably advance our understanding of the processes that lead to aging and determine lifespan.

However, it is also realized that the classic models are all short-lived laboratory organisms. This may limit their value as models for human aging, and a broader comparative basis is currently sought in the scientific community. Aging research directed towards social insects, and the honeybee in particular, is still in its infancy. Nevertheless, some interesting patterns start to emerge with mutually corroborating proximate and ultimate explanations of lifespan. The large, experimentally accessible plasticity in aging rate in the honeybee provides a prime opportunity to study a strong case of epigenetic regulation of lifespan (Omholt and Amdam, 2004). We are beginning to understand how resource optimization at the colony level is driving multiple, physiological changes in the individual with drastic consequences for aging. In this context, it seems possible that the honeybee can become a key invertebrate model for understanding the molecular regulatory control of facultative longevity extension, a research area that is currently dominated by the nematode *Caenorhabditis elegans*. The honeybee model may also prove ideal to integrate these mechanistic studies with biodemographic concepts—we can apply the essence of biodemographic research—actuarial analysis of biological patterns in large-scale experiments—to more phenomena than just organismal death. In sum, the temporal dynamics of honeybee behavior, physiology, and gene expression can be explored in relation to social lifespan, implying that the aging process can be studied at ascending levels of biological organization from molecules to colonies (Rueppell *et al.*, 2004).

## ACKNOWLEDGMENT

We would like to thank John Tomkiel and Jennifer Tsuruda for improving the manuscript with helpful suggestions. G.V.A. was supported by the Norwegian Research Council, project # 157851/432, and funding was provided to G.V.A. and O.R. by the National Institute on Aging, PO1 AG 22500.

# Ants as Naturally Long-lived Insect Models for Aging

Joel D. Parker and Karen M. Parker

*This chapter explains in what respects ants can be useful models in understanding the mechanisms of aging. It includes an introduction highlighting how ants fulfill a need for long-lived model systems in aging research. Three ant model systems are then described including their relevant natural history characteristics, collection and laboratory maintenance. Practical considerations are given for molecular studies and techniques. Finally, an overview is given of the available genomic resources and types of comparative studies that are possible.*

## Why Ants?

Humans owe their relatively long life span to living in societies that reduce the risk of extrinsic mortality. Other organisms in organized societies are also expected to exhibit a similar lengthening of life span over evolutionary time. One hundred million years before the first human stood up and walked, social insects existed in societies with cities, roads, division of labor, farming, slave making, and organized group defenses (Hölldobler and Wilson, 1990). Sociality has resulted in a 10- to 100-fold increase in the life span of queens in ants, bees, and termites, a trend that was rigorously demonstrated using phylogenetic methods to compare life span and social structure across the insects (Figure 24.1; Keller and Genoud, 1997). The evolution of sociality and its associated increase in life span show a general trend that has independently evolved several times.

Ants represent an ideal system for studying how evolution effects the changes necessary for long life. In addition to the differences in life span among species, there are also order-of-magnitude differences in life span between different castes in a single species. For example, queens of the ant *Lasius niger* have been known to live nearly 29 years in a lab, while workers live for only a few years and males a few weeks (Kutter and Stumper, 1969; Hölldobler and Wilson, 1990). Given that the same egg can become either a queen or a worker, differential gene expression seems to be the key difference between those two castes.

The traditional model systems used to study aging (*Drosophila melanogaster*, *Caenorhabditis elegans*, *Mus musculus* and *Saccharomyces cerevisiae*) all share a short generation time, making them ideal experimental systems in terms of laboratory rearing and experimental manipulations. Unfortunately, this has introduced a bias in the types of life histories that have been sampled in modern aging research as almost all the mechanisms proposed for aging have been limited to these systems. Some of these mechanisms are not thoroughly understood in an evolutionary context and may not truly represent adaptations necessary for long life. Hence, these mechanisms need verification in long-lived species like humans. In addition, studies of long-lived species such as ants may also reveal new and novel life span extending processes and mechanisms that have withstood the test of evolutionary time.

## The Ant Model Systems

Ants as a group share certain important life history characteristics, such as living in family groups with overlapping generations. Ants are haploid-diploid; the queens and workers are diploid and female, whereas males are haploid and develop from unfertilized eggs. In monogynous colonies, there is one reproductive queen per colony, with sterile workers who do not contribute directly to the reproduction of the colony. Sexual winged queens and males are produced by the colony at specific times of the year. Queens of monogynous colonies remove their wings after mating and found a new colony independently (claustral founding). For polygynous species, where there is more than one reproductive queen per nest, newly mated queens are accepted back into their colonies. In these cases, new colonies are typically formed by budding.

For aging research, there are two ant species and one genus that are particularly well suited for development into model systems. The species *Lasius niger* and the genus *Pogonomyrmex* have considerable life spans and are easy to rear in laboratory settings. The third species, *Solenopsis invicta*, has a variety of modern genomic tools available such as a large microarray and a large cDNA

**Figure 24.1.** Sociality causes an increase in longevity. Redrawing of Figure 2 from Keller and Genoud 1997 showing how extreme life spans evolved multiple times in association with the evolution of sociality.

sequence database. These species are all very common in the Holarctic, western North America, and the southern United States, respectively.

### LASIUS NIGER

Queens of the common black ant, *Lasius niger*, have the longest recorded life span in the laboratory of 28 and 3/4 years (Kutter and Stumper, 1969). This monogynous species occurs in the Holarctic region in forests and farm land. In central and northern European meadows, they occur in densities up to 1 mature colony per square meter. Colonies can be marked by placing a concrete paving slab over the colony entrance. The colony places brood underneath the slab for warming during the nonwinter months, which simplifies collection. The colonies do not seem to migrate, facilitating long-term monitoring and collection. Colonies can be huge with 10,000 or more workers, although smaller young colonies are easily maintained under laboratory conditions. *Lasius niger* has been extensively used in ecological studies as well as in genetic studies assessing colony relatedness, mating number, and sex ratio evolution (Fjerdingstad *et al.*, 2002; Fjerdingstad *et al.*, 2003; Jemielity and Keller, 2003; Fjerdingstad and Keller, 2004). A recent search of the Web of Science Internet database yielded 141 publications on *L. niger*.

This species has large mating flights in mid- to late summer when hundreds of newly mated deallate queens can be collected. New laboratory colonies can be started in glass test tubes filled halfway with water with a tight wad of cotton holding the water back. The founding queen is placed in the tube which is closed with a cotton plug (Figure 24.2).

The tubes are placed in the dark for approximately six weeks, until the first minims emerge. The cotton plugs are removed from the tubes, which are placed inside plastic boxes with additional water tubes. The inside walls of the plastic boxes are painted with Fluon<sup>®</sup>, a fluoropolymer that most insects have difficulty climbing (available from Whitford Worldwide). Colonies will produce

full-sized workers after approximately one year and can be transferred to progressively larger boxes as the colony grows. Best results are obtained when colonies are kept at 22°C with 60% constant humidity. *Lasius niger* prefers liquid food, and our current food mix is 1:1:2 ground meal worms:eggs:honey plus 1% volume of liquid baby vitamins. To facilitate pipetting, the meal worms are flash frozen with liquid nitrogen and ground into a fine powder with a mortar and pestle. Aliquots of the mixture are stored frozen at -20°C and diluted 1:1 with water just before use. Colonies are fed three times a week and are given one or several drops of food, depending on their size.

### POGONOMYRMEX

The approximately 20 North American species of the seed harvester ant genus *Pogonomyrmex* are possibly the most studied genera of ants in the world with two books and a large body of primary literature is dedicated to them (Cole, 1968; Taber, 1998; Johnson, 2000; 2001).

## 24. Ants as Naturally Long-lived Insect Models for Aging

**Figure 24.2.** Founding *Lasius niger* queens. Queens being placed into water tubes after collection and stored in the dark until the first minims emerge.

**Figure 24.3.** *Pogonomyrmex rugosus* laboratory colony. The colonies are kept in plastic boxes normally used for rodent housing. There is an additional small box with water tubes for the area where the queen and brood live.

*Pogonomyrmex* contains the longest lived ant species recorded in the field, 30 years for *P. salinus* (Porter and Jorgensen, 1988). The best candidate model species within the genus *Pogonomyrmex* are *P. rugosus*, *P. barbatus* and *P. occidentalis*.

These monogynous, multiple mating species are extremely common in the western deserts of North America, forming large conspicuous disc- or mound-shaped colonies. The colonies rarely move, facilitating permanent marking and long-term demographic studies. All of these species sting and can be very aggressive. The mating flights are usually rain triggered in the mid- to late summer months. Queens can be collected after mating flights and colonies started in water tubes as for *L. niger*, transferring them to larger boxes with additional water tubes as needed (Figure 24.3).

Being desert ants, they should be kept at 30 to 35°C. Seed harvesters are poor climbers, but Fluon® is

**Figure 24.4.** *Solenopsis invicta* laboratory colony. The colonies are kept in plastic boxes used for small rodent housing.

recommended to help contain them within their plastic boxes. A more elegant design is a sandwich style nest with either soil or plaster (see Johnson website for pictures and details). *Pogonomyrmex* should be fed pesticide-free grass seed or small bird seed, dead insects such as frozen crickets or meal worms, and a 1:1 mixture of honey and water. Colonies can be raised to large numbers and, in many cases, can produce sexuals in 2 to 3 years.

### SOLENOPSIS INVICTA

From a molecular biology viewpoint, the most attractive model ant species is the red imported fire ant, *Solenopsis invicta*. Although queens live only 2 to 5 years, they have the advantage of existing in polygynous and monogynous colonies. This ant has the most extensively developed genomic tools available with a large cDNA EST database and a microarray chip nearing completion (J. Wang and L. Keller, pers. comm.) A BAC library is also available for purchase (see website list). Primary tissue culture and gene expression studies have been successfully employed using *S. invicta* (Chen, 2004). In addition, the first gene directly affecting social structure (i.e., queen number) was discovered and cloned from *S. invicta* (Krieger and Ross, 2002).

*Solenopsis invicta* are common where introduced and easily cultured in the laboratory. Their transient, shallow nests make it easy, if not sometimes painful, to collect mature colonies with queens. An entire nest can be shoveled into a Fluon® -coated bucket and water added slowly. *Solenopsis invicta* form living rafts in response to flooding, and the floating colony raft can be scooped from the water and placed into plastic boxes treated with Fluon® (Figure 24.4).

Newly mated queens can also be collected after mating flights in the early summer and colonies started in water tubes as for *L. niger* and *Pogonomyrmex*. Their optimal laboratory temperature is 25 to 30°C. Their dietary requirements are more demanding, requiring freshly

killed insects and a constant source of water. Specific method descriptions and food recipes can be found online (see Internet section of the appendices).

There are two problems that must be considered when working with *S. invicta*. First, it is impossible to avoid being stung on a regular basis when working with these small, aggressive ants. Some people develop sensitivity to the stings and can experience life-threatening anaphylactic shock (Solley *et al.*, 2002). Second, this is a highly destructive and invasive species that should never be transported to, or kept in, warm moist regions of the world where they have not already been established.

## Sampling at the Colony Level

Mature queens of single-queen colonies such as *Pogonomyrmex* and *L. niger* are almost impossible to collect due to the depth and size of the colonies. Fortunately, the genotype of a queen can be determined by genotyping male allates from the colony. As males are the product of unfertilized eggs, a sample size of 6 will cover 99% of the queen's genome. The genotype of the father(s) of the colony, as well as the queen's, can also be reconstructed by sampling workers. In both cases, such sampling will not negatively impact large colonies and represents a benign way to monitor the genetic structure of extant, wild long-lived populations.

Social insects should be sampled at the level of colony or group of colonies for molecular studies. When the queen has been fertilized by only one male, all of her daughters are full sisters and share the same haploid father and diploid mother. Thus, workers from a monogynous colony headed by a singly mated queen are identical for 75% of their genome. This can lead to pseudo-replication, as colonies represent closely related families with related genetic backgrounds. Measurements of a group of 25 workers consisting of 5 workers from 5 different colonies cannot be considered 25 independent samples because of within-colony relatedness. Instead, this example contains measurements of 5 independent colonies, each consisting of the average from 5 workers. Thus, in most cases, worker colony samples should be averaged and one value taken per colony for statistical tests.

## Molecular Methods

There are some practical considerations one should keep in mind when isolating DNA, RNA and protein from ants. Queens tend to be very high in fat content before their mating flight as well as in their physogastric form. Supplementary extractions with ether to remove this fat can be helpful for DNA and RNA isolation. Ants also tend to have much harder exoskeleton and higher surface-to-mass ratio than *Drosophila*, and complete homogenization of tissue can be difficult without a bead-type shaker homogenizer.

Some experiments are better conducted on dissected tissues or body sections. Physogastric queens lay large quantities of eggs and the mRNA profiles of the queens can become dominated by that of the eggs. Males contain a large amount of sperm and subsequently large amounts of DNA for their body weight. Beginning a DNA extraction with dissected vas deferens containing sperm represents an immediate 10-fold purification. The formic acid in Formicine ants can also be problematic as was found in protein preparations from *L. niger* workers (Parker *et al.*, 2004a). The acidity can effect isolation and gel loading buffers as well as interfere with enzyme activity assays. The efficiency of phenol extractions in DNA isolations can also be adversely affected by the acid.

## Genetics

Recently, the standard of proof in molecular biology has required demonstration of gene function by knocking out or overexpressing a gene in an experimental system. This comparison is not yet possible at the organismal level in ants either through selective breeding or gene transfer, but has been successfully achieved for primary tissue culture in *S. invicta* (Cònsoli, 2002; Chen, 2004). To date, no one has developed an immortal cell line for any social insect. Eventually, one may find a way to breed the ant model systems above, either by simulating the natural mating conditions or by artificial insemination as is done for honey bees, but neither has yet been accomplished.

The lack of a genome sequence for ants does not pose as much of a practical problem as one might think. Although *S. invicta* is the only ant species with a very large cDNA sequence database, differential gene expression studies with specifically targeted genes or suppressive subtractive hybridization are still possible using genomes already sequenced. Specific genes can be cloned by aligning sequences from the honeybee, fruit fly, mosquito, silk worm and fire ant sequence databases using the program CODEHOP (Rose *et al.*, 1998) with the *Lasius niger* codon usage table selected. This technique has been successfully employed to clone numerous *L. niger* genes, including an extracellular SOD, which was not thought to exist in insects (Parker *et al.*, 2004b).

## Comparative Studies

Ants as a group are extremely diverse, and this diversity lends itself to many types of comparative studies across species and across populations. There are also exploitable differences across caste and sex within a single species. Some of these represent reversals of typical life span correlations with size and longevity as observed in humans and birds. For example, there are two sizes of workers in the weaver ant, *Oecophylla smaragdina*. The major (large) workers perform the dangerous tasks

## 24. Ants as Naturally Long-lived Insect Models for Aging

outside the colony and have shorter life spans than the minor (small) workers who remain within the highly protected nest. But this difference in life span remains intact even in a protected laboratory environment (Chapuisat and Keller, 2002). It would be interesting to investigate if there are metabolic differences between these two sizes of worker ants.

The phenomena of monogynous/polygynous colonies have evolved independently many times across a wide range of ants and other social insect taxa. There is evidence that, within the same species, queens of monogynous populations live longer than queens of polygynous populations as predicted by evolutionary theory (Keller and Genoud, 1997). *Solenopsis invicta* is an excellent system to investigate life-span variation within a single species but across populations with different social structure as it has both polygynous and monogynous populations. In addition, the genetic basis for this difference in queen number is already known (Krieger and Ross, 2002).

One possibility for cross-species comparisons is the many cases of social parasites. Socially parasitic ants lack a worker caste and invade a host colony where their reproductive brood are raised by the host colony workers. In the genus *Pogonomyrex*, there are socially parasitic ants who live only 1–3 years and have recently evolved from a shared common ancestor of their longer lived hosts (*P. barbatus* and *P. rugosus* (Johnson *et al.*, 1996; Parker and Rissing, 2002). They represent an opportunity to investigate the evolution to a shorter life span once the relevant processes are discovered.

Reproductive rate correlates with life span such that highly fertile individuals have shorter life spans than less fertile members of the same species (Williams, 1957; Charlesworth, 1980; Partridge and Gems, 2002). Yet this fecundity/longevity tradeoff is reversed for queens and workers. The queen of a large social insect nest must lay eggs at a rapid rate to maintain the number of sterile workers in the colony, and yet she has an extremely long life span (Rueppell *et al.*, 2004). This reversal of the fecundity/longevity tradeoff has been shown true even without the morphological and physiological differences which are present between queen and worker ants. In the Ponerine ant *Platytyrea punctata*, all workers are capable of producing diploid workers, yet the reproductive workers live significantly longer than their non-reproductive counterparts (Hartmann and Heinze, 2003).

Given that castes share the same genome, the differences in life span must be based on differential gene expression at some point(s) in their life history. This provides the foundation for testing gene expression differences already associated with aging in model systems. If the mechanisms hypothesized for life span extension in model systems are truly general, then there should be evidence of these same mechanisms being used in queen ants. One such mechanism, the resistance to oxidative stress conferred by superoxide dismutase

(SOD), was recently tested in a comparison of cytoplasmic SOD activity and expression levels across all castes (Parker *et al.*, 2004a). The study found that a high level of cytoplasmic SOD does not correlate with life span as for previous work in *Drosophila* (Orr and Sohal, 1994; Sohal *et al.*, 1995; Hari *et al.*, 1998; Sun and Tower, 1999; Arking *et al.*, 2002; Spencer *et al.*, 2003) and is in agreement with previous comparative studies (Perez-Campo *et al.*, 1998; Barja, 2002).

These small, highly fecund and extraordinarily long-lived queens must overcome all of the physiological problems of maintaining mitochondria, proteins which are degraded, damaged and/or incorrectly folded, as well as accumulative damage to DNA and membranes that are associated with long life. Queens in particular must do all of these things an order of magnitude longer than workers, and while reproducing at a high enough rate to sustain a colony. All of these individual molecular processes represent potentially fruitful lines of inquiry that could reveal novel aging resistance mechanisms.

## Conclusions

It should not be overlooked that only those processes verified by both unnatural life-span manipulations in the laboratory and naturally occurring evolved differences can be considered as true proven causes of life-span variation. Without verification, one will never know whether the mechanisms uncovered in the traditional model systems are artifacts of laboratory stress or specific to short-lived organisms. Testing in the laboratory will guard against making up “just-so” stories based solely on observed natural correlations. The challenge is to combine studies across both types of systems to discover what processes truly underlie the human aging process. Ants offer one of the best insect models to build this bridge.

## ACKNOWLEDGMENTS

We thank Michel Chapuisat and Stephanie Jemielity for providing helpful comments and suggestions. # Gene Expression and the Extended Longevity Phenotypes of *Drosophila melanogaster*<sup>1</sup>

Robert Arking

*Flies show three different types of longevity phenotypes, only one of which is characterized by significant increases in both the mean and maximum life span. This arises as a result of an experimentally induced delay in the onset of senescence. The net result of this phenotype is a significant increase in the length of the "health span," coupled with no significant change in the "senescent span." It is the purpose of this chapter to summarize what we know about the gene expression patterns and pathways that appear to be critically involved in allowing the expression of the one longevity phenotype which extends longevity by delaying the onset of senescence.*

## Introduction

There was once a time when the view that model organisms would actually lead us to informative views regarding human aging was but a pious hope. That time has passed. Much of what we now know or suspect about human aging is based on studies originally done in model organisms. It turns out that the major gene systems regulating aging are highly conserved public mechanisms; the characterization of the genetic and metabolic *pathways* involved in longevity regulation, and the environmental conditions necessary for their expression, required the integration of data from the four most commonly used species: yeast, worm, fly, and mouse. A good review of the various genetic attributes and tools that make *Drosophila melanogaster* such an excellent experimental tool for investigation of the aging phenomenon is found in chapter 22 by Miwa and Cohen. This chapter will be concerned with the three different longevity phenotypes known in this organism and the nature of the gene expression patterns characteristic of each, with special emphasis on the extended longevity phenotype brought about by a delayed onset of senescence.

The laboratory experiments done over the past few decades have allowed the robust identification of four different—but intertwined—genetic and physiological pathways which seem to regulate longevity in all

four of our model systems. These four major public longevity processes may be summarily listed as follows: (1) *Metabolic Control*, (2) *Stress Resistance*, (3) *Genetic Stability*, and (4) *Reproductive Effects*. Information regarding different patterns of senescence is still sketchy but we will deal with it under the fifth heading of *Patterns of Senescence*. [A more extensive discussion of these topics in all four model systems is given by Arking (2005a)]. Each of these categories should be regarded, not as an autonomous set of metabolic reactions, but rather as sets of regulatory reactions that are more closely linked to one another than to any of the other categories. Such a view obviously permits the existence of crosstalk between these several network hubs. Much of the variation inherent in aging may stem from such cross-reactions. Table 25.1 contains an outline summary of these major processes which play an important role in bringing about differential longevity and senescence in *Drosophila melanogaster*. These processes may be induced or repressed by a variety of stimuli, including pharmaceutical interventions.

## The Three Longevity Phenotypes of *Drosophila*

One fact that has emerged from the past several decades of aging research is that aging is not simple. The work that my colleagues and I have done on *Drosophila* longevity bears this out. We reported that aging in our *Ra* strain of wild-type flies is rather complex, being characterized by at least three different extended longevity phenotypes, each of which was induced by specific stimuli and had different demographic mortality and survival profiles (Arking *et al.*, 2002). As shown in Figure 25.1A, the first longevity phenotype (Type 1) is a delayed onset of senescence that leads to a significant increase in both mean and maximum life span of the experimental strain.

<sup>1</sup>Adapted from Chapter 7 of book by Arking (2005a).

TABLE 25.1  
Summary comparison of main longevity pathways in *Drosophila melanogaster*

Process	Major genes or pathway	Effect
<b>Metabolic control</b>		
via CR	<i>indy, rpd3, Sir2</i>	CR slows rate of gene expression change relative to WT. Downregulates synthesis, turnover, & reproduction. No consistent up-regulation pattern. CR effect is relatively rapid.
via ISP	<i>InR, chico, forkhead</i>	ISP affects hormones which indirectly affect longevity by altering stress resistance levels. See "Repro Effects" below. Forkhead is key transcription factor which increases stress resistances.
via Nuclear-mito interactions	–	Cybrids show longevity intermediate between nuclear & mitochondrial donors.
<b>Stress resistance</b>	<i>CuZnSOD, MnSOD, catalase, Gpx, hsp, others</i>	Up-regulation of different ADS genes by various techniques usually leads to increased oxidative/other stress resistance. Likely basis of extended longevity; QTL confirmation of ADS basis in one strain. Tissue-specific protective effects.
<b>Genetic stability</b>	–	Genome appears to be highly stable in normal flies. No evidence for regional or overall genomic dysregulation.
<b>Reproductive effects</b>	ISP, JH, Ecdysone, <i>EcR, DTS-3</i>	ISP induces JH synthesis which induces egg production and 20HE synthesis. At high levels, 20HE represses resistance to various stressors, & reduces life span. At moderate levels, longevity & stress resistance significantly increase.
<b>Patterns of senescence</b>	–	Various sensory & locomotor abilities do not age in unison. Long-lived mutants do not delay the senescence of all their functions but retain some & lose others as do normal-lived animals.

The second longevity phenotype (Type 2), shown in Figure 25.1B, is an increased early survival that leads to a significant increase in mean but not in maximum life span. The third longevity phenotype (Type 3), shown in Figure 25.1C, is an increased later survival, which leads to a change in the maximum (LT<sub>90</sub>) but not in the mean life spans.

Analysis of the mortality data supports these statements. The Type 1 phenotype yields a Gompertz curve which is significantly different from that of the control strain (Figure 25.2A).

Analysis of the data suggests that the Type 1 phenotype involves a ~50% reduction in the mortality rate doubling time (MRDT) of the long-lived strain (8.8 days) relative to the normal-lived strain (5.8 days). Although not a direct measure, the MRDT is a commonly used proxy indicator of comparative aging rates. However neither the Type 2 long-lived populations (Figure 25.2B) nor the Type 3 long-lived populations (Figure 25.2C) show any sustained alteration in aging rates relative to their controls, but rather show only a transient decrease in either early or late life but not both.

Moreover, it should be pointed out that the same phenotype may be induced by multiple different stimuli. For example, the Type 1 delayed onset of senescence

phenotype may be induced in flies by (a) caloric restriction (Pletcher *et al.*, 2002), (b) by the down-regulation of the insulin-like signaling pathway (Tatar, Partridge refs), (c) by up-regulation of the antioxidant defense system (ADS) plus altered mitochondrial properties (Arking *et al.*, 2002), (d) by drugs which inhibit histone deacetylases (Kang *et al.*, 1999), and by other mechanisms as discussed below. What is it that unites all these varied stimuli and mechanisms into bringing about a Type 1 phenotype? What is it that distinguishes them from the stimuli which yield only the Type 2 or 3 phenotypes? The remainder of this chapter will attempt to answer these questions.

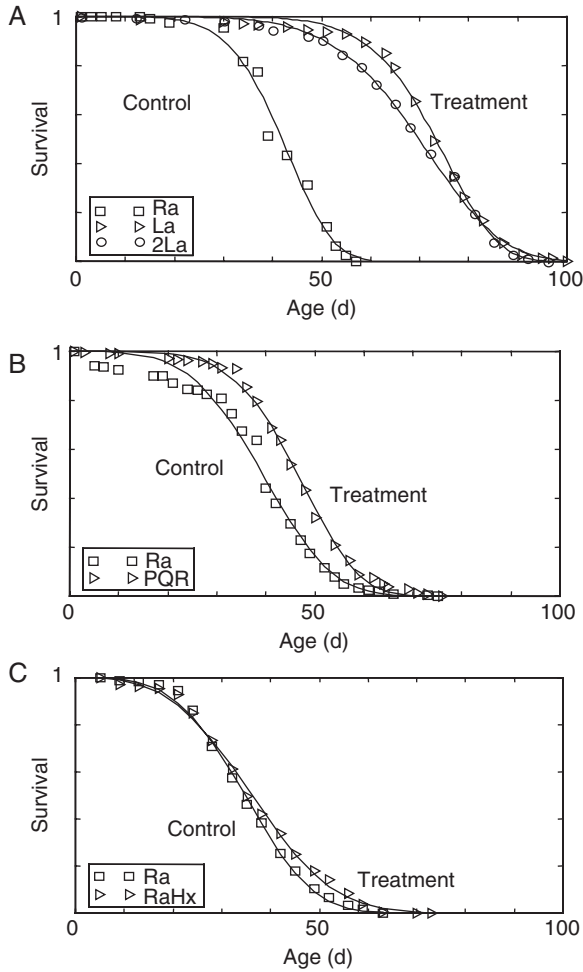

## Gene Expression Pathways Yielding an Extended Longevity

### METABOLIC CONTROL OF LONGEVITY

#### *Metabolic control of longevity via caloric restriction*

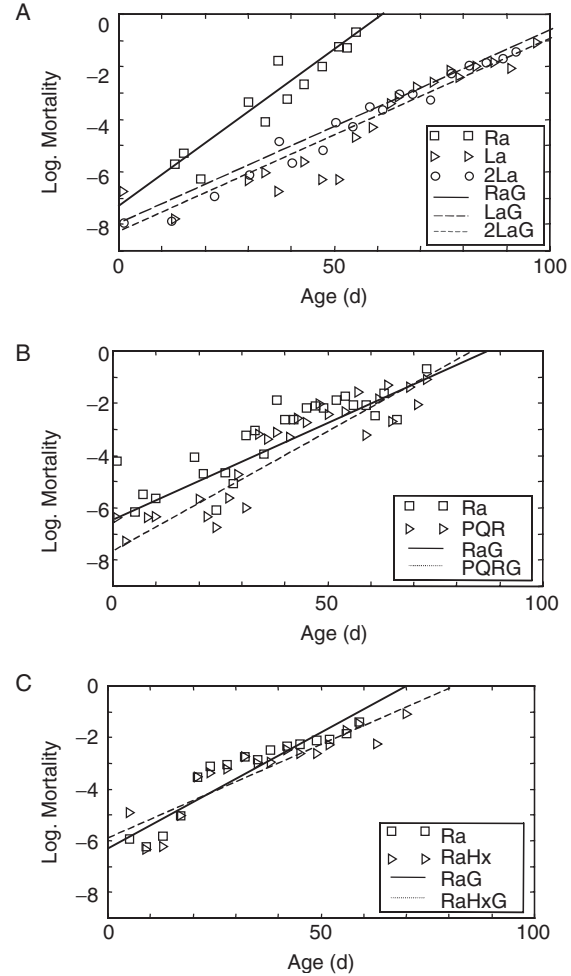

Although the effect of dietary restriction (CR) was first demonstrated in rodents in 1934, and although there have been a number of investigations of nutritional effects on longevity of *Drosophila*, it was not until 1996 that the first repeatable report appeared showing that CR was effective in altering the fly's life span (Chapman and Partridge,

25. Gene Expression and the Extended Longevity Phenotypes of *Drosophila melanogaster*

**Figure 25.1.** (A) Survival curves of the normal-lived Ra strain and of two long-lived strains (La and 2La) sequentially derived from it by a direct selection for delayed female fecundity. Each survival curve is based on the age-specific values obtained from two or three replicate cohorts consisting of at least 250 mixed sex individuals each. The Ra, La and 2La curves are significantly different (log-rank test = 530.16,  $df = 2$ ,  $P < 0.0001$ ). See Arking *et al.* (2000a) for experimental details. (B) Survival curves of the normal-lived Ra strain and the PQR strain selected from it by direct selection for paraquat resistance. Each survival curve is based on the age-specific values obtained from mixed sex cohorts of 250–450 animals each. The two curves are significantly different (log-rank test = 24.76,  $df = 1$ ,  $P < 0.00005$ ). See Vettraino *et al.* (2001) for experimental details. (C) Survival curves of the normal-lived Ra control strain and the longer-lived Ra heat-treated strain. The animals were subjected to a nonlethal heat shock (37°C for 90 minutes) early in life at days 5–7 after eclosion. They were then maintained under controlled optimal conditions, and their survival was monitored. The two curves are significantly different (log rank test = 17.84,  $df = 1$ ,  $P < 0.00005$ ). See Keuther and Arking (1999) for experimental details. (After Arking *et al.*, 2002)

1996). Raising the adults on food which contained only 33% of the nutrients found in the standard food allowed a ~34-day increase in the median life span and a ~31-day increase in the maximum life span (Pletcher *et al.*, 2002). Analysis of the age-specific mortality rates for this

**Figure 25.2.** (A) The hazard or force of mortality curves of the normal-lived Ra strain and of two long-lived strains (La and 2La) sequentially derived from it by a direct selection for delayed female fecundity. Each mortality curve is based on the age-specific values obtained from two or three replicate cohorts consisting of at least 250 mixed sex individuals each and was calculated using the Kaplan–Meier survival procedure in SPSS v.7. See Figure 25.1A for statistical significance. (B) The hazard or force of mortality curves of the normal-lived Ra strain and the PQR strain selected from it by direct selection for paraquat resistance. Each mortality curve is based on the age-specific values obtained from mixed sex cohorts of 250–450 animals each and was calculated using the Kaplan–Meier survival procedure in SPSS v.7. See Figure 25.1B for statistical significance. (C) The hazard or force of mortality curves of the normal-lived Ra control strain and the longer-lived Ra heat-treated strain. The animals were subjected to a nonlethal heat shock (37°C for 90 minutes) early in life at days 5–7 after eclosion. They were then maintained under controlled optimal conditions, and their survival was monitored. The mortality curve was calculated using the Kaplan–Meier survival procedure in SPSS v.7. See Figure 25.1C for statistical significance. (After Arking *et al.*, 2002)

experiment showed that they did not begin to increase from the minimal values observed in the young until ~15 days in the control animals and about ~45 days in the CR animals. If this increase in the age-specific mortality is taken as indicating the age of onset of

senescence, then the ~30-day delay in the age of onset of senescence in the CR animal essentially accounts for all the extra longevity noted in the survival curves. From a demographic point of view, the population enters what appears to be a period of stasis in which the age-specific mortality rate does not increase, and so this results in an extension of the young and healthy portion of the life span, as suggested in Figure 25.1A.

Gene expression analysis of the ad libitum (AL) and CR animals showed that >1% of the assayed genes showed a significant change in their expression. The genome is normally quite stable, and so our interest is focused on those few genes that do change. As a general rule, these changes occur more slowly in the CR set than in the control set. Those genes that increase with age in both sets comprise mostly genes involved with innate immunity and detoxification, enzyme inhibitors, and all sorts of genes involved in the response to various stresses. These data suggest that aging animals—regardless of their diet or chronological age—are under increasing stress from pathogens. It appears as if the proximate cause of death in old flies is infection (Tower *et al.*, 2004). An upstream cause of these proximate stresses may well be a loss of mitochondrial function, and the 458 gene probes down-regulated with age are consistent with this idea. The loss of energy production associated with decreased mitochondrial function is a major factor in the loss of function characteristic of aging. Most interesting is the CR-induced down-regulation of at least one gene (*methuselah* (*mth*), see below) known to significantly extend longevity when mutated. Its down-regulation under CR conditions suggests that the wild-type *mth* might act as a negative regulator of extended longevity. There is no obvious reduction in reproductive activities in the CR animals, and so it cannot be attributed only to a shift of energy from reproduction to somatic maintenance (Mair *et al.*, 2004). CR appears to extend longevity in the fly by ameliorating many of the normal transcriptional changes that occur with age. A model for the mechanisms involved in the onset of senescence is presented below and by Arking (2005b).

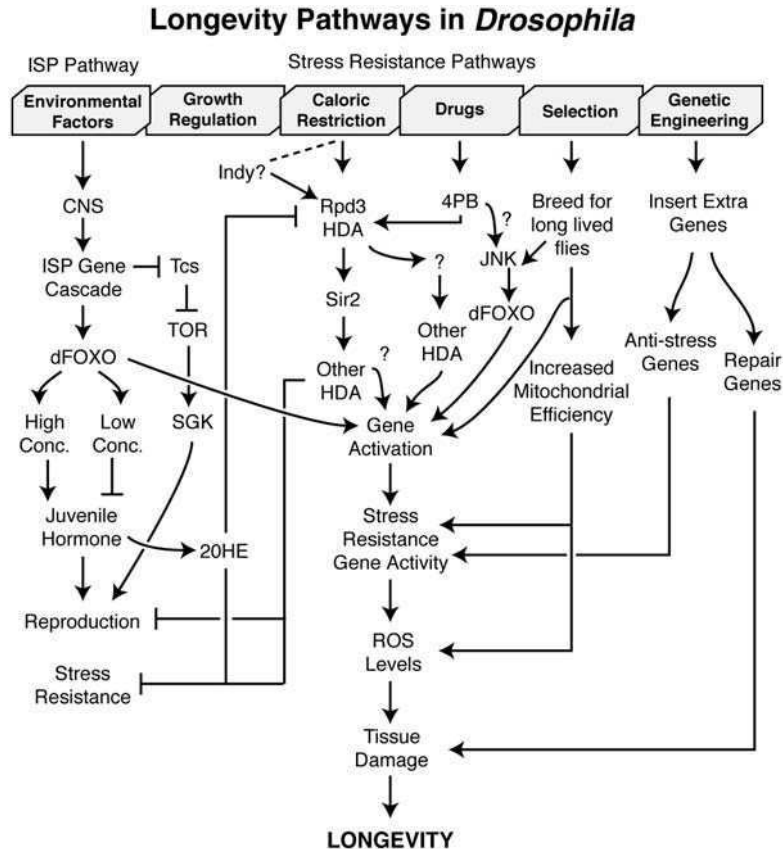

As was noted with CR in the mouse, different strains or mutants may have different sensitivity spectrums to CR. The *chico* mutant expresses its maximum life span at a higher food concentration than does the wild-type control (Clancy *et al.*, 2002). Other mutants show similar changes in their optimal food concentration. Thus the amount of food needed to trigger the CR response is not fixed in a species but is itself the outcome of the organism's genotype and nutritional environment. It is known that the organism actually has several pathways that sense its nutritional state. The TOR signaling pathway (see Figure 25.3) senses the amino acid levels so as to modulate growth or longevity.

There may well be other specific nutrient-sensing pathways. Their variable interactions with the nutritional environment and with each other may well account for

the existence of different sensitivity spectrums to CR noted above.

The preceding discussion describes what CR does to a fly. But how does it do it? What gene pathways are involved? The evidence here is less detailed but still informative. Two different histone deacetylases are involved in mediating the CR response. Flies carrying a mutant *rpd3* deacetylase gene and raised on normal media have a mean and median life span about 40% longer than that of their wild-type controls (Rogina *et al.*, 2002). But *rpd3* mutants raised on low caloric food have a life span identical to that obtained if they are raised on normal food. The fact that the CR treatment has no effect on these mutants implies that the wild-type allele of the *rpd3* gene plays a role in the CR response. Even more interesting is the response of the *Drosophila* *Sir2* gene to CR and to *rpd3*. Wild-type animals subjected to CR show an approximate doubling in the level of *Sir2* gene expression, while *rpd3* mutants raised on normal food also show an approximate doubling in the level of *Sir2* gene expression. Thus the normal allele of *rpd3* seems to inhibit the *Sir2* gene expression that is necessary for the CR effect. In another series of experiments, it was shown that if the *Sir-2* histone deacetylase gene of *Drosophila* is up-regulated by feeding the animal a known sirtuin activator such as resveratrol (the longevity extending component of red wine), then life span is significantly extended even though the animals are fed AL (Wood *et al.*, 2004). Conversely, flies lacking a functional *Sir-2* gene failed to extend their longevity when fed resveratrol. Thus activation of *Sir-2* seems to be essential for the expression of CR-dependent extended longevity. It is reasonable to conclude that both these genes are components of the genetic pathway mediating CR expression, related perhaps in the manner suggested in Figure 25.3. It should be noted that there is much disagreement over the details of this interaction, and this is now an active area of investigation.

Another gene possibly involved in CR is the *indy* gene which encodes a metabolite transporter protein responsible for the uptake and transport of Krebs and citric acid cycle intermediates through the gut epithelium and into the appropriate organs (Knauf *et al.*, 2002). Homologous genes exist in nematodes and mammals. Flies carrying a mutation in this gene display a 90% increase in their mean life span and a 50% increase in their maximum life span (Rogina *et al.*, 2000). In flies, the *indy* gene is normally expressed primarily in the midgut, fat body (liver equivalent) and oenocytes, which are the main sites of intermediary metabolism. It is not unreasonable to assume that the mutant-induced down-regulation in the activity of this metabolite co-transporter protein brings about a lower effective concentration of essential metabolites in the cell, thus creating a metabolic state similar to that induced by CR. One possible interpretation of its role in the CR pathway is shown in Figure 25.3.

**Figure 25.3.** A schematic diagram integrating all the pathways empirically known to yield a Type 1 (delayed onset of senescence) longevity phenotype in *Drosophila melanogaster* (after Arking, 2005a).

A very important insight into the nature of the CR response was provided by an experiment in which flies were initially raised on either a CR or AL dietary regime and were then switched at various ages to the alternative diet (Mair *et al.*, 2003). AL-raised flies normally have a higher age-specific mortality rate than do CR-raised animals. But after a AL → CR shift, the animals rapidly adopt the age-specific mortality rate characteristic of animals who have been raised on a CR regime for their entire life. A corresponding rapid upward shift in mortality rate is observed following a CR → AL shift. What this means is that the *age-specific mortality rates have no cellular memory*; change the physiological state of the cell and you change the resulting mortality rate. An AL → CR shift, for example, induces the animal to alter its regulatory pathways and shift its gene expression pattern from a pro-growth pattern to a pro-stress resistance pattern. The consequent change in damage patterns affects the mortality rate. The mortality rate is due only to the current levels of damage occurring in the organism. The animal's prior history does not directly play a determining role in its current mortality rate, although certainly the existence of prior unrepaired damage must have some effect. This finding implies that CR/ISP-dependent aging is an environmentally dependent

cell-level function, and the presence of the systemic regulatory mechanisms in multicellular eucaryotes does not invalidate this statement.

A cautionary note is in order here: not all flies react to CR in the same manner as described above. Our selected La and Ra strains have a different response pattern (Arking, unpublished data). Mediterranean fruit flies (*Ceratitis capitata*) are distantly related to *Drosophila* and might reasonably be expected to react to CR in the same manner if one assumes that the CR mechanism is highly conserved and public. However, a recent study reported that the Mediterranean fruit fly shows a more or less constant longevity at various levels of diet restriction with a sharp decrease in mortality once the diet falls below 50% of the ad libitum level (Carey *et al.*, 2002). There is no evidence for an increase in longevity at some consistent level of dietary restriction. Reproduction occurred across the range of diets tested. The mortality increase occurred in both sexes even though males have no obvious counterpart to the energetic demands of egg production in females. On the other hand, these same flies lived longer when subjected to a “feast or famine” dietary regime (Carey *et al.*, 2004). This latter regime likely resembles the normal situation in the wild, and so perhaps that environment selects for animals that can

go into a survival mode when food becomes transiently scarce. These data suggest that there are intra- and interspecific differences in the CR response, which is thus a highly conserved but not universal mechanism.

*Metabolic control of longevity via insulin-like signaling pathway*

The insulin-like signaling pathway (ISP) was initially investigated for its effects on growth and size of the fly, and it was demonstrated that mutants affecting the activity of ISP did affect these parameters (Weinkove and Leivers, 2000). The ISP also affects blood sugar levels. The fly possesses five insulin-like proteins with significant homology to the mouse and human insulin proteins. These proteins are expressed in several tissues but most particularly in small clusters of insulin-producing cells (IPCs) in the brain (Rulifson *et al.*, 2002). These workers showed that ablation of these IPCs caused retarded growth and elevated carbohydrate levels, and that a normal phenotype could be restored by expressing one of the *Drosophila* insulin-like proteins. Thus there is a remarkable conservation of the insulin-based gluco-regulatory mechanisms in flies and mammals with respect to its effects on growth and blood sugar. Once the experimental data allowed the concept of a conserved longevity regulation mechanism to become clear from the work done with yeast and nematode, then the fly's ISP was investigated to see if it also regulated the fly's longevity. There are some obvious phenotypic differences between homozygous and heterozygous mutants in genes comprising the ISP, but the important point made clear by these investigations is that certain of these mutants can significantly increase longevity.

As you might expect, flies with no ISP activity at all are lethal. But in rare cases, one can construct homozygous flies which contain two different mutations, each with a defect in a different part of the gene. Such unusual animals have a low but detectable level of ISP activity (~25% or less) and can survive through adulthood. These "heteroallelic" homozygotes contain two different mutations in their insulin receptor gene (*InR*; homologous to the *C. elegans daf-2* gene) and gave rise to dwarf adults with different longevity effects on the two sexes (Tatar *et al.*, 2001). Females expressed a delayed onset of senescence, with an 87% increase in their mean life span and a ~45% increase in their maximum life span. These homozygous mutant females are small because the ISP controls cell size, and the low activity levels result in small cells and slow growth. They are sterile because the low ISP activity results in a significant decrease in the juvenile hormone levels which are known to be essential for reproduction (see Reproductive Effects). Male homozygotes are also small and semisterile, for the same reasons. On the other hand, the males show no statistical change in their mean life span even though they have an increased mortality during early to mid-adult life followed by a lower mortality rate thereafter. Incidentally, the

smaller effect of the ISP on males seems to be a general phenomenon, and we will touch on it in Reproductive Effects.

Both heterozygous and homozygous *InR* mutants have an impaired synthesis of the steroid hormone, ecdysone (Tu *et al.*, 2002). This suggests that the increased longevity associated with the heterozygous *InR* mutants is likely dependent on a decreased level of juvenile hormone synthesis and the consequent reduction of ecdysone synthesis to levels that do not repress the animal's level of stress resistance (see Reproductive Effects for a description of the mechanisms which tie these several observations together).

Flies which are either heterozygous or homozygous for a certain mutation in their *IRS* proteins (associated with the cytoplasmic side of the *InR*) also yield long-lived females but not males (Clancy *et al.*, 2001). These flies were also observed to be more resistant to oxidative stress than their controls. Thus disabling the *InR* and/or *IRS* genes is sufficient to down-regulate the entire ISP.

Finally, the *dFOXO* gene of *Drosophila* was shown to have sequence homology with the *daf-16* gene of *C. elegans*, and to function in the regulation of growth (Kramer *et al.*, 2003). Flies heterozygous for the *dFOXO* gene are incapable of expressing the extended longevity otherwise resulting from a mutational down-regulation of the *InR* gene (Hwangbo *et al.*, 2004). This functional test demonstrates that the *dFOXO* gene is downstream of *InR*. Thus the structure of the ISP is the same in yeast and nematode and fly, for effects on the upstream genes such as *InR* must be mediated through the downstream *dFOXO* transcription factor. If the latter is mutationally inactivated, then the upstream signals are ignored. This factor is believed to activate various stress-resistance genes and repress various pro-growth genes in a manner similar to that demonstrated in the nematode. Both of these actions will result in a slower accumulation of age-related oxidative damage and in a delayed onset of senescence, as described in Stress Resistance and External Longevity.

The simplest conclusion of these several experiments is that the modulation of longevity via the ISP is highly conserved from yeast to mammals. The fact that longevity regulation in the fly is intertwined in the same system with the regulation of growth, cell size, and fertility suggests that the fly ISP has multiple specific regulatory functions compared to a nematode. This is consistent with the fact that the fly has at least four independent isoloci of the PI3K gene, each of which apparently controls different sets of processes, while humans have at least 16 PI3K genes (Samuels *et al.*, 2004). This increased signaling complexity, which might have arisen as a consequence of the increased size and morphological complexity of the fly, might well account for its apparent greater genetic complexity.

Important though it is, the ISP is not the only signaling pathway involved in assaying nutrient availability.

25. Gene Expression and the Extended Longevity Phenotypes of *Drosophila melanogaster*

The TOR signaling pathway is an important regulator of growth and size and is found in organisms from yeast to humans. Experiments with *Drosophila* show that the TOR pathway senses amino acid availability and uses this information to modulate activity of the S6 kinase regulatory gene so as to enhance growth and repress extended longevity (Kapahl *et al.*, 2004). It also plays an important role in regulating autophagy, or the digestion of the cell's own components for energy (Klionsky, 2004). It was found that either over-expression of the upstream *Tsc1* and *Tsc2* genes, or dominant-negative mutations in the *TOR* or *S6K* genes, gave rise to extended longevity. As briefly summarized in Figure 25.3, these data suggest that the two upstream genes act as negative regulators of the TOR or S6K genes, which themselves act as a negative regulator of longevity and a positive regulator of growth. It seems likely that the TOR pathway acts in parallel with, and perhaps even overlaps, the ISP.

*Metabolic control of longevity via nuclear-mitochondrial interaction*

There exists a large body of information regarding the role of mitochondria in aging. But there is almost no definitive data regarding the role of nuclear-mitochondrial interaction in the *Drosophila* aging process. This, however, does not mean that nuclear-mitochondrial interaction does not occur in flies, for there are at least three lines of suggestive evidence to the contrary. Taken together, they suggest but do not prove that the observed changes stem from some alteration in nuclear-mitochondrial communication.

First, Ballard and James (2003) found that mitochondria and nuclei taken from animals indigenous to different parts of the species' geographic range yielded low fitness flies when combined. This might come about if the mitochondria had evolved so as to be most effective in certain environments. Combining a (genetically different?) mitochondria from one area with a nucleus which evolved in a different region might result in organelle incompatibilities and hence a decreased life span.

Second, the same laboratory collected strains of *Drosophila simulans* (a close relative of *D. melanogaster*) from comparable environments and assayed their longevity as well as aspects of their mitochondrial function. They found that a particular long-lived strain was characterized by a high mitochondrial efficiency. Complex IV of their mitochondria's electron transport chain is more efficient than is the case in normal-lived control strains, as evidenced by their lower than normal oxygen consumption but normal levels of ATP production (Melvin *et al.*, 2005). The nuclear encoded protein subunits of the complex responsible for the increased efficiency turned out to contain several point mutations which resulted in amino acid changes, the presence of which are highly correlated with the altered mitochondrial function. It is reasonable to suspect that the selection of chance mutations in nuclear encoded mitochondrial proteins

bespeaks the likely existence of metabolic signals that coordinate nuclear and mitochondrial activities and provide the feedback signals necessary to the selection process.

Third, as a result of the selection experiment summarized in Figure 25.1A, we wound up with a long-lived La strain and a normal-lived Ra control strain. But their extended longevity arises in part from the fact that the La mitochondria produce from ~20 to ~40% less H<sub>2</sub>O<sub>2</sub> than do the normal Ra mitochondria (Ross, 2001). Using the Ra and La strains, Driver and Tawadros (2000) set up various crosses that allowed them to combine mitochondria from different selected strains with the same normal-lived Ra nucleus. They then examined the resulting "cybrid" strains to see if any of the combined genomes had an effect on longevity. They showed that combining mitochondria from either normal-lived strain (Ra or Rb) with the Ra nucleus led to no change in longevity; but combining either of the long-lived mitochondria (La or Lb) with the Ra nucleus led to a significant change. Thus, the Lamt strain achieves about 40% of the extended longevity seen in the La strain solely because it has La type mitochondria. It would seem that mitochondria can make a significant contribution to longevity. Possible mechanisms for this phenomenon have been put forth elsewhere (Arking *et al.*, 2002). The important point here is that different mitochondrial genomes appear to set up different stable metabolic equilibrium settings with the Ra nucleus, and each of these permits different longevity to be expressed.

Whether any of these three cases constitutes nuclear-mitochondrial interaction is still to be determined. The fact that two different labs using different strains and different approaches have observed similar sorts of data

TABLE 25.2  
Effect of nonlethal stressors on longevity\*

Stressor	% Response of experimental	Molecules involved**
<b>Animals over controls</b>		
Cold	5%	hsp
Heat	10%	hsp & ADS
Hypergravity	12%	hsp
Physical activity	20%	ADS
Irradiation	20%	ADS & hsp
Caloric restriction	50%	ADS & others
Oxidative Stress Resistance	33-60%***	ADS & others

\*data adapted from Figure 1 of Minois (2000).

\*\*hsp = heat shock proteins; ADS = antioxidant defense system proteins.

\*\*\*response noted after selection or transgenic modification of genome.

suggests that nuclear-mitochondrial interactions might also take place in *Drosophila*.

**STRESS RESISTANCE AND EXTENDED LONGEVITY**

It has long been observed that mild or nonlethal stress often has the apparently paradoxical effect of benefiting the organism by increasing its longevity (Minois, 2000). Conversely, it has also been suggested that all long-lived strains and mutants exhibit some form of stress resistance (Parsons, 1995; Johnson *et al.*, 1996). This relationship is thought to reflect the fact that their natural environment usually exerts substantial, albeit variable, stresses on organisms. Evolutionary considerations of Darwinian fitness will thus impose a premium on genotypes conferring metabolic efficiency and stress resistance (Parsons, 1997, 2003). The magnitude of the effects of stress resistance on longevity are summarized in Table 25.3.

We will examine four complementary lines of evidence bearing on the relationship of stress resistance and extended longevity in *Drosophila*. The first involves the use of strains selected for extended longevity, followed by an analysis of the mechanisms responsible for the altered phenotype. The second involves standard mutational techniques in which candidate genes thought to play an important role in longevity are inactivated, and the life span of the experimental animals is assayed to see if the original hypothesis was correct or not. The third approach involves “genetic engineering” or transgenic

work in which extra copies of candidate genes are inserted into experimental animals and their longevity is then assayed to determine if the added gene has a significant effect on the life span. The fourth approach involves the environmental induction of stress response genes and the analysis of their effect on the longevity of the tested animals.

As a result of our studies on the biochemistry and stress resistance properties of the long-lived La strains, we knew that the only predictive factor clearly and significantly associated with extended longevity in our strains was an enhanced resistance to oxidative stress (Arking *et al.*, 1991; Force *et al.*, 1995). Thus it seemed logical to conclude that the long-lived La animals probably live long because of higher-than-normal activity of the antioxidant defense system genes early in life. Quantitative trait loci (QTL) mapping is a genetic method of identifying small chromosome regions which have a significant statistical effect on longevity, and may be viewed as a genome-wide scan that allows one to identify interesting genes for further investigation. Curtsinger and Khazaeli (2002) did such a procedure on recombinant inbred strains derived from the La and Ra strains discussed above. They found four QTLs located on chromosomes 2 and 3 of the (La × Ra) recombinant inbred strains that accounted for almost all of the selection response. The major QTLs for both paraquat resistance and longevity are coincident with each other and are centered over a small region of chromosome 3L which contains the loci of the CuZnSOD

TABLE 25.3  
Summary of genetic interventions testing the relationship between resistance to oxidative stress and altered longevity

Manipulation	Genes involved	Effect on life span	Effect on stress resistance	Reference
Selection for long life	CuZnSOD, MnSOD	Increased	Increased	Arking <i>et al.</i> (2000a)
	Catalase	Increased	Increased	Arking <i>et al.</i> (2000b)
	CuZnSOD?	Increased	Increased ox stress, also increased starvation & desiccation resistance	Rose (1984)
Catalase reduced	Cat	Decreased	No data	Mackay & Bewley (1989)
Catalase increased	Cat	No effect	Increased	Orr & Sohal (1992)
SOD1 reduced	CuZnSOD	Decreased	Decreased	Phillips <i>et al.</i> (1989)
SOD1 increased	CuZnSOD	Increased	Increased	Parkes <i>et al.</i> (1998)
		Increased (some strains)	Increased (some strains)	Sun & Tower (1999)
		Increased	Increased	Orr & Sohal (1993)
SOD1 & cat increased	CuZnSOD, cat	Increased	Increased	Orr & Sohal (1994)
		.....No increase over SOD alone.....		Sun & Tower (1999)

		No effect	No effect	Mockett <i>et al.</i> (1999)

## 25. Gene Expression and the Extended Longevity Phenotypes of *Drosophila melanogaster*

gene, and of several heat shock protein (hsp) genes. Both of these gene sets are involved in stress resistance. The other QTLs seem to be involved in maintaining female fertility. (One of these other QTLs appears to involve the ecdysone receptor (EcR) gene, which is involved in reproductive processes; see the section on Reproductive Effects.) The several genes involved exert their effects over the first six weeks of life but not thereafter. There are other minor contributors to the extended longevity phenotype (Curtsinger *et al.*, 1998), but the available data strongly indicates that the La strains live long primarily because of a specific up-regulation of antioxidant defense genes.

This finding supported our candidate gene approach in which we assayed the quantitative changes in the mRNA levels and the antioxidant enzyme activity levels of several loci during the development and early adult life of the normal-lived Ra and long-lived La strains (Dudas and Arking, 1995). In addition, we used antibodies to measure the actual amount of CuZnSOD protein present in these strains (Hari *et al.*, 1997). The mRNA data demonstrate that, at day 5 in the L strain, there appears to be a coordinately regulated significant increase in the mRNA levels of CuZnSOD, CAT, and xanthine dehydrogenase (XDH). There is a nonsignificant increase in glutathione-S-transferase (GST) mRNA during the same time period. These increases in mRNA levels are accompanied by significant increases in the enzyme activity of CuZnSOD, CAT, and GST. Other experiments showed that the amount of SOD-specific protein is proportionately increased in the La strain during the same time period (Hari *et al.*, 1998). Thus it seems reasonable to conclude that these alterations in gene expression in the long-lived strain are the result of a transcription-level change that alters the enzymatic arsenal available to the organisms. But these changes in gene expression have biological meaning only if they reduce the amount of oxidative damage in the long-lived animals.

The higher level of antioxidant gene expression and enzyme activities do in fact bring about a life-long and significant reduction in the levels of the most common oxidative damages in proteins or lipids in the long-lived L strain. There exists an inverse correlation between the levels of antioxidant enzyme activity (Dudas and Arking, 1995) and the levels of oxidative damage (Arking *et al.*, 2000a). It seems reasonable to conclude that these animals developed the ability, as a consequence of artificial selection, to turn on a regulatory process that coordinately activates the antioxidant defense genes early in life, thereby protecting the animals against the oxidative damage to vital molecules and thus delaying the onset of senescence until their antioxidant defenses fall to normal levels. Reverse-selecting these long-lived strains for shortened longevity (Arking *et al.*, 2000a,b) reverts their antioxidant gene expression patterns to control levels. Only the antioxidant genes (and certain other enzymes operationally connected to them) show these

correlated and coordinate changes in gene expression. Other metabolically important enzymes which do not affect the antioxidant proteins do not show any significant changes as a result of selection (Arking *et al.*, 2000a). The reversal in life span was accompanied by a specific reversal in the expression of only the antioxidant genes and genes necessary to their function. Incidentally, an independent replicate strain (Lb) has the same longevity patterns as does the La line but uses different specific patterns of antioxidant gene expression (Arking *et al.*, 2002b). One interpretation of these data is that the overall oxidative stress level of the organism may be more important than which particular antioxidant gene is over-expressed. Another is that different signaling pathways may be involved.

Taken all together, this series of experiments reveals the existence of a causal relationship between antioxidant gene expression, oxidative stress resistance, levels of oxidative damage, and longevity in these selected strains of *Drosophila*.

In a parallel, simultaneous, and independent experiment, Michael Rose (1984) used a different wild-type progenitor stock but the same indirect selection protocols as used for the Wayne State University (WSU) lines to create a set of long-lived strains termed the University of California-Irvine (UCI) long-lived lines. Interestingly enough, the physiological traits associated with the UCI selected lines overlap those associated with the WSU lines, for both sets of strains of strains are significantly more resistant to environmental stresses than their respective controls. The two are resistant to a different spectrum of stressors, which may well be the result of the different genetic backgrounds used in their different progenitor stocks. The UCI lines are resistant to starvation, desiccation, and oxidative stress; and selection for increased starvation or desiccation resistance was later shown to lead to increased longevity (Rose *et al.*, 1992; Harshman *et al.*, 1999). The WSU lines are mildly resistant to desiccation but mostly resistant to oxidative stress (Force *et al.*, 1995). Although several kinds of stress resistance are associated with extended longevity, it may not be a coincidence that the only common stress resistance in all these strains is that of oxidative stress.

Genetic data generally support these selection experiments. Phillips *et al.* (1989) created a CuZnSOD-null mutant of *Drosophila* and showed that the absence of this enzyme activity significantly decreased viability and longevity. Subsequent analysis by the same group (Parkes *et al.*, 1998) showed that the absence of the CuZnSOD gene has a number of important pleiotropic effects such as (1) adult sensitivity to paraquat, (2) male sterility, (3) female semisterility, (4) adult hyperoxia sensitivity, (5) larval radiation sensitivity, (6) developmental sensitivity to glutathione depletion (an important antioxidant molecule), and (7) adult life-span reduction. Before one could confidently interpret these results, it was necessary to determine whether these alterations stemmed

from an increase in the rate of aging or from some abnormal pathology. An experiment was done showing that these CuZnSOD-null mutants showed an acceleration, relative to the wild-type control, of the normal age-related temporal changes in the expression of certain other genes (Rogina *et al.* 2000). Since the acceleration in the temporal expression of these other genes was proportional to the shortened life span, then this was interpreted as showing that the shortened life span of the CuZnSOD-null mutants is due, not to an abnormal pathological process, but to an increase in the rate of aging. This interpretation suggests that the aging rate is directly proportional to the animals' level of antioxidant capacity and resistance to oxidative stress, a finding in keeping with the selection results discussed above.

In contrast to the SOD data, acatalesemic mutants of *Drosophila* are essentially normal when reared under standard conditions as long as they have at least 3% of the normal catalase expression level (Mackay and Bewley, 1989), a finding consistent with the transgene work done on this gene (Orr and Sohal, 1992), which suggests that catalase is not normally a rate-limiting factor in longevity.

Transgenic technology, which allowed the insertion of an extra gene(s) into an otherwise normal organism, was early used to test the effects of increasing the level of CuZnSOD gene expression on the longevity and aging of the altered animals. The early experiments inserted single copies of either CuZnSOD or catalase into the test organisms, but their results were inconclusive for a variety of reasons. However, the tandem over-expression of both CuZnSOD and catalase in the same animal did extend median and maximum longevity by up to 34% in some lines while simultaneously retarding oxidative damage and increasing oxidative resistance (Orr and Sohal, 1994; Sohal *et al.*, 1995). Sun and Tower (1999) used a controllable transgenic system that allowed them to control when CuZnSOD over-expression would take place in adult flies. This system allowed increases in mean life span of up to 48%. These two transgenic alterations of gene expression ostensibly affected all tissues of the organism at all stages. But there is much information showing that most genes have characteristic tissue and stage-specific expression patterns. Thus it was important when Parkes *et al.* (1998, 1999) showed that a GAL4-UAS transgene expression system which selectively targeted CuZnSOD expression to the adult motor neuron was capable both of (a) restoring the normal adult life span of CuZnSOD-null mutants and (b) extending by 40% the adult life span of an otherwise wild-type fly. Over-expression of CuZnSOD in the adult central nervous system, adult muscle or larval body has no effect on adult longevity. It turns out that adult *Drosophila* have a surprising lack of CuZnSOD activity in their central nervous system relative to the rest of the body (Klichko *et al.*, 1999). It may be that the flies' motor neurons may have the lowest age-related failure threshold of the whole body and would normally be the first critical

tissue to fail. Thus using transgenes to increase their resistance to oxidative stress may have the effect of postponing the age at failure of this critical tissue and thus result in lengthening the life span.

Scientific progress does not occur in a straight line. The validity of the three transgene experiments described above have been challenged by two of the researchers involved on the basis that an increased longevity was observed only in those cases where the control flies had a comparatively short life span (Orr and Sohal, 2003). In their rethinking of the matter, shorter lived control lines are helped by CuZnSOD over-expression, but genetically robust controls showed little or no effect. This reassessment casts doubt only on the efficacy of increasing life span by increasing only CuZnSOD expression; it does not affect experiments showing that suites of antioxidant genes are over-expressed in long-lived strains (e.g., Table 25.3) or that different antioxidant genes act together in a cooperative manner in the fly (Missirlis *et al.*, 2001) or experiments involving robust control flies. It is a likely possibility that the reason for the failure of some transgenes to significantly affect the life span of some flies is that an organism with an inefficient metabolism and low levels of available ATP is simply not in a position to effectively reallocate the energy saved due to lowered oxidative damage levels to increased somatic maintenance. In the La strain, the effective use of the increased antioxidative defense enzymes requires the simultaneous alterations of metabolism (e.g., shifting from glycolysis to the pentose shunt) so as to support the enzyme functions, as well as mitochondrial changes that yield an increased efficiency and thus increase the levels of available ATP (Arking *et al.*, 2002). Pathways—both genetic and metabolic—need to be changed if an animal is to live long. Altering the expression of one gene without altering the necessary pathways may bring about only a weak effect.

MnSOD is the mitochondrial version of superoxide dismutase. Given the crucial role of mitochondria in energy metabolism and ROS generation, it seemed logical that this gene product would likely play an important role in modulating the life span. This assumption is borne out by our selection data (Arking *et al.*, 2000a) and by the transgenic data of Sun *et al.* (2000). These researchers used their controllable transgene system to induce the over-expression of MnSOD only in adult flies but not in the developmental stages, thus avoiding complications in the analysis. They reported that MnSOD showed increases in expression of up to 75%. This yielded a 33% increase in mean life span and a 37% increase in maximum life span. The simultaneous over-expression of both CuZnSOD and MnSOD led to a complicated situation wherein each transgene partially inhibited the over-expression of the other, but nonetheless still resulted in the two genes having partially additive effects on life span (Sun *et al.*, 2004). Phillips and his colleagues (2000) have also used transgenes to over-express the MnSOD

## 25. Gene Expression and the Extended Longevity Phenotypes of *Drosophila melanogaster*

gene in wild-type animals and find that they obtain life span extensions of about 30%. They also note that the over-expressed MnSOD gives an incomplete rescue of the CuZnSOD-null mutant, thus establishing that the two enzymes operate in functionally different compartments. Conversely, destroying the MnSOD mRNA and thus silencing this one gene in a normal animal results in a disruption of mitochondrial function, an increased sensitivity to oxidative stress, and a striking ~80% reduction in mean and maximum life span (Kirby *et al.*, 2002). In contrast, Mockett *et al.* (1999) reported that their transgenic MnSOD lines did over-express MnSOD mRNA, protein and enzyme activity but did not show an increased life span relative to the controls. This finding may well have to do with the genetic background of their control strain; if so, it represents a limitation, but not a refutation, of the ability of any one specific antioxidant gene to increase life span for the reasons presented above.

Given the complexity of the stress resistance process, it is inevitable that other genes are involved. Glutathione is perhaps the most abundant low molecular weight antioxidant present in the animal and represents a potential clue to other candidate genes. Mockett *et al.* (1999) over-expressed the glutathione reductase gene in transgenic *Drosophila* and obtained up to 100% over-expression of the enzyme. Longevity was significantly enhanced under hyperoxic conditions but not under normoxic conditions, suggesting that glutathione reductase may not be a rate-limiting factor in antiaging defenses under normal conditions but may well be one when the level of oxidative stress is elevated. This is very similar to the effects of glutathione-S-transferase on nematode longevity (Leiers *et al.*, 2003).

Another set of candidate genes are those which regulate the expression of the antioxidant structural genes. Four different mutant searches have identified such genes. In the first, Lin *et al.* (1998) did P-element mutagenesis of the 3rd chromosome and screened for long life (relative to the *white* control strain) at 29°C. One homozygous mutant, named *methuselah* (*meth*), lived up to 35% longer and was more resistant to paraquat, starvation and high temperature. The *meth* gene appears to code for a transmembrane G protein-coupled receptor presumably involved in the regulation of stress response genes. Other data suggest it may be a negative regulator of these genes. Recent data suggest that the ligand for this *meth* receptor is the stunted (*sun*) protein, but the functional pathways involved are not yet known. The second search also used P-element mutagenesis but focused on the second chromosome and identified two groups of transacting mutants, one of which acted as if they were normally positive regulators of CuZnSOD and catalase in wild-type animals and the other of which acted as if they were normally negative regulators. The third approach showed that up-regulation of the JNK signaling pathway made the animals much more resistant to oxidative stress

while increasing both their mean and maximum life spans (Wang *et al.*, 2003). Finally, the fourth approach used microarrays to conduct a genome-wide search for genes which responded to chronic exposure to oxidative and other stresses (Giradot *et al.*, 2004). The data show the existence of both general and specific responses to these different stressors, and indicate the existence of a complex interlocking network of stress response genes. The point is that four independent experiments have demonstrated that single genes seem to extend longevity by up-regulating the animal's ability to withstand various types of stress, and that these individual genes may well be components of a larger network of stress response genes.

The heat-shock protein (HSP) genes were initially found in *Drosophila*. Much work has demonstrated that these proteins have significant effects on stress resistance and longevity in all organisms. There are two complementary findings: first, the expression of the HSP genes is affected by aging; and second, the up-regulation of some (but not all) of these genes can significantly affect longevity. Aging animals usually express abnormal patterns of HSP expression relative to young animals (Niedzwiecki and Fleming, 1990). Two reports (Wheeler *et al.*, 1995; King and Tower, 2000) show that hsp22 mRNA is up-regulated during aging, particularly in the head. In addition, an earlier onset of hsp22 and hsp23 mRNA accumulation in *Drosophila* flies selected for increased longevity was also reported (Kurapati *et al.*, 2000), suggesting a possible correlation between hsp22 levels and longevity. Using genetic techniques to over-express hsp22 in motorneurons led to a 30% increase in longevity and stress resistance (Morrow *et al.*, 2004a). Conversely, knocking out the hsp22 gene so that flies could not express the HSP22 protein led to a 40% decrease in their longevity, coupled with an increased sensitivity to stress (Morrow *et al.*, 2004b). Finally, a ubiquitous over-expression of hsp22 throughout the entire body also led to a reduction in life span as well as an increased sensitivity to heat and oxidative stress (Bhole *et al.*, 2004). Looking at the data as a whole, we can see that increased longevity and stress resistance depend not just on the over-expression of the hsp22 gene, but on its being expressed in the appropriate tissues at the appropriate time and in a balanced manner relative to the expression of stress resistance genes in other tissues. Failure to achieve this balanced expression harms, rather than helps, the organism. This may come about because an unbalanced expression of one stress response gene may inappropriately down-regulate other stress response genes. This hypothesis assumes that there exists a stress response gene network of some sort, as has been noted in the nematode (Morley and Miramoto, 2004). Empirical evidence to support this assumption is provided by a DNA hybridization screen which identified at least 13 genes which were activated by exposure to heat, oxidants, and starvation (Wang *et al.*, 2004). The involvement of

the HSP in extended longevity is shown by the fact that a beneficial effect of HSPs on aging and stress resistance is observed when organisms are preconditioned by exposure to a mild stress before being exposed to a subsequent damaging stress (hormesis: see LeBourg *et al.*, 2001; Hercus *et al.*, 2003).

Taken all together, the different types of experiments discussed above show that (1) there are a variety of different but interacting stress resistance pathways and (2) almost all tested long-lived animals are also stress-resistant. Both Parsons (2003) and Rattan (2004) have long argued the existence of a tight relationship between stress resistance and longevity. The reciprocal experiments in which one directly up-regulates a known stress response gene, such as *hsp26* or *hsp27*, have been done and results in flies having a significant increase in both stress resistance and longevity (Wang *et al.*, 2004). This experiment shows that at least some stress resistant animals are also long-lived. Taken together, the several sets of experiments verify the fundamentals of Parsons's (2003) argument.

## GENETIC STABILITY

There are two aspects to genetic stability in *Drosophila*. One aspect has to do with the structural integrity of the DNA and the genome. The other has to do with the nonstructural epigenetic modification of the genome. We shall discuss them in sequence.

It was once hypothesized that aging might be the result of genomic instability and/or gene dysregulation, but recent data indicates instead that the genome is actually very stable during the adult period. For example, even though 86% of the genes assayed significantly changed their expression during the entire life cycle (i.e., embryo to young adult; Arbeitman *et al.*, 2002), only 9% of the genes in the *Drosophila* genome showed significant age-dependent changes in their levels of expression during adult aging. Furthermore, plotting the genomic distribution of this small set of changeable genes reveals no obvious clustering of the genes at particular chromosomal regions, such as telomeres or centromeres, once thought to be particularly unstable (Pletcher *et al.*, 2002). In addition, there is also no evidence for a genome-wide gene dysregulation. There is, however, extensive evidence supporting the idea that gene expression during adult aging is a precisely regulated process and probably represents a continuation or alteration of that experienced early in life. Independent studies using enhancer-trap techniques show that the expression of many genes changes in their own stereotypical patterns with age (Helfand and Rogina, 2000). If these aging changes were the result of some stochastic loss of function, then one would not expect such a random process to yield different but predictable signature patterns. A different enhancer-trap study found that the rate of change of expression in some cases was correlated with changes in longevity under various conditions (i.e., temperature), suggesting that the

changes are indicators of physiological function and not of some stochastic loss of genome stability (Seroude *et al.*, 2002). Genes encoding functionally related proteins, such as cell-cycle proteins or metabolic enzymes, tend to be expressed at similar times during the life cycle, again suggesting a functional basis for the observed changes (Arbeitman *et al.*, 2002). Finally, a spatial analysis of individual gene patterns of expression throughout the entire adult body revealed that each gene had its own characteristic signature tissue localization; a finding not compatible with stochastic genomic instability (Seroude *et al.*, 2002). Each of these phenomena can be best understood as reflecting the operation of signal transduction mechanisms over the life course.

Of course, genetic stability is affected by the relative levels of mutation and repair processes. As was documented for the other model organisms, decreased DNA repair activity leads to widespread somatic mutations and a consequent loss of function. For example, Leffelaar and Grigliatti (1984) isolated several temperature-sensitive DNA repair mutants which acted so as to significantly decrease adult longevity relative to controls when raised under restrictive conditions. Another DNA repair protein (Rrp1) was shown, when over-expressed, to be capable of reducing the level of somatic mutations in animals exposed to oxidative stress (Szakmary *et al.*, 1996). The normal functioning of these and other repair genes likely plays an important role in maintaining genetic stability.

Woodruff and Nitikin have reinvestigated the somatic mutation theory of aging using the technique of P-element insertional mutagenesis (Nitikin and Woodruff, 1995; Woodruff and Nitikin, 1995). This technique has the advantage over radiation in that it allows the experimenter to induce defined and controllable numbers of random single mutations. They find convincing evidence that the induction of somatic genetic damage can reduce life span in *Drosophila* but that the effect is dependent on the particular species of fly involved and the type of transposable element used. The literature suggests that even in the heterozygous condition, recessive mutations can reduce life span by ~1–2%, and synergistic interactions between different deleterious mutations have the potential to further increase this effect to a statistically significant level. This possibility was tested by Woodruff and Thompson (2003), and their data indicate that the accumulation of undetected somatic mutations could, under special circumstances, reduce longevity by as much as ~22% over a period of 16 generations in a *Drosophila* system. These data suggest that a direct relationship between increased somatic genetic damage and the age of onset of senescence does actually exist.

Taken all together, the data suggest that the genome is remarkably stable during the aging process, that most of the genes do not show significant alterations in gene expression during this process, and that the observed changes in gene expression represent the dynamic regulation of specific genes in response to the changing

physiological status of the organism. Note that none of the foregoing implies that these regulated gene expression patterns constitute an aging program.

If the genome of an organism is so stable, then how can environmental influences affect its operation? Epigenetic regulation of gene expression occurs when somatic cells use either DNA methylation to modify the genetic material itself, or histone acetylation/methylation to modify those proteins that intimately interact with the genetic material (Jaenisch and Bird, 2003; Czermin and Imhof, 2003). These epigenetic modifications arise in an orderly fashion during development, or stochastically during aging, or as the result of long-term external influences such as diet. This phenomenon was first detected in *Drosophila* in 1930 as the occurrence of variable phenotypes in neighboring somatic cells of an individual fly. Neighboring cells in the same tissue had different patterns of gene expression, suggesting a particular instability of their genomes. A gene later shown to be important in that process, *Su(var)3-9*, is now known to be a histone methyltransferase and has conserved orthologs in yeast and humans (Schotta *et al.*, 2003). The importance of these phenomena for the topic of aging is that the repression of various stress-resistant genes in normal-lived *Drosophila* is brought about in part by the epigenetic effects of histone deacetylation in those nucleosomes about which the chromatin is coiled. The absence of acetyl groups on the histone causes a tight winding of the chromatin about the nucleosome, making it difficult for various transcription factors to gain access to the gene promoters. Acetylation of the histone causes a loosening or partial unwinding of the chromatin about the nucleosome, allowing the genes to be activated by the various factors. It turns out that a drug approved by the FDA for use with various diseases, 4-phenylbutyrate (4PB), inhibits the action of histone deacetylases and thereby induces hyperacetylation of the histones. Kang *et al.* (2002) fed this drug to normal-lived *Drosophila* and found that the optimal concentrations yielded a Type 1 phenotype, increasing the mean and maximum survival in both sexes by ~30 to 52% , depending on the sex and genetic background. The drug had no effect on the fly's fecundity or body weight. Furthermore, the treated flies are resistant to starvation, oxidative stress, and loss of locomotor ability. All of these observations are consistent with a heightened stress resistance. Assays of gene expression showed that a number of stress-resistant genes (including CuZnSOD) were induced by the drug, and that their induction was accompanied by altered levels of histone acetylation. These findings are intriguing for several reasons. First, they show that manipulation of the epigenetic code to specifically affect genetic stability is sufficient to significantly alter gene expression. Second, they demonstrate that pharmaceutical intervention is capable of significantly altering longevity. Third, they show that treatment of middle-aged adults yields significant delays in the onset of senescence.

## REPRODUCTIVE EFFECTS

The antagonistic interaction between the soma and germ line cells first observed in the nematode also is found in the fly. In fact, there is much more information available in *Drosophila* on the several hormones involved and their various inhibitory and stimulatory effects on longevity (Tatar *et al.*, 2002, 2003; Hwangbo *et al.*, 2004).

Cells of the CNS, the par intercerebralis, secrete insulin-like peptides (ILPs), which are directed to certain target cells as well as being released systemically. These insulin-like peptides (particularly dILP2) directly or indirectly stimulate certain neuroendocrine cells such as the corpora allata to produce one of the two key hormones in the insect, juvenile hormone (JH). dILP2 acts so as to activate the ISP and thus inactivate dFOXO and the stress resistance/somatic maintenance pathways. The ISP likely operates in the cells of the CNS as well as in the peripheral tissues. In the fly, the fat body cells in the head play a particularly important role, since these cells appear to regulate dFOXO, and thus control the aging of the organism, when activated (Hwangbo *et al.*, 2004). The ISP operating in the gonad–somatic cell axis can activate or inhibit the synthesis of juvenile hormone (JH). Thus the longevity-extending effects of mutants affecting the ISP presumably arise out of interference with the operation of the ISP portion of the process. Longevity arises from the interaction of control centers in the gonads, central nervous system, and head fat body cells with the various peripheral somatic tissues.

JH is essential for reproduction. It is known to promote vitellogenesis and reproduction in insects, and to inhibit adult diapause (a nonreproductive long-lived somatic state characteristic of, for example, overwintering adults). In the gonad, JH stimulates egg development and also stimulates the synthesis of the active form of the second key insect hormone involved in our story, 20-hydroxy-ecdysone (20HE). This steroid hormone is well known for its effects on development, and the molecular details of its action within the cell have been worked out—particularly the fact that the 20HE must bind with a bipartite receptor protein in the nucleus if it is to specifically activate its target genes (Riddiford *et al.*, 2000; Tatar, 2003). What is particularly interesting in the current context is that the known inhibitory effect of JH on the stress resistance of the adult may well be mediated through 20HE. The relationships of these two hormones are quite complex, and the interested reader should refer to Pu *et al.* (2005) for details.

Simon *et al.* (2003) have shown that animals bearing heterozygous mutations in the ecdysone receptor (EcR) protein, one component of the nuclear receptor protein complex, exhibit increased longevity relative to control animals. This locus is the probable site of a QTL known to be involved in longevity (Curtsinger *et al.*, 1998). The animals have a higher metabolic rate coupled with a lower rate of spontaneous activity. More interestingly, they are also significantly more resistant to oxidative stress, heat,

and starvation than are normal animals. This implies that the increased life span and the increased stress resistance both are the result of a decrease in the effective concentration of the 20HE in the cells. Interestingly enough, female age-specific fecundity was increased in these heterozygous mutants relative to normal animals, suggesting that moderate levels of 20HE are compatible with both an extended longevity and an enhanced fecundity. A comparable increase (~42%) in life span was obtained in a separate experiment by use of a temperature-sensitive mutant (*DTS-3*) that affects ecdysone synthesis in females. Because this gene product is inactivated at high temperatures, then one can effectively turn it on or off simply by transferring the fly from a permissive temperature (20°C) to a restrictive temperature (29°C). Doing such shifts at different times indicates that the greatest effect of the decreased hormone levels on longevity takes place within the first two or three weeks of adult life. Finally, feeding 20HE to these mutant female flies abolished that extended longevity in a dose-sensitive manner and also reversed their resistance to the stress of starvation. As little as  $10^{-3}$  M 20HE added to the food allowed the females to have a normal life span.

Absence of ecdysone is lethal. But these three experiments taken together clearly show that high levels of 20HE have a negative effect on longevity and on stress resistance. Thus the JH stimulation of the gonads to synthesize and secrete the high levels of 20HE leads to a shorter (i.e., normal) life span. This decreased life span may well arise from the concomitant repression of stress resistance observed in these experiments. Using mutants to reduce the level of 20HE to a moderate (~50%) level brings about an extended longevity and an enhanced fecundity, as do experiments in which the effective level of the receptor protein is manipulated. Note that the Type 1 phenotype obtained with either manipulation yields a ~45% increase in mean life span in both sexes and is about equal to the increase in life span obtained with selection, caloric restriction, or ISP mutants.

There is another aspect to the topic of reproductive effects on longevity. Reproduction requires the female fly to expend a considerable amount of energy. Individuals in which the energy demands of the reproductive system are not synchronized with the energy production ability of the somatic cells are likely to die when the demands exceed the supply. A formal analysis of the interplay between the age-related energy demand and supply led to a hypothesis about a mechanism which predicts two critical periods in the life history of an individual fly (Novoseltsev *et al.*, 2003). The first crisis occurs at early ages when the increased energy demand becomes greater than the available energy supply. This would often result in a “premature” or nonsenescent death and would presumably involve females in which their intrinsic rate of egg production is greater than can be supported by their intrinsic mitochondrial energy production. In other words, the weaker flies would preferentially die at this

first stressful period in their lives. The stronger and surviving flies lay eggs at some more or less constant rate while their available energy supply is gradually decreased by various senescent processes. Eventually, they do not produce enough energy to simultaneously maintain their reproductive activities and to resist the various environmental stresses associated with living. The initially strong flies preferentially die late in life from a senescent-caused death precipitated by their inability to meet the cumulative energy demands placed upon them.

The reader will observe that these two mechanisms of reproductive effects on longevity—the hormonal mechanisms and the energy demands—are not contradictory but are really the same process as described on the one hand from the cell and tissue level of the geneticist, and on the other hand from the organismic level of life history theory.

## Patterns of Senescence

Do all tissues of the fly age together and at the same rate? Our early work suggested that both normal- and long-lived animals undergo the same sort of senescent process, losing different traits in the same sequence and at the same stage (Arking and Wells, 1992). Since the animals do not lose all functions at the same time, it also implies that different tissues age at different rates. Is there any data to support this implication? The fact that there is a defined spatio-temporal pattern of gene expression during the aging process (Seyroude *et al.*, 2002), coupled with the fact that at least 9% of the genes are known to undergo transcriptional changes during aging (Pletcher *et al.*, 2002), suggests that it is unlikely that all tissues of the fly age together and at the same rate. Some data to support this supposition were presented by Cook-Wiens and Grotewiel (2002). They showed that different behaviors of the fly, utilizing different sensory systems, age at different rates. For example, locomotor and olfactory performance decreases with age even while the aging animal maintains its ability to respond to electric shock and light. Different sensory-motor behaviors decline at different rates within the same animal. What is most interesting is the fact that these olfactory and locomotor declines occurred at the same rate and at the same times in normal-lived control animals as they did in long-lived stress-resistant (*mth*) mutants. Thus genetic manipulations that enhance resistance to oxidative stress and extend life span do not necessarily protect against functional senescence in all pathways. We not only age in an individual manner, but each individual ages in a heterogeneous manner.

## How Do Different Pathways Yield a Common Type I Phenotype?

Figure 25.3 summarizes the known activation and/or inhibition signals generated by each of the several

longevity-extending mechanisms known to be operative in flies, which we have discussed above. The schematic is somewhat speculative in detail, but its tying together of the several known methods of inducing stress resistance with the expression of extended longevity as described in the foregoing text is most likely correct in concept. The important point to note is that all the interventions listed are known to induce the Type 1 longevity phenotype (i.e., delayed onset of senescence) (see Figure 25.1A). The ISS pathway, certainly, and the JNK pathway, probably, are involved in producing this phenotype. The details of the CR pathway are still being worked out. Even given our incomplete knowledge, it seems as if all inducers of the Type 1 phenotype work by effecting some common regulatory nexus, probably the dFOXO3 transcription factor that is known to activate or repress various stress resistance genes.

The interesting thing about the Type 1 phenotype is that delaying the onset of senescence means that the inflection point characteristic of such survival and mortality curves is shifted to some later time (see Figures 25.1A, 25.2A). What happens at that inflection point, regardless of its chronological value, that shifts the population from a state of health into a state of senescence? Senescence is the stochastic and nonprogrammed loss of function which becomes obvious as the reproductive period ends. This is a time-independent process, occurring at about two years in a mouse but at about fifty-five years in a human. What triggers its onset? In the fly, it has been shown that the repression of the ISP results in the activation of the dFOXO gene, and in the activation or repression of a whole suite of downstream genes under its singular or joint control (Murphy *et al.*, 2003). These downstream genes include a variety of stress resistance genes, including a number of molecular chaperones (hsp genes). Mutational inactivation of these downstream hsp genes reverses the extended longevity brought about by ISP repression. This leads to the emerging view that the beneficial effects of the ISP are mediated in part via these downstream hsps, which protect the cells in various ways against the accumulation of unrepaired damage to the cell's proteome (Marsh and Thompson, 2004) as well as the deleterious effects of ROS on the mitochondria and other cell structures. Up-regulation of the ISP, possibly via the increased production of the ILPs or growth factors such as IGF-1 under the control of the fly's glucoregulatory system, represses the expression of these downstream hsps and presumably of various antioxidant defense genes as well. This results in the down-regulation of damage control systems, the accumulation of unrepaired damage, and the gradual onset of senescence as various critical thresholds within the cell are exceeded. The individual nature of aging may be explained by individual and environmental variations in gene product levels, damage rates, repair levels, and so forth; all of which may be the outcome of various gene epistatic effects. A more extensive

description of this model may be found in Chapter 9 of Arking (2005a).

# Annual Fish as a Genetic Model for Aging

Pudur Jagadeeswaran

*Nothobranchius* fish have a lifespan of approximately one year whereas zebrafish live up to 4–5 years. This finding suggested that if classical genetic approaches could be adapted to *Nothobranchius*, these annual fish would become an ideal vertebrate genetic model for studying longevity genes. In this chapter, we provide arguments and approaches for utilizing *Nothobranchius* to study the genetics of aging. Because *Nothobranchius* has a relatively short lifespan, has multiple strains, is a diploid organism, has high fecundity and most importantly is able to lay eggs until the end of their lives, this fish is an excellent animal model for studying genetics of vertebrate longevity. Various approaches to isolate long-lived mutants are described along with their utility for discovering antiaging drugs.

## Introduction

Aging is a universal process conserved in evolution, which cripples the organism at the end stages of life, ultimately resulting in death (Hamet and Tremblay, 2003). Since the dawn of time, man wanted to be eternal and always wished to conquer aging and death. While ecologically conquering aging may not be compatible for normal evolution, improving the quality of life and extending the lifespan remain the major goals of aging research. For example, in classical studies on dietary restriction, it has been shown that a caloric restriction extends the lifespan (Masoro, 2005). In addition, reduction of oxidative stress by antioxidants has been shown to extend the lifespan in several organisms (Droge, 2003). Since all biological pathways are controlled by genes and their products, one would anticipate that there will be genes whose function, if they are modulated, may result in the extension of lifespan, including those involved in the processes mentioned above such as dietary restriction and oxidative stress (Johnson and Wood, 1982). In fact, recently such information on genes conferring longevity has been gathered using different model organisms and using both classical genetic methods as well as surrogate genetic approaches (Kenyon, 2005). In model organisms such as *Drosophila* and *C. elegans*, long-lived mutants

have been selected by genetic approaches (Helfand and Rogina, 2003; Luo, 2004). In mice, the extension of the lifespan has been noted by modulating the gene dosage, utilizing transgenic methods and by using knockout methods (Liang *et al.*, 2003). In these two approaches, the identification of mutant phenotypes by classical genetic methods is a powerful genetic approach that allows the identification of genes in an “unbiased” manner in a given pathway, as opposed to the gene-by-gene approach employed by knockout studies as well as by transgenic methods. Furthermore, even if one has to overexpress genes or knock out the genes to identify the players involved in aging, large-scale mutagenesis methods by retroviral insertion and expression methods would be suitable in a global search for genes conferring longevity. At present, neither classical genetic approaches nor large-scale insertion mutagenesis methods and overexpression studies have been applied to study aging in vertebrates, largely because of the difficulties of applying these approaches in the classical vertebrate model organism, the mouse.

Recently, fish have become genetic models for studying vertebrate development and disease (Kimmel, 1989; Patton and Zon, 2001). We and others have conceived the utility of fish as a model organism for studying genetics of aging (Gerhard *et al.*, 2002; Herrera and Jagadeeswaran, 2002). In this chapter, arguments are put forth that fish are excellent genetic models for studying aging, and opinions are provided for why annual fish are better models for studying the genetics of aging as compared to other species of fish (Herrera and Jagadeeswaran, 2004). Furthermore, the applications of annual fish to study aging and the detailed approaches and their advantages are described.

## Aging Genetic Models

The gene mutations extending the lifespan are more important in understanding molecular basis for aging than the mutations in genes resulting in shorter lifespans. This is because studies on shorter lifespans are debatable due to the fact that the observed effect could be due to pathological consequences of the mutations rather than

a result of true aging. Over the past decade, information on the longevity genes has accumulated and now we have an impressive list of longevity genes provided by SAGE KE from yeast through mice. In *C. elegans*, *daf* and *age-1* genes control the dauer state, an alternative larval state where these larvae are able to thrive despite the fact that food is scarcely available (Dorman *et al.*, 1995; Kimura *et al.*, 1997; Van Voorhies and Ward, 1999). These larvae could live up to two months in contrast to well-fed worms which live for about three weeks. Daf-2 is homologous to the insulin receptor. In this organism, an insulin-like hormone initiates a signaling cascade via *daf-2* which ultimately activates AKT kinases to phosphorylate the forkhead transcription factor Daf-16 so that it is retained in the cytoplasm to favor the reproductive growth of the organism (Paradis and Ruvkun, 1998). When *daf-2* is mutated, the forkhead transcription factor translocates to the nucleus and induces a group of stress resistance genes required for the dauer state, including super oxide dismutase gene. However, such a pathway may not be significant for vertebrates, because a mutation in an insulin receptor would develop insulin resistance and even diabetes—not a longer lifespan.

One of the best studies with known experimental evidence for extending life is dietary restriction, which extends life in every organism tested (Hursting *et al.*, 2003). Studies to understand the basis of dietary restriction resulted in identification of altered expression of several genes using microarray analysis (Weindruch *et al.*, 2001). However, deciphering the details of the molecular basis for extending the lifespan through restricting the diet is difficult and requires other approaches such as the use of genetics. Recently, Guarente and his colleagues have identified the *sir-2* locus coding for NAD-dependent histone acetylase, which silences large regions of DNA and slows down aging in yeast (Guarente and Picard, 2005). Interestingly, caloric restriction, which produces more NAD, also slows down aging in other organisms, including humans. When an extra copy of the *sir-2* homologue is placed in *C. elegans* and a similar homologue was placed in yeast, these organisms lived substantially longer (Tissenbaum and Guarente, 2001). Presently, this pathway seems to be common to organisms tested and also fits with dietary restriction, but it still remains to be tested in higher organisms.

In *Drosophila*, mutations like *methuselah*, and over-expression of Cu/Zn super oxide dismutase, can extend the maximum lifespan (Lin *et al.*, 1998; Parkes *et al.*, 1998). In mice, SHC gene product has been shown to respond to reactive oxygen species, and a mutation in this gene has been shown to increase the lifespan (Migliaccio *et al.*, 1999). Several such examples support the theory of oxidative damage and appear to display a common theme, although exceptions exist.

Comparison of gene expression between phylogenetically related organisms with different lifespans may reveal the critical differences between these organisms. Although

this approach may produce the comprehensive differences between two organisms, it is difficult to pinpoint the genes which are responsible for lifespan differences since there may be tremendous variations in gene expression. Furthermore, a given pathway in an organism is more or less efficient depending upon the threshold levels of the factors involved in that pathway. The threshold levels of the factors may be different for different organisms, even though they are normal to the organism. Sifting for the true gene expression related to the lifespan differences over the background of normal threshold value differences will be difficult. Centenarian studies using SNPs to detect the longevity genes have yielded certain markers; however, this may not yield other possible genes affecting the lifespan (Perls *et al.*, 2002). The above impressive list of genes and multiple theories imply that there are several mechanisms that may operate to prolong the lifespan. However, given the multifactorial nature of aging, the current list of genes may not be complete. Since vertebrate genes are more numerous, more novel genes that are not conserved in the lower model organisms that are specific to vertebrates may be identified. Therefore, a vertebrate genetic model that is amenable for large-scale genetic screens for aging is needed.

## Fish as Vertebrate Models of Aging

Earlier studies have suggested that fish age in a way that is similar to other vertebrates (Woodhead, 1998). Several factors that are thought to be important in the aging process have been studied in fish. For example, oxidative stress as a causative agent of senescence and the protective role of antioxidant enzymes were tested in the teleostei, taking peroxidase as the representative enzyme (Nayak *et al.*, 1999). O6-Methylguanine-DNA methyltransferase, an enzyme considered to play an important role in the repair of DNA lesions induced by alkylating carcinogens, showed a significant decrease in its activity in the liver with advancing age (Aoki *et al.*, 1993). Antagonistic pleiotropy between attractiveness and survival, or linkage disequilibrium between attractive and deleterious alleles, has been observed in fish (Brooks, 2000). Dietary restriction and lower environmental temperature retard the aging processes in a few fish species, showing gradual senescence (Patnaik *et al.*, 1994). Furthermore, given the large number of fish species (approximately 25,000), there is a larger selection from which to study the aging process. These observations strongly suggest that fish in general are a good model for studying aging. However, fish genetics has not yet been expanded as a model for aging.

## Consideration of Zebrafish as Models for Aging

Since its introduction by Streisinger, the zebrafish has become a popular genetic model for studying

## 26. Annual Fish as a Genetic Model for Aging

development and disease because of its many advantages (Jagadeeswaran *et al.*, 2005; Streisinger *et al.*, 1981). One advantage is that zebrafish embryos are transparent, so a developing embryo and its morphology could be easily observed. Breeding zebrafish under laboratory conditions is extremely easy; the embryos grow for 72 hours until they hatch. Other advantages include high fecundity (the female fish can lay up to 200 eggs), short generation times, ease of *in vitro* fertilization, and amenability for large-scale mutagenesis. In addition, features such as transparency of embryos and generation of diploids from haploid eggs make the model even more attractive for identifying recessive mutations. Described below are the principles of genetics in zebrafish and how mutants are isolated and mapped to identify the genes that are affected. Mutagenesis is performed by dipping zebrafish males in ethylnitrosourea (ENU) to cause multiple, random point mutations throughout the genome of the germ cells (spermatogonia). Mating of an ENU-treated male with a wild-type female zebrafish will yield the F1 progeny that will carry as many as 1000 random mutations. Thus, saturating the genome with mutations is possible because theoretically, in 100 fish,  $10^5$  mutations can be generated. The fish from the F1 generation is then bred to a wild-type fish to generate the heterozygous F2 progeny. Homozygous fish are generated by performing brother–sister matings of the F2 generation. A screen on this F3 progeny for mutant phenotypes constitutes a classical three-generation screen. More than 1000 developmental mutants have been isolated using this strategy. Recently, several imaginative screens have been performed to isolate mutants related to thrombosis, lipid absorption, bone defects, and so forth. Adult screens are more difficult when compared to embryonic and larval screens, because rearing the F3 generation fish to adulthood requires more time and space. In identifying embryonic mutant phenotypes, many laboratories have also used two-generation screens as an alternative method. In this method, haploid or homozygous mutant progeny can be generated directly from the F1 females. Haploid embryos are generated by the *in vitro* fertilization of eggs obtained from a heterozygous F1 female with male sperm whose DNA was destroyed by treatment with ultraviolet light. Although these sperm do not contribute DNA, they can still initiate fertilization and allow the development of haploid embryos, which are viable for up to 3 days postfertilization. If these eggs are subjected to early high-pressure treatment (EP) immediately after fertilization, these haploids will become diploid embryos, which are fully viable. In the EP treatment, hydrostatic pressure causes disruption of spindle formation, which is required for the separation of sister chromatids and polar body extrusion following fertilization. The resulting gynogenetic diploid larvae possess only maternally derived genes that are homozygous for most loci (heterozygosity may arise from recombination events in meiosis I). Thus, this EP treatment allows for a two-generation mutagenesis

screen that will identify mutant-carrier females one generation ahead of classical approaches. Once a mutant of interest is identified, the mutant loci can be identified by a positional cloning strategy as described below.

An F1 female mutant carrier is crossed with a male zebrafish that is polymorphic for many loci when compared with the strain used to generate mutations. From this progeny, homozygous mutants are generated by brother–sister mating. To map the mutant locus, two pools of genomic DNA are created from normal and mutant zebrafish (20 zebrafish per genomic DNA preparation) in the above progeny of brother–sister mating. Multiple sets of primers are then used to amplify known microsatellite markers that span the zebrafish genome at an average resolution of 10 cM. Due to the fact that recombination will shuffle both genes and markers in meiosis, markers not linked to the mutant loci, or distal to the loci, will be present in both normal and mutant pools, while linked markers will be present in only one of the two pools. Once a marker is identified showing linkage to a mutant gene, further analysis using additional flanking markers and a larger number of genomes will establish close linkage. Bacterial artificial chromosomes that contain the linked markers could then be sequenced to identify the mutant gene. However, with the availability of genome information, the painstaking efforts of positional cloning will be replaced by the candidate gene approach once a closer linkage is identified. By rescuing the mutant through introducing the functional cDNA or by inhibiting the gene function by antisense approaches, the mutant gene could be confirmed.

In addition to the above approach, there has recently been a major success in the retroviral insertion mutagenesis approach, which identified several hundred genes involved in development (Amsterdam *et al.*, 2004). It has been shown that mouse retroviral vectors pseudotyped with a VSV-G envelope infect the fish germ line after injecting the virus into blastula-stage embryos at the 1000–2000-cell stage. Retroviruses are attractive candidates for insertional mutagenesis, because they had been shown to integrate into many different sites in mammalian and avian chromosomes. Importantly, they integrate without rearrangement of their own sequences or significant alterations to host DNA sequences at the site of insertion—essential features for easily cloning genes disrupted by insertions. Once the infectious retrovirus is injected into the zebrafish embryos and the founder lines are generated, they are mated pairwise and the resulting F1 fish are tested for multiple insertions of the retroviral genome. Those with multiple insertions are then pair-mated and F2 families are raised. Again mating six pairs of siblings will generate homozygous insertional mutants, and one could score for the phenotypes similar to the screening done in ENU mutagenesis. However, the relatively low efficiency of insertional mutagenesis in contrast to the ENU mutagenesis limits the utility of this method for small laboratories. Also, this method will

result in the inactivation of the gene rather than producing hyperactive and hypoactive alleles that are possible by the ENU mutagenesis.

Because of the above advantages of the zebrafish model, we tested its utility as a genetic model for studying aging by initially establishing the zebrafish lifespan (Gerhard *et al.*, 2002; Herrera and Jagadeeswaran, 2002; Herrera and Jagadeeswaran, 2004). Another group independently performed such studies (Gerhard *et al.*, 2002). Both of these studies revealed that zebrafish have a lifespan of approximately 4 years. Furthermore, Kishi and his colleagues have identified several potential aging biomarkers such as senescent associated  $\beta$ -galactosidase activity in skin and oxidized protein accumulation in muscle (Kishi, 2004). In contrast, markers such as accumulation of lipofuscin granules (which accumulate in muscle cells with advancing age) were not found. Another study revealed the decline of muscle function with advancing age by studying the bone curvature (Gerhard *et al.*, 2002). Even though some differences exist in the expression of biomarkers when compared to mammals, zebrafish nevertheless showed gradual senescence as observed in other fish species. In spite of this information on biomarkers, classical genetic studies will take long periods of study since zebrafish have long lifespans. Therefore, we suggested that zebrafish do not qualify as an ideal model because of their long lifespan. However, Gerhard and Cheng have recently argued that studying more than one fish may be useful for comparative aging (Gerhard *et al.*, 2004). While it is a good argument, the utility of such comparative studies in identifying longevity genes is questionable.

## Genetics of Aging

Unlike performing genetic studies for development and disease, aging genetics is more complicated because of certain features that are unique to this phenotype. For example, the organism becomes old in the process of selecting for longevity and, thus, even if we find a long-lived organism, its reproductive ability would have declined, making it difficult to recover the organism. Thus, the parental population must be continuously bred until we are able to identify the progeny that has a long span. This could also be achieved by preserving parental sperm. In some organisms like *C. elegans*, they can be maintained in a cryogenically frozen state, facilitating the easy maintenance of large numbers of strains (Johnson, 2003). Thus, it is possible to identify the progeny of those that have long-lived survivors and recover them from a frozen state. While such advantages exist in lower organisms, the logistics of large-scale screens in vertebrates, like mice, to recover the organism from frozen sperm samples is not particularly practical. A similar situation exists in zebrafish as well because even if we preserve sperm, by the time we identify the long-lived survivors and then recover the mutation, it becomes

an arduous task. Thus, a vertebrate model organism that circumvents these problems is needed.

## Annual Fish as Models for Aging

We believe that *Nothobranchius rachovvi*, a killifish, is a better vertebrate model for longevity genetics because their maximum lifespan is about ten months (Herrera and Jagadeeswaran, 2004). *Nothobranchius rachovvi* are teleostei like zebrafish and have already been used in aging studies. They have been shown to begin senescent changes at approximately four months of age. They are relatively easy to breed and are approximately 2 inches in size. The females lay approximately 20 eggs per day. *Nothobranchius rachovvi* can breed even at an old age until the very end of their lives. This occurs because the natural habitat of these fish dries out seasonally. In order to preserve their species, these annual fish developed schemes to lay eggs up to the time of death. In the laboratory, eggs are collected in peat moss and then stored in a dry container for four months. The eggs hatch when placed in water, and they grow at 28–30°C. The larvae mature by the age of 3–4 weeks when males develop colors and are easy to distinguish from females. Since they belong to the cyprinodontiformes form of fish, the information on the zebrafish and fugu fish gene sequences should be useful in obtaining polymorphic EST markers for *Nothobranchius*. There are about 40 species of *Nothobranchius*, and most *Nothobranchius* species have a diploid number of chromosomes ranging from  $2N = 16$  to 28. Recently, another group claimed that *Nothobranchius furzeri* has the shortest lifespan of 2 months under circulating water conditions, which is similar to what we observed for *Nothobranchius rachovvi* under these same conditions. We do not know the normal lifespan of *Nothobranchius furzeri* under stagnant water conditions. Furthermore, different strains of *Nothobranchius rachovvi* are available, whereas for *furzeri* we do not know whether multiple strains are available. A prerequisite for genetic mapping is the availability of strains. Thus, *Nothobranchius rachovvi* is an ideal vertebrate organism that has a short lifespan if we could adapt the mutagenesis methods that are well established in zebrafish and medaka. These protocols for mutagenesis are standard and should be easily adaptable for the annual fish. In addition, several genetic markers for *Nothobranchius* have already been isolated.

From our published work, *Nothobranchius* would be a good vertebrate model for studying the genetics of longevity due to its shorter lifespan. However, the survivorship curves as presented appear to be less rectangular than the one we obtained for zebrafish (Austad, 2004). Furthermore, in the work of Walford on *Cynolebias*, the curves are rectangular (Liu and Walford, 1969). The difference between their work and our work is the difference in temperature at which the fish were maintained. Thus, optimization of survivorship curves is

required using different temperatures. In addition, another possible cause for a nonrectangular curve is the existence of pathogens. We believe the alternation of one or two degrees in temperature maintenance of *Nothobranchius* as well as a clean water system will make a significant impact on the survivorship curves. Before using this fish, conditions for optimal growth and maintenance should be established. Since these fish have been used in commercial sales and the conditions for growth and maintenance are available from vendors, they should be helpful. For example, water quality, temperature, presence of good amounts of denitrifying bacteria, elimination of bacterial contamination, and appropriate monitoring of pH and ammonia are some of the conditions which might provide us with the desired rectangular shape of the survivorship curves. Since bubbles generated in the water circulation system may be causing the early deaths, the efficiency could be improved by using tanks that are connected at the bottom, whose water is recirculated slowly.

It is well established that heterosis or hybrid vigor exists in organisms. Thus, the effects of heterosis on longevity using progeny derived from the crossing of two strains should be determined. Studies on several parameters such as the body weight, growth, their physical activity measurable by analyzing images of locomotion captured by a video monitor system, the gill movements per minute, and lateral line responses observable by movements in response to a pendulum should help in determining any differences among the strains and their progeny. Additional important information on differences between survivorship curves among the parental strains and their hybrid progeny is also needed. A compilation of these curves will assist us in forming an appropriate baseline for the survivorship curves. Any noticeable increase in longevity among these hybrids would help determine an accurate time point for the selection of longevity mutants. In *Nothobranchius*, embryos must be kept dormant for four to twelve months before they can be hatched. The effect of dormancy over the lifespan needs to be investigated by keeping the eggs under dry conditions for different periods of time. We still do not know whether there is a decline in reproductive activity with age, so measurement of the egg-laying activity of *Nothobranchius* as a function of age is important. Due to the fact that fish embryos can be diploidized from haploid eggs, we can increase the speed of generating homozygous mutant fish (one generation is needed rather than two) for recessive mutations. The principle of generating the gynogenetic diploids is described above. This should be easily adaptable for this annual fish. The haploid eggs of females of the F1 progeny are fertilized *in vitro* with UV irradiated sperm and subjected to high pressure to rapidly generate diploid F2 progeny. The embryos can then be kept under dry conditions as described above. The lifespan of the F2 progeny can be analyzed for their similarities to normal survivorship curves.

This information would provide us with two facts: first, the diploidization is feasible; and second, the gynogenetic diploids behave as wild-type normal fish as far as their survivorship curves are concerned. Important information that is also needed is the histology to look for any observable pathology. Since zebrafish histology and other fish histology and pathology are available, again it should be relatively easy to extend this information for the annual fish.

## Mutagenesis of Annual Fish

### CHEMICAL MUTAGENESIS

The ENU mutagenesis has been applied to many organisms and should be applicable to *Nothobranchius*. However, this requires the demonstration of efficiency of ENU mutagenesis in this species. Such results would form the basis for pursuing large-scale saturation mutagenesis in *Nothobranchius* to identify mutant fish with extended lifespan. To identify longevity mutants of *Nothobranchius*, the male *Nothobranchius* should be mutagenized with ENU and mated with normal females generating progeny with many heterozygous mutations representing either a gain of function or a loss of function. The specific mutation rate could be estimated by using phenotypic pigmentation patterns. To estimate a specific locus mutation rate, mutagenized males from a blue strain are mated with a red strain partner. The number of fish expressing these traits when they are homozygous in the progeny will predict the efficiency of ENU mutagenesis and the mutation rate. In ENU mutagenesis of zebrafish, the specific locus mutation frequency is as high as  $0.9\text{--}1.3 \times 10^{-3}$  (Solnica-Krezel *et al.*, 1994). With the mutation rate of  $1.27 \times 10^{-3}$  if the distribution of mutations in the genome could be approximated by Poisson distribution, about 87% of the genes would be detected with an average of two mutations per locus, and for this approximately 1600 genomes must be screened to obtain one mutation for a given locus. Given the established methods in zebrafish, one would expect that high mutation rates will be achieved in *Nothobranchius*. The following scheme as a screen for selection of long-lived mutant fish is proposed: first, females from ENU mutagenized F1 progeny are used that generate gynogenetic diploids from each of these females. From this progeny, males and females are separated and kept in large tanks. This will prevent further breeding, although the density of the fish should be taken into consideration. Since the longest survivor in *Nothobranchius* is about 10 months, fish are selected for 12 months as lifespan. This gives approximately 20% longer life. The long-lived F2 diploid survivors are used to generate F3 homozygous. The survivorship curves of wild-type progeny of the two strains are compared to the survivorship curves of the above homozygous mutant progeny. The shift of the mutant progeny lifespan curve to the right compared

to controls will confirm the longevity mutant. This homozygous progeny is then bred to a different strain of *Nothobranchius*, which would be polymorphic for many loci for mapping the mutant locus. Once the long-lived mutants are isolated for identification of the gene responsible for the phenotype, it should be possible to map the longevity mutant locus by using linkage methods. Since large chunks of DNA are syntenic in the *Nothobranchius* genome when compared to the zebrafish genome, the maps and the synteny of genes in zebrafish as well as those from mammals should be useful to predict candidate genes once a marker linked to the longevity phenotype is identified. For this, approximately 250 markers that are spaced approximately 10 cM and spanning the entire genome are needed for mapping longevity mutants. Since a large number of zebrafish EST sequences and a significant amount of genomic sequence from fugu fish as well as zebrafish are already available, it should be possible to choose a number of conserved EST marker primers in order to identify polymorphism that span the entire *Nothobranchius* genome. Based upon the existing linkage maps of zebrafish, the marker (EST) primers located approximately 10 cM can be selected. It should then be possible to amplify the total RNA using the above primers to find polymorphisms between two strains of *Nothobranchius* by SSCP or by DNA sequencing.

#### INSERTIONAL MUTAGENESIS

The insertional inactivation of genes by retroviral mutagenesis has been successfully employed in zebrafish as described above. How will this be useful in longevity selection? The underlying rationale for insertional mutagenesis in aging studies is that the inactivation of genes that have negative influence on the lifespan might increase the lifespan. Since it is easy to detect dominant genes, first dominant screens should be conducted by simply injecting the retroviruses into the *Nothobranchius* embryos and then the fish should be selected that are long lived and should be used further to identify the genes that are affected. This concept could also be extended further for recessive screens either by diploidization or by three-generation screens to identify the long-lived *Nothobranchius*. The methods that are used in zebrafish for insertional mutagenesis should be applicable for the annual fish.

#### Transgenesis and Overexpression of Genes in Annual Fish

Transgenic technology has been recently introduced in zebrafish, and many promoters have been expressed in a tissue-specific manner. Conditional misexpression of genes in certain tissue has been achieved by using GAL4-UAS system (Scheer and Camnos-Ortega, 1999). In this system two different kinds of transgenic strains, called activator and effector lines, are developed. In the

activator line, the GAL4 (yeast transcriptional activator) gene is placed under the control of a tissue/cell specific promoter, while in the effector line the gene of interest is fused UAS (Upstream Activating Sequences, the DNA-binding motif of GAL4). Once the effector line is crossed to the activator line, the effector gene is expressed in a specific tissue because the GAL4 is supplied by the tissue specific promoter and will bind to the UAS and drive the effector gene transcription. Recently, the utility of the Cre/lox system has been demonstrated in the zebrafish model by developing a conditional myc-induced T cell acute lymphoblastic leukemia (Langenau *et al.*, 2005). Thus, in addition to GAL4-UAS system, this technology is available for fish. Depending upon the strength of the promoter and taking into account the positional effects, the gene expression could be modulated and the effects on longevity could be studied. Thus, it is conceivable that one could express genes that affect metabolism or oxidative stress pathways or insulin receptor mediated pathways to overexpress these genes. The information gained from studying invertebrate genes could also be used to verify whether mechanisms that are operative in invertebrates are conserved in vertebrates. However, this is a biased approach and would require prior knowledge of the genes that may be involved in lifespan extension. Furthermore, due to the fact that such studies could be performed in mice, one may question the utility of the fish model in such studies. However, since the *Nothobranchius* is amenable for large-scale unbiased overexpression of genes by using the above vectors that could specifically express genes in certain tissues, with the knowledge of information gained from large scale microarrays depicting the tissue-specific genes, one could construct libraries of such genes and generate transgenic lines on a large scale to verify which ones will have prolonged lifespan. These approaches require further testing.

#### Dietary Restriction and Oxidative Stress in Annual Fish Mutants

Once the mutagenesis is achieved, dietary resistant mutants and oxidative stress resistant mutants could be selected which might suggest genes involved in such a mechanism. For example a paraquat resistance mutant could be selected and then tested for lifespan extension. Similarly, mutants could be fed with a high fat and high nutrient diet which, in contrast to dietary restriction, should shorten the lifespan and the mutants that live under these conditions could be selected. However, these require careful feeding experiments. Likewise, by feeding  $\omega$ -3 fatty acids, the mutants that do not prolong the lifespan in the presence of  $\omega$ -3 fatty acids could be selected. All these imaginative screens will be feasible once the *Nothobranchius* model is available as a genetic model.

## Annual Fish as a Tool for Screening for Antiaging Drugs

In 1999, we suggested that zebrafish could be used as a model for drug discovery (Jagadeeswaran *et al.*, 1999). Due to the availability of a large number of chemical compounds and the ease of screening the larvae, a number of mutants are being investigated to reverse the phenotype with these chemicals. Such reversal of phenotypes has been applied to aortic coarctation (Peterson *et al.*, 2004). This phenotypic reversal is feasible because the larvae are small and it is possible to accommodate screening in a 96-well format in tiny volumes such that only small amounts of chemical are used. However, in longevity studies such screening depends on the availability of compounds on a large scale and continuous replacement of the chemicals to accommodate for their half-lives. Interestingly, there are several naturally occurring compounds that are either antioxidants or participate in metabolic pathways that affect aging. Thus, in the future, it is anticipated that large-scale screens could be undertaken using *Nothobranchius* as a model to discover more new natural products that may have an effect on the extension of lifespans. For example, individual leaf extracts could be placed in tanks of *Nothobranchius* fish to see which of these extracts would prolong the lifespan. Once the extract is identified, the active compounds could be characterized and be synthesized by pharmaceutical companies. Thus, *Nothobranchius* could be useful in rapidly discovering drugs that will extend vertebrate lifespan.

## Conclusions

The above suggestion that *Nothobranchius* would be a useful model for studying longevity genes is novel, and it is the first time that the genetic approach utilizing the annual fish is suggested, although Walford first noted the utility of annual fish in aging research (Liu and Walford, 1969). Such a utility will depend upon establishing conditions for chemical mutagenesis, isolating markers for linkage analysis, and identifying long-lived *Nothobranchius* mutants. Since these are straightforward, this is a feasible goal. This model will also be used in overexpression of genes by transgenesis and identification of antiaging drugs. Future identification of longevity genes may ultimately allow the identification of human homologues involved in aging. Only time will tell whether this beautiful aquarium fish will be useful in furthering the knowledge on aging. May the genome sequencers embrace this annual fish for eventually sequencing its genome!

# The Use of Mature Zebrafish (*Danio rerio*) as a Model for Human Aging and Disease

Evan T. Keller, Jill M. Keller, and Gavin Gillespie

*Zebrafish (*Danio rerio*) have been extensively utilized for understanding mechanisms of development. These studies have led to a wealth of resources including genetic tools, informational databases, and husbandry methods. In spite of all these resources, zebrafish have been underutilized for exploring the pathophysiology of disease and the aging process. Zebrafish offer several advantages over mammalian models for these studies, including the ability to perform saturation mutagenesis and the capability to contain thousands of animals in a small space. In this review, we will discuss the use of mature zebrafish as an animal model. The challenges of developing and maintaining a colony of aging zebrafish will be addressed. Specific examples to support the use of mature zebrafish as an animal model will be provided, including the demonstration of clinical pathology and that age-associated changes in various phenotypes can be observed in aging zebrafish.*

## Introduction

Zebrafish (*Danio rerio*) have proven to be an outstanding animal model for exploring vertebrate development and genetics (Detrich *et al.*, 1999). Zebrafish have several advantages for study of developmental biology, including conservation of developmental genes across vertebrates, small size (which allows for large numbers of animals to be kept in a relatively small area), their external fertilization and transparent embryos (allowing direct visualization of development), the ease with which water soluble drugs and chemicals can be administered, and their amenability to large-scale saturation mutagenesis studies. These are unique aspects of zebrafish among currently used vertebrate animal models. Ongoing activities in the zebrafish community have resulted in a multitude of resources available to researchers using this animal model. For example, the formation of a National Zebrafish Stock Center (University of Oregon) has provided a central resource for wild-type stocks, mutant and transgenic lines, and extensive information on genetics of zebrafish. In addition, a variety of antibodies and cDNA libraries are available, and an extensive informatic web-based network has been created (Sprague *et al.*, 2003).

Furthermore, the extensive genetic characterizations that zebrafish have undergone, including a detailed micro-satellite genetic linkage map (Knapik *et al.*, 1998) and the ability to select for mutagenized genes (Wienholds *et al.*, 2003), provides a cutting edge ability to rapidly take advantage of this animal model.

The widespread resources and genetic characterization of these animals have led to many exciting discoveries related to developmental biology. However, this wealth of resources has been underexploited for evaluation of biology or pathophysiology of mature zebrafish. Most scientists evaluate zebrafish at the embryonic/neonate stages after mutagenesis or toxin exposure. Thus, it is plausible that many mutation- or toxic-mediated effects that occur in late life will not be identified. It follows that a wealth of information with great relevance to human biology and disease is being overlooked (Dooley *et al.*, 2000).

## Husbandry of an Aging Zebrafish Colony

There are several excellent manuals regarding zebrafish husbandry (Westerfield 1995). However, development and maintenance of aging zebrafish poses some unique challenges which we will describe.

## DISEASE PREVENTION

In any zebrafish colony, the appearance of disease could impact the whole colony, resulting even in death of the entire colony. Thus, disease prevention in a colony is critical. In an aging colony, this takes on a great urgency as one cannot readily replace the old fish that die and several years of work can be destroyed through introduction of a lethal pathogen or water impurity. Several filtration and detoxification methods are used in zebrafish facilities (Figure 27.1). These include methods such as ultraviolet filtration, to kill pathogenic bacteria from reaching the tank, and biological filters, to harvest bacteria that can denitrify the water. Accordingly, it is best to maintain an aging colony as an isolated colony in a barrier facility.

**Figure 27.1.** Zebrafish facility. (A) ZMod setup showing individual tanks that each hold between 20 and 30 fish. (B) Physical filtration system that uses filters to clear water. (C) Biological filtration system that uses beads with large surface area to allow for growth of bacteria that diminish nitrates in the water.

Stocking of a zebrafish colony should be performed using internal breeding.

#### POPULATION DENSITY

Population density can clearly affect the environment that the fish live in. In an aging colony, as individual fish die and are removed from a tank, the overall population density in that tank will be altered. This may confound studies when comparisons are made among different tanks. Thus, one should consider their experimental goals if this is an important issue. One method to minimize the impact of population density changes is to replace a dead fish with another fish. We typically use another zebrafish strain that we can clearly identify as different from the experimental strain (e.g., longfin versus shortfins).

#### ANIMAL AGE IDENTIFICATION

Clearly, in an aging colony, accurate identification of individuals' ages must be provided. Thus, attention must be given to establishing a record-keeping system and housing method that allow fish ages to be identified. We typically maintain approximately 20–30 fish from any one birthdate in a tank that is clearly labeled with the

birthdate of the fish. When using animals, consideration should be given to the fish's ages in order to minimize time of the experiment. For example, if one needs fish at 6 months and 2 years of age, it would be more efficient to start the 2 year fish aging, and then approximately 1.5 years later, start the 6 month fish aging. This will result in both groups reaching their target ages at the same time and thus allow for consistency during animal collection and test procedures. Additionally, it will serve to minimize overall experimental time (in this example, to approximately 2 years) as opposed to aging the 6-month-old animals and then starting the 2-year-old animals.

#### Zebrafish as Model for Human Disease

Zebrafish have been used extensively in a variety of medical and scientific disciplines including cardiology, neurology, ophthalmology, and environmental toxicology. However, the majority of these studies have explored developmental aspects. Studies in mature zebrafish, and even their normal anatomy, have been largely unexplored, though they have tremendous potential as animal models for diseases that occur later in life. Their small size makes

**Figure 27.2.** Sagittal section of zebrafish. This demonstrates a reconstruction of several individual sections of a zebrafish to create a high-resolution sagittal section. Stained with hematoxylin and eosin.

zebrafish amenable to rapid histological analysis (Figure 27.2).

We must understand their normal anatomy in order to detect pathology. In terms of serving as animal models for human disease, there are several examples. For instance, the recent cloning of the Huntington's disease gene homologue in zebrafish (Karlovič *et al.*, 1998) has broad implications for the importance that a mature zebrafish model may provide towards understanding this disease's pathophysiology. A mutation in *vHnfl* has also been recently cloned in zebrafish, which is orthologous to a gene mutated in human polycystic kidney disease (PKD) (Sun *et al.*, 2001). As in human disease, this zebrafish mutant forms cysts in its kidneys, representing a potential model of human glomerulocystic kidney disease. Zebrafish have also been found to express amyloid precursor protein (APP), presenilin (PS)-1, and apolipoprotein E (apoE), which have all been implicated in familial Alzheimer's disease (FAD) (Leimer *et al.*, 1999; Monnot *et al.*, 1999). Zebrafish PS-1 has been found to promote aberrant secretion of Abeta42 similar to FAD-associated PS1 mutations (Leimer *et al.*, 1999). Zebrafish have been proposed as an ideal vertebrate system in which to model cancer as well (Amatruda *et al.*, 2002; Stern *et al.*, 2003). Thus, the mature zebrafish has tremendous potential as a model of adult and late-life human diseases.

### Zebrafish Models of Blood Disorders

In order to capitalize on zebrafish for exploring pathophysiology, a thorough understanding of its normal physiology is required. For example, the zebrafish is especially suitable for studies involving hematopoiesis (reviewed by Ward *et al.*, 2002). The anatomical and morphological features of hematopoiesis are comparable to those in mammals (Amatruda *et al.*, 1999). Zebrafish possess both erythroid and myeloid compartments, and there is strong conservation of hematopoietic gene expression, including transcription factors and signaling pathways (Conway *et al.*, 1997; Liao *et al.*, 1998; Oates *et al.*, 1999). Large-scale genetic screens have resulted in the identification of hundreds of mutant phenotypes, including many with hematopoietic disorders (Weinstein *et al.*, 1996). Several of these mutants present almost identical phenotypes to those of human hematopoietic diseases. For example, the *sauternes* mutant has anemia due to a defect in the

erythroid  $\delta$ -aminolevulinic synthase (ALAS2) gene, an enzyme involved in heme biosynthesis (Brownlie *et al.*, 1998). Mutations in ALAS2 in humans cause congenital sideroblastic anemia, with many characteristics that resemble the *sau* phenotype. The *sau* mutant is the first animal model of this human disease. These mutants being recovered have tremendous potential for increasing our knowledge of normal hematopoietic processes as well as the pathophysiology of hematopoietic disorders. However, there is a serious lack of data describing the normal hematological characteristics of zebrafish. Normal hematological reference values for zebrafish are critical for interpreting results seen in mutant fish due to mutagenesis studies, transgenic applications, environmental stresses, or xenobiotic exposure.

Towards this goal, normal hematological and clinical chemistry parameters in adult zebrafish have been reported (Murtha *et al.*, 2003b). Hematological values for zebrafish, including leukocyte differential counts and total erythrocyte counts, were within the ranges reported for mammalian species and fish. The predominant leukocyte seen in zebrafish was the lymphocyte, with smaller numbers of monocytes, neutrophils, eosinophils, and basophils. With the exception of increases in alanine transaminase (ALT), amylase, and phosphorus values, results of serum biochemical analysis were also within the normal ranges reported for mammalian species and fish. Serum biochemical studies of healthy fish are scarce, and results vary widely. Phosphorus values were only slightly higher than the upper range reported in some publications. ALT and amylase activities were most likely falsely increased due to some hemolysis in the samples. In summary, we believe these values will be useful in future studies that examine various disease models in zebrafish, normal aging of zebrafish, and screens of mutagenic zebrafish lines.

### Zebrafish as a Model for Aging

Many species of fish have been used as an experimental model for aging (Woodhead 1978; Patnaik *et al.*, 1994; Woodhead 1998); thus in addition to defining mechanisms of disease, zebrafish may be useful for exploring the process of aging. Recent studies have provided initial evidence that zebrafish have a median lifespan of approximately 36 to 42 months with a maximum lifespan of up to 66 months (Gerhard *et al.*, 2002b), indicating that zebrafish undergo an age-related increase in mortality rate. More recently, a shorter median and maximum lifespan was reported for zebrafish, with 31 and 45 months, respectively (Herrera *et al.*, 2004). The different results in these two studies may be a reflection of strain variation and differences in housing and environmental parameters. These findings, however, set the groundwork for identification of genes that control longevity. Aging zebrafish have been demonstrated to develop several phenotypes similar to aging mammals (Table 27.1), including the

TABLE 27.1  
Aging phenotypes recognized in zebrafish

Phenotype	Finding	Reference
Median lifespan	36–42 months	(Gerhard <i>et al.</i> , 2002b)
Maximum lifespan	66 months	(Gerhard <i>et al.</i> , 2002b)
Heat shock protein 70	Decreased with age	(Murtha <i>et al.</i> , 2003a)
Heat shock factor 1	Increased with age	(Murtha <i>et al.</i> , 2003a)
Senescence-associated $\beta$ -galactosidase staining	Observed in skin with aging	(Kishi <i>et al.</i> , 2003)
Protein oxidation	Increased with age in muscle	(Kishi <i>et al.</i> , 2003)
Spinal curvature	Observed with aging	(Gerhard <i>et al.</i> , 2002b)

appearance of senescence-associated  $\beta$ -galactosidase staining and oxidized protein (Kishi *et al.*, 2003). Additionally, spinal curvature occurs with age in zebrafish (Gerhard *et al.*, 2002b).

Fish have been said to show three types of senescence: rapid, gradual, and negligible. Teleost fish, of which zebrafish are members, generally undergo gradual senescence, as observed in most vertebrates (Kishi *et al.*, 2003). Whether or not zebrafish undergo gradual senescence as well is not yet fully understood, though they are reported to show increasing senescent morphology with aging, including spinal curvature and muscle degeneration (Gerhard *et al.*, 2002b). It has also been suggested that zebrafish may undergo “very gradual senescence” based on molecular changes, including senescence-associated  $\beta$ -galactosidase activity and accumulation of oxidized protein with age in the face of continuously proliferating myocytes and constitutive telomerase activity in adult zebrafish (Kishi *et al.*, 2003). While Kishi *et al.* (2003) did not find age-related changes in BrdU incorporation, telomerase activity, and lipofuscin accumulation in zebrafish, it is important to note that the oldest fish examined in that study were 24–31 months old, which is less than the median lifespan reported for zebrafish, and may not reflect what occurs in truly “old” fish. In many teleost fish, age-related increases in mortality rate, accumulation of lipofuscin, lipid peroxidation, collagen cross-linking and decreases in growth rate, reproductive capacity and protein utilization are clearly observed (Patnaik *et al.*, 1994). Zebrafish demonstrate an age-related increase in mortality rate (Gerhard *et al.*, 2002b; Herrera *et al.*, 2004) though accumulation of lipofuscin (Kishi *et al.*, 2003), and decreases in growth rate (Gerhard *et al.*, 2002b) have not been observed in zebrafish thus far. Other parameters, including lipid peroxidation, collagen cross-linking, reproductive capacity, and protein utilization, have not yet been examined specifically in zebrafish with respect to aging.

Populations of guppies kept under various conditions of culture have shown survival curves similar to those seen in populations of small mammals (Comfort 1960;

Comfort 1961; Comfort 1963; Woodhead 1998). In these studies, guppies showed a median and maximum lifespan of approximately 36–44 and 55–60 months, respectively, which is quite similar to what has been reported in survival curves for zebrafish (Gerhard *et al.*, 2002b). In addition, the tissues of these guppies showed marked aging changes comparable to those seen in the tissues of aging mammals, including senile changes in the gonads, liver, kidneys, and brain (Woodhead *et al.*, 1983; Woodhead 1984; Woodhead *et al.*, 1984). These anatomical changes in various organs during aging have also been noted in other teleost species, confirming an increase in degenerative changes and pathological symptoms with age (Patnaik *et al.*, 1994). One method of manipulating longevity, caloric restriction, has been documented to extend the lifespan of some mammals (Weindruch 1996). Similarly, dietary restriction has been shown to retard the aging processes in several teleost species showing gradual senescence (Patnaik *et al.*, 1994), underscoring the similarities between the biology of aging in fish and mammals. While caloric restriction studies utilizing zebrafish have not yet been reported, preliminary studies are underway to determine its effects in zebrafish (Gerhard *et al.*, 2002a). Taken together, these results support a commonality in mechanism of aging processes in vertebrates.

Fish have several advantages for use as a model for the study of aging (reviewed by Woodhead 1978; Patnaik *et al.*, 1994), including the availability of large cohorts of offspring from single matings, their ectothermic nature which facilitates modulation by external environmental changes, and lower costs for breeding and maintenance. Zebrafish may serve as an excellent model of the biology of aging, particularly allowing for the identification of longevity assurance genes (genes that promote longevity). The zebrafish is readily amenable to large-scale mutagenesis studies which may detect and discover genes involved in pathways of the aging process. Generation of mutations and screening for mutant phenotypes can be achieved faster, on a larger scale, and more cost effectively than in mammalian systems (reviewed in

Gerhard *et al.*, 2002b). Thus, the zebrafish is an experimentally expedient organism similar to invertebrate models such as *C. elegans* and *Drosophila*, but with the anatomic and physiological complexities of a vertebrate.

While there are many advantages to the zebrafish as a model of aging, there are also some disadvantages which must be taken into consideration. Much like the mouse, zebrafish have a substantially longer lifespan than invertebrate models of aging such as *C. elegans* and *Drosophila*. Thus, while as a vertebrate they are phylogenetically much closer to humans than are these invertebrate models, their generation time is much longer, so aging studies utilizing zebrafish are likely to be more time consuming than with invertebrate models. Physiologically, the respiratory system of the zebrafish is very different from that of mammals, making them a poor model for studies involving respiratory physiology or respiratory diseases. In addition, zebrafish have considerable ability to regenerate tissues such as the heart (Poss *et al.*, 2002), which shows only minimal regeneration in mammals following injury, making the zebrafish a useful model for dissecting the molecular mechanisms of cardiac regeneration and comparative studies of regeneration, but perhaps limiting its usefulness for direct comparisons of regeneration in aging studies. Finally, fish are greatly influenced by their environment (Beverton 1987), and many environment variables, including temperature (Liu *et al.*, 1975), lighting (Raymond *et al.*, 1988), population density (Lorenzen *et al.*, 2002), water quality (Klontz 1995), and nutrition (Comfort 1960; Comfort 1963), must be tightly controlled in order to accurately interpret data obtained from aging studies. Despite these disadvantages, zebrafish still have many advantages and the potential for contributing to our knowledge of aging and complementing what has been learned in other organisms. Information regarding age-related changes specifically in zebrafish is very scarce. It is critical to characterize normal age-related changes in order to understand the effects of mutagenesis and transgenes in mature zebrafish.

## Heat Shock Proteins

### AGING AND HEAT SHOCK PROTEINS

A characteristic feature of aging is a progressive impairment in the ability to maintain homeostasis in the face of environmental challenges. Heat shock proteins (Hsps) consist of a family of proteins that modulate stresses to the body. Hsps are ubiquitous, highly conserved proteins that have been found in the cells of all organisms studied thus far, including plants, bacteria, yeast, flies, and vertebrates. They are part of a multigene family that has been divided into 6 subfamilies based on molecular size, ranging from 8 to 150 kD (Jaattela 1999). Some are expressed constitutively, whereas others are induced by various types of metabolic or environmental stresses such as heat, ischemia, heavy metal ions, ethanol, nicotine,

viral agents, surgical stress, and reactive oxygen species. Hsps are expressed in response to a mild stress which allows the cells to adapt to gradual changes in their environment and survive otherwise lethal conditions (Welch 1992; Whitley *et al.*, 1999). Transcription of Hsp genes requires the activation and translocation to the nucleus of heat shock transcription factors (Hsfs), which recognize sequence elements (heat shock elements — HSEs) located within the Hsp gene promoters. The HSE consists of a series of pentameric units (5'-nGAAAn-3') (Santoro 2000). Inactive Hsfs exist as monomers bound to Hsp70 and other chaperones. Once activated, they trimerize into an active form that is capable of binding to the promoter site of the stress protein gene and initiating transcription and translation (Whitley *et al.*, 1999).

The expression of various types of Hsp protein and mRNA levels in response to heat stress has been shown to decrease with age in a variety of species from flies to rats. Old fruit flies were found to have a loss of resistance to oxidative stress induced by heat shock. This loss correlated with an increase in protein damage and a decrease in protection from the heat shock proteins (Fleming *et al.*, 1992). The expression of protein and mRNA levels in members of the Hsp70 family in response to heat shock was found to be decreased with age in rat neurons (Pardue *et al.*, 1992), hepatocytes (Rogue *et al.*, 1993; Wu *et al.*, 1993), and myocardium (Locke *et al.*, 1996). Based on measurements of Hsp70 mRNA stability and transcription in rat hepatocytes, it was demonstrated that the age-related decline in Hsp70 expression was a result of a decline in Hsp70 transcription. Interestingly, this age-related decrease in Hsp70 expression was reversible with caloric restriction. Caloric restriction is the only experimental manipulation known to retard aging and increase survival in mammals (Heydari *et al.*, 1993). In addition, this decline in Hsp70 transcription correlated with a decrease in the binding of Hsf1 to the heat shock element. This decreased binding activity was not due to reduced levels of Hsf1. In fact, Hsf1 levels were actually higher in hepatocytes from old rats, apparently due to a decrease in the degradation of Hsf1 since Hsf1 mRNA levels do not change and the synthesis of Hsf1 decreases with age (Heydari *et al.*, 2000). Similarly, hearts from aged rats exposed to heat stress demonstrated a reduction in Hsf1 activation, Hsp72 mRNA, and Hsp72 protein content, though myocardial Hsf1 protein content was similar between age groups (Locke *et al.*, 1996). Thus, it appears that during aging, the levels of Hsf1 remain constant, but the ability of this transcription factor to bind DNA is decreased in aged animals.

An age-related decline in Hsp72 expression was also seen in organ-cultured samples of normal human skin. Although the time course of Hsp72 expression was similar in both young and aged groups, a lower level of induction was achieved in the aged group (Muramatsu *et al.*, 1996). A similar decline in Hsp47 expression is seen in aged mouse and human fibroblasts exposed to heat stress.

Hsp47 is a collagen-specific chaperone which participates in the processing and secretion of procollagen in the ER. This decline was regulated by transcriptional mechanisms and was characterized by a greater retention of procollagen molecules in the ER lumen of cells from old subjects (Miyaiishi *et al.*, 1995). Similarly, cultures of primary human peripheral lymphocytes exposed to heat stress revealed an age-related attenuation in the expression of many heat shock proteins, including Hsp70, Hsp90, Hsp60 (Rao *et al.*, 1999). Murine and human fibroblasts also showed a decline in heat shock protein expression with age upon heat treatment (Miyaiishi *et al.*, 1995).

Given the central role of Hsps in cellular homeostasis, it seems likely that an impaired ability to produce Hsps in aging cells in response to stress could contribute to the increased incidence of infections and general morbidity and mortality that is seen in the elderly when exposed to stress.

### ZEBRAFISH AND HSPTS

A variety of heat shock proteins and the heat shock transcription factor Hsf1 have been identified and cloned from zebrafish (Krone *et al.*, 1994; Graser *et al.*, 1996; Lele *et al.*, 1997b; Santacruz *et al.*, 1997; Rabergh *et al.*, 2000). Many of these heat shock genes exhibit complex patterns of constitutive and inducible expression during embryonic development (Krone *et al.*, 1997). For example, the Hsp90alpha gene is expressed at low levels constitutively but is strongly upregulated during heat shock, whereas Hsp90beta is expressed at much higher levels constitutively but is only weakly induced following heat shock in all stages of development examined in zebrafish embryos (Krone *et al.*, 1994). Hsp70 and Hsp47 mRNA levels have also been shown to increase dramatically in response to heat stress, whereas the constitutively expressed heat shock cognate hsc70 exhibits only a slight increase. In contrast, exposure of zebrafish embryos to ethanol strongly induced Hsp47 but not Hsp70, demonstrating a differential response of the Hsps in zebrafish embryos (Lele *et al.*, 1997a). Two isoforms of Hsf1, termed zHsf1a and zHsf1b, have been identified and cloned in zebrafish and are expressed in a tissue-specific fashion upon exposure to heat stress. Specifically, both forms are expressed in the gonads under all conditions, but in the liver zHsf1a is increased with heat shock whereas zHsf1b is decreased, indicating a unique, tissue-specific regulation of Hsf1 upon exposure to increased temperatures (Rabergh *et al.*, 2000).

We have shown that mature zebrafish respond to heat shock with both nuclear translocation of Hsf1 and production of several Hsps in a variety of tissues (Murtha *et al.*, 2003a), similar to what has been reported in other species. More specifically, we found that Hsp70 and Hsp47 were induced in response to heat stress in a tissue-specific manner, while Hsp90 $\alpha$ , Hsp90 $\beta$ , and Hsf1 were

expressed constitutively and not induced by heat stress. Though Hsf1 RNA levels did not change with heat stress, Hsf1 protein translocated to the nucleus following heat stress, indicating activation of this transcription factor. Mammalian species show a similar pattern of Hsp and Hsf expression and Hsf activation in response to heat stress (Santoro, 2000). Furthermore, we found that aging modulates heat shock responsiveness and Hsp70 expression in zebrafish. Specifically, both basal and induced levels of Hsp70 were less in mature versus young zebrafish, which is consistent with previous reports in a variety of other species (Heydari *et al.*, 1994; Kregel *et al.*, 1995; Lee *et al.*, 1996; Liu *et al.*, 1996; Pahlavani *et al.*, 1996). We also observed that Hsf1 mRNA levels were elevated in mature compared to young zebrafish and that heat shock did not induce Hsf1 mRNA expression in either age group but did induce nuclear translocation. This is also consistent with previous reports on Hsf1 expression and induction in other species (Locke *et al.*, 1996; Heydari *et al.*, 2000; Locke, 2000), in which Hsp70 levels are diminished with age in the face of increased Hsf1 levels, which is thought to be due to a decreased ability of Hsf1 to bind DNA in aged animals. This provides evidence that zebrafish can serve as a novel vertebrate model to study the mechanisms of aging and response to environmental stress. In addition, these results also have the potential to elucidate the mechanisms underlying many disease processes which show abnormal Hsp expression, including atherosclerosis, congestive heart failure, fever, infection, Alzheimer's disease, cancer, and autoimmune disease (Whitley *et al.*, 1999).

### Summary

The zebrafish has tremendous potential as a model of human disease and aging. It is already proving to be an excellent model for several human diseases, and there is an increasing wealth of resources available to the zebrafish community. In addition, aging phenotypes and age-associated molecular changes in pathways such as the heat shock response have been demonstrated in zebrafish, and zebrafish have been shown to have many similarities to aging mammals including gross, cellular, and molecular characteristics. Despite the many advantages to using mature zebrafish as an animal model, it has been underutilized in studies of aging and adult-onset or age-related diseases. Studies regarding normal physiology and age-related changes in zebrafish are very scarce, and it is critical to more fully characterize mature zebrafish in order to understand the effects of mutagenesis and transgenes in mature zebrafish. Characterization of normal zebrafish biology and physiology, as well as defining molecular mechanisms of stress response and aging, should help provide a foundation for future studies utilizing adult zebrafish.

# Zebrafish as Aging Models

Shuji Kishi

*Zebrafish (Danio rerio) are well recognized as a powerful model for genetic studies in developmental biology. The zebrafish system has also given insights into several human diseases such as neurodegenerative, hematopoietic and cardiovascular diseases and cancer. The aging process affects these and various other human disorders, and it is important to compare age-related disfunctions at the organismal levels among vertebrates. From the point of view in comparative and evolutionary biology of aging, the aging process of zebrafish remains largely unexplored, and little is known about functional aging and senescence, compared with higher vertebrates including mammals. In our recent studies to assess aging phenotypes in zebrafish, we identified several potential biomarkers of zebrafish aging. In aging zebrafish, we have detected senescence-associated  $\beta$ -galactosidase activity in skin and oxidized protein accumulation in muscle. In contrast, our initial study showed that lipofuscin granules, which accumulate in postmitotic cells, were not obvious in muscle of zebrafish at fairly advanced age. In agreement with this observation, there were continuously proliferating myocytes in muscle tissues of aged fish. More intriguingly, we found that zebrafish have constitutively abundant telomerase activity in adult somatic tissues, implicating the unlimited replicative ability of cells throughout their lives. Taken together, some stress-associated markers are up-regulated, and minor histological alterations and lesions are occasionally observed during the aging process of zebrafish. However, our current studies and other evidence of remarkable reproductive and regenerative abilities suggest that zebrafish show very gradual senescence. By using those biological and biochemical aging markers already characterized in normal zebrafish, analyses of transgenic and mutant fish be readily performed for development of zebrafish aging models for age-dependent human diseases and progeroid syndromes. These efforts will help to elucidate the role and molecular mechanisms of common or different pathways of aging among vertebrates from fish to humans and also will contribute to the discovery of possible therapeutic interventions and potential drugs applicable to many age-associated diseases in the future.*

## Introduction

The bony fishes (Osteichthyes) represent the largest class of vertebrates, with some 24,000 extant species. However, only limited data are available on aging and senescence of just a few of these species (Patnaik *et al.*, 1994). Several small tropical species, such as the guppy (*Lebistes reticularis*) (Reznick *et al.*, 2001; Reznick, 1997), and a species of annual fish (*Cynelobias bellottii*) (Valdesalici and Cellerino, 2003), manifest increased mortality with age typical of gradual senescence and definite lifespan (Belinsky *et al.*, 1997; Finch and Austad, 2001; Finch and Ruvkun, 2001). In addition, age-related degenerative changes characteristic of gradual senescence, such as loss of muscle fibers, endocrine abnormalities, decline in reproductive capacity, increased cancer incidence, and increases in various pathological lesions, have been documented in other fish species (Patnaik *et al.*, 1994). In comparison to these fish, the aging process of zebrafish has not yet been addressed adequately.

A number of aging theories have been proposed, including oxidative or genotoxic stress and damage, telomere metabolism, regulation of caloric restriction (CR), and control of metabolic energy rate. A growing body of evidence suggests that reactive oxygen species (ROS) may regulate the aging process and may participate in cellular replicative senescence. Consistent with a role for ROS in senescence, examination in cell-culture systems showed that older cells have higher levels of ROS than younger ones (Finkel and Holbrook, 2000). Moreover, treatment with sublethal concentrations of hydrogen peroxide induces a senescence-like phenotype in primary human and rodent fibroblast (Chen and Ames, 1994; Sohal and Weindruch, 1996; Wolf *et al.*, 2002), termed "stress-induced premature senescence" (Toussaint *et al.*, 2000). On the other hand, antioxidant treatment or low-oxygen condition prolongs the lifespan of cells (Finkel and Holbrook, 2000). The free radical theory of aging, which proposes that oxidative stress increases with age, may provide some clues to this phenomenon. Specifically, reactive oxygen intermediates (ROI) act as second messengers culminating in activation of signal transduction pathways and subsequently changes in the activity of various transcription factors. Another theory holds that cellular replicative senescence is regulated by factors that govern the shortening of telomeres in dividing cells of the adult tissues and organs.

Telomeric TTAGGG repeats in vertebrates, which protect chromosome ends, are shortened with each division of most cells in the adult due to lack of telomerase activity (Blackburn, 2001). However, compelling evidence indicates that the ability of telomerase to elongate telomeres is regulated by several other telomere-binding factors with multiple interacting proteins, which construct a huge “telosome” complex (Blackburn, 2001; Liu *et al.*, 2004; Rodier *et al.*, 2005).

The CR paradigm provides additional support for this hypothesis. CR, which decreases oxidative stress, delays the appearance of expression of several age-associated genes (Sohal and Weindruch, 1996). Use of high-density oligonucleotide arrays and genome-wide transcript profiles in mice and flies revealed that aging was accompanied by a differential gene expression pattern with indications of a marked stress response and lower expression of metabolic and biosynthetic genes (Lee *et al.*, 1999; Pletcher *et al.*, 2002; Zou *et al.*, 2000). Most alterations were either completely or partially prevented by caloric restriction, the only intervention known to retard aging in mammals. Transcriptional patterns of calorie-restricted animals suggest that caloric restriction retards the aging process by causing a metabolic shift toward increased protein turnover and decreased macromolecular damage. On the other hand, oxidative damage is repaired less well in telomeric DNA than elsewhere in the chromosome, and oxidative stress accelerates telomere loss, whereas antioxidants decelerate it. Therefore, oxidative stress is also an important modulator of telomere loss, and telomere-driven replicative senescence is primarily a stress response. Among oxidative stress, regulation of CR, and telomere metabolism, there also seems to be a significant cross-talk mechanism with each other in the course of the aging process. However, genetic evidence of this mechanism in higher vertebrates has not been elucidated yet.

The propagation of a species could depend in principle either on the unlimited maintenance of its individuals or on the ability to renew the population with young members. Nature most commonly has chosen the latter option. Renewal is typically achieved by the setting aside of a pristine lineage of genetic information in the germ line, which is passed on by sexual reproduction. In contrast, the somatic lineage of all animals declines and degenerates with age, giving rise to phenotypic changes recognized as aging. Studies in model organisms have begun to map out important genes and pathways that seem to regulate the pace of aging and that are remarkably conserved from yeast to worm and insect. These studies have the great advantage that one can use genetic approaches to search directly for mutations that change lifespan. This makes it possible to identify mechanisms in a way that is independent of any preconceived model of aging. Recently, the analysis of such mutations that affect lifespan has revealed several different pathways that influence the aging process. These include, notably, signaling molecules from the Insulin-like

growth factor-1 (IGF-1)-FoxOs (the FoxO subfamily of forkhead transcription factors) pathway which are highly conserved in evolution and have been identified in yeast, flies, and worms as regulating aging (Guarente and Picard, 2005; Kenyon, 2005; Murphy *et al.*, 2003). Thus once a gene has been identified as regulating aging in lower organisms it can be tested in mice by knockout or transgenic technologies. However, our inability to do forward genetics in vertebrates places serious restrictions on the types of genes we might find. Moreover, it seems quite likely that genetic screening in invertebrates will miss genes affecting cellular proliferation in adults, which confers on mammals with their relatively longer lifespan. Additionally, those unique genes and their functions related to longevity in vertebrates are not likely to be found in unicellular organisms and other invertebrate model systems. To address these questions in a more tractable and high-throughput setting, alternative vertebrate model systems are needed. Since zebrafish offer a number of advantages for the study of diseases and for tissue and organ development, we begun utilizing zebrafish as a new vertebrate model to explore the aging and senescence process with pathophysiological phenotypes. As part of this ongoing effort, mutagenesis and transgenesis approaches are expected to be extremely useful.

Zebrafish have proven to be an outstanding animal model system for studying vertebrate development using both genetic and genomic approaches. For instance, large-scale chemical mutagenesis strategies have been used to identify numerous zebrafish mutants with developmental abnormalities or defects. However, current approaches lack the ability to demonstrate developmental imprinting and identify adult or late-age onset mutants that can perturb the aging process. Although *C. elegans* and *Drosophila* are well-established aging models which have been used to identify a number of single gene mutations resulting in extended or shortened lifespan, these relatively shorter-lived invertebrates are unlikely to provide information on essential genes and molecular mechanisms that are unique to longer-lived vertebrates as described above. For instance, it is difficult to address the organ-specific aging process in nervous, cardiovascular, immune, and musculoskeletal system of invertebrates. Moreover, invertebrates cannot be utilized to explore developmental and aging functions of vertebrate-specific features such as the kidney, a multichambered heart, multilineage hematopoiesis, a notochord, and neural crest cells.

Mutagenesis is one of the best approaches for identifying a gene function. Of vertebrates studied to date, mutations can be generated and recovered most readily in zebrafish. Furthermore, as a result of recent advances in technology, zebrafish can be utilized for both forward genetics and, importantly, reverse genetics. For example, transgenesis coupled with chemical mutagenesis can be employed for the analysis of promoter activity and specificity utilizing an effective *in vivo* reporter system such as GFP (Dodd *et al.*, 2000). It is also possible to use

high-throughput transgenic approaches such as GFP-positive embryos to study the function of gene products by taking advantage of the transparency of fish during its developmental stages. More recently, the Targeting Induced Local Lesions in Genomes (TILLING) approach coupled with a direct resequencing strategy of a target gene in mutagenized genomic DNA has been developed in the zebrafish system (Henikoff *et al.*, 2004; Wienholds *et al.*, 2002; Wienholds *et al.*, 2003). This approach, along with other related methods, brings zebrafish reverse genetics to a level equivalent with that of mice. Therefore, functional genetic and genomic analysis of signaling pathways involved in aging of zebrafish will be readily possible, once we identify effective and robust aging markers.

The zebrafish system is already well established in developmental biology, and recently zebrafish models have been used in disease-based biomedical studies. In marked contrast, the aging process of zebrafish has not been significantly addressed, so that there is little known with respect to the aging process and cellular senescence in zebrafish. Susceptibility to most human chronic diseases is affected by the aging process. Therefore, it is crucial to know how zebrafish aging is compared with aging in mammals, particularly since we also view zebrafish as a useful surrogate model for multiple human diseases. Moreover, through comparative studies of aging among vertebrates, we may be able to learn how we can take advantage of the certain unique properties in lower vertebrates, such as multiple organs' regeneration and indeterminate growth, which have been lost during mammalian evolution.

### Identification of Biomarkers of Zebrafish Aging and Senescence

As has already been mentioned, compared with other model organisms, the aging process of zebrafish is in a very early stage of investigation, and we are currently unable to tell precisely how the fish age physiologically, and what the pathophysiological symptoms and lesions are, in zebrafish aging and in their age-associated diseases, respectively. Therefore, first and foremost, it is important to set forth some principles for evaluating the functional aging process in zebrafish.

To determine effective biomarkers of aging in zebrafish, we have analyzed the following potential markers in zebrafish aging: (a) age-dependent accumulation of oxidative damage in proteins and lipofuscin accumulation (oxidation aging marker); (b) senescence-associated  $\beta$ -galactosidase (SA- $\beta$ -gal) activity (enzymatic aging marker); (c) age-dependent telomere length and metabolism, and telomerase activity (telomeric aging marker); (d) age-dependent competence for caudal (tail) fin regeneration (regeneration aging marker); (e) age-associated growth rate and size in a restricted space and time period (growth size aging marker); (f) age-related changes

in locomotor activity (behavioral aging marker) and age-dependent changes of activity in circadian rhythm and decline of melatonin secretion (circadian aging marker).

### AGING MARKERS BASED ON OXIDATION OF MACROMOLECULES

Aerobic metabolism and the corresponding generation of ROS is the most widely recognized cause of aging, although many questions remain regarding the detailed mechanism of action of ROS in organismal aging (Chien and Karsenty, 2005; Hadley *et al.*, 2005). Several lines of evidence argue that macromolecular oxidation by ROS is responsible for functional declines or inappropriate roles of proteins, lipids, and DNA (Balaban *et al.*, 2005). It seems likely that the accumulation of these oxidized dysfunctional macromolecules becomes a hallmark of progression of aging in zebrafish, as commonly recognized in other aging animals.

Protein oxidation has been detected by estimating its carbonyl content by Western blotting analysis (Dalle-Donne *et al.*, 2003). In current studies, we have identified increasing accumulation of oxidized proteins with age in skin, muscle, and brain of zebrafish, when we examined the samples from 6–30-month-old fish. However, we have not detected difference in ovary where we observed a constant amount of oxidized proteins. We have also measured the accumulation of the oxidized lipid by-product, lipofuscin, as the “age pigment,” one of the most prominent age-related cellular alterations reported in many organisms (Brunk and Terman, 2002; Terman and Brunk, 2004). Although in our initial studies, we did not detect lipofuscin accumulation in 24-month old fish, our currently updated results indicate that gradually increased accumulation of lipofuscin occurs at 30 months and even more significantly at 42-months. In addition to muscle tissues, lipofuscin accumulation was observed in brain, liver, kidney, but not intestine, with advancing age. For each experiment, we examined 10–15 fish samples, and quantified the results by image intensities of Western blotting for oxidized proteins and by capturing images to count fluorescent spots for lipofuscin. Statistical analysis of these oxidative-stress-associated markers is currently in progress, but the relevance of the markers is already evident.

### SENESCENCE-ASSOCIATED (SA)- $\beta$ -GALACTOSIDASE AS AN ENZYMIC AGING MARKER

Acidic senescence-associated- $\beta$ -galactosidase (SA- $\beta$ -gal) is histochemically detectable at pH 6 upon senescence in cultured cells *in vitro* and aged skin *in vivo* (Dimri *et al.*, 1995). This SA- $\beta$ -gal marker can differentiate between the replicatively senescent state and the simply quiescent state during growth-arrest. This marker has been used to identify senescent cells in selected tissues from several aging animal models *in vivo* (Cao *et al.*, 2003;

**Figure 28.1.** Whole-body detection of SA- $\beta$ -gal activity in adult zebrafish of different ages (Kishi *et al.*, 2003). After whole-mount fixation of adult zebrafish with whole body, SA- $\beta$ -gal staining was performed at pH 6 in 9, 17, 22, and 31-month-old zebrafish samples. As shown in this figure, younger 9-month-old fish exhibited very faint background staining in some abdominal regions, whereas several different levels of staining in individual fish were observed in 17- and 22-month-old fish. The staining patterns of each fish varied in these age groups. Some individuals showed fairly strong staining, while others were relatively variable. On the other hand, all examined 31-month-old fish exhibited notably intense staining over their entire bodies.

Keyes *et al.*, 2005; Varela *et al.*, 2005). We previously reported on SA- $\beta$ -gal induction during the aging process in zebrafish *in vivo* (Kishi, 2004; Kishi *et al.*, 2003). We demonstrated significant increases of SA- $\beta$ -gal activity in skin from aged (more than 31 months) versus young (less than 17 months) zebrafish (Kishi *et al.*, 2003) (Figure 28.1).

The presence of SA- $\beta$ -gal has been determined further in 6, 18, 30, and 42-month-old fish for more than 10 fish in each age group. We have newly developed a quantitative approach through conversions of captured actual images into pixel images scored in zebrafish embryos and adults. Based on scanning of the fixed parts of the trunk region in adult fish, the images were converted into pixels, and a prominent increase of SA- $\beta$ -gal intensity was found with age. In our studies, SA- $\beta$ -gal activity of zebrafish appeared to correlate well with their chronological ages.

On the other hand, in zebrafish embryos under genotoxic or oxidative stress, induction of SA- $\beta$ -gal was successfully measured qualitatively and quantitatively (Figure 28.2).

This will open up a new avenue for screening of potential aging mutants by the embryonic senescence phenotype in zebrafish without spending lengthy time-of-lifespan analyses.

#### TELOMERIC AGING MARKERS

All vertebrate telomeres contain a characteristic 6-base repeated sequence, TTAGGG (Meyne *et al.*, 1989). According to the telomere hypothesis, DNA replication in somatic cells leads to telomere shortening, which forms the basis of a cellular mitotic clock (Sherr and DePinho, 2000). Moreover, several premature aging syndromes lead to accelerated loss of telomeric DNA, which eventually results in accelerated replicative senescence of the cells (Kipling *et al.*, 2004; Metcalfe *et al.*, 1996; Pandita, 2002; von Zglinicki *et al.*, 2005). Cumulatively, these results suggest that it is also possible to ascertain aging and senescence phenotypes in zebrafish by qualitative and quantitative measurements of telomere metabolism and maintenance.

**Figure 28.2.** Whole-mount SA- $\beta$ -gal detection of genotoxic stress-induced embryonic senescence. Wild-type zebrafish embryos were treated with IR (0, 10, and 20 Gy) at 6 hpf. Subjected embryos were raised by 6 dpf. The 6-day larval fish were fixed and stained for SA- $\beta$ -gal. Both 10 and 20 Gy of IR obviously induced SA- $\beta$ -gal in larval zebrafish. While 10 Gy-treated larval fish did not exhibit a particularly abnormal phenotype with more than 90% survival rate, 20 Gy-treated larval fish showed severe malformation and did not subsequently survive at all.

To detect and measure telomeric DNA in zebrafish, we have adopted a previously established procedure utilizing quantitative measurement of *in situ* hybridization (Q-FISH) with a fluorescence-labeled telomere-specific probe (Miller *et al.*, 1992). Importantly, telomeric repeat sequences of TTAGGG are conserved in all vertebrates, from fish to humans. Thus, zebrafish telomeric sequences can be detected by the same procedure used for human telomeres, utilizing a fluorescein- or Cy3-conjugated peptide nucleic acid (PNA) probe as confirmed previously (Baerlocher and Lansdorp, 2004; Sola and Gornung, 2001). Since zebrafish embryos are transparent, we can easily detect the telomere signals through fluorescence

## 28. Zebrafish as Aging Models

microscopy by staining with the PNA probe. We could quantify the fluorescence intensity of zebrafish telomeres by the telomere analysis program, TEL-TELO V1.0a, developed and provided by Peter Lansdorp at the Terry Fox Laboratory, as previously performed for human and mouse telomeres (Baerlocher and Lansdorp, 2004).

We have also performed Southern blot analysis to confirm telomere lengths in muscle from 6, 18, 30, and 42-month-old fish for 10 fish in each age group. Southern analysis can demonstrate length of terminal restriction fragments (TRF), containing DNA with uniform telomeric TTAGGG repeats, obtained by digestion of genomic DNA using *Hinf*I and *Rsa*I restriction enzymes in zebrafish, as well as in humans and mice. Through Southern analysis in adult fish muscle samples, we found that the telomere lengths were stochastically shortened late in the life of the fish (e.g., at more than 30 months), irrespective of their constitutive telomerase activity throughout their lives.

Telomerase is a ribonucleoprotein complex that consists of two main subunits: TR, the telomerase RNA template for addition of TTAGGG repeat sequence (telomerase RNA complex, TERC); and TERT, telomerase reverse transcriptase catalytic subunit of telomerase and other associated proteins. While TR is expressed ubiquitously and constitutively in various types of cells, TERT is not expressed in most normal somatic cells. However, stem cells and germ cells as well as approximately 80–85% of cancer cells express TERT in humans.

Zebrafish telomerase activity has been examined by Telomeric Repeat Amplification Protocol (TRAP) assay, which is a sensitive and efficient PCR-based telomerase detection method (Wright *et al.*, 1995). There is a causal relationship between telomerase expression, telomere maintenance and extension of cellular lifespan in mammalian cells. Due to tightly regulated expression of TERT as described above among normal tissues of adult humans, telomerase activity is almost undetectable except in germ-line cells, although very small amounts of activity are detectable in bone marrow, peripheral blood lymphocytes, and skin epidermis. In addition, mice normally exhibit telomerase activity in colon, liver, ovary, and testis but not in brain, heart, stomach, and muscle. However, strikingly in zebrafish, the results showed the constitutive activation of telomerase in nearly all the tissues, including muscle, heart, and brain, throughout their lives (Kishi *et al.*, 2003) (Figure 28.3).

Once the unlimited growth potential and remarkable regeneration ability of zebrafish is appreciated, the above results may not seem surprising. On the other hand, strong link between cell proliferation and telomerase activity is biologically and evolutionarily very intriguing.

### REGENERATIVE CAPACITY AS AN AGING MARKER

Several vertebrates display the ability to regenerate parts of their body after amputation. Teleost fish,

**Figure 28.3.** Relative telomerase activity in whole zebrafish embryos at various developmental stages (0, 6, 24, 48, and 72 hpf), and in skeletal muscle from adult fish of various ages (5, 15, and 24 months old) (Kishi *et al.*, 2003). Telomerase activity was examined by TRAP assay in extracted protein samples ( $n = 3$  in each bar). Samples of B6 mouse skeletal muscle (4 weeks old) were almost undetectable levels in telomerase activity.

including zebrafish, can regenerate multiple tissues and organs, including spinal cord, retina, heart, and fins even at mature adult stages (Keating, 2004; Poss *et al.*, 2003). We have analyzed the age-dependent alterations in the ability of zebrafish to regenerate its caudal (tail) fin. Zebrafish fins normally regenerate rapidly following amputation. Regeneration occurs within a few weeks via processes resembling amphibian limb regeneration. Following amputation, differentiated bone cells apparently dedifferentiate and enter the cell cycle, rapidly divide, and migrate from the stump to form a regenerated blastema. Formation of the blastema is followed by a period of rapid growth with continued proliferation of some blastema cells matched by withdrawal of other cells to form new bone. There was clear difference in regeneration ability of caudal fin between young fish and old fish. This ability to regenerate declines with age in zebrafish as in most other fish reported. Thus, statistical analysis of data from the 18-month and 30-month-old fish provided baseline information for age-dependent decline of wound-healing and regenerative ability.

At the molecular levels in regeneration, previous experiments with regenerating fins in zebrafish have shown that members of the *Msx* family of homeodomain-containing transcription factors play key roles during blastema formation and patterning. Importantly, adult zebrafish have a remarkable capacity to regenerate the heart in a process that involves up-regulation of *msxB* and *msxC* genes. In addition, the hearts of zebrafish with mutations in the *Mps1* mitotic checkpoint kinase, a critical cell cycle regulator, failed to regenerate and formed scars (Poss *et al.*, 2003; Poss *et al.*, 2002a; Poss *et al.*, 2002b). Preceding *Msx* activation (Akimenko *et al.*, 1995), there is a marked increase in the expression of *Notch1b* and *DeltaC*, which have been shown to be up-regulated during fin and heart regeneration (Raya *et al.*, 2003), suggesting a role for the Notch signaling pathway in the activation of

the regenerative response. In this regard, Notch activation is at the base of the decisive event for proliferation and/or differentiation in a number of resident stem cells (Conboy *et al.*, 2005; Raya *et al.*, 2003), including those of hematopoietic, neural, gastrointestinal, and skeletal muscle lineages. Whether such stem or progenitor cells exist in zebrafish regenerative tissues and organs, whether they play a role in the regenerative response, and whether they are the origin of constitutive telomerase activity remain to be elucidated. The involvement of the Notch signaling pathway during regeneration is of biological and biomedical importance and warrants further investigation in connection with by telomerase and telomere regulation. Thus, in the next stage of regeneration studies on zebrafish aging, it will be required to investigate the molecular network in detail, taking into consideration aging stem cells. Advances in regeneration studies in zebrafish aging will undoubtedly aid in the implementation of strategies for regenerative medicine in human aging.

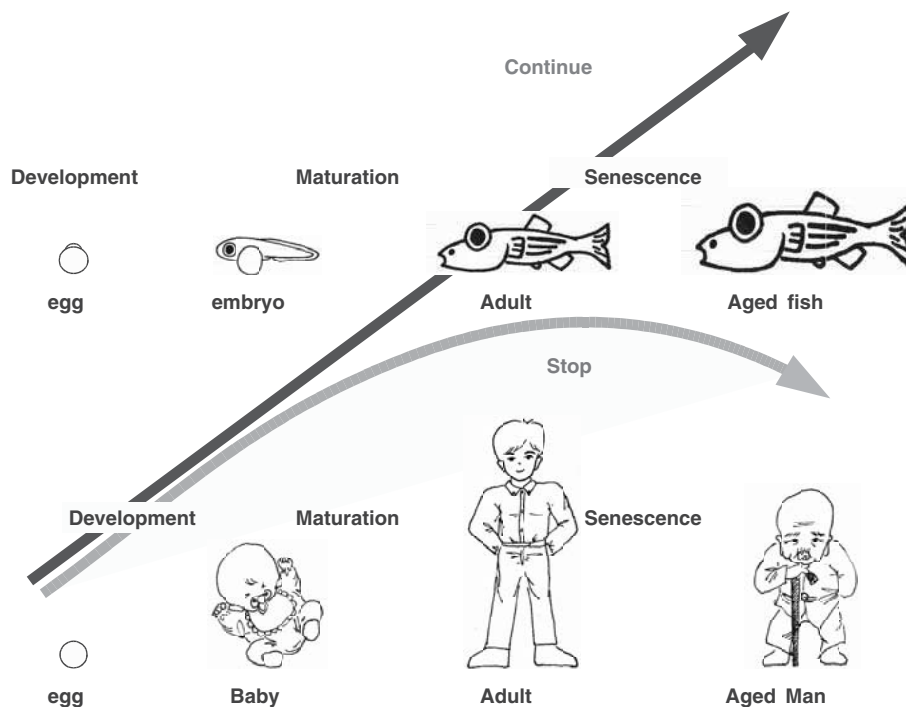

#### GROWTH RATE AND OVERALL SIZE AS AGING MARKERS

Most organisms exhibit determinate growth—up to the point at which growth no longer occurs. However, indeterminate growth may occur when it offers advantages in fitness or reproductive prowess. It was already

hypothesized that zebrafish exhibit a capacity for unlimited growth (Gerhard *et al.*, 2002), and our study supported this notion. This is clearly different from humans and other mammals that cease growing after reaching sexual maturation (Figure 28.4).

This indefinite growth regulation may indicate an evolutionary attempt to compensate for senescence with age. Similarly, age did not seem to simply deter continued growth, as small aged fish retained comparable ability to grow as small young fish. Instead, growth merely slowed as body size increased regardless of age.

On a different note, other factors such as environmental conditions can play a pivotal role in modulating growth regulation. Indeed, we have demonstrated that given adequate nourishment, living space available or density conditions directly governed the mean final size reached by fish in each tank. It may be postulated that density could act as a trigger to stop growth and to affect other processes by stimulating some sort of “space” sensors in zebrafish that allow them monitor their own surroundings, analogous to normal cells that stop division in response to contact inhibition. Alternatively, high density conditions may stimulate some form of communication with other members within close proximity, simulating the function of pheromones in insects. While this remains to be elucidated in future studies, it was important for us to establish

**Figure 28.4.** Potential differences in growth and aging between zebrafish and humans. Zebrafish continue growth past sexual maturation throughout life, with remarkable regenerative capability given adequate food, space, and good husbandry. On the other hand, human and other mammals cease growing after reaching sexual maturation as their function of age. The illustration provided here is modified from the original Japanese literature, having the translated title “Learning Biology through Medaka Fish,” which was written by Nobuo Egami in 1989.

density-dependence of growth before undertaking further experiments on zebrafish growth and aging.

Our current data suggest that the propensity to grow can decrease with increased size, but not simply chronological age. Both older (18–30 months) and younger (6–18 months) fish exhibited similar patterns of growth throughout their lives as long as their sizes are almost same, indicating that they are similar in “biological age” albeit different in chronological ages. Subsequently, growth never clearly plateaued or stopped altogether up to the end of the final measurement, supporting the indefinite growth in zebrafish.

IGF-1 is known to play crucial roles in growth and development in all vertebrates. Several lines of evidence from studies in a variety of vertebrate species suggest that the ligands (IGFs), receptors (IGF receptors), and ligand-binding proteins (IGF-binding proteins) evolved early during vertebrate evolution (Barbieri *et al.*, 2003; Katic and Kahn, 2005). While central action sites of IGF-1 in invertebrates and higher vertebrates are currently well understood, little is known in the teleost models where their tissues and organs sometimes undergo continual and indeterminate growth, except for some fish of commercial importance. However, the IGF-1 signal that involves downstream signaling molecules, such as members in the protein deacetylase Sir2 family or the forkhead transcription factors FoxO subgroup, is believed to be one of the most prominent aging-associated pathways. Actually, CR definitely links up with the IGF-1 signaling pathway. In this respect, there is an exception to the common notion that CR extends lifespan in some fish, because “ferox trout” achieve long life by eating more, not less (Mangel and Abrahams, 2001). Most recently, the lifespan of guppies with CR (low food) was not extended, compared with the high-food population, and total fecundity are higher in high-food population with reproduction throughout their lives and with subsequent reproductive senescence (Reznick *et al.*, 2004). Thus apparent patterns of senescence in guppies derived from natural populations, with respect to either mortality or reproduction, were not simply controlled by levels of food availability in the laboratory, according to the common notion. Therefore, fish may have alternative or different control mechanisms of the IGF-1/Sir2/FoxO pathways in their fitness. Further investigations of this pathway in the zebrafish model may reveal a novel control mechanism between CR and aging in lower vertebrates.

#### AGING MARKERS BASED ON BEHAVIOR AND CIRCADIAN RHYTHMS

We are also attempting to document age-related changes in behavior and circadian rhythms of adult zebrafish. These studies on zebrafish aging markers have been pursued in collaboration with Irina Zhdanova at the Boston University School of Medicine.

It has been reported that zebrafish is a diurnal vertebrate with a clear circadian pattern of daytime activity and nighttime rest (Cahill, 1996; Cahill, 2002; Dekens *et al.*, 2003; Delaunay *et al.*, 2000; Hurd *et al.*, 1998; Kazimi and Cahill, 1999). Zhdanova has been studying the sleep-like state in zebrafish, using a high-throughput image-analysis system (Zhdanova *et al.*, 2001). Previous studies have shown that the sleep-like state in zebrafish has fundamental similarities with sleep in mammals, including characteristic postures, elevated arousal threshold to sensory stimulation and a compensatory rest rebound following rest deprivation (Zhdanova *et al.*, 2001). “Sleep” in zebrafish can be induced by conventional hypnotics, diazepam and sodium pentobarbital, and the circadian hormone melatonin (Zhdanova *et al.*, 2001). While the age-related decline in human sleep is a well-known phenomenon, it is not yet established whether this is true in lower vertebrates.

In order to determine whether sleep alteration could be a sensitive behavioral marker of aging, we have assessed the effects of zebrafish age on the sleep-like state. Using image analysis of locomotor activity, we documented the overall duration and continuity of sleep-like behavior (defined as period of immobility of 3 min or more, with increased arousal threshold) and changes in arousal threshold during this behavioral state in young and aged zebrafish adults. Our results on the intrinsic circadian rhythm of activity in larval and adult zebrafish maintained under constant conditions have also shown that the endogenous circadian period becomes more variable in adults, compared with larval fish. This might result from the weakening of the circadian oscillator with age or reduction in nighttime melatonin secretion.

By conducting a continuous 10-day analysis of zebrafish locomotor activity under constant conditions, we have compared the amplitude and period of the circadian rhythm in fish of 12 and 36 months of age and determined whether these circadian parameters might serve as a useful marker of aging. Preliminary results comparing locomotor activity in young (12-month-old) and old (36-month-old) zebrafish suggest that aging may be associated with an increased stochastic variability in locomotion. If these results are confirmed in a larger sample, extreme changes in locomotor activity might potentially represent an interesting biological marker of aging in zebrafish.

We have also assessed the circadian rhythm of melatonin production (levels in the pineal gland) and excretion (levels in the surrounding water). There are two major reasons to use melatonin levels as a prospective biological marker in zebrafish aging studies. In humans, melatonin secretion is known to be highest in children of 3–5 years of age, and to decline with age. Similar age dependency of melatonin levels was documented in other species as well. In our preliminary results, adult zebrafish also have significantly lower melatonin production, compared to zebrafish larvae. We are assessing whether

melatonin levels further decline in aged fish, by comparing melatonin production in young and old zebrafish. In addition, the assessment of the circadian rhythm of melatonin production is widely considered to be the most sensitive way to document individual phases of the circadian rhythm and its changes. In zebrafish, a temporal pattern of melatonin secretion can be determined by measuring melatonin levels in different tissues, including the pineal gland or brain. Importantly, the relatively high amounts of melatonin excreted into the medium (surrounding water) allow the melatonin rhythm to be repetitively sampled without disturbing the animal. We have successfully used both methods in our studies of zebrafish circadian physiology. Thus, we can longitudinally measure melatonin excretion in individual fish from young to old age (6-months to 42-months old), in order to establish whether the decline in the circadian amplitude and/or the degree of entrainment to environmental cues can serve as useful biomarkers of aging in zebrafish.

### Effects of Oxidative Stress and Genotoxic Stress on Zebrafish Aging and Senescence

Several lines of evidence suggest that genotoxic or oxidative stress promote the aging process (Campisi, 2005; Finkel and Holbrook, 2000; Lombard *et al.*, 2005). It is well known that the aging process diminishes the capability to adapt to environmental stresses. We hypothesized that genotoxic and oxidative stress leads to mutations and general declines in reproductive ability, ultimately producing the spectrum of age-related characteristics in zebrafish. Support for this idea comes from the fact that radiation increases genetic mutations and leads to premature aging in animals, such as mice and Medaka fish (*Oryzias latipes*) (Curtis, 1963; Egami and Eto, 1973; Ferbeyre and Lowe, 2002; Trifunovic *et al.*, 2004; Tyner *et al.*, 2002; Celeste *et al.*, 2002). Therefore, we have subjected embryos and adult zebrafish to genotoxic or oxidative stress and measured aging markers over the lifespan of the fish. To determine the effects of genotoxic and oxidative stresses on zebrafish aging, we have analyzed the effects of ionizing radiation (IR) and hydrogen peroxide (HP)/t-butyl hydroperoxide (tBH) on both embryos and adults using the markers already described. For quantitative aging markers we expect to see changes in activity that correlate with age; the rate of change should also correlate with the stress applied. In this manner, we can detect changes in aging in fish in a much shorter time intervals than would be required to measure mortality rates.

Typical features of cells derived from humans with premature aging syndromes include hypersensitivity to genotoxic stress and DNA damage such as IR (Cheng *et al.*, 2004; Naka *et al.*, 2004; Nove *et al.*, 1986; Smith and Paterson, 1980; Thacker, 1994). It has been reported that IR during embryogenesis shortens the lifespan in

Medaka fish (Egami and Eto, 1973). Although shortened lifespan was demonstrated, no other phenotypic markers of aging were reported at that time. An aging phenotype induced by IR was also observed in mice (Curtis, 1963). IR has been used to perform mutagenesis in zebrafish, whereas the biological effects of IR on the fish themselves have not been examined in detail. To address this question, we initially exposed zebrafish adults and embryos to several doses of IR and observed the short-term as well as long-term biological effects. We have already examined radiation doses of 5 to 40 Gy for embryos (6–24 hours post fertilization, hpf) and adult fish (3 to 30 months old). Overall cell-cycle profiles and the level of apoptotic cells were studied in whole embryos by flow cytometry at 48 hpf. When embryos were irradiated at 6 hpf with 20 Gy, we observed an aberrant increase in apoptotic cells at 48 hpf, followed by subsequently causing malformation of the entire embryos later on, with decreased survival by 5 days post fertilization (dpf). In contrast, the survival rate is greater than 90% at 5 dpf in 10 Gy-irradiated animals, without obvious malformation as well as abnormal apoptosis induction in early development. Moreover, no embryos survived for more than 10 days following 20 Gy of irradiation, which may be due to an inability to start eating. Intriguingly, these embryos exposed to IR induced SA- $\beta$ -gal activity by 6 dpf, indicating genotoxic stress-induced premature senescence, can be observed during the early development of zebrafish (Figure 28.2). We have raised group of embryos irradiated with 10 Gy at 6 hpf in groups at 6, 18, 30, and 42 months of ages. Each age group of embryos need to be raised to adulthood to examine the radiation effects late in life, as compared with irradiated control animals. These experiments are currently in progress.

It is noteworthy that 25–40 Gy of irradiation killed a large number of adult fish in a dose-dependent manner within 3 months after IR exposure, with possible acute lesions, as recently reported in the literature (Traver *et al.*, 2004). On the other hand, 20 Gy did not significantly affect survival rates even after 6 months postirradiation. Therefore, based on these pilot studies, we intend to examine the chronic effects of 20 Gy on adult fish during aging.

There are several lines of evidence that suggest that oxygen free radicals can contribute in an undetermined way to the aging process (Balaban *et al.*, 2005). Physiologically, superoxide is generated by the mitochondrial respiratory chain. The transformation of superoxide into HP and then, under certain conditions, into hydroxyl radicals appears to play an important role in various respiratory chain diseases (Taylor *et al.*, 2003). These may influence the aging process through mutagenesis of mitochondrial DNA (mtDNA) and an increased rate of shortening of telomeric DNA. Therefore, we are interested in the relationship between ROS production and telomere metabolism resulting from genotoxic and oxidative stress in zebrafish by measuring protein

oxidation, lipid peroxidation, and the extent of oxidized DNA. The effects of ROS on telomeres seem to be mediated through the susceptibility of the telomeric GGG sites to DNA damage. ROS actively attack these telomeric regions, predisposing to DNA strand breaks and damage leading to increased telomere shortening. Importantly, fibroblasts from donors of several premature aging syndromes, such as ataxia–telangiectasia (A–T) with mutations in the *ataxia telangiectasia mutated* (*ATM*) gene and Hutchinson–Gilford progeria syndrome (HGPS) with mutations in the *lamin AC* gene (*lmna*), have short telomeres (Allsopp *et al.*, 1992; Metcalfe *et al.*, 1996; Smilenov *et al.*, 1997), consistent with reduced cell division potential *in vitro*. Recently, it has been suggested that ATM functions in the cellular response to oxidative damage (Ito *et al.*, 2004; Reliene *et al.*, 2004; Rotman and Shiloh, 1997; Watters, 2003). Support for this hypothesis comes from observations that ATM-deficient cells are very sensitive to the toxic effects of hydrogen peroxide, nitric oxide and superoxide treatment, as well as to exposure of IR (Green *et al.*, 1997; Takao *et al.*, 2000; Ziv *et al.*, 2005). Moreover, ATM-deficient mice have elevated markers of oxidative stress, particularly in organs such as the cerebellum, which are consistently affected in individuals with A–T (Barlow *et al.*, 1999a). In addition, elevated levels of Cu/Zn superoxide dismutase exacerbate specific features of the murine ATM-deficient phenotype, including abnormalities in hematopoiesis and radiosensitivity (Peter *et al.*, 2001). Accordingly, we have employed both hydrogen peroxide (HP) and t-butyl hydroperoxide (tBH) as sources of oxidative stress to zebrafish to establish baseline information. Because tBH is poorly hydrolyzed by catalase, we can examine the effect of oxidative damage irrespective of variation and difference in catalase activities in organisms. We have exposed embryos to HP (100  $\mu$ M) or tBH (300  $\mu$ M) from 6 hpf for 3 days, and then raised them for 6, 18, 30, and 42 months, to observe late-onset aging phenotypes by oxidative stress early in life. These stress exposure studies examining multiple aging biomarkers already described above are currently underway.

### Significance of Telomere and Telomerase in Zebrafish Aging and Senescence

As mentioned above with respect to the telomeric aging markers, the end of chromosomes termed telomeres consists of repeat sequences of TTAGGG, which are conserved in all vertebrates, from fish to humans. Telomerase is essential for maintaining telomere length and chromosome stability in stem cells, germline cells, and cancer cells. The telomerase ribonucleoprotein complex consists of two essential components, a catalytic protein component and an RNA molecule, that provide the template for telomeric repeat synthesis. Telomere shortening and telomerase activation in human somatic cells

have been implicated in cell immortalization and cellular senescence. We previously reported that zebrafish have constitutive telomerase activity throughout life (Kishi, 2004; Kishi *et al.*, 2003). To study the role of telomerase and telomere in cellular immortalization and organismal mortality, we assayed telomerase activity and telomere length in primary zebrafish fibroblasts, in spontaneously immortalized cell clones, and in zebrafish embryos and adult tissues. In both primary fibroblasts and spontaneously immortalized clones, telomeres were maintained at stable lengths with telomerase activity during a certain number of passages. During early development *in vivo*, telomere length was also stably maintained and telomerase activity was prominently detectable at all stages, indicating that there is maternal carryover of telomerase before the embryonic gene expression. To determine if telomere shortening occurs with concomitant maintenance of telomerase activity throughout life *in vivo*, we monitored both telomerase and telomere in muscle tissues from zebrafish of many different ages. Telomere length was similar among different ages up to 24-months, whereas stochastic variation of telomere length appeared with more advancing age, as describe already. Differences in telomere lengths among several different tissues from organs in adult zebrafish have not been determined but need to be elucidated, while we know that zebrafish have constitutive telomerase activity in all of the examined tissues throughout their lives. These findings suggest that there is a unique regulation of zebrafish telomerase during development and aging *in vivo*. In contrast to human tissues, since all zebrafish tissues examined had constitutively active telomerase, there must be some differences in tissue homeostasis via the species-specific telomerase and telomere regulation *in situ* among vertebrates during evolution. In any case, the presence of telomerase in these tissues may reflect the ease of immortalization of primary fish cells relative to human cells in culture, indeterminate growth, and remarkable regenerative ability throughout life.

It should be noted that telomere shortening may limit the regenerative capacity of cells *in vivo* by inducing cellular senescence characterized by a permanent growth arrest of cells with critically short telomeres. To examine whether organ regeneration is impaired by telomerase inhibition and telomere shortening in zebrafish *in vivo*, we monitored caudal fin regeneration after amputation in telomerase-knockdown adult zebrafish. Our study has shown that telomere shortening is caused in regenerated fins and inhibits a subpopulation of cells with critically short telomeres from entering the cell cycle. This subpopulation of regenerated cells with impaired proliferative capacity exhibited induction of SA- $\beta$ -gal activity. These studies provide experimental evidence for the existence of an *in vivo* process of premature senescence induced by telomerase knockdown and critical telomere shortening that has functional impact on tissue regeneration in zebrafish.

## Potential Model Systems for Premature Aging Syndromes in Zebrafish

There are no perfect models for human aging, but zebrafish are vertebrates, and therefore are more closely related to human than commonly used invertebrate models. They are more likely to be similar to humans in many biological and biomedical traits such as genes, developmental processes, anatomy, physiology, behaviors, and diseases. This is an obvious advantage because invertebrate animals do not share these traits with humans. The invertebrates are more extensively used in identifications and comparisons of fundamental aging mechanisms, likely conserved in entire organisms rather than biologically complex traits in pathophysiology at the cellular and biochemical levels of organization where zebrafish share many features with humans.

Most premature aging models in vertebrates are derived from mutant and genetically manipulated mice. Zebrafish will probably become an alternative model for study of premature aging to recapitulate some of the human progeroid syndromes, such as ataxia telangiectasia (A-T), Fanconi anemia (FA), dyskeratosis congenita (DC), and Hutchinson-Gilford progeria syndrome (HGPS), because we have known that the molecular structures and functions of the genes and proteins responsible for these diseases are highly conserved between zebrafish and humans.

Functional aberrations of ATM protein cause a genetic disease A-T. We have recently demonstrated that zebrafish ATM (zATM) is functionally conserved at least in part because zebrafish embryos with disrupted ATM showed radiation hypersensitivity as observed in A-T patients and ATM-knockout mice (Imamura and Kishi, 2005). Since multiple aging/senescence-associated markers are readily monitored, it is worthwhile trying to identify premature senescence phenotypes in ATM-deficient zebrafish embryos as a representative model. Moreover, once a stable model system of zebrafish for human progeroid syndromes including A-T is established, it will become a powerful tool for characterizing molecular functions in the signal transduction pathway and using chemical genetic approaches for drug screening.

### ZEBRAFISH MODEL OF ATAXIA TELANGIECTASIA

A-T is an autosomal recessive disorder characterized by progressive cerebellar degeneration, immunodeficiency, cancer predisposition, gonadal atrophy, growth retardation, premature aging, and hypersensitivity to IR (Lavin and Shiloh, 1997; McKinnon, 2004). Cells from A-T patients generally have short telomeres and are also highly sensitive to IR (Kishi and Lu, 2002; Metcalfe, *et al.*, 1996; Meyn, 1995; Pandita *et al.*, 1995; Shiloh, 1995; Smilenov *et al.*, 1997). The molecular cloning of the gene responsible for A-T, *ATM*, has allowed a better understanding of both ATM function and the A-T pleiotropic phenotypes (Savitsky *et al.*, 1995a; Savitsky *et al.*, 1995b;

Taylor, 1998). The ATM gene encodes a nuclear phosphoprotein (Chen and Lee, 1996; Scott *et al.*, 1998), with serine/threonine protein kinase activity for which many downstream molecules, such as p53, Chk2, Mdm2, NBS1, BRCA1, 53BP1, SMC1, FANCD2, H2AX, Pin2/TRF1, and TRF2, which control cell cycle check points, DNA double-strand break or repair pathway, and telomere metabolism, have been identified as substrates (Kastan and Lim, 2000; Kishi and Lu, 2002; Kishi *et al.*, 2001; Pandita, 2002; Shiloh, 2003; Tanaka *et al.*, 2005). ATM functions as a potent protein kinase that is activated by DNA damage, such as IR, to phosphorylate target substrates. The identification of these potential substrates places ATM in a signal transduction pathway, through which it functions to regulate cell-cycle checkpoints that mediate the DNA damage response and telomere homeostasis (Verdun *et al.*, 2005).

As a model system, ATM-knockout mice have been created in several laboratories by specific germline inactivation of the ATM gene (Barlow *et al.*, 1996; Elson *et al.*, 1996; Herzog *et al.*, 1998; Xu *et al.*, 1996). Fibroblasts isolated from ATM-knockout mice display similar cellular phenotypes to those observed in cells from A-T patients (Elson *et al.*, 1996). Also, phenotypically, ATM-deficient mice display a variety of growth defects, meiotic defects, immunological abnormalities, radiation hypersensitivity and cancer predisposition, similar to those seen in A-T patients, confirming the most common pleiotropic roles of ATM. Early resistance to apoptosis in the developing central nervous system (CNS) of ATM-knockout mice has been observed after IR, especially in diverse regions of the CNS including the cerebellum (Herzog *et al.*, 1998), which is markedly affected in A-T. Interestingly, the neurological defects in A-T become apparent early in life, suggesting that they likewise originate during development (Herzog *et al.*, 1998). However, little is known about ATM expression and function during early development in lower vertebrates, such as zebrafish.

To develop a zebrafish A-T model, we first isolated zebrafish ATM (zATM) cDNA. We recently provided the zATM cDNA sequence as a predicted primary structure (Imamura and Kishi, 2005). At the amino acid level, the overall identity was 58% between zATM and hATM. The high degree of conservation between zATM and hATM especially within the kinase domains (81% identity) strongly suggests that the catalytic activity of these proteins is conserved. The decreasing levels of identity outside the catalytic domains may reflect potential differences in regulation of these proteins between species, though this remains to be elucidated. Importantly, a number of amino acids corresponding to sites that are found to be mutated in A-T patients are highly conserved between hATM and zATM (Gilad *et al.*, 1996). In actuality, Garg *et al.* recently reported that a kinase-inactive form of the zATM catalytic domain exhibited dominant-negative activity in human and zebrafish cell lines (Garg *et al.*, 2004). The presence of these conserved

amino acid sites further attests that corresponding zATM mutants from chemically point-mutated zebrafish genomes can probably be identified.

We also outlined zATM expression patterns during early development of zebrafish embryos. We observed that zATM mRNA was ubiquitously expressed during gastrulation and early neurulation. Differential tissue expression was evidenced by increased mRNA levels at later developmental stages in the eye, brain, and somites, with relatively weak expression in the trunk and tail. The profile of zATM expression is consistent with previous observations in *Xenopus* (Hensey *et al.*, 2000) and mice (Chen and Lee, 1996; Soares *et al.*, 1998), which also show increased expression of ATM in CNS, suggesting a common importance in early development of the nervous system among vertebrates.

By using antisense-morpholino oligonucleotides (MOs) to achieve *in vivo* elimination of zATM expression, we observed that loss of zATM leads to abnormal development and increased lethality in the early stages of development upon IR-induced DNA damage. Our results strongly support a model for structural and functional conservation of ATM's role in the DNA damage response among vertebrates from fish to human.

Our reported results also support the notion that ATM heterozygous phenotypes resemble those caused by protein dosage reduction, in genomic chromosomal instability and cancer susceptibility, which may all be due to diminished cell-cycle checkpoint function. We suspect that this hypothesis would be relevant not only to human A–T carriers, but also to heterozygous A–T zebrafish. However, there are conflicting data on the role of ATM heterozygosity in cancer risk (Concannon, 2002; FitzGerald *et al.*, 1997; Laposa *et al.*, 2004; Spring *et al.*, 2002). On the one hand, Barlow *et al.* argued that ATM heterozygous mice showed no evidence of increased acute radiation toxicity, although the mice intriguingly displayed premature greying and decreased survival at higher sublethal doses of irradiation (Barlow *et al.*, 1999b), suggesting progressive senescence with DNA damage.

ATM function is essential for telomere metabolism as well as DNA damage response. ATM is required for telomere maintenance and chromosome stability because inactivation of ATM causes telomere shortening (Metcalfe *et al.*, 1996; Pandita, 2002). Importantly, terminal deletions of *Drosophila* chromosomes can be stably protected from end-to-end fusion despite the absence of all telomere-associated sequences. The sequence-independent protection of these telomeres suggests that recognition of chromosome ends might contribute to the epigenetic protection of telomeres. In zebrafish as well as in mammals, ATM can be activated by DNA damage and could act through a telomerase-independent mechanism to regulate telomere length, protection, and homeostasis. It has been demonstrated that the *Drosophila* homolog of ATM is encoded by the telomere fusion (*tefu*) gene (Bi *et al.*, 2004; Oikemus *et al.*, 2004; Queiroz-Machado *et al.*,

2001; Silva *et al.*, 2004; Song *et al.*, 2004). In the absence of ATM, telomere fusions occur even though telomere-specific Het-A sequences are still present in *Drosophila*. Highly spontaneous apoptosis is observed in ATM-deficient tissues, indicating that telomere dysfunction induces apoptosis in *Drosophila*. Suppression of this apoptosis by p53 mutations suggests that loss of ATM activates ATM-independent but p53-dependent apoptosis through an alternative DNA damage-response mechanism. Furthermore, loss of ATM reduces the levels of heterochromatin protein 1 (HP1) at telomeres and suppresses telomere position effect, suggesting that recognition of chromosome ends by ATM prevents telomere fusion and apoptosis by recruiting chromatin-modifying complexes to telomeres (Oikemus *et al.*, 2004).

Epigenetic control apparently provides a mechanism not only for the position effect at telomeres on the transcription of nearby genes but also for the reversible silencing of telomerase expression that occurs as a natural consequence of cellular proliferation and differentiation. There exists significant overlap between indirect telomeric regulation pathways and cell-cycle checkpoint pathways, suggesting that these discrete genetic elements—namely, ATM, p53, p21, and TERT—synergistically cooperate to inhibit tumorigenesis and to govern aging. Mutations in these pathways have been known to contribute to cancer formation and senescence occurrence in mammals. Besides genetic control, the incorporation of epigenetic regulatory mechanisms provides another line of defense against these negative occurrences. Although the debate still continues, there is significant evidence to view the process of cellular senescence as an *in vitro* model for human aging. In addition to A–T, other disorders such as Werner's syndrome, dyskeratosis congenita, ulcerative colitis, and atherosclerosis have been linked to aberration of telomere homeostasis, and other aging-related lesions could be related to changes in cellular microenvironment resulting from the presence of senescent cells. Therefore, simply restoring direct telomerase activity as a putative therapeutic strategy rather than fine-tuning telomere homeostasis necessitates further study to elucidate the link between genetic and epigenetic modulations of telomerase in humans (Lai *et al.*, 2005). This is a relevant argument considering our observation of zebrafish telomerase and telomere regulation *in vivo* because as mentioned above, their telomere metabolism is not simply regulated by detectable telomerase activity, particularly very late in life with stochastic telomere shortening in the presence of constitutive telomerase activity.

In any case, once a stable line of zebrafish with ATM disruption or inactivation has been obtained, it will be possible to use the zebrafish A–T model to identify candidate therapeutic interventions. On a broad scope, zebrafish additionally couple the power of genetics and functional genomics for efficient mutant screening. As such, a zebrafish model system for A–T will be amenable to studies directed towards identifying functional modifier

genes that affect the ATM signaling pathway, as well as ultimately identifying small molecules that can ameliorate functional disorders caused by ATM mutations.

With respect to a future direction of this study, pilot screens of genetic mutants have been conducted using F2 heterozygous embryos under genotoxic or oxidative stress. Developmental defects and premature senescence phenotype have been confirmed in F3 homozygous recessive embryos. These results imply that a large-scale screen using a chemical mutagen will allow us to identify physiologically relevant players in the stress-associated signaling pathway as targets for the interventions in aging and age-associated diseases. However, positional cloning of the point mutations of a target gene will still be time consuming for identifying whether *ATM* or the other related gene is critical for readout of the zebrafish mutants.

Further studies of DNA damage response and ATM function in zebrafish may serve to unravel the regulation of genomic integrity and pleiotropic features, including progeroid manifestation, as the functional roles of ATM seem to have been commonly conserved or have commonly evolved among vertebrates from fish to humans.

#### ZEBRAFISH MODEL OF FANCONI ANEMIA

Regarding Fanconi anemia (FA), researchers have recently turned to zebrafish to help them unravel conserved signaling pathways (Liu *et al.*, 2003). Although FA is a relatively rare genetic disease, the genes involved in FA function as part of a large network of DNA damage response/repair, and the phenotypic features of FA consist of a combination of developmental and somatic abnormalities, including alterations reminiscent of premature aging (Giannelli, 1986; Tischkowitz and Hodgson, 2003; Willingale-Theune *et al.*, 1989). Liu and colleagues have recapitulated some of the clinical manifestations of human FA by knocking down the zebrafish *FANC-D2* gene, thereby providing a new model for probing the underlying causes of these phenotypes (Liu *et al.*, 2003). They have identified the zebrafish homolog of human FANCD2, which encodes a nuclear effector protein that is monoubiquitinated in response to DNA damage, targeting it to nuclear foci where it preserves chromosomal integrity. Fancd2-knockdown zebrafish embryos developed defects similar to those found in children with FA, including shortened body length, microcephaly, and microphthalmia, which are due to extensive cellular apoptosis. Intriguingly, developmental defects and increased apoptosis in Fancd2-knockdown zebrafish are corrected by injection of human Fancd2 or zebrafish bcl-2 mRNA, or by knockdown of p53, indicating that in the absence of Fancd2, developing tissues spontaneously undergo p53-dependent apoptosis. Thus, Fancd2 is essential during embryogenesis to prevent inappropriate apoptosis in neural cells and other tissues undergoing high levels of proliferative expansion,

implicating this mechanism in the congenital abnormalities observed in human infants with FA.

Although characterizations of premature senescence phenotypes in the zebrafish FA model are still needed, taking into account molecular interaction and signaling crosstalk between Fancd2 and ATM (Taniguchi *et al.*, 2002), FA and A-T will be one of the most prominent genetic diseases for the zebrafish models of human “premature aging syndromes.”

#### TARGETED KNOCKDOWN OF ZEBRAFISH TELOMERASE TO RECAPITULATE DYSKERATOSIS CONGENITA

Dyskeratosis congenita (DC) is a severe, inherited, bone marrow failure syndrome, with associated cutaneous and noncutaneous abnormalities. DC patients also show signs of premature aging and have an increased occurrence of cancer. Accelerated telomeric erosion is a molecular hallmark of DC (Mitchell *et al.*, 1999; Ruggero *et al.*, 2003). DC can originate through (i) mutations in *DKC1*, which result in X-linked recessive DC; (ii) mutations in the RNA component of telomerase (*TERC*), which result in autosomal dominant DC; and (iii) mutations in other, currently uncharacterized, genes, which result in autosomal recessive DC. As *DKC1* encodes dyskerin, a protein component of small nucleolar ribonucleoprotein (snoRNP) particles, which are important in ribosomal RNA processing, DC was initially described as a disorder of defective ribosomal biogenesis. Subsequently, dyskerin and *TERC* were shown to closely associate with each other in the telomerase complex, and DC has since come to be regarded as a telomerase deficiency disorder characterized by shorter telomeres. These findings demonstrate the importance of telomerase in humans and highlight how its deficiency (through *DKC1* and *TERC* mutations) results in multiple abnormalities including premature aging, bone marrow failure and cancer. Identification of the gene(s) involved in autosomal recessive DC will help to define the pathophysiology of DC further, as well as expand our insights into telomere function, aging and cancer. Through the challenge with targeted knockdown of zebrafish telomerase, it is likely that a novel vertebrate model system can be developed for studies of DC. In this respect, studies of evolutionary and comparative biology in telomerase and telomere metabolism are important because zebrafish have a constitutive telomerase activity that is apparently different from the human telomerase regulation. There is first and foremost a need to compare the importance of telomerase in zebrafish and in humans, by trying to recapitulate DC phenotypes in a zebrafish model.

#### Prospective Basic Studies of Aging and Senescence in Zebrafish

The potential maximum lifespan of zebrafish is more than five years (Gerhard *et al.*, 2002), though the differences

among strains as well as between genders need to be clarified. Thus, while searching for late age-onset disease models and long-lived mutants is extremely important and worthwhile trying, it will be tough and tedious work because of current paucity of baseline information on zebrafish aging. On the other hand, we have been planning to isolate zebrafish mutants like progeroid syndromes in humans as described above. Genetic manipulations of several genes related to pathophysiological aging symptoms into zebrafish embryos have the potential to unveil some important aspects of the molecular mechanisms of senescence through the use of easier traceable developmental stages. Without performing lengthy lifespan analyses and long-term studies of age-associated alterations and lesions in the animal, it may be possible to pick up predictable late-age onset phenotypes in early developmental stages. Although an “antagonistic pleiotropy” theory of aging is needed concerning phenomena early- versus late-in-life, antagonistically pleiotropic genes and processes that benefit organisms turn out to be detrimental immediately after stress rather than later in life. Based on the fact that senescence induced by stress exposure is recognized as “stress-induced premature senescence” at cellular levels in the cell culture system (Toussaint *et al.*, 2000), probably it is amenable at organismal levels in animal model systems. During mouse embryogenesis, the absence of the BRCA1 full-length isoform causes embryonic senescence that is carried out by p53 (Cao *et al.*, 2003). Usually, p53, the clearest example of an antagonistically pleiotropic gene product, has early-life benefit suppressing cancer development, but has late-life detrimental cost compromising tissue functions with age. However, once BRCA1 is disrupted, p53 turns out to be harmful to embryonic survival by inducing senescence during development. Thus, DNA-damaging stress as well as BRCA1 deficiency triggers p53-dependent stress-induced premature senescence in cells and in organisms. Moreover, embryonic senescence in p63-deficient mice as well as accelerated aging phenotypes in conditional p63-disrupted adult mice have been most recently reported in the literature (Keyes *et al.*, 2005). These lines of recent evidence strongly support the notion that it is possible to assess biological aging phenomena in model organisms without having to perform more time-consuming chronological aging studies.

Importantly, nematodes and fruitflies have no cancer or other abnormal growth during aging, in contrast to their common occurrence in vertebrates from fish to humans with advancing age. Having relevance to these phenomena with regard to cell growth characteristics, nematodes with a constant number of cells lack somatic cell replacement, whereas insects such as the fruitfly have limited but detectable cell proliferation in some adult tissues. On the other hand, mammalian tissues contain different proportions of the cells that are continuously replaced in adults but are of great importance to outcomes of organismal aging through replicative senescence

of critical cells. However, humans possess only a limited capacity to restore their missing or injured body parts. Therefore, stimulating regenerative capability may circumvent some tissue deterioration in aging humans. Adult zebrafish have been shown to possess a remarkable capacity for regeneration. Zebrafish regenerate almost all tissues and organs such as fins, spinal cord, retina, and heart. By dissecting molecular mechanisms of zebrafish regeneration, it may be possible to illuminate novel factors that can stimulate a regenerative response in higher vertebrates. Thus, research of regeneration in zebrafish during the aging process will contribute to aging medicine as well as to regenerative medicine in humans.

With respect to amenability of genetic manipulations through forward genetic and reverse genetic approaches, robust zebrafish genetics will obviously hold the key to success. However, zebrafish have a relatively long generation time and fairly long lifespan compared with those of nematodes and flies, which slows down experiments that require breeding and analyzing offspring as well as longitudinal aging studies. Nevertheless, zebrafish are one of the most genetically pliable/tractable (visually traceable) and biologically attractive animal models. Presumably, specific gene expression and its function and a role of tissue-specific stem and progenitor cells in aging will be actively and progressively investigated in zebrafish, closely connected with regeneration studies.

#### POSSIBLE INVOLVEMENT OF TUMOR SUPPRESSOR GENE PRODUCTS, P53 AND pRB, IN ZEBRAFISH AGING

The tumor suppressor proteins p53 and pRB regulate cellular replicative senescence and organismal aging. Tumor suppressor mechanisms may represent evolutionary antagonistic pleiotropy because tumor suppressor genes benefit organisms early in life due to suppression of cancer. However, these genes may become harmful later during the aging process, compromising tissue functions. Importantly, telomere attrition in cells induces replicative senescence accompanied by activation of the p53 and pRB pathways. In zebrafish, the p53 pathway is known to exist with relevant functional conservation (Cheng *et al.*, 1997; Langheinrich *et al.*, 2002), but zebrafish pRB pathway has not been reported. Recent studies demonstrated that zebrafish p53 is involved in the tumor suppressor mechanism *in vivo* (Berghmans *et al.*, 2005; Patton *et al.*, 2005).

There are diverse stimuli for inducing cellular senescence. Both extrinsic and intrinsic factors are involved in these stimuli. Particularly, within intrinsic factors, tumor suppressors play an important role in the initiation, establishment, and maintenance of the cellular senescence phenotype. For example, the fundamental signaling pathways are governed by p53 and pRB in relation to telomeric homeostasis (Jacobs and de Lange, 2004; Zhang *et al.*, 2005). The downstream targets of these two tumor suppressors are the cyclin-dependent kinase inhibitors

(CDKs) p21 and p16<sup>INK4a</sup>, respectively. p21 and p16<sup>INK4a</sup> as well as other CDKs inhibit the cell-cycle progression, and in some cases these CDKs also induce a cellular senescence phenotype. Moreover, ARF, another upstream tumor suppressor which regulates p53, is a crucial mediator of senescence in mammalian cells, whereas it is likely that zebrafish may have an alternative or different upstream pathway, given the insight that teleost fish apparently lack an *ARF* gene (Gilley and Fried, 2001; Langenau *et al.*, 2005), as discussed later.

p53 is a key player in DNA damage response and cell-cycle checkpoints as well as in mammalian cancer development. Activation of the transcriptional functions of p53 through DNA damage or other stresses can result in cell-cycle arrest, apoptosis, or senescence depending on the cellular environment and the upstream signal. It is well established that loss of p53 function abrogates replicative senescence in mammalian cells. Importantly, critically short and/or dysfunctional telomeres, resembling damaged DNA, trigger the p53-mediated DNA damage response (Campisi, 2005).

To characterize p53 signaling in zebrafish, Langheinrich *et al.* (2002) have studied the roles of p53 and its main negative regulator, Mdm2, in zebrafish by generating early embryonic knockdowns and examining the involvement of p53 in DNA damage-induced apoptosis. p53-deficient embryos, induced by injection of MOs, were morphologically indistinguishable from control embryos, when unperturbed, whereas Mdm2 knockdown embryos were severely apoptotic and arrested very early in development. Double knockdowns showed that p53 deficiency rescued Mdm2-deficient embryos completely, as seen earlier in mice (Jones *et al.*, 1995; Montes de Oca Luna *et al.*, 1995). p53 deficiency also markedly decreased DNA damage-induced apoptosis in zebrafish embryos, elicited by ultraviolet irradiation or the anticancer drug compound camptothecin. Zebrafish p21 appeared to be a downstream target of p53, as revealed by relative p21 mRNA levels determined by real-time RT-PCR analysis. As far as can be predicted on the basis of results with zebrafish p53 knockdown by MOs, zebrafish embryos are presumably amenable for studying p53-mediated DNA damage response and cell-cycle regulation at the downstream pathways.

Most recently, stable p53-deficient zebrafish mutant lines were isolated by using target-selected mutagenesis strategy, from 2,679 individual *N*-ethyl-*N*-nitrosourea (ENU)-mutagenized F1 male fish (Berghmans *et al.*, 2005). Homozygote p53<sup>M214K</sup> mutant fish were characterized for DNA damage (IR) response, and the mutants appeared resistant to apoptosis induction in response to irradiation. Unlike wild-type control fish embryos, irradiated p53 mutants were resistant to apoptosis induction and failed to up-regulate p21 with aberrant cell-cycle checkpoint. More importantly, within 1 year of age, more than one quarter of the mutant fish developed malignant peripheral nerve sheath tumors. With the use of

mutant fish as a unique platform, further functional modifier gene screens and small molecule screens will be readily available in the future. Although aging and senescence phenotypes in p53 mutant fish have not been addressed in the literature, our ongoing studies of aging in these fish may be able to elucidate functional roles of zebrafish p53 in DNA damage- and telomere-associated senescence response.

In addition to p53, zebrafish p53 family members, p63 and p73, have been identified and their cDNAs cloned (Bakkers *et al.*, 2002; Lee and Kimelman, 2002; Rentzsch *et al.*, 2003; Satoh *et al.*, 2004). Furthermore, they appear to be more highly conserved than p53 among vertebrates. Functional analysis of zebrafish p63 in embryonic senescence might be interesting because a recent report showed that p63-deficient mouse embryos express high levels of SA- $\beta$ -gal activity (Keyes *et al.*, 2005).

In terms of the upstream pathways that signal through p53, the functional links involving phosphorylation of p53 by kinases such as ATM/ATR/DNA-PK have not been fully elucidated in zebrafish. Nevertheless, zebrafish represent a promising model organism for future compound-based and genetic screens. Zebrafish-based efforts will also help to identify and characterize new drugs and new targets to ameliorate human genome instability diseases including cancer. However, to realize this goal, the comparative genetic pathways in vertebrates from fish to humans need to be elaborated.

A wide variety of genotoxic stresses, including IR and ultraviolet (UV) radiation, lead to p53 activation (Sancar *et al.*, 2004). As part of this activation, posttranslational modifications of p53, phosphorylation and ubiquitination have paramount impacts on protein stability and functional regulation (Wahl and Carr, 2001). While several pathways can lead to p53 stabilization, one of the most prominent key regulators is Mdm2, which functions as a ring-finger ubiquitin ligase, although Mdm2 may have other additional mechanisms of p53 inactivation than degradation through ubiquitination. Importantly, Mdm2-mediated ubiquitination of p53 is controlled by ATM-dependent mechanisms that regulate the ability of Mdm2 to bind p53 (Maya *et al.*, 2001). ATM-dependent phosphorylation of human Mdm2 on Ser395 is one of the most rapid responses to IR, which presumably compromises p53 degradation. However, in zebrafish Mdm2, the serine residue corresponding to Ser395 in human is not present (Thisse *et al.*, 2000), suggesting that relatively stable zebrafish p53 may not be necessary to be compromised by phosphorylated Mdm2 for degradation, or that it may be constitutively degraded by unphosphorylated Mdm2 more rapidly than in mammals.

ATM is a main Ser/Thr protein kinase for phosphorylation of p53, especially in response to IR in mammals (Figure 28.5).

In humans, ATM, as well as ATR and DNA-PK, directly phosphorylate p53 on Ser15, which is within the N-terminal transactivation domain (Kim *et al.*, 1999;

## 28. Zebrafish as Aging Models

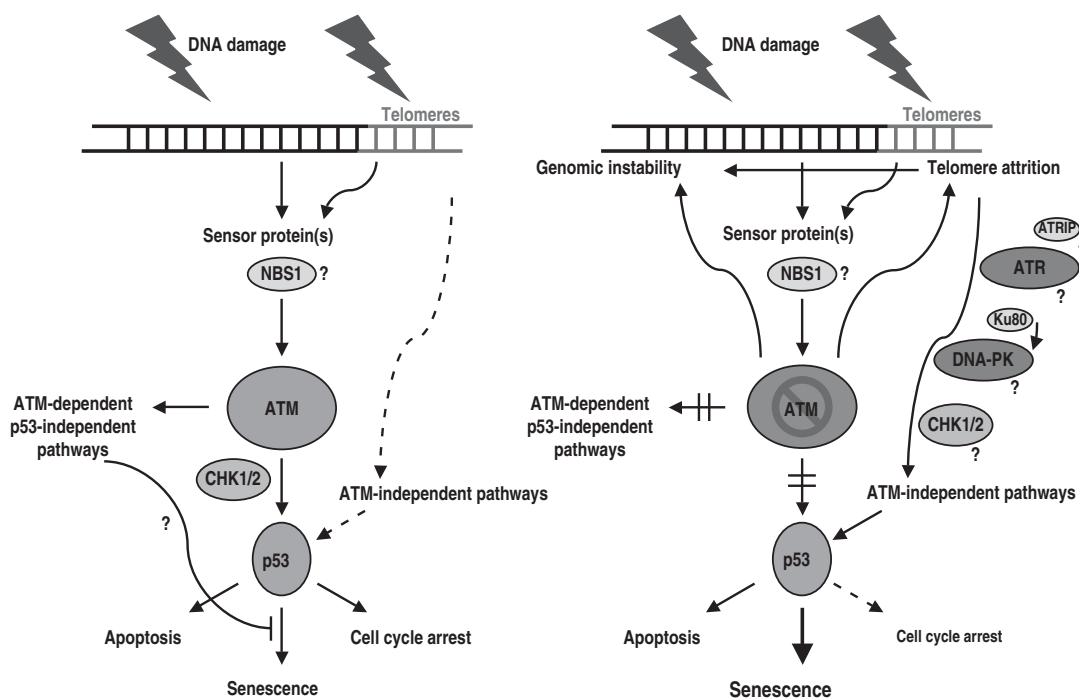

**Figure 28.5.** Sequence comparison of the N-terminal amino acids corresponding to 1–37 in human p53 between human, mouse, *Xenopus*, and zebrafish. The N-terminal phosphorylation sites, S6, S15, S20, S33, and S37, of p53 are compared among the species. Only S15 in human p53, which corresponds to S6 in zebrafish, is a well-conserved site.

Lavin and Khanna, 1999; Shiloh, 2001; Shiloh, 2003). This site is putatively conserved, but in zebrafish p53 the position is Ser6 followed by S(6)QE (Cheng *et al.*, 1997). In humans, Ser15 phosphorylation interferes with Mdm2 binding to p53 (Shieh *et al.*, 1997). Moreover, DNA damage induced by IR also results in ATM-dependent activation of Chk2 (Chehab *et al.*, 2000; Hirao *et al.*, 2000; Matsuoka *et al.*, 2000; Shieh *et al.*, 2000). Activated Chk2 phosphorylates Ser20 of human p53, which is also within the Mdm2-binding region and the phosphorylation of Ser 20, reduces the binding of Mdm2 (Chehab *et al.*, 1999; Unger *et al.*, 1999). However, zebrafish p53 does not contain a phosphorylation site equivalent to Ser20. Phosphorylation sites equivalent to Ser33 and Ser37 of human p53 are likewise lacking in zebrafish p53. Intriguingly, it has been shown that a Ser20 to Ala mutation generates a less stable form of human p53 (Chehab *et al.*, 1999; Unger *et al.*, 1999), whereas wild-type zebrafish p53 contains Ala10 followed by FA(10)E at the site equivalent to FS(20)D in human (Cheng *et al.*, 1997) (Figure 28.5), suggesting permanent instability or basic lack of function through the Mdm2 pathway. More importantly, the zebrafish genome contains homologues of those checkpoint regulators and kinases, but thus far, to our knowledge, apparently lacks an ARF homologue. ARF is a small protein generated from the CDKN4 locus, and the same region also encodes the CDK4 inhibitor p16. ARF is a tumor suppressor and an important inhibitor of the ubiquitin ligase Mdm2, thus antagonizing p53 degradation. In addition, nucleolar relocalization of Mdm2 by ARF connotes a novel mechanism for preventing p53 turnover and provides a framework for understanding how stress signals cooperate to regulate p53 function. In mammals, ARF also connects pathways regulated by the pRB and p53. ARF inactivation reduces p53-dependent apoptosis induced by oncogenic signals. If it is also in zebrafish, the consequences may reveal that zebrafish don't utilize the protein turnover machinery to regulate p53 activity through the ARF-Mdm2-p53 pathway. Furthermore, since zebrafish p53 lacks the potentially targeted Chk1 and Chk2 phosphorylation sites Ser33 and Ser37, the Chk1/Chk2-p53 pathway might differentially function through an alternative mechanism in zebrafish. This is worthwhile investigating from the comparatively biological and evolutionary point of view among vertebrates because p53, as a critical tumor suppressor, is among

the most commonly mutated genes in human cancers (Vogelstein, 1990; Vogelstein and Kinzler, 1992; Vogelstein and Kinzler, 2004; Vogelstein *et al.*, 2000). In humans, the Chk2 kinase is also a known tumor suppressor, and a wide variety of cancer-associated mutations and defects have been identified (Bartek and Lukas, 2003; Motoyama and Naka, 2004). Importantly, consistent with the tumor suppressor function of Chk2, recent studies demonstrated that Chk2 activation, caused by telomere attrition, triggers replicative senescence in human cells (Gire, 2004; Gire *et al.*, 2004; Oh *et al.*, 2003). In contrast, cancer-related defects in Chk1 are rare, and so far seem limited to some gastrointestinal carcinomas (Bartek and Lukas, 2003). Therefore, the zebrafish Chk1/Chk2 pathways need required to be characterized in terms of their role in cancer biology as well as for DNA damage and senescence response in zebrafish.

Collectively, p53 is a crucial molecule for regulation of the responses to DNA damage, cell-cycle arrest, apoptosis, and senescence. Critically short or dysfunctional telomeres trigger a p53-dependent DNA damage response possibly through ATM activation (Bakkenist *et al.*, 2004; d'Adda di Fagagna *et al.*, 2003; Herbig *et al.*, 2004). Moreover, telomere dysfunction enhances sensitivity to IR in mice. Loss of p53 function delays or abrogates the replicative senescence of human cells irrespective of the ATM states. However, both p53-independent ATM pathways and ATM-independent p53 pathways must be involved in the diversified regulations of senescence response (Figure 28.6).

Importantly, p53-dependent senescent growth arrest is reversible at least in some human cells, whereas the other senescent arrest, which is induced by the p16/pRB pathway, is irreversible even with subsequent inactivation of p53, p16, or pRB (Beausejour *et al.*, 2003; Dirac and Bernards, 2003). So far, the involvement of the p53/p21 pathway in cell-cycle regulation and apoptosis has been demonstrated in several experiments using zebrafish, and we have already confirmed p53-dependent premature senescence induction during development and adult fin regeneration of zebrafish. The importance of the pRB pathway in zebrafish aging and senescence response remains to be characterized, and further elucidation of the signaling pathways and their network may reveal evolutionary conservation of mechanisms among vertebrates.

**Figure 28.6.** Possible schematic presentation of a model for DNA damage-mediated senescence response in the ATM-p53 axis. In the presence or absence of ATM, a different balance of ATM-dependent and ATM-independent senescence response probably occurs through p53. ATM can maintain genome and telomere integrity. In the absence of ATM, genomic instability and telomere attrition are aberrantly induced by DNA damage and p53 is still activated through an ATM-independent pathway. This ATM-independent p53 activation leads to much more prominent induction of senescence, in other words accelerated premature senescence, in an A-T patient. The ATM-independent p53-dependent pathway may involve ATR, DNA-PK, and Chk1/2. ATRIP and Ku80 seem to function as sensor proteins of DNA damage to ATR and DNA-PK, respectively (Falck *et al.*, 2005). NBS1 could be another sensor protein responsible for ATM (Falck *et al.*, 2005).

### ZEBRAFISH FOR A MODEL OF NUTRITION-RELATED AND AGE-DEPENDENT CHRONIC DISEASES WITH OXIDATIVE STRESS

Oxidants are generated under various physiological conditions that include mitochondrial electron transport, peroxisomal fatty acid metabolism, phagocytosis by macrophages, and bone resorption by osteoclasts. However, increased oxidative stress has been correlated to a varying extents with common age-related diseases, such as adult-onset diabetes mellitus, atherosclerosis, some types of cancer, and some forms of neurodegeneration including cerebellar ischemia.

The increasing prevalence of obesity and other nutrition-related chronic diseases, which usually accompany aging, has prompted considerable efforts to understand their pathogenesis and treatment. One experimental approach is to overexpress, inactivate, or manipulate specific genes that regulate energy metabolism and fat storage. Many such techniques are fully amenable and have been established as routine tools in zebrafish, as well as in *Drosophila* and *C. elegans*. In the future, these elegant models will be complementarily helpful in dissecting endocrine problems and metabolic pathways, associated with aging and senescence. Particularly, once zebrafish counterparts of essential signaling molecules, such as Sir2 and FoxOs, involved in regulation of energy

metabolism are available, development of model systems appear to be within of our current technologies and fat storage, are obtained, development of new vertebrate aging models appears to be within the scope of our current technologies.

### AGING IMMUNITY IMPORTANCE OF INNATE IMMUNITY IN ZEBRAFISH

Finch and Crimmins proposed that the reduction in lifetime exposure to infectious diseases and other sources of inflammation has made an important contribution to the historical decline in old-age mortality (Finch and Crimmins, 2004). This will likely also be true in zebrafish, because one of the most critical problems in their husbandry late in life derives from multiple microbial infections. Resistance to microbial infectious diseases obviously declines with age in adult zebrafish. The cellular components involved in defense against pathogens/microbial agents are beyond the scope of this article. However, it should be noted that zebrafish have an almost complete set of the Toll-like receptors (TLRs) (Jault *et al.*, 2004; Meijer *et al.*, 2004). The TLR family is an evolutionarily conserved component of the innate immune system that responds to specific pathogen-associated molecular patterns (Takeda *et al.*, 2003), and important lines of evidence indicate that the innate

immune system in zebrafish can be the primary layer of defense against microbial pathogens. Rag-1-deficient zebrafish that lack adaptive immunity have normal life expectancy in regular fish water, which notoriously contains multiple pathogens (Wienholds *et al.*, 2002). Importantly, adult zebrafish have a strikingly high expression of TLRs in the skin (Jault *et al.*, 2004), which may be highly relevant to their primary mechanism of defense against pathogens by the innate immune system. Aged adult zebrafish are naturally more susceptible to tuberculosis caused by *Mycobacterium marinum*, where TLRs and innate immunity play prominent roles of defense. This implies that age-dependent functional declines of the innate immune system including the TLRs expression levels are crucial for infectious diseases followed by inflammations late in life of zebrafish. However, zebrafish aging-associated immunity has not been investigated so far in detail. Due to declines of both innate and adaptive immune functions with age, leading to increased susceptibility to infectious diseases and cancer in vertebrate animals, importance of the immune system in aging zebrafish needs to be recognized and immunological senescence should adequately be studied with respect to various age-dependent diseases.

### Zebrafish Aging and Senescence Research for Drug Discovery and Geriatric Medicine

Zebrafish have become a widely used model organism because of their fecundity, their morphological and physiological similarity to mammals, the existence of many genomic tools, and the ease with which large-scale and phenotype-based screens can be performed. Because of these attributes, zebrafish may provide opportunities to accelerate the process of drug discovery (Goldsmith, 2004; Yeh and Crews, 2003; Zon and Peterson, 2005). By combining the scale and throughput of *in vitro* screens with the physiological complexity of animal studies, the zebrafish system promises to contribute to several aspects of the drug development process, including identification of the molecular target, recapitulation of the disease, lead compound discovery and toxicology testing (Hill *et al.*, 2005; Parg, 2005). At present, assessment of toxicity often occurs independently from efforts to discover lead compounds and improve their potency. High-throughput zebrafish toxicity assays combine many of the advantages of *in vitro* and *in vivo* toxicity models, making it possible to assess toxicity much earlier in the drug development process.

Moreover, large-scale genetic and MO-based screens allow unbiased discovery of genes that cause a desired phenotype (Dodd *et al.*, 2004; Rubinstein, 2003). Zebrafish screens for genetic or epigenetic perturbations that suppress a disease phenotype can be used to discover novel therapeutic targets. These attributes might also enhance the efficiency of several steps in the drug development process for aging and age-associated diseases.

Historically, numerous drugs have been discovered by observing phenotypic changes in whole animals exposed to small molecules, but these discoveries have often been serendipitous and are usually arduous. However, if we can utilize zebrafish through the power of functional genomics and phenomics, the genome-wide study of gene dispensability by quantitative analysis of phenotypes can be performed as a large-scale and systematic screen in zebrafish to identify small molecules that can suppress multiple disease phenotypes (Love *et al.*, 2004; MacRae and Peterson, 2003; Pichler *et al.*, 2003). This apparently has the potential to contribute so enormously in the search for drugs against complex diseases that zebrafish aging can truly become a paradigm in gerontology diseases and geriatric medicine when we adopt zebrafish aging as a paradigm of gerontology.

Many genetic or environmental manipulations that alter lifespan in model organisms also alter survival following acute stresses such as oxidative damage, genotoxic stress, and thermal stress. Thus, in flies and worms, mutations that enhance lifespan also increase resistance to oxidative stress. This is also true for most of the small number of mutations that increase lifespan in mice. In lower organisms, this coupling of stress responses and aging mechanisms has proved a useful tool in identifying new genes that affect the aging process without the need for performing lengthy lifespan analyses. Therefore, it is quite possible that this approach may also be applied to the identification of zebrafish aging mutants and pharmacological agents that slow the aging process or extend lifespan through enhanced resistance to oxygen radicals or other stresses. To facilitate high-throughput mutant and drug screens in zebrafish aging, we have developed SA- $\beta$ -gal-based colorimetric and fluorometric quantitation assays to monitor a marker of premature senescence in zebrafish embryos. We have first verified that the signal intensity of SA- $\beta$ -gal is dramatically increased both in aging fish and in embryos exposed to stress. We are further validating the assay by demonstrating that known signaling molecules and genetic mutations, which would be expected to modulate oxidative stress response or telomere metabolism, are linked to SA- $\beta$ -gal induction in embryos. Screening for potential aging mutants in zebrafish is also in progress. In these screens, chemical/radiation-induced oxidative/genotoxic stress is used to identify mutant fish, which either enhance or suppress activity of the SA- $\beta$ -gal depending on the sensitizing regimen. We have already isolated several candidate mutants that show enhanced response to stress. Our novel approach of mutant analysis in zebrafish has the potential to accelerate the identification of new aging mutants and to contribute to future drug discovery for pharmaceutical interventions in geriatric medicine.

Finally, although this chapter has not dealt with aging histopathology in zebrafish, traditional histopathological analysis is important for assessing aging phenotypes in animals versus humans. We previously reported some

age-dependent histological and/or pathologic alterations in a few selected organs of zebrafish at fairly advanced age (Kishi *et al.*, 2003). However, we still need to extensively examine aging tissues and organs. We also need to investigate the possible relationship of age-related functional impairments of organs as a cause of exponentially increasing mortality in aging zebrafish.

## Conclusions

The genetics-based study of zebrafish aging will be an invaluable approach in determining many common aspects of age-associated diseases among vertebrates. While the progressive discoveries of fundamentally common mechanisms of aging in *C. elegans* and *Drosophila*, as well as in mice, are of great importance in the field, more extensive groundwork will be required for in-depth studies of complex issues in aging, using a powerful vertebrate model organism. Zebrafish have been extensively exploited for developmental studies, and currently a number of research scientists are aiming to utilize this animal as an alternative model for multiple human diseases. However, only minimal data are available regarding late adult-onset and age-related alterations or aging lesions in any of the commonly used wild-type and mutant lines of zebrafish. Therefore, to fully utilize the potential of zebrafish as an animal model for understanding human aging and diseases, we need to advance our knowledge of zebrafish diseases and pathology with age. The future use of this model organism in biomedical science will contribute to our ability to intervene in human aging and will be relevant to the discovery of small molecules as drugs to ameliorate human disease states.

## ACKNOWLEDGMENTS

I greatly acknowledge the contributions of Junzo Uchiyama, Irina Zhdanova, and Shintaro Imamura to this work. I am grateful to Peter Bayliss and Eriko Koshimizu for their contributions in our laboratory. I am also very grateful to Thomas Roberts for his support and continued encouragement. I really thank Andre Rosowsky for his critical reading of this manuscript. Finally, I thank Junko Kishi, Shunsuke Kishi, and Shota Kishi for their helpful preparation of this manuscript. This work is funded by research grants from A-T Children's Project, the Ellison Medical Foundation, and NIA/NIH to S.K.

# Telomeres in Aging: Birds

Susan E. Swanberg and Mary E. Delany

*This chapter describes the use of avian species (the domestic chicken *Gallus domesticus* in particular) as model organisms for research in telomere biology and aging. Presented here are key concepts of avian telomere biology including characteristics of the model: the karyotype, telomere arrays, telomere shortening as a measure of the senescence phenotype or organismal aging, and telomerase activity in avian systems, including chicken embryonic stem cells, chicken embryo fibroblasts, the gastrula embryo and DT40 cells. Key methods used to measure telomere shortening and telomerase activity, and to conduct expression profiling of selected genes involved in telomere length maintenance are noted, as are methods for conducting gain- and loss-of-function studies in the chicken embryo. Tables containing references on general topics related to avian telomere biology and poultry husbandry as well as specific information regarding chicken orthologs of genes implicated in telomere maintenance pathways are provided. Internet resources for investigators of avian telomere biology are listed.*

## Introduction: The Chicken as a Model Organism

The versatility and utility of the domestic chicken as a developmental model was recently celebrated in a special issue of the journal *Developmental Dynamics* [(2004) 229, 413–712]. The chicken is one of the primary models for vertebrate developmental biology and a model organism for the study of virology, immunology, cancer and gene regulation (Tickle, 2004; Antin and Konieczka, 2005). With a 6.6X draft sequence of its genome completed, the chicken is poised to become even more valuable in traditional fields of study and also in aging research.

The earliest recorded descriptions of the chicken as a model for biological processes are attributed to Hippocrates and Aristotle, who wrote about embryonic development in fertilized chicken eggs. Twentieth-century embryologists authored numerous treatises describing, diagramming, and providing detailed photographs of the chicken during development (Hamburger and Hamilton, 1951; Romanoff, 1960; Eyal-Giladi and Kochev, 1976), which promoted use of the chicken embryo as a model for study of mechanisms including morphogenesis; neurogenesis; somatogenesis; limb, limb-digit and

craniofacial development; left–right symmetry; axis development and others. The extensive use of the chicken as a model for early vertebrate development and its role in biomedical research has of necessity produced a detailed and comprehensive body of knowledge about basic chicken biology (Scanes *et al.*, 2004; Stern, 2005). Add to all of this the accessibility of the chicken embryo, the relative economy of breeding and maintaining chickens and the ease of manipulation of embryonic and adult tissues and the chicken becomes an obvious choice as a model for the study of organismal and cellular senescence.

## Aging and Replicative Senescence

Cellular or replicative senescence (*in vitro*) is often utilized as a model for the aging process (*in vivo*) due to the hypothesis that cellular aging recapitulates organismal aging (Wadhwa *et al.*, 2005). The central dogma of replicative senescence holds that cultures of vertebrate fibroblasts have a limited capacity for proliferation. After a finite number of cell divisions, proliferation slows and culture arrest ensues. The barrier represented by culture arrest, termed the Hayflick Limit, is accompanied by a number of morphological changes including increased cell size, increased nuclear and nucleolar sizes, increased vacuolation of the cytoplasm and endoplasmic reticulum, expression of senescence-associated markers such as beta-galactosidase, and other changes in morphology and gene expression (Cristafalo *et al.*, 2004 and references therein).

A genomic alteration associated with cellular or replicative senescence in a variety of organisms, including the chicken, is the shortening of telomeres (Prowse and Greider, 1995; Taylor and Delany, 2000; Swanberg and Delany, 2003). Shortened telomeres induce a DNA damage response, signaling cell cycle arrest. If the damage cannot be repaired, a checkpoint response results in further arrest or apoptosis. An alternative or complementary model for telomere-induced replicative senescence is loss of the protective effect of accessory proteins, such as TRF2, at the telomeres (Karlseder *et al.*, 2002). Reactivation of telomerase or induction of the ALT (alternate lengthening of telomeres) pathway may provide protection against apoptosis or senescence and

facilitate transformation and immortalization by stabilizing telomeres (Swanberg and Delany, 2003 and references therein).

The prevailing explanation for telomere shortening, the end-replication problem, is based on the inability of DNA polymerase to replicate the ends of a linear chromosome, resulting in the incomplete replication of the 5' end of the daughter strand. Telomerase is able to offset telomere shortening by adding telomere repeats to the parent strand which generates a longer telomere in the daughter strand. The telomerase holoenzyme is composed of two elements, telomerase rRNA, TR, which contains the template for addition of telomeric repeats (Greider and Blackburn, 1989) and telomerase reverse transcriptase, TERT, the component which catalyzes the addition of repeats to the parent-strand chromosome end (Lingner *et al.*, 1997). Most normal, adult vertebrate somatic cells, with the exception of cells from the lab mouse (*Mus musculus*), do not exhibit telomerase activity (Levy *et al.*, 1992; Kim *et al.*, 1994; Wright and Shay 2002; Levy *et al.*, 1992). Not only does telomerase maintain telomeres of proliferating cells, it is also implicated in oncogenesis (Greider and Blackburn, 1989).

In addition to the end-replication problem and the compensating function of telomerase, telomere length is impacted by proteins that bind to and contribute to the architecture of the telomere. The thousands of duplex DNA telomere repeats are, for the most part, packaged in closely-spaced nucleosomes (Blackburn, 2001). However, the G-rich 3' overhang assumes a terminal loop (t-loop), which displaces one of the duplex strands forming a related structure (D-loop). The D-loop t-loop is stabilized by telomere-binding proteins and their interaction partners (Greider 1999; Griffith *et al.*, 1999; Wei and Price, 2003). Closed chromatin loops resembling t-loops have been observed in chicken using electron microscopy (Nikitina and Woodcock, 2004).

Telomere-repeat-binding factors 1 and 2 (TRF1 and 2) bind to double-stranded telomeric DNA (Wei and Price, 2003). TRF1, which induces telomeric DNA strands to bend, loop and pair (Bianchi *et al.*, 1997; Smogorzewska *et al.*, 2000), may produce shortening of telomeres by sequestering the 3' overhang from telomerase (van Steensel and de Lange, 1997). TRF2 is described as protective of telomeres in some studies (Karlseder, 2003) and as a negative regulator of telomere length in other studies (Smogorzewska *et al.*, 2000; Stansel *et al.*, 2001). Overexpression of TRF1 or TRF2 produces a progressive shortening of telomeres (Ohki and Ishikawa, 2004 and references therein). Tankyrase 1 and 2 have the ability to bind TRF1, resulting in the ADP-ribosylation of TRF1 and the release of TRF1 from telomeric DNA. Overexpression of tankyrase 1 results in the removal of TRF1 from the telomeres followed by telomere elongation (Smith and de Lange, 2000).

In addition to the tankyrases, TRF1 and TRF2, Rap 1 and Pot 1 are involved in telomere maintenance. Rap1

interacts with TRF2, and Pot 1 may coat and protect both G-strand overhangs and the displaced G strand of a t loop (Bauman and Cech, 2001; Tan *et al.*, 2003). Other proteins known to be relevant to telomere length regulation include c-myc, an oncogenic transcription factor which regulates cell proliferation, differentiation and apoptosis (Piedra *et al.*, 2002). Down-regulation of c-myc is believed to be a prerequisite to differentiation (Skerka *et al.*, 1993; Baker *et al.*, 1994) and c-myc reactivates telomerase in transformed cells by inducing expression of its catalytic subunit TERT (Wu *et al.*, 1999).

Chicken orthologs of TRF1 and 2, tankyrase 1 and 2, TR, TERT, c-myc, Rap 1 and Pot 1 have been characterized. In addition, chicken orthologs of the helicases that are missing or mutated in the progeroid disorders, Werner and Bloom Syndrome, have been identified but not studied. The Werner (WNR) and Bloom (BLM) proteins, both RecQ-Q helicases, have been implicated in telomere maintenance pathways (Du *et al.*, 2004). Table 29.1 lists chicken genes related to telomere length regulation, their human orthologs and relevant references.

## The Chicken as a Paradigm for Aging Research

Organisms frequently used in aging studies include yeast, *Drosophila*, *C. elegans*, and *M. musculus*, the laboratory mouse. With all of these well-characterized models available, particularly a mammalian vertebrate as well-studied as the lab mouse, why use an avian model? The advantages of using a vertebrate are obvious, and the mouse would at first glance appear to be a better choice than the chicken except for shortcomings of the mouse vis-à-vis the study of aging and oncogenesis. For example, mice have a very short lifespan. In contrast, maximum life expectancies of many species of birds approach the human life expectancy (Forsyth *et al.*, 2002; Austad, 1997). Lifespan is significant, as cellular and genetic mechanisms governing cell proliferation are likely conserved in longer-lived species.

In addition to the issue of lifespan, laboratory mouse somatic cells retain telomerase activity and do not appear to display division-dependent telomere shortening (Prowse and Greider, 1995; Forsyth *et al.*, 2002; Kim *et al.*, 2002). Mouse models of telomere shortening have been developed, but it takes several generations in the telomerase knockout mouse (TR-/TR-) to achieve a phenotype that demonstrates division-dependent telomere shortening (Cheong *et al.*, 2003). In contrast, human and chicken somatic cells lack telomerase, with down-regulation of telomerase occurring early in development. Division-dependent telomere shortening is established in chicken chromosomes (*in vivo* and *in vitro*) and human chromosomes. In human, mouse and chicken, highly proliferative tissues such as embryonic cells and intestine as well as transformed cells exhibit telomerase activity

(Taylor and Delany, 2000; Forsyth *et al.*, 2002; Swanberg and Delany 2003; Delany *et al.*, 2003).

Unlike mouse fibroblasts, both chicken and human primary fibroblast cells are generally refractory to spontaneous immortalization (Lima and Macieira-Coelho, 1972; Lima *et al.*, 1972; Macieira-Coelho and Azzarone, 1988; Prowse and Greider, 1995). In addition, critically short human telomeres induce senescence

either by activating p53 or by inducing the p16/RB pathway, and suppression of both pathways is required to suppress senescence of aged human cells. In mouse, the p16/RB response to telomere dysfunction is not active (Smogorzewska and de Lange, 2002). In contrast, the senescence pathways of chicken and human fibroblast systems thus far seem to share more similarities than differences (Kim *et al.*, 2002); see Table 29.2. For an

excellent review of the developmental regulation of telomerase activity in human, mouse, chicken and flowering plants, see Forsyth *et al.* (2002).

### Features of the Chicken Genome Relevant to the Study of Aging

The chicken karyotype consists of 39 pairs of chromosomes, which is typical of most avian species. The genome is organized as eight pairs of cytologically distinct macrochromosomes, the Z and W sex chromosomes and thirty pairs of small cytologically indistinguishable microchromosomes (ICSGS, 2004). As in other vertebrates, chicken telomeres consist of a highly conserved hexanucleotide repeat, 5' TTAGGG<sub>(n)</sub> 3'. The cytogenetic features of the telomere repeat were first described in chicken by Nanda and Schmid (1994). Molecular features of telomeric DNA in the chicken genome were described in 2000 (Delany *et al.*). Although the avian genome is one-third the size of the human genome (1.25 pg versus 3 pg/haploid cell), the amount of telomeric DNA sequence is five to ten times more abundant in birds than in humans (Delany *et al.*, 2000; Nanda *et al.*, 2002). Higher telomere repeat content in the chicken is likely due to the high number of chromosome ends ( $2n = 78$  or 156 chromosome termini), the load of interstitial telomeric DNA and the presence of an unusual category of ultra-long telomeric arrays (see Figure 29.1).

Telomeric DNA in the chicken can be categorized into three main array size classes. Class I telomere repeats are 0.5–10 kb in length and exhibit discrete and genotype-specific banding patterns. Class I repeats are interstitially located and show no evidence of telomere shortening. Class II repeats are 10–40 kb and appear on Southern blots as the typical overlapping smear of TRFs; Class II arrays show evidence of terminal location based on digestion by *Bal* 31 and exhibit division-dependent shortening in somatic tissues. Class III telomeres are hundreds of kilobases in size and range to 3 megabases. Shortening of these arrays has not been established because of the inability to resolve changes of 100s of nucleotides (typical telomere erosion) in the context

**Figure 29.1.** Image of pulse-field gel showing chicken Class I, II and III telomere arrays. Class II arrays are analyzed for telomere shortening.

of 100s to 1000s of kilobases of the Class III arrays (Delany *et al.*, 2000). In order to resolve Class III arrays on a gel, special pulse field gel electrophoresis parameters are required (Delany *et al.*, 2000).

Not all avian species exhibit the Class III arrays (Delany *et al.*, 2000; Nanda *et al.*, 2002). Current models suggest that the Class III arrays of the chicken map to a subset of microchromosomes, perhaps serving to protect these small genetic elements from erosion and/or contributing to high microchromosome recombination rates (Delany *et al.*, 2000; Delany

*et al.*, 2003). It is important to note that the existence of megabase telomere arrays in chicken does not diminish the power of the chicken as a model for division-dependent telomere shortening as it appears to be the shortest telomere or the unprotected telomere which triggers genome instability (Hemann *et al.*, 2001; Karlseder *et al.*, 2002).

Telomerase activity and telomere-shortening profiles in avian cells *in vivo* and *in vitro* mirror what is observed in human cells. Telomerase activity is developmentally regulated *in vivo* with high levels of telomerase in early-stage chicken embryos (preblastula through neurula) and during organogenesis all organs surveyed up to 10 days of embryonation (E10) followed by down-regulation for most somatic tissues. Constitutive telomerase activity continues for “renewable” tissues, including intestine, spleen, and organs or cells of the reproductive system. An average decrease of 3.2 kb in telomere length was observed from the early embryo to the adult (Taylor and Delany, 2000). *In vitro* observations include absence of telomerase from nontransformed primary cells (CEFs) contrasted with telomerase activity in cultured blastodermal cells, cES cells and in every transformed avian cell type surveyed to date (Table 29.3 ).

As measured by mean TRF, the *in vitro* rate of telomere shortening observed in Class II arrays in CEFs is approximately 50 bp of telomeric DNA per population doubling. Yet calculation of percent telomeric DNA at representative passages revealed that an average of 63% of the telomeric DNA was eroded in CEFs by senescence. The greatest loss of telomeric DNA occurred precipitously in later passages. These data suggest two mechanisms of telomere shortening: (1) telomere attrition due to the end-replication problem and (2) catastrophic erosion preceding culture arrest (Swanberg and Delany, 2003).

TABLE 29.3  
Telomerase Positive Transformed Avian Cell Lines  
(Adapted from Swanberg and Delany, 2003)

Cell name	Description
RP-19	Turkey B cell
DT40	Chicken B cell (bursal lymphoma)
RP-9	Chicken B cell (bursal lymphoma)
MSB-1	Chicken T cell (spleen tumor cells <i>in vitro</i> )
MQ-NCSU	Chicken macrophage (peripheral blood)
QT6	Quail fibroblast (fibrosarcoma)
QT35	Quail fibroblast (fibrosarcoma)
LMH & LMH/2A	Chicken hepatocyte (hepatocellular carcinoma)

### Tools for Utilizing the Chicken in Aging Studies

A variety of techniques for the study of telomere biology are available, including telomere terminal restriction fragment (TRF) analysis, fluorescence *in situ* hybridization (FISH), variations of polymerase chain reaction (PCR), and the telomere repeat amplification protocol (TRAP). For an excellent summary of selected methods utilized to measure telomere length, see Nakagawa *et al.*, (2004). A list of references pertaining to techniques used in the study of telomere biology is contained in Table 29.4.

### TELOMERE TERMINAL RESTRICTION FRAGMENT ANALYSIS

First described in Harley *et al.*, 1990, telomere terminal restriction fragment analysis establishes mean telomere length in a tissue or cell sample or percent of telomeric DNA present in one sample relative to another. To measure mean telomere length, genomic DNA is first digested with a restriction enzyme or a cocktail of restriction enzymes followed by electrophoretic separation through an agarose gel. It is essential that DNA concentration be equivalent in each lane. The gel is Southern blotted and hybridized to a TTAGGG(n) probe labeled with a radionuclide or a fluorochrome producing a smear of fragments. Densitometry readings taken at a number of locations along the smear are summed and averaged. Mean telomere length is defined as  $\sum(OD_i)/\sum(OD_i/L_i)$  where  $OD_i$  is the densitometer output and  $L_i$  is the length of the DNA at position  $i$ . Sums are calculated over the range of lengths covered by the smear of TTAGGG-hybridized DNA (Harley *et al.*, 1990, Swanberg and Delany, 2003).

In order to measure percent telomeric DNA present in one sample relative to a calibrator sample (Harley *et al.*, 1990), DNA is restricted, separated by gel electrophoresis, Southern blotted, and hybridized as with the determination of mean TRF length. However, rather than taking densitometry readings at discrete locations along the length of the smear of telomeric DNA, total telomeric DNA is measured by calculating the total integrated signal ( $\sum OD_i$ ) over the same range of fragment sizes used for mean TRF analysis. Total integrated signal in this range is measured in each lane of any given gel, and results are expressed as a percentage of the signal from the earliest passage (Harley *et al.*, 1990; Swanberg and Delany, 2003). The measurement of TRFs reveals a high

degree of variability within cell lines prepared from single embryos of a highly inbred line, and mean TRF measurements are also subject to variability resulting from drift in the subpopulations within a culture. Therefore it is advisable to assay using more than one method to obtain a biologically relevant picture of telomere attrition or erosion (Swanberg and Delany, 2003).

### FISH

Telomere arrays have been examined in a wide sampling of avian species, including chicken, using fluorescence *in situ* hybridization (FISH) (Nanda and Schmid, 1994; Nanda *et al.*, 2002). While the Nanda study was not quantitative, the existence of large telomere arrays in birds was quite apparent using traditional FISH techniques. Telomere quantitative fluorescence *in situ* hybridization (telomere Q-FISH), a variation of this method, has been utilized effectively in several organisms. Using Q-FISH, telomere length is expressed as a ratio of telomere fluorescence in cells that have undergone erosion to telomere fluorescence in cells in the same tissue section with intact telomeres. The inherent disadvantage of Q-FISH is that only a small subset of telomeres can be examined at any one time relative to the bulk methods (e.g., TRF analysis) (Nakagawa *et al.*, 2004 and references therein).

### PCR-BASED METHODS FOR TELOMERE LENGTH MEASUREMENT

A technique that addresses some of the limitations of Q-FISH is single telomere length analysis (STELA). Using STELA, a 20-mer noncomplementary oligonucleotide with a TTAGGG tail is linked to the G-rich 3' overhang of the telomere. The TTAGGG tail is then ligated to the complementary 5' strand of the telomere. PCR is performed using one primer for the linked oligo and a second primer recognizing unique subtelomeric sequence. Use of this technique requires identification of subtelomeric sequences, which has not yet been accomplished in avian species, but should be possible in chicken now that the genome is sequenced (Nakagawa *et al.*, 2004 and references therein). Edges of telomeric DNA were identified in the draft sequence for the macrochromosomes (ICGSC, 2004, see supplementary information).

A second PCR-based technique that can be used to compare the abundance of telomere repeats is quantitative real-time PCR (Q-PCR). This technique quantifies the fold-difference between telomere-repeat copy number in an experimental sample compared to a reference DNA sample. Disadvantages of this method are that it does not determine absolute telomere length and that interstitial telomere sequences, present in avian species, will be measured as well as terminal repeats (Nakagawa *et al.*, 2004 and references therein). This should not be a problem if telomere shortening is being measured, because the number of interstitial repeats should not change relative to terminal repeats unless dramatic genome

reorganization such as a breakage-fusion-bridge cycle is occurring.

#### TRAP ASSAY

The telomerase repeat amplification protocol (TRAP) assay, first described by Kim *et al.* (1994), relies upon primer extension of an oligonucleotide by telomerase. Cells are lysed and cellular protein extracts are incubated with an oligonucleotide to which a series of TTAGGG repeats will be added when telomerase is present in the cell extract. Variations of the TRAP assay exist, including radioactive or nonradioactive gel-based detection, ELISA-based detection and semiquantitative or quantitative protocols. For an excellent review of the TRAP assay and many of its iterations, see Saldanha *et al.* (2003).

#### GENE EXPRESSION ANALYSIS

Real-time fluorescence-based PCR and RT-PCR have emerged as powerful methods for examining gene expression patterns in many contexts. In traditional PCR, an amplicon which accumulates after a predetermined number of cycles is analyzed by gel electrophoresis. In real-time PCR, reactions are characterized by the PCR cycle at which amplification of a target molecule is first detected by release of a fluorescent signal in real time. The greater the quantity of the target molecule in the reaction mix, the earlier a significant increase in fluorescence will be measured. Quantitation is accomplished with reference to a threshold cycle, ( $C_t$ ), defined as the fractional cycle number at which fluorescence, generated by the increase in PCR product, exceeds a set threshold above the baseline. For an excellent treatise on fluorescence-based real-time PCR, refer to Bustin *A-Z of Quantitative PCR* (2004).

Recently, real-time quantitative TaqMan PCR was utilized to look at expression of genes involved in chicken telomere maintenance pathways. Chicken primers and fluorescent probes were developed for seven target genes (tankyrase 1, tankyrase 2, TRF1, TRF2, cTERT, cTR and c-myc) as well as for three housekeeping genes for normalization purposes. In cell culture, chicken GAPDH mRNA levels were found to show the least standard deviation for all samples examined, and therefore GAPDH values were used to normalize the target gene values.

Analysis of mRNA expression patterns of the target genes in CEFs, DT40, the gastrula embryo and cES cells revealed up-regulation of tankyrase 2, TRF1, TRF2, c-myc, cTERT and cTR in DT40 cells, with c-myc levels up-regulated 184-fold in DT40 relative to the gastrula and 282-fold in DT40 relative to CEFs and cES cells. Telomerase holoenzyme components (cTERT and cTR) were present, although at low levels, in CEFs and were up-regulated in DT40, cES cells and the gastrula relative to CEFs. Down-regulation of TRF1, c-myc, cTERT and cTR appeared to be a feature of senescing CEFs that had

survived an average of 30.5 PD (Swanberg *et al.*, 2004; Swanberg and Delany, 2005). For a detailed discussion of these expression patterns as well as primer and probe sets, for target and housekeeping genes, see Swanberg *et al.* (2004) and Swanberg and Delany (2005).

#### ELECTROPORATION, RNAi AND MORPHOLINOS

One of the requirements for a good model system is the ability to do gain- and loss-of-function experiments. Techniques exist to perform such experiments in chicken. A number of investigators utilize electroporation to introduce exogenous DNA into the chicken embryo *in ovo* (Muramatsu *et al.*, 1997). For an excellent review of electroporation techniques *in ovo*, see Krull (2004). Loss-of-function experiments can be conducted by introducing short, interfering RNAs (siRNAs) or morpholinos into the chick embryo.

Double-stranded RNA-mediated interference (RNAi), a naturally occurring mechanism which results in the silencing of gene expression, has become a very powerful tool for experimental gene suppression in a number of organisms. The phenotypes observed with RNAi silencing of gene expression range from knock-down to knockout (Agrawal *et al.*, 2003). RNAi was successfully exploited in chicken (*in ovo*) for gene silencing (Bourikas and Stoeckli, 2003; Pekarik *et al.*, 2003; Krull 2004; Sato *et al.*, 2004). In addition to siRNAs, RNAi morpholinos were used in loss-of-function studies in chicken. For example, Sheng *et al.* (2003) used morpholino oligonucleotides to knock down expression of genes in the future neural plate of the chicken embryo.

#### GENOMIC TOOLS

Information regarding web-based tools for sequence and bioinformatics analysis of avian species, BAC and cDNA libraries, chicken gene chips and a number of other websites of interest to researchers are contained in Table 29.5. For further detail on cDNA arrays for chicken gene expression analysis, see Burnside *et al.* (2005). Tutorials oriented toward the biologist new to bioinformatics can be found in Antin and Konieczka (2005). Both Antin and Konieczka (2005) and Dequeant and Pourquie (2005) describe additional resources for the study of chicken genomics.

#### TELOMERES AS A TOOL FOR AGE DETERMINATION IN BIRDS

Estimating age in unmarked bird populations is of primary interest to many disciplines. The relationship between telomere shortening and chronological age was studied recently by determination of the telomere rate of change (TROC) or "telomere clock" in a number of bird species. Measuring the length of TRFs in DNA from erythrocytes and plotting mean telomere length against the maximum lifespan in years for each species, a correlation between TROC and lifespan was indicated.

In most of the species studied, telomeres appeared to shorten more slowly in long-lived birds than short-lived birds. Interestingly, in a particularly long-lived bird, Leach's storm petrel, telomeres did not shorten with age, but lengthened (Vleck *et al.*, 2003, Haussmann *et al.*, 2003).

In another study examining DNA from erythrocytes, it was found that while telomere length in blood cells declined between the chick stage and the adult in two species of long-lived seabirds, telomere length in adults was not related to age. This study cautioned that rates of telomere loss were not constant with age and that there was a great deal of interindividual variation in the magnitude of telomere loss (Hall *et al.*, 2004). It should be noted that avian erythrocytes are the product of erythroid progenitor cells capable of extended self-renewal (Beug *et al.*, 1994) and therefore are likely to possess a significantly different telomere-length maintenance pathway than the majority of somatic cells whose telomeres typically demonstrate division-dependent shortening. It would not, therefore, be surprising to find that telomere shortening profiles in this renewable cell population would bear a greater resemblance to the profiles of other renewable tissues than to the telomeres of nonrenewable cell populations such as fibroblasts.

### Research Resources: Stocks and Lines, Cells and Cell Lines

A variety of avian stocks and lines are available to the investigator of telomere biology. Genetic stocks and mutant lines are listed in an Avian Stocks Database linked to the Poultry and Avian Research Resources: Living Stock Populations website of the Animal Science Department, University of California, Davis (see Table 29.5 for URL). In addition, a selection of transformed and nontransformed avian cells and cell lines are available through the American Type Culture Collection (see Table 29.5 for URL). Protocols for primary culture of isolated chicken tissues can be found in Fresheny, *Culture of Animal Cells: A Manual of Basic Technique* (2000).

### Husbandry

A number of excellent resources on basic chicken biology and husbandry are available including Sturkie's *Avian Physiology* (2000) and Scanes' *Poultry Science* (2004). In addition, the United States Department of Agriculture and several other agencies or associations provide both web-based and written materials on poultry husbandry and animal welfare. Table 29.5 contains web-based resources on poultry husbandry and related topics.

### Conclusions

The study of telomere biology and telomere maintenance pathways has provided and will continue to provide a great deal of insight into the processes of replicative senescence, the relationship between cellular senescence and organismal aging, the genesis of cancer, and the regenerative potential of embryonic stem cells. Use of *in vivo* and *in vitro* avian systems to facilitate research in these fields can only add to our body of knowledge. With the 6.6X draft sequence of the chicken genome now available, the chicken is a much more powerful model.

Investigation of telomere maintenance pathways in the chicken and other birds establishes, among other things, that nonrenewable cells and tissues exhibit little or no telomerase activity accompanied by division-dependent telomere shortening; that embryonic cells and tissues as well as transformed cells exhibit high levels of telomerase; and that many telomere-associated genes are expressed differentially in pluripotent, differentiated and transformed cell systems, much as is seen in human systems. TERT and TR genes are transcribed in at least one telomerase-negative cell type, which suggests that the regulation of telomerase activity is more complex than merely switching the genes for telomerase enzyme components on and off. While telomere shortening profiles are unlikely to be the equivalent of rings on a tree for the determination of chronological age, comparisons of telomere status in pluripotent vs. differentiated, transformed vs. nontransformed and early passage vs. senescent cells are informative. Considerable work is necessary to fill in gaps, but the chicken model for telomere biology offers the opportunity to study a vertebrate system free from many of the issues inherent in the murine model. Chickens, therefore, have the potential to become the new "lab rat" for aging research.

# Domestic and Wild Bird Models for the Study of Aging

D.J. Holmes and M.A. Ottinger

*Comparative gerontologists now recognize that birds as a group are exceptionally long-lived for their body sizes, especially given their lifetime energy expenditures, and that domestic and wild avian models hold significant potential for understanding basic aging processes. Some domestic birds, including chickens, pigeons, quail and small cage bird species, are actually already well developed as laboratory models, and have been used for years in studies of neurobiology, reproductive biology, and developmental biology, as well as other disciplines. Avian models have already yielded a significant body of information about aging-related changes in fertility, neuroendocrinology and reproduction, as well as adult neuroregeneration and the basis of cellular resistance to oxidative damage. Field ornithologists have gathered a wealth of demographic data relevant to senescence in wild bird populations, which represent excellent systems for monitoring and developing biomarkers of aging—including changes in immune function—in outbred wild vertebrates subject to natural evolutionary forces. The slow aging of birds is accompanied by exceptionally slow or even negligible reproductive aging in many species, including wild seabirds. While the development of molecular resources for carrying out aging studies with birds lags behind that for classical mammalian and invertebrate laboratory models, the past decade has seen an increase in the use of birds in the field of aging. The development of promising, long-lived avian biogerontological models will require judicious use of the comparative method, adaptation of standard aging biomarkers for use in new domestic and wild bird models, and vigorous and creative interdisciplinary collaboration.*

## Introduction

The class Aves consists of around 9,000 bird species with an enormous range of body sizes, habits and life histories (Sibley and Monroe, 1990, 1993; Gill, 1995; Bennett and Owens, 2002). As in mammals, there is overall a reliable, inverse correlation between species life spans and body size for birds. As a rule, however,

birds are significantly longer-lived and age more slowly than mammals of similar size. Many avian species routinely live up to three times longer than mammals of equivalent body mass. Even some of the tiniest birds, like the broad-tailed hummingbird (*Selasphorus platycercus*, body weight approximately 5 g), have reliably documented life spans in the wild of over 10 years. Songbirds often survive over five years in the wild; small cage parrots, like the budgerigar “parakeet” (*Melopsittacus undulatus*), regularly live over 15 years under favorable conditions in captivity. Some migratory seabirds survive for over 50 years; even the small (90 g) common tern, *Sterna hirundo*, lives up to 25 years or more in the wild. The slow aging rates seen in birds are correlated with delays in onset and a slower progression of aging-related pathologies, including cardiovascular disease, infertility, neoplasia, osteoarthritis and diabetes.

Over the past decade we and others have emphasized the potential utility of avian models for aging studies (see, for example, Holmes and Austad, 1995a,b, 2004; Austad, 1997; Holmes *et al.*, 2001; Holmes, 2003; Holmes and Ottinger, 2003). Comparative gerontologists now recognize that birds are exceptionally long-lived, and could be used to address key questions about basic aging processes. Less generally acknowledged, however, is the fact that certain bird species—wild *and* domestic—are *already* quite well developed as models for some key correlates of aging, including declines in fertility, neuroendocrine changes, and potential defenses against the aging-related damage thought to be caused by reactive oxygen species.

In this chapter we review recent progress in the application of avian models for aging and aging-related physiological and biochemical processes, and we revisit reasons we believe that birds have special potential for modeling aging in long-lived animals like humans (Table 30.1). We review the advantages, disadvantages and pitfalls of extending aging studies to include domestic and wild bird models, and we make some recommendations for developing avian models for aging studies over the next decade.

TABLE 30.1  
Advantages and drawbacks of avian models for studies of basic aging processes

---

Advantages:

1. Birds are in general significantly longer-lived than mammals of comparable body size and lifetime energy expenditures
2. A growing body of evidence suggests that birds have special adaptations for resisting or slowing oxidative damage to cells and tissues
3. Many cage and domestic bird species are feasible and economical to maintain for aging studies, and some are already well developed as biomedical models
4. Genome sequencing has been completed for the domestic chicken, for which there are well-characterized strains with distinct physiological properties
5. Additional data are now emerging on the genetics underlying important physiological differences between highly specialized strains of domestic poultry
6. Many birds exhibit extremely slow or even negligible reproductive aging
7. Wild birds provide excellent systems for monitoring aging in outbred wild vertebrates subject to natural evolutionary pressures
8. Birds are already being utilized in aging studies, and reliable biomarkers of avian aging have been identified

Drawbacks:

1. Long-lived animals like birds can be costly to maintain for longitudinal aging studies
  2. The best-developed domestic avian laboratory models for aging studies are galliforms (e.g., chicken, quail), which are relatively short-lived
  3. Genetic resources are currently limited for non-poultry avian models of aging; isogenic inbred laboratory strains of any bird are currently unavailable
  4. Studies utilizing songbird models in the laboratory have focused primarily on neuroethology or nutrition rather than aging
  5. Studies of aging biomarkers in wild bird populations require monitoring of variables that are difficult to control or monitor over individuals' life spans
  6. The development of good avian aging models and biomarkers, including wild species, requires adequate funding and interdisciplinary collaboration
- 

## Birds as Exceptionally Long-lived Animal Models

Like mammals, birds have a wide range of aging patterns, life spans, and patterns of reproductive decline. In general, however, birds are long-lived, slowly aging animals, and some species age even more slowly for their body sizes than humans and other primates. Even small songbirds, seabirds and hummingbirds enjoy surprisingly long life spans in the wild under natural mortality pressure, despite extremely high metabolic rates (often several times higher than similar-sized mammals) and total lifetime energy expenditures (5 or more times higher) (Table 30.2) (for earlier reviews, see Austad, 1993; Holmes and Austad, 1995a,b; Holmes *et al.*, 2001; Holmes and Ottinger, 2003).

Some avian longevities are more comparable to those of humans and other primates than those of the short-lived rodents and invertebrates typically used as laboratory aging models. This means that avian aging processes may in some respects be more relevant than those of standard animal models for understanding basic aspects of human aging. Since birds, like mammals, are homeotherms, or "warm-blooded" animals. Therefore, any

antiaging mechanisms they possess could be expected to generalize well to specific mechanisms underlying longevity in mammals. In particular, it has been suggested that birds may model specific adaptations for combating oxidative and glycoxidative processes thought to be primary causes of aging-related cellular damage (Harman, 1956; Del Maestro, 1980; Cerami, 1985; Monnier *et al.*, 1991, 1999; Kristal and Yu, 1992; Barja, 1998 ).

### AVIAN LONGEVITY IS CONSISTENT WITH EVOLUTIONARY PREDICTIONS

Why do birds live so long? In the past, it was often argued that life spans and aging rates in warm-blooded vertebrates were constrained by the "rate of living" (Pearl, 1928; Rose, 1991). This argument was based on a robust, positive correlation between animals' body size and longevity, and an equally strong, inverse association between life spans and basal metabolic rates. This generalization is clearly refuted, however, when the long life spans of birds and bats are compared with those of nonflying relatives of similar size. These disproportionately long-lived animals are particularly interesting to comparative gerontologists, especially considering the higher metabolic rates and lifetime oxygen expenditures

### 30. Domestic and Wild Bird Models for the Study of Aging

TABLE 30.2  
Life spans and approximate lifetime energy expenditures in mice, humans and some typical birds  
(c = from records of captive individuals)

Species	Maximum documented longevity (years)	Body mass (g)	Estimated lifetime energy expenditure (kcal)
Mouse ( <i>Mus domesticus</i> )	6 (c)	20	250
Human ( <i>Homo sapiens</i> )	122 (c)	50,000	800
Japanese Quail ( <i>Coturnix japonica</i> )	6	90	460
American Robin ( <i>Turdus migratorius</i> )	14	77	1,336
Budgerigar ( <i>Melopsittacus undulatus</i> )	19 ± (c)	40	1,440
Raven ( <i>Corvus corax</i> )	69 (c)	1,200	1,400
Starling ( <i>Sturnus vulgaris</i> )	21	71	2,100
Canary ( <i>Serinus canaria</i> )	24 (c)	22	3,200
Broad-tailed Hummingbird ( <i>Selasphorus platycercus</i> )	5	14	8,834

Data from Lasiewski and Dawson, 1967; Altman and Dittmer, 1972; Gavrilov and Dolnik, 1982; Carey and Judge, 2000. Records for most wild birds are based on banding records from the field, and probably underestimate potential life span in captivity. Most longevities were validated using similar values from more than one large sample for a given species. Lifetime energy expenditures were calculated using published estimates of basal or resting metabolic rates.

of long-lived fliers (Finch, 1990; Austad and Fischer, 1991; Partridge and Barton, 1993). Evolutionary senescence theory predicts that organisms subject to natural selection in the form of high natural mortality rates from predation, disease, or accident will evolve life-histories characterized by rapid maturation, early reproductive investment, and relatively high fecundity (Medawar, 1952; Williams, 1957; Edney and Gill, 1968; Rose, 1991). Short life spans are a correlate of this evolutionary scenario, in which there is no long-term reproductive or genetic advantage to delayed or slow aging. Conversely, in the absence of high mortality rates and intense selection for reproductive investment early in life, natural selection should favor delayed maturity, repeated but smaller episodes of reproductive investment, and long-term somatic maintenance. In the latter scenario, organisms with effective defenses against predators and other sources of mortality, including the ability to fly, will also be expected to evolve long life spans and the molecular mechanisms supporting long-term somatic maintenance. In other words, effective antiaging adaptations—including, presumably, the ability to combat oxidative and glycoxidative damage—are most likely to be exhibited by organisms with naturally long life spans,

including vertebrates like bats, mole-rats, and birds. A substantial amount of comparative data supports the idea that slow aging has accompanied the evolution of flight, in both birds and mammals (for reviews see Pomeroy, 1990; Partridge and Barton, 1993; Holmes and Austad, 1995b).

#### BIRDS MAY HAVE SPECIAL CELLULAR AND MOLECULAR ADAPTATIONS FOR DELAYING AGING

##### *Avian defenses against ROS damage*

There is growing experimental evidence that birds have unusually effective defenses against aging-related damage to specific tissues, cells, and molecules. Reactive oxygen species (ROS) are now implicated in a growing assortment of aging-related deteriorative processes. Since they are a normal by-product of oxidative metabolism, ROS theoretically should be generated at higher rates by organisms, like birds, with high metabolic rates. But data collected over the past decade using birds from several different orders, including canaries, pigeons, budgerigars and starlings, suggest that birds have better defenses against oxidative damage than short-lived

laboratory rodents (see, for example, Barja *et al.*, 1994a,b; Pamplona *et al.*, 1996; Barja, 1998; Barja and Herrero, 1998; Herrero and Barja, 1998; Ogburn *et al.*, 1998, 2001; Perez-Campo *et al.*, 1998; Pamplona *et al.*, 1999a,b; Jaensch, 2001; Ku and Sohal, 1994; Chapter 16, “Estimation of the Rate of Production of Oxygen Radicals by Mitochondria,” by Sanz and Barja). These defenses probably involve a complex array of mechanisms, including more efficient mitochondrial metabolism, as well as superior protection against—and repair of—damage by prooxidant molecules to DNA and other cellular components. They may include inducible defenses, like antioxidant enzymes, as well as constitutive or structural defenses, such as lower levels of saturated fatty acids in cell or mitochondrial membranes.

*Avian defenses against glycosylative and glycoxidative damage*

Data from the veterinary clinical literature on a wide taxonomic range of bird species show that healthy birds' blood glucose levels are typically two to three times higher than those of normal mammals. Glucose interacts with proteins, nucleic acids, and other molecules through a series of nonenzymatic reactions called “glycosylation” and “glycoxidation” (for reviews, see Monnier, 1990; Monnier *et al.*, 1991, 1999). These reactions can produce a plethora of harmful compounds referred to as “AGEs,” or advanced glycosylation end-products, which are thought to contribute to the functional declines associated with aging. Without specialized defenses against AGEs or their formation, particularly in light of their high metabolic rates, birds would be expected to be more susceptible to these compounds than their mammalian counterparts (Monnier, 1990; Monnier *et al.*, 1991, 1999; Holmes and Austad, 1995a; Holmes *et al.*, 2001). Some recent studies suggest that birds produce lower amounts of particular AGEs, or may have adaptations for preventing AGE-related damage (see, for example, Iqbal *et al.*, 1999; Monnier, 1999).

*Avian aging, telomere length, and telomerase activity*

Telomeres, conserved nucleotide sequences on the ends of linear chromosomes that are essential for replication, have been shown to shorten with age in somatic cells of humans, and are implicated in cellular senescence in mice (Harley, 1995; Granger *et al.*, 2002). There is also interest in a possible relationship between telomere length, telomerase activity, and animal aging and life span. So far, neither telomere length nor telomerase activity has been shown to correlate consistently with species-specific aging rates or life spans, either in birds or mammals. Some recent studies focusing on wild bird populations of species with a range of longevities have reported associations between maximum documented species life span, individual age, and telomere length and telomerase activity (Hausmann *et al.*, 2003; Vleck *et al.*, 2003); others have failed to show a correlation (Delany, 2000;

Hall *et al.*, 2004; Chapter 29, “Telomeres in Aging: Birds,” by Swanberg and Delaney). As more data on the relationships between avian life span, individual age, and measures of telomere length and telomerase activity are collected using a range of cell and tissues types, the apparent conflict should be reconciled.

## Domestic Bird Models for Aging Studies

Although mainstream gerontologists have come to recognize the merit of adapting avian models, there have been relatively few full-fledged life-span studies using birds. Birds, however, actually have been used in many recent studies generating data applicable to basic aging processes, as well as in other biomedical disciplines with direct relevance to the biology of aging. Many cage and domestic bird species are feasible and economical to maintain, and some of these have long served as laboratory models for developmental and reproductive biology (chickens and quail), neuroendocrinology (quail, zebra finches and canaries), cardiovascular disease (pigeons and quail), and bone physiology (turkeys and quail). Since birds are egg-layers, avian embryonic cells and tissues are readily harvested for cell-culture or other in-vitro studies. Furthermore, classic embryology studies of the domestic chick provide the foundation for studies in research areas of emerging concern—specifically, the developmental basis for many adult diseases, including diseases of aging. Any maternal influences on avian embryonic development act before the egg is laid, hence these influences can be separated from other effects by experimental manipulation of parent or embryo.

We and our colleagues have found birds to be hardy, economical and very useful laboratory animals for studies of cellular resistance to oxidative damage, relationships between telomere length and life span, neuroendocrine aging and plasticity, and basic mechanisms of fertility loss in females. The genome has been sequenced for the domestic chicken, and chicken microarrays are now commercially available and readily applicable to studies of the closely related Japanese quail. A number of laboratories are now applying these and other state-of-the-art molecular methods for addressing the genetic basis for neurobiological, reproductive and other physiological traits in domestic poultry, as well as in laboratory songbird models (see, for example, Kaiser *et al.*, 2003; LaMont, 2003; Cheeseman *et al.*, 2004; Clayton, 2004; Mott and Ivarie, 2004; Hillier *et al.*, 2004; Wade *et al.*, 2004; Wong *et al.*, 2004; Smith *et al.*, 2005).

## AVIAN MODELS FOR REPRODUCTIVE AND NEUROENDOCRINE AGING

Domestic poultry models are particularly well-developed for studies of relatively rapid reproductive and neuroendocrine aging. Although their life spans have been documented at over 15 years, domestic chickens (*Gallus domesticus*) are short-lived for their size, and hens

### 30. Domestic and Wild Bird Models for the Study of Aging

typically undergo reproductive aging during the first two years of egg production. The smaller, and substantially shorter-lived, domestic Japanese quail (*Coturnix japonica*) is in many ways an ideal bird model for studies of rapid reproductive and neuroendocrine aging, since its life history is very similar to that of a laboratory rodent. Quail maintained on long days (15L:9D) mature in 8 weeks, maintain peak production for about 10 months, and show fertility declines (30–50%) by 70 weeks of age, with complete ovulatory failure as early as 18 months. Aging females exhibit irregular egg production associated with diminished hypothalamic response to ovarian steroids (Ottinger and Bakst, 1995; Ottinger, 1996). Reproductive aging is relatively rapid (1–2 yrs) in quail hens, yet they have a substantially longer documented postreproductive life span (2–4 yrs) than that of rodents. Quail can be maintained inexpensively and bred in large numbers. The Ottinger lab has used an outbred domestic quail strain for two decades in studies of reproductive physiology and neuroendocrine aspects of aging in male birds (Ottinger *et al.*, 1997; Panzica *et al.*, 1996; Ottinger, 1998; Ottinger, 2001; Ottinger *et al.*, 2004).

Avian reproductive anatomy lends itself well to studies of basic mechanisms controlling female fertility and reproductive aging (Johnson, 2000; Holmes *et al.*, 2003). Most adult female birds have only one functional ovary. Unlike the mammalian ovary, however, in which developing follicles are contained in a capsule, the avian ovary has a lobular structure like a bunch of grapes, with a yolky hierarchy of large preovulatory follicles readily accessible on the outside. This arrangement makes it practical to measure or administer hormones, growth factors or other substances directly from or into individual follicles.

Birds adapted to temperate zones, including poultry and some small cage birds, like finches, often use photoperiod as the primary cue for the timing and onset of reproduction. In these species, manipulation of the photoperiod is a convenient, noninvasive means of shutting down the reproductive neuroendocrine axis. Since some photoperiodic regulation of reproduction occurs in the hypothalamus, the manipulation of photoperiod avoids the experimental confound of elevated GnRH and gonadotropins that accompany surgical castration.

In captivity under hospitable conditions, some birds (e.g., quail, budgies) have postreproductive life spans of one-third or more of the total life span (Woodard and Aplanalp, 1971; Holmes *et al.*, 2001). Zebra finch hens exhibit significant declines in egg production after several years (Holmes, unpublished data). Female birds and mammals both produce the vast majority of their primary oocytes, or developing eggs, before or shortly after birth (Tokarz, 1978; Guraya, 1989). This fundamental reproductive trait sets birds and mammals apart from most female fishes, amphibians and reptiles, in which

new oocytes are produced as needed throughout reproductive life. For this reason, avian models are particularly relevant for studying the role the finite oocyte pool plays in the timing of reproductive aging. In mammals, fertility loss is generally thought to be correlated with age-related declines in stores of viable primary oocytes. Another advantage of egg-laying is that it facilitates studies of early gonadal development and the examination of primordial oocytes early in life. Domestic birds are excellent models for exploring the effects of early manipulation of embryonic development on health later in life and during aging.

Surprisingly little research has focused on natural variability in ovarian aging in birds of different orders or divergent life-history patterns. Studies of reproductive aging in domestic poultry, however, usually focusing on the heavier poultry breeds, have shown striking differences between strains in fertility, and some aspects of ovarian aging are well documented. For example, Leghorn chickens, referred to as “layers,” have been bred for very high, consistent egg production levels (nearly one egg per day). In contrast, the heavier “broiler” poultry strains, bred for meat production, may lay under 200 eggs per year. There has been no systematic comparison of ovarian aging in long- and short-lived species in the class Aves as a whole. Moreover, there has been no concerted effort to establish whether common physiological, biochemical or genetic mechanisms are responsible for fertility loss in birds and mammals.

We have begun studies comparing reproductive aging in female quail, budgerigars, and wild terns in an attempt to determine the relative contributions of declining primordial oocyte stores, steroid hormones, gonadotropins and GnRH (gonadotropin-releasing hormone) in short- and long-lived bird species. These bird models are all diurnal, with highly stereotypical, easily identifiable courtship behaviors; egg production and fertility are also readily and noninvasively quantified.

Quail and budgerigars both have a high incidence of ovarian cancers, presumably resulting from the breakdown of normal apoptotic signaling. In species which ovulate frequently, the avian ovary is potentially an excellent model for the “rupture and repair” mechanisms implicated in ovarian cancer formation (Giles *et al.*, 2004). To our knowledge, there have been no studies of the molecular basis of aging-related dysregulation of healthy ovarian cellular signaling in longer-lived, non-poultry bird species.

The bones of female birds generally serve as a repository for calcium and other minerals needed for egg production. Female quail develop increasingly fragile bones as they age; these birds are a well-characterized model for the effects of hormones, vitamins and other factors on osteoporosis (see, for example, Keatzel and Soares, 1985).

*Reproductive aging in the domestic hen*

The domestic chicken is one of the classical models for developmental and reproductive biology, and many fundamental physiological correlates of ovarian aging in hens are thoroughly documented (Johnson *et al.*, 1986; Bahr and Palmer, 1989; Ottinger and Bakst, 1995). As egg production declines (between about 30 to 90 weeks of age), the normal recruitment of small white follicles into the preovulatory hierarchy slows, as does follicular maturation. Yolky preovulatory follicles become less sensitive to the surge of luteinizing hormone (LH) that normally stimulates ovulation. Administration of LH or gonadotropin-releasing hormone (GnRH), has been shown to stimulate ovarian response in aged hens, with older hens responding more slowly than young ones (Ottinger and Soares, 1988; Wu and Ottinger, unpublished data). Old hens are also less sensitive to progesterone and may require more to trigger a preovulatory LH surge (Williams and Sharp, 1978; Ottinger and Soares, 1988). Granulosa cells from old hens have been shown to have more follicle-stimulating hormone (FSH) receptors and to produce more progesterone (P4) in response to FSH administration than those of younger hens (Johnson *et al.*, 1986; Bahr and Palmer, 1989; Johnson, 2000a, 2000b). This has been attributed to membrane-level changes, rather than actual P4 secretion in response to the cyclic AMP stimulation that normally triggers P4 production.

Estrogen production in birds occurs primarily in small white prehierarchal follicles, and therefore may play a minor role in loss of ovulatory competence. While estrogen is less dominant in the bird than in the mammal ovary, declines in estrogen may be partly responsible for declining follicular responsiveness. Decreased responsiveness of granulosa cells of hierarchal follicles could be attributable to lower estrogen secretion by a declining pool of small follicles, as well as altered responsiveness to gonadotropins and GnRH (Bahr and Palmer, 1989). The proportion of the original follicular pool that is required for ovulation to occur, however, is unknown.

While age-related changes in follicular populations have not been quantified over the reproductive life span of any bird, follicular atresia rates have been shown to increase with age in domestic hens. Approximately 20 percent of smaller ( $\leq 8$  mm) prehierarchal follicles undergo atresia in younger hens; this rate increases as fertility declines. Atresia rate increases have been attributed to declines in FSH, which normally inhibits atresia. Atresia and its regulation, however, may be expected to vary a great deal between poultry and exotic bird species.

Apoptosis, the programmed cell death that is a normal part of development and aging, has been intensively studied in the ovary of the chicken and, to a lesser extent, in the Japanese quail (Yak *et al.*, 1998; Volentine *et al.*, 1998; Johnson, 2000a,b; Bridgham and Johnson, 2001; Johnson *et al.*, 2002). Changes in populations of mitotic and apoptotic cells in prehierarchal follicles have been

quantified during chicken development and during a significant portion of the reproductive life of chickens and quail (Waddington *et al.*, 1985; Waddington and Walker, 1988; Kitamura *et al.*, 2002; Johnson, 2000). Many of the same molecules involved in mammalian apoptotic signaling and follicular development have also been shown to function in the ovaries of chickens and quail.

*The Japanese quail as a model for male neuroendocrine aging and neuroplasticity*

Over the past 20 years, the Ottinger laboratory has used the Japanese quail extensively as a model for aging-related declines in reproduction, focusing on a variety of changes in behavioral, gonadal, metabolic, sensory and central neuroendocrine function (for reviews, see Ottinger, 1991; 1996; 1998; 2001). Male quail mirror many aspects of mammalian neuroendocrine aging, but they offer some important advantages over laboratory rodent models. Unlike that of most mammals studied, the male hypothalamic–gonadal system retains plasticity during aging. This plasticity is most obvious in the recovery of male courtship and mating behavior in studies in which males were given exogenous testosterone (Ottinger *et al.*, 1997; Ottinger, 1998). Even very aged, infertile males respond to testosterone replacement and recover full reproductive behavior, including restored immunoreactivity of cells containing aromatase enzyme (AROM-ir) in the preoptic region of the hypothalamus. Furthermore, the critical role of AROM-ir for the expression of male courtship and mating behavior is seen in aging males that remain reproductively active without exogenous testosterone treatment. These males have significantly larger AROM-ir cells in the preoptic region (Ottinger *et al.*, 2004). Age-related declines in male reproductive function are also reflected in the function of the GnRH-1 system, including reduced hypothalamic GnRH-1 content, fewer GnRH-1 immunoreactive cells, and lower-amplitude GnRH-1 pulses *in vitro* (Ottinger *et al.*, 2004). These age-related hypothalamic changes provide a platform for identifying the sequence of neuroendocrinological events eventually culminating in loss of reproductive function. The retention of neuroplasticity in quail hypothalamic systems also offers the opportunity to examine and manipulate age-sensitive signals that appear to decline selectively during reproductive senescence.

*Caloric restriction improves reproductive performance in poultry*

Caloric restriction (CR) is a well-established experimental paradigm in biogerontology, and the beneficial effects of long-term CR have been documented for a broad range of animal taxa, including invertebrates. Reliable effects of CR typically include extended life span, delayed onset of aging-related diseases, sustained healthy metabolic and endocrine function, and delayed loss of reproductive capacity (for reviews, see Weindruch and Walford, 1988; Finch, 1990; Masoro, 1993, 2001). Shorter-term caloric

## 30. Domestic and Wild Bird Models for the Study of Aging

TABLE 30.3  
Effects of caloric restriction on reproductive and hormonal parameters in adult male Japanese quail after 8 weeks of treatment

Treatment Group	Mean body weight (g)	Mean testes weight (g)	LH (ng/ml plasma)	Androgen (pg/ml plasma)	Corticosterone (ng/ml plasma)
Ad lib-fed controls	115 <sup>a</sup> ± 1.8	3.1 <sup>a</sup> ± 0.2	7.2 <sup>a</sup> ± 0.5	2828 <sup>a</sup> ± 317	3.1 <sup>a</sup> ± 0.6
20% restriction	97 <sup>b</sup> ± 1.8	3.3 <sup>a</sup> ± 0.2	4.7 <sup>b</sup> ± 0.5	1392 <sup>b</sup> ± 304	1.8 <sup>a</sup> ± 0.6
40% restriction	75 <sup>c</sup> ± 1.8	2.2 <sup>b</sup> ± 0.2	2.5 <sup>c</sup> ± 0.5	266 <sup>c</sup> ± 304	7.2 <sup>b</sup> ± 0.6

<sup>a,b,c</sup>: Different letters denote values that are significantly different within a column (1-way ANOVA (d.f. 1,2;  $p < 0.05$ ) with Student-Newmann-Keuls test post hoc).  $n = 6$  for each treatment group. References: Mobarak, 1990; Ottinger *et al.*, 2005.

or food restriction has also been routinely used by the poultry industry for many years to improve egg production and extend the reproductive life span of laying hens (see, for example, McDaniel, 1983; Sexton, 1989; Miles and Leeson, 1990; Zuidhof *et al.*, 1995; Walsh and Brake, 1999). While poultry biologists have not generally employed the standardized experimental protocols currently used by biogerontologists, in which CR is begun in young animals and continued for the natural life span, there is a wealth of published studies of effects of chronic or short-term food restriction on poultry. The levels of proteins, fatty acids, and other nutrients required for optimizing productivity in domestic egg- and meat-producing birds have been precisely determined, and micronutrients have been adjusted in the feed of “restricted” birds to compensate for their reduced calorie intake.

Results of avian feed-restriction studies are consistent on the whole with the antiaging effects of moderate (10–25 percent) CR on laboratory rodents and primates. CR initiated before full maturation slows the onset of puberty in chickens. Restricted hens are generally healthier, have lower mortality rates, and hatch more chicks over their life spans than controls (Joseph *et al.*, 2002). CR of 30 percent or more impairs or prevents reproduction in these birds, as in mammals (McDaniel, 1983; Bronson, 1989; Ottinger and Soares, 1988). Unlike in mammals, severe restriction followed by resumption of control feeding and restoration of the appropriate photoperiod, however, reinstates reproduction at relatively high levels, even in breeders previously exhibiting aging-related reproductive declines (Walsh and Brake, 1999). This procedure termed “forced molting” is often used to prolong reproduction.

The Ottinger lab has conducted CR experiments to determine the level of caloric intake needed for optimal reproductive performance and long-term health in a strain of heavy broiler chickens (bred for meat rather than egg production) (Byerly *et al.*, 1984; Ottinger and Soares, 1988; Holmes and Ottinger, 2003). In these studies, control birds became reproductive earlier than 10- and 20-percent CR hens when CR was initiated before

complete maturity, with females producing eggs and males beginning sperm production earlier than either CR group. But fertility in controls declined relatively quickly, thereafter, and control birds developed other health problems. Both CR groups in this study matured more slowly and were reproductive longer, producing more chicks during the reproductive life span than controls. Hence many of the responses of chickens to CR were similar to those observed in short-lived laboratory rodents (for reviews, see Merry and Holehan, 1979; Bronson, 1989; Nelson *et al.*, 1995).

Ottinger and colleagues have also tested the effects of moderate, short-term CR on reproduction in male Japanese quail, and examined some of the neuroendocrine mechanisms involved in this effect (Mobarak *et al.*, 1988; Mobarak, 1990; Holmes and Ottinger 2003; Ottinger *et al.*, 2005) (Table 30.3). Twenty- and 40-percent CR quail both matured more slowly than controls and exhibited lower levels of plasma LH. The effects of 40-percent restriction were quite severe, and included reduced testes weight, low plasma testosterone, and elevated plasma corticosterone. However, when injected with GnRH, males in both CR treatment groups had sufficient LH stores to release measurable levels of LH, suggesting that CR had suppressed gonadotropin release at the hypothalamic level, rather than suppressing LH production. This effect is consistent with that seen in food-restricted rodents (Bronson, 1989; Nelson *et al.*, 1995). Subsequently, another experiment subjected male quail to an identical CR treatment protocol, but castrated them at two weeks of age, prior to diet treatment. When CR males were later subjected to LHRH pituitary challenge, all exhibited a normal LH response. In a third study, hypothalamic content and turnover of catecholamines were quantified in adult male quail that had been raised on CR. Twenty-percent CR altered only dopamine (DA) content in the ventromedial hypothalamus. More severe (40-percent) CR reduced both DA and norepinephrine (NE) content in the ventromedial hypothalamus. In addition, DA and NE turnover (determined after treatment with alpha-methyl-paratyrosine) were reduced (Ottinger *et al.*, 2005). These results indicate that, in birds, CR may exert its

effect through altered levels of catecholamines, which in turn stimulate GnRH-1 release and regulate normal reproduction in both sexes.

No full-length, classical biogerontological study of the effects of caloric restriction on molecular, cellular or pathological aging processes has yet been conducted using an avian model. But the beneficial effects of shorter-term CR on health and reproduction in poultry are likely to act through central-nervous-system effects on neuroendocrine and metabolic regulatory systems, as in mammals. Recent research supporting a central role of the IGF-1 pathway in aging and its modulation in invertebrates and vertebrates alike illustrates the need for more comparative studies of the neurophysiological effects of CR in vertebrates. Since CR also appears to protect animals against aging-related oxidative damage, and birds seem unusually resistant to this type of damage, long- and short-lived birds would make very interesting animal models for full-scale caloric restriction studies.

#### NON-POULTRY DOMESTIC AVIAN MODELS FOR AGING STUDIES

##### *Avian models for learning and neuroregeneration*

Small songbirds, including canaries, zebra finches, and sparrows, as well as small parrots and pigeons, have been used for decades in neurobiology, particularly in studies of song learning and reproductive and courtship behavior. More recently, these laboratory bird models have also become the focus of research on the potential for regeneration of certain brain regions. Male canaries normally change their songs each new breeding season as they come into reproductive readiness. This seasonal change is correlated with the death and subsequent regrowth of neurons located in song centers in the brain (see, for example, Kim *et al.*, 1994; Nottebohm *et al.*, 1994; Doetsch and Scharff, 2001). This type of adult neurogenesis has no direct counterpart in laboratory rodent neurobiological models. Studies of the molecular basis of avian neuroregeneration could be critically important for expanding the potential for therapeutic brain repair in humans.

The potential for neuroregeneration has also been demonstrated in other bird models. Japanese quail have been shown to exhibit a reduction in ganglion cells during aging (Ryals and Westbrook, 1988). Interestingly, however, quail retain the ability to regenerate hair cells in the inner ear, even after damage that has been inflicted throughout the life span (Ryals and Westbrook, 1990, 1994). Furthermore, selected brain regions show an age-related decline in neurogenesis in aging male quail (Lauay *et al.*, unpublished data).

##### *Other promising domestic avian laboratory models*

Longer-lived, non-galliform bird models are also poised for development for comparative aging studies. These

include small domestic cage birds, like the budgerigar (*Melopsittacus undulatus*) (a small parrot with a maximum life span  $\geq 20$  years). There is a great deal of clinical veterinary information available for small parrots, captive husbandry practices are well established, and maintenance costs are comparable to those for laboratory rodents. We (in collaboration with Steven Austad) have found budgies to be economical and feasible laboratory animals for aging studies. We have used these birds, as well as quail, in comparative studies of cellular resistance to oxidative damage (Ogburn *et al.*, 1988, 2001).

In earlier reviews we have evaluated several other domestic birds with special potential as new laboratory models for aging studies, including small finches, pigeons, and sparrows (Table 30.4; Holmes and Austad, 1995a; Holmes and Ottinger, 2003; see also Austad, 1997). The most promising avian laboratory models are rodent-sized, outbred, relatively long-lived species which are commercially available. They are also economical to maintain and breed, and have husbandry practices which are well established. They include popular pet birds, like budgerigars (order Psittaciformes; maximum life span 20 years), canaries and zebra finches (order Fringillidae; maximum life span 25 and 9 years, respectively). Lifetime energy expenditures for all these birds exceed those of comparably-sized rodents. The lifetime oxidative liability of the 15-g zebra finch, for example, has been calculated at about twice that of humans. The white-crowned sparrow, a migratory North American songbird, is also a good laboratory bird model, and has been used for years in studies of neuroethology, migration, nutrition and physiology (see, for example, Murphy and King, 1990).

#### Wild Birds as Models for Aging Studies

Wild birds in nature, as well as more traditional domestic laboratory birds, have a great deal of potential for aging studies. Field biologists have now been banding and gathering data on wild bird populations for decades, generating a wealth of information relevant to the basic biology of aging, including evolutionary aging and life-history theory. Mark-recapture studies have now accumulated decades worth of demographic data for many other wild bird species, and the quality of much of these data is excellent (see, for example, Newton, 1989). Bird studies have other advantages for studies of aging and life-history trade-offs: because birds lay eggs, the effect of reproductive investment on subsequent aging can be experimentally manipulated by transferring or removing eggs or nestlings.

Changes in mortality rates and reproductive success consistent with aging have been documented for many bird populations (Holmes and Austad, 1995; Holmes *et al.*, 2001). Other indications of avian aging in the wild include higher parasite loads in older birds, as well as reduced fitness of offspring produced by aging parents.

TABLE 30.4  
Avian laboratory model species with special potential for aging studies

Species and order	Body weight	Maturation time and MLS*	Qualifications and advantages	Drawbacks and special considerations
Japanese Quail ( <i>Coturnix japonica</i> ): Galliformes	100 g	6 yrs (C)	Fully domesticated. Excellent breeder. Extensive literature on behavior, reproduction, neuroendocrinology, and aging. Short-lived, but longer than laboratory rodents; very rapid reproductive aging.	Very short-lived for a bird; reproductive declines at 1 year. Sexes distinguishable.
Budgerigar ( <i>Melopsittacus undulatus</i> ): Psittaciformes	45 g	5–6 mos; 15–20 yrs (C)	Domesticated. Very good breeder. Extensive pet-husbandry and clinical literature including aging-related pathologies; some research on neurobiology. Some published studies of resistance to oxidative damage. Moderately long-lived with moderately slow reproductive aging. Prone to tumors, obesity, diabetes.	Longer-lived than laboratory rodents. Sexes distinguishable.
Canary ( <i>Serinus canaria</i> ): Passeriformes	30 g	15–20 yrs (C)	Domesticated. Good captive breeder. Extensive research and clinical literature including behavior, neurobiology, husbandry and including aging-related pathologies. Moderately long-lived with moderately slow reproductive aging. Less tumor-prone than budgies.	More difficult to breed than zebra finches or budgies. Longer-lived than laboratory rodents. Sexes distinguishable by song.
Zebra Finch ( <i>Taeniopygia guttata</i> ): Passeriformes	15 g	2–3 mos; 9 yrs (C)	Domesticated. Excellent captive breeder. Extremely high lifetime energy expenditures. Good husbandry information available; less clinical literature. Used extensively in behavior, physiology and neurobiology research.	Less clinical and pathological information available. Small body size makes blood and tissue collection difficult; longer-lived than laboratory rodents. Sexes distinguishable.
Pigeon ( <i>Columba livia</i> ): Columbiformes	250 g	4–6 mos; 35 yrs	Domesticated. Breeds well in captivity; husbandry information available. Large clinical, behavioral physiological and neurobiological literature. Free-radical production and oxidant status have been studied. Strains are available that are prone to special aging-related condition, e.g. cardiovascular disease.	Longer-lived than smaller pet bird species. Sexes not distinguishable.
White-crowned Sparrow ( <i>Zonotrichia leucophrys</i> ): Passeriformes	20–25 g	10–11 mos; approx 9 yrs (W)	Wild stock only, but captives can be maintained in substantial numbers. Extensive research literature on nutrition, physiology, neurobiology and behavior.	Not commercially available. Breeding difficult in captivity. Sexes similar.

\*MLS = maximum reliably documented life span. "C" denotes longevity record from captive representatives; "W" denotes record from mark-recapture records from wild populations.  
References: National Research Council, 1981; Murphy and King, 1990; Ku and Sohal, 1993; Nottebohm *et al.*, 1994; Holmes, *et al.*, 2001; Holmes and Austad 1995a; Austad, 1997; Ottinger, 2001; D. Nelson, pers. comm.; F. Nottebohm, pers. comm.

In addition, several teams of field ornithologists have published reports of aging-related declines in immunity in wild birds (for an earlier review, see Holmes and Austad, 2004).

#### AVIAN IMMUNOSENESCENCE IN THE WILD

The physiological declines associated with senescence, including declines in both innate and acquired immune defenses against parasites and pathogenic microorganisms, have been thoroughly documented in laboratory animals and humans (Wollscheid-Lengeling, 2004). But the fitness deficits associated with advancing age in the wild, where animals experience a full range of natural hazards, stresses and diseases, are far less well understood (Miller, 1996). Recently, reliable aging-related declines in aspects of either cellular or humoral immunity have been reported in wild populations of several bird species, including barn swallows (*Hirundo rustica*), collared flycatchers (*Ficedula hypoleuca*), and ruffs (*Philomachus pugnax*) (Saino *et al.*, 2003; Cichoń *et al.*, 2003; Lozano and Lank, 2003).

Lozano and Lank measured cell-mediated immunity in the ruff, a shorebird, using a measure of delayed hypersensitivity to phytohemagglutinin, a nonspecific mitogen foreign to the avian immune system. Males showed a marginally significant age-related decline in cellular immune response; this effect was more pronounced in nonbreeding than in breeding males, which probably expend significant amounts of energy defending territories. In a study focusing on the humoral immune response of barn swallows by Saino *et al.* (2003), banded swallows were immunized repeatedly against Newcastle disease virus. Breeding individuals showed declining antibody responses with advancing age (barn swallows live 5 to 7 years in the wild), and this trend was more likely to be statistically significant for females. Secondary humoral responses were considerably lower overall in females than males, as were initial antibody titers prior to secondary vaccination. This finding is consistent with the greater parental investment typical of females in this species. Cichoń *et al.* (2003) challenged the immune systems of nesting female flycatchers with sheep red blood cells, another nonspecific antigen. Older females mounted an antibody response only about half that shown by younger breeders. This result was correlated with a trend for older females to fledge offspring of lower body mass than those of young and middle-aged birds.

It remains unclear what contribution such age-related changes in immune responses actually make to senescence-related mortality in the wild, where environmental factors may be more important physiological stressors than the effects of aging. Studies like these, however, represent an exciting effort by ecologists and field zoologists to begin incorporating reliable biomarkers

of aging into studies of population biology and mating systems, life-history evolution, or other aspects of avian behavioral ecology.

#### AVIAN MODELS OF EXTREMELY SLOW TO NEGLIGIBLE REPRODUCTIVE AGING

Patterns of reproductive aging vary even more widely among birds than among mammals studied to date. As predicted by evolutionary aging and life-history theory, the slower aging of birds relative to mammals is generally reflected in slower reproductive aging in birds of both sexes (for reviews, see Holmes *et al.*, 2003; Holmes and Ottinger, 2003; 2004). Bird species that mature and reproduce extremely slowly, including seabirds (e.g., albatrosses, terns, and gulls) and large raptors (e.g., condors), tend also to be among the longest-lived, with some species holding longevity records of 50 years or more.

Even shorter-lived wild birds exhibit much slower aging than mammals of equivalent body size. Many small (under 50 grams) passerine songbirds have average life spans of over several years in the wild, and exhibit steady declines in reproductive aging. Reproductive declines in these birds are often more than twice as slow as those of similar-sized captive rodents (McCleery and Perrins, 1988; Newton, 1989; Gustafsson and Pärt, 1991; Clum, 1995; Newton and Rothery, 1997). For example, the rat-sized (110 g) American Kestrel (maximum recorded life span of over 10 years), a small raptor, shows little reproductive aging for up to 7 years or so.

Wild seabirds, including gulls, albatrosses, fulmars and terns, typically exhibit little or no loss of reproductive fitness even at the end of their natural life spans in nature (>50 yrs for some fulmars), and even when rising mortality rates suggest significant deterioration of other physiological systems. Since few seabirds have been maintained in captivity, it remains unclear how long the postreproductive life spans might be for these species if their natural life spans could be prolonged in captivity. Terns (order Charadriiformes), for example, have an extreme life-history strategy typical of pelagic seabirds, characterized by slow sexual maturation, low lifelong reproduction rates (2–3 chicks fledged per year), long life spans, and very slight to negligible declines in reproductive success after peak fledging success is reached at about 15 yrs (Nisbet *et al.*, 1999; Nisbet, 2002a,b). This kind of very sustained reproductive investment is thought to have evolved only in animal populations with extremely low adult mortality rates (<10 percent per year). The extremely slow to negligible aging typical of seabirds is rare in wild bird or mammal populations, and its physiological basis merits additional study.

Long-lived animals with exceptionally slow reproductive aging likely have physiological or molecular mechanisms for prolonging fertility, and basic reproductive aging processes may differ significantly between long- and short-lived species (Finch, 1990; Austad, 1993; Martin *et al.*, 1996; Austad and Holmes, 1999; vom Saal *et al.*, 1994). With the exception of primates, however, few long-lived animal models have been developed for exploring basic mechanisms of delayed fertility loss. Studies of the physiological correlates of avian reproductive aging have largely been limited to short-lived poultry species (for exceptions, see Clum, 1995; Ottinger *et al.*, 1995; Nisbet *et al.*, 1999, 2002a). We have emphasized the potential of wild bird populations for studies of exceptionally slow—or even negligible—reproductive aging under natural conditions in earlier reviews (Holmes *et al.*, 2003; Holmes and Ottinger, 2003).

#### PITFALLS OF AVIAN AGING STUDIES IN THE WILD

Good studies of basic aging patterns and processes in wild animals in nature depend on the ability to quantify and repeatedly measure reliable biomarkers of aging in substantial numbers of individuals. The statistical approaches currently used by avian demographers are in many cases robust and sophisticated, taking into account potential biases inherent in this type of data. As we have illustrated above, bird studies have other advantages as well. On the other hand, studies of the effects of aging in wild animal populations have some drawbacks for investigating basic mechanisms of aging. The natural habitat of a wild bird is far removed from the pampered and protected environment enjoyed by inbred rodents, and carefully controlled longitudinal studies of aging in wild animals are much more difficult. Intrinsic causes of mortality (endogenous aging-related physiological declines) in these studies will be in many cases indistinguishable from extrinsic causes, like predation, disease, and other environmental stressors.

Wild bird populations are outbred and genetically variable. As in aging studies employing mammalian models (including humans), wild birds that live to older ages and survive repeated measurement of biomarkers may not be genetically representative of the population as a whole. Even in laboratory studies, the longest-lived animals in the population have passed through a significant selective “bottleneck”; this effect may be even more pronounced in the wild under natural selective regimes. Nonetheless, studies of exceptionally and naturally long-lived animals in the wild can contribute in important ways to our understanding of basic aging processes, providing important links between

biogerontology, evolutionary and population biology, and natural history.

#### Birds as Models for Aging Studies: Special Challenges and Recommendations

Until recently, the selection of animal models in biogerontology has been driven primarily by economy, feasibility, and simplicity. Most key advances in our understanding of fundamental molecular and cellular aging processes have resulted either from the use of short-lived, rapidly aging species—inbred laboratory rodents, roundworms, flies—or highly specialized cell lines. But the most popular biogerontological animal models not only have life histories quite dissimilar to those of humans and most domestic animals, they also lack the very trait biologists most wish to understand and emulate: the ability to resist aging. The vertebrate animal models currently best developed for studies of aging, laboratory rats and mice, are highly suitable for use in controlled experiments, but, ironically, are poorly adapted for aging. As the field of aging has evolved, so has our understanding of the promise of carefully selected “nontraditional” vertebrate models for aging, including certain primate species, exceptionally long-lived animals like naked mole-rats, bats and birds.

Other recent reviews have emphasized the importance of a judiciously applied comparative approach to selecting animal models for aging studies, employing a variety of distantly related animal species, and identifying a range of potential molecular “solutions” to the problem of long-term somatic maintenance and repair (Finch, 1990; Austad, 1993; Austad and Holmes, 1999). As we have illustrated in this chapter, a number of bird species are poised for use as the kind of exceptionally long-lived laboratory models needed to apply this approach.

There are additional, obvious challenges to the development of avian aging models. Although some cage birds have been domesticated for over a century, and some basic genetic information is available on the species we have highlighted here, genetic resources for experimental bird models (including information about genetic variability, commercially inbred or isogenic strains, genetic markers and gene sequence libraries) lag far behind those available for use with traditional laboratory animals. It requires a concerted effort by the biogerontological research community and funding agencies to direct resources toward developing new animal models. Since birds typically are significantly longer-lived than laboratory rodents, well-conceived, longitudinal avian aging studies will inevitably take longer and require substantial financial investment if they are to be worthwhile. Accepted techniques for the measurement of standard aging biomarkers will need to be adapted and calibrated

for new avian models. This effort will require careful collaboration and communication between biogerontologists and other zoologists, as well as a synthetic and interdisciplinary dialog among scholars in the field who are well versed in accepted methodologies in the field of aging, as well as evolutionary principles and comparative zoology.

## ACKNOWLEDGMENTS

D. Holmes acknowledges the support of INBRE grant P20RR16454-01 (National Institutes of Health) to the University of Idaho during the preparation of this paper. M.A. Ottinger acknowledges National Science Foundation grant #9817024. A. Bressler assisted with the preparation of the manuscript.

# A Transgenic Mini Rat Strain as a Tool for Studying Aging and Calorie Restriction

Isao Shimokawa

*Mini rats, a transgenic strain of rats whose somatotrophic axis was suppressed by overexpression of the antisense growth hormone gene, were shown to live longer than nontransgenic wild-type rats (−/−), when heterozygous for the transgene (tg/−); homozygous (tg/tg) rats died slightly earlier due to neoplastic causes. As observed in (tg/−) rats, moderate suppression of the somatotrophic axis produced some phenotypes similar to those in (−/−) rats subjected to calorie restriction (CR), a well-known experimental intervention favoring longevity in animals. Thus, comparative studies using (tg/−) rats with the CR paradigm will help us understand the role of the somatotrophic axis in regulation of lifespan and aging. Furthermore, the level of suppression of the somatotrophic axis in (tg/−) rats was not as severe as in other mice models, and thus, experiments can be performed within physiological ranges.*

## Introduction

In the last decade, since Ames dwarf mice with spontaneous mutation of the *prop-1* gene were reported to live longer than their wild-type counterparts (Brown-Borg *et al.*, 1996), over 10 rodent longevity models, in which a single gene has been spontaneously mutated or genetically engineered, have been reported (Miskin and Masos, 1997; Migliaccio *et al.*, 1999; Coschigano *et al.*, 2000; Flurkey *et al.*, 2001; Mitsui *et al.*, 2002; Shimokawa *et al.*, 2002; Blüher *et al.*, 2003; Holzenberger *et al.*, 2003). Many of the mice used show a reduction in growth hormone (GH)-insulin-like growth factor (IGF)-1 signaling or insulin signaling (Liang *et al.*, 2003). The importance of these models can be stressed in two ways. First, the DAF-2-AGE-1 pathway in nematodes increases lifespans when the signal input is reduced (Hekimi and Guarente 2003). These two molecules are orthologues of mammalian insulin or IGF receptor (Kimura *et al.*, 1997) and phosphatidylinositol 3-kinase (PI3K; (Morris *et al.*, 1996)), respectively. In fruit flies, mutation of the “Chico” gene, an orthologue of mammalian insulin receptor

substrates, in the insulin-like pathway is also known to result in an extended lifespan (Clancy *et al.*, 2001). These findings suggest that insulin or IGF-1 signaling is an evolutionarily conserved pathway that controls longevity in animals. Second, calorie restriction (CR), a well-known experimental intervention for lifespan extension in a wide range of organisms, also suppresses GH-IGF-1/insulin signaling (Masoro, 2003), suggesting that CR increases animal lifespans partly through a reduction in the signaling pathway (Shimokawa *et al.*, 2003).

In the following chapter, a transgenic strain of mini rats whose somatotrophic axis was suppressed by overexpression of the antisense GH gene (Matsumoto *et al.*, 1993) is described and compared with CR rats in terms of lifespan, pathology, and selected biomarkers potentially related to the effect of CR.

## Mini Rats and Their Husbandry

The transgenic rats were produced from founders created by introducing fusion genes into rat embryos (Matsumoto *et al.*, 1993); their genetic background was Jcl:Wistar (Japan Clea, Inc., Tokyo, Japan). The transgene consisted of four copies of thyroid hormone response elements, rat GH promoter, and antisense cDNA sequences for rat GH. Transgenic offspring expressed the rat GH antisense transgene in the pituitary gland, and exhibited dwarfism as early as 3 weeks of age. Antisense GH-mRNA expression was detected by RT-PCR in the pituitary gland, spleen, and thymus in transgenic rats at 6 months of age, but not in the lungs, liver, heart, kidneys or testis (Shimokawa *et al.*, 2002).

Male and female transgenic rats showed a reduced growth rate but almost normal reproduction function, although maturation seemed to be slightly delayed and the fecundity in female transgenic rats was slightly lower than in control female Wistar rats.

F1 hybrid rats (Jcl:Wistar-TgN (ARGHGEN)1Nts × Jcl:Wistar) were also generated at our laboratory animal center to moderate the reduced level of suppression

of the somatotrophic axis. The experimental animals were referred to as (tg/tg), (tg/-), and (-/-) with respect to the presence of the transgene.

At 4 weeks of age, weanling male rats were transferred to a barrier facility (temperature, 22 to 25°C; 12-h light/dark cycle), housed separately, and maintained under specific pathogen-free (SPF) conditions. The procedure for monitoring the SPF status was fully described elsewhere (Shimokawa *et al.*, 2002) and has been maintained since 1997 when the rat colony was established.

Rats were provided with a CR-LPF diet (Oriental Yeast, Tsukuba, Japan) based on the formula of Charles River (CRF-1), but with a protein fraction of 18.2%; the original CRF-1 diet contains 22.6% protein on a weight basis. All rats were fed a CR-LPF diet and water ad libitum (AL) after weaning. At 6 weeks of age, rats were divided into two diet groups: one group (AL) continued to receive food ad libitum, while the other (CR) was provided every other day with 140% of the mean daily food intake of the AL group in each rat group 30 min before the lights were turned off. This regimen successively restricted the food intake of the CR rats by 30% that of the AL group during the entire experimental period. However, it also yielded a 2-day cycle in the pattern of food intake in the CR group, with most of the allotted food being ingested within the first 24-h. When the food intake pattern confounded serum insulin and other hormones, the CR group was subdivided into CR1 and CR2, rats sacrificed within the first 24-h after feeding and within the following 24-h, respectively. Consequently, when sacrificed in the CR1 phase, the CR group consumed the similar amount of food as each AL group before sacrifice.

The body weights and food intake of rats in each group during the lifespan study are illustrated in Figure 31.1.

It should be noted that both the body weight and food intake of (-/-)-CR rats were similar to those of (tg/-)-AL rats for a considerable period of the

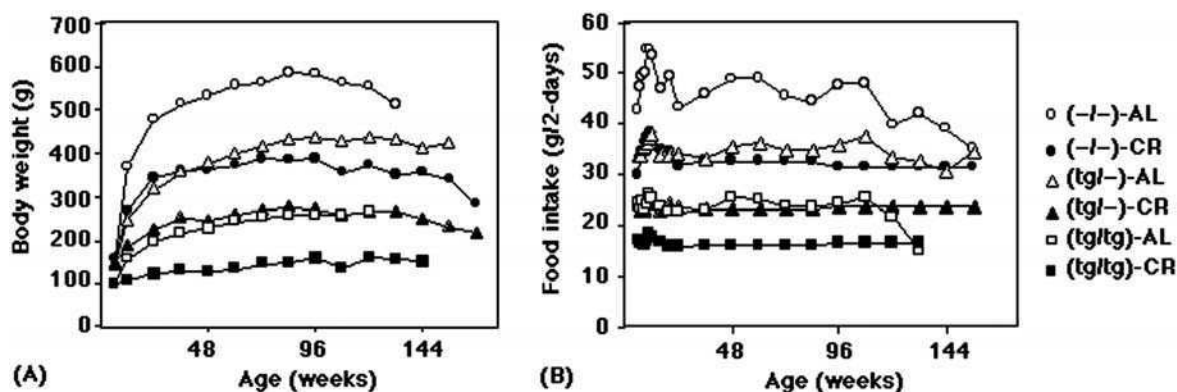

experiment. Thus, comparative studies using (tg/-)-AL and (-/-)-CR rats could give insight into the role of the GH-IGF-1 axis in CR.

Pulsatile secretion of GH has yet to be analyzed in all rat groups; however, an immunohistochemical study revealed that the number of GH-positive cells was markedly reduced in (tg/tg) rats compared with (-/-) rats (Shimokawa *et al.*, 2002). Plasma IGF-1 concentrations at 6 months of age are provided in Table 31.1. The IGF-1 concentration decreased by 43% in (tg/-)-AL rats and by 74% in (tg/tg)-AL rats compared with (-/-)-AL rats. CR further decreased the IGF-1 concentration in each rat group; values in the CR2 phase were slightly lower than in the CR1 phase. It should be noted that the IGF-1 level was slightly lower in (tg/-)-AL rats than (-/-)-CR rats.

### Lifespan and Pathology

The survival curves of (-/-), (tg/-), and (tg/tg) rats fed ad libitum and the effect of CR on (-/-) and (tg/-) rats were published previously (Shimokawa *et al.*, 2002; Shimokawa *et al.*, 2003). At the 25th percentile survival point, the lifespan was increased by 10% in (tg/-)-AL rats compared with (-/-)-AL rats (Table 31.2). In contrast, the lifespan of (tg/tg)-AL rats was diminished by 9%. CR increased the lifespans of (-/-), (tg/-), and (tg/tg) rats by 11, 10, and 19%, respectively.

Postmortem examinations were performed to determine the prevalence of selected diseases and analyze probable causes of death. Prevalence of pituitary adenoma did not differ between (-/-)-AL and (tg/-)-AL rats, but was significantly decreased in (tg/tg)-AL rats (Table 31.3). CR reduced the prevalence of pituitary adenoma compared to the AL group in (tg/-) rats, while statistically insignificant in (-/-) and (tg/tg) rats. Prevalence of chronic nephropathy was also significantly reduced in (tg/-) and (tg/tg) rats, and similarly, CR also decreased the prevalence. Although the number of rats

**Figure 31.1.** (A) Mean body weights of each rat group in the longevity study;  $n = 30$  for each group at the start of the study, except the (tg/tg)-CR group ( $n = 10$ ). Data are not depicted when the number of rats was below five, because of spontaneous death. (B) Mean food intake (g/rat/2 days) of the rat groups in the longevity study ( $n = 10$ , respectively). Data are not depicted when the number of rats was below five.

### 31. A Transgenic Mini Rat Strain as a Tool for Studying Aging

TABLE 31.1  
Circulating concentrations of IGF-1, insulin, and glucose in not-fasting rats at 6-months of age

	(-/-)			(tg/-)			(tg/tg)		
	AL	CR1	CR2	AL	CR1	CR2	AL	CR1	CR2
IGF-1 (ng/ml)	1094 ± 119	864 ± 79 <sup>b</sup>	773 ± 60 <sup>b, c</sup>	627 ± 90 <sup>a</sup>	346 ± 40 <sup>b</sup>	n/a	266 ± 23 <sup>a</sup>	170 ± 11 <sup>b</sup>	n/a
Insulin (ng/ml)	102 ± 49	15 ± 10 <sup>b</sup>	18 ± 10 <sup>b</sup>	22 ± 18 <sup>a</sup>	20 ± 26	28 ± 30	21 ± 19 <sup>a</sup>	n/a	m/a
Glucose (mg/dL)	126 ± 34	112 ± 12	102 ± 4	106 ± 18	90 ± 16	91 ± 12	106 ± 17	n/a	n/a

Data represent means ± SD ( $n = 3$  to  $6$ ). <sup>a</sup> $p < 0.05$  vs (-/-)-AL group, <sup>b</sup> $p < 0.05$  vs the group AL in each rat group, <sup>c</sup> $p < 0.05$  vs the group CR1 in each rat group by a post hoc test (Fisher's protected least significant difference test) for multiple comparisons after 1-factor ANOVA. AL, groups of rats fed ad libitum. CR1 and CR2, groups of rats subjected to 30% calorie restriction, while sacrificed in the first day and the second day of 2-day feeding cycle, respectively (see the rat husbandry for the CR regimen, a modified alternate-day-feeding, used in the present study).

TABLE 31.2  
Summary of lifespans

Survival points (percentile)	(-/-)		(tg/-)		(tg/tg)	
	AL	CR	AL	CR	AL	CR
50th	126 ± 7	142 ± 12	138 ± 14	157 ± 4	118 ± 1	145 ± 3
25th	140 ± 3	155 ± 10	154 ± 5	169 ± 6	127 ± 2	151 ± 4

Values represent the age (weeks) of each survival point of lifespan (±SE).  $n = 30$  for (-/-) and (tg/-) rats at the start of the study, while 55 in (tg/tg)-AL rats and 35 in (tg/tg)-CR rats. A part of the data was published elsewhere (Shimokawa *et al.*, 2002; Shimokawa *et al.*, 2003). The survival rates were estimated using Kaplan–Meier product limit estimates. Although the survival curves are not shown in this chapter, the effect of CR was confirmed to be statistically significant in each rat group by the logrank test using the software “StatView 5.0” (SAS Institute, Cary, NC).

TABLE 31.3  
Prevalence of selected diseases in rats dying spontaneously

	-/-		tg/-		tg/tg	
	AL	CR	AL	CR	AL	CR
$n$	30	26	30	30	39	17
Pituitary adenoma	20	13	22	8 <sup>a, b</sup>	8 <sup>a</sup>	2 <sup>a</sup>
Chronic nephropathy						
Total	25	2 <sup>a</sup>	8 <sup>a</sup>	0	0	0
Mild	17	2	7	0	0	0
Moderate	5	0	1	0	0	0
Severe	3	0	0	0	0	0
Cardiac thrombus	6	0	3	0	0	0

$n$ , the number of rats examined. <sup>a</sup> $p < 0.05$  versus -/- (AL) rats. <sup>b</sup> $p < 0.05$  versus tg/- (AL) rats. The total number of chronic nephropathy is statistically analyzed, but not the frequency of nephropathy by severity.

TABLE 31.4  
Probable causes of death

	-/-		tg/-		tg/tg	
	AL	CR	AL	CR	AL	CR
Neoplastic (subtotal)	15	18	22	14	37 <sup>a</sup>	11
Pituitary adenoma	5	8	11 <sup>c</sup>	2 <sup>b</sup>	1 <sup>c</sup>	0
Tumor of subcutis or bone	5	3	4	2	5	0

Tumor of visceral organs	1	2	2	2	4	2
Leukemia or lymphoma	0	1	2	3	21 <sup>d</sup>	8
Others	4	1	2	0	4	0
Non-neoplastic (subtotal)	15	8	8	16	2	6
Cardiac thrombus	6	0	3	0	0	0
Prostatitis/lower urinary tract obstruction	1	3	1	5	0	0
Others (determined)	1	0	0	2	0	3
Undetermined	7	5	4	9	2	3

Data represent the number of rats. The proportion of each category or disease was analyzed by  $\chi^2$  test or Fisher exact test. <sup>a</sup> $p < 0.05$  and <sup>c</sup> $p < 0.10$  versus -/- (AL) rats. <sup>b,d</sup> $p < 0.05$  versus tg/- (AL) rats.

that suffered from cardiac thrombi was limited, the prevalence was reduced in (tg/tg) rats; this was also seen in CR rats.

Probable causes of death differed among the three rat groups (Table 31.4). The (tg/tg) rats died mostly of neoplastic diseases, particularly leukemia, which was never observed in (-/-) rats. To assess the contribution of neoplastic causes of death to the shortened lifespan of (tg/tg) rats, conditional survival curves for neoplastic causes of death were generated (Figure 31.2).

In this analysis, nonneoplastic causes of death were considered to be the same censorship as random sacrifice of rats (see Shimokawa *et al.*, 1991 for details). Analysis confirmed that (tg/tg)-AL rats died earlier than other rats from neoplasms. The survival curve of (tg/-)-AL rats did not differ from that of (-/-)-AL rats, suggesting that the increased survival of (tg/-) rats is mostly due to delayed nonneoplastic causes of death. The proportion of pituitary adenoma as the cause of death increased in (tg/-)-AL rats compared with (-/-) rats, although the prevalence of pituitary adenoma was similar between the two groups. It is possible therefore that, in (tg/-)-AL rats, the reduced incidence of lethal nonneoplastic disorders contributes to lifespan extension, and thus, pituitary adenoma as a cause of death increased even though the onset and progression of pituitary tumors was not affected. In contrast, CR significantly decreased the prevalence of pituitary adenoma and the proportion of related deaths, suggesting that CR suppresses pituitary tumorigenesis. CR seemed to delay the occurrence of neoplastic causes (data not shown) as well as nonneoplastic causes of death in (-/-) and (tg/-) rats as

**Figure 31.2.** Conditional survival curves of the neoplastic causes of death. Non-neoplastic deaths were considered to be the same censorship as random sacrifice of rats. Survival curves were produced using Kaplan–Meier product limit estimates and compared using the log rank test (Shimokawa *et al.*, 1991).

seen in the inhibited prevalence of cardiac thrombi and proportion of related deaths.

At present, pathologic analyses of long-lived mice are limited; however, it has been reported that the occurrence of neoplastic causes of death is delayed in Ames mice (Ikeno *et al.*, 2003). Because GH and IGF-1 are anabolic hormones that might increase the risk of several cancers (Ibrahim and Yee, 2004), the reduced GH-IGF-1 axis was expected to reduce the occurrence or progression of neoplastic diseases, thus delaying neoplastic causes of death.

### 31. A Transgenic Mini Rat Strain as a Tool for Studying Aging

TABLE 31.5  
Fasting blood glucose and insulin concentrations in the transgenic rats

	(-/-)		(tg/-)		(tg/tg)	
	AL	CR	AL	CR	AL	CR
Glucose (mg/dL)						
Young	109 ± 14	112 ± 7	105 ± 21	108 ± 10	94 ± 5	94 ± 6
Old	116 ± 9	106 ± 6	108 ± 3	109 ± 14	72 ± 10	83 ± 13
Insulin (ng/ml)						
Young	7.3 ± 4.5	4.5 ± 2.0	3.7 ± 1.6	2.4 ± 1.6	n/a	n/a
Old	41.6 ± 39.3	43.5 ± 37.5	29.4 ± 22.3	19.7 ± 24.6	n/a	n/a

Blood samples were drawn from the tail vein without anesthesia between 9:00 and 12:00 after overnight fasting. "Young" represents the age between 6 and 8 months; "Old" represents the age between 24 and 25 months. Data represent means ± SD of 4 to 7 rats. 3-f ANOVA analyzed the main effects of rat group, diet, and age.

Immunological analysis of transgenic rats demonstrated that the proportion and activity of NK cells in splenocytes were reduced significantly in (tg/tg) rats compared with (-/-) and (tg/-) rats (Shimokawa *et al.*, 2002). NK cells are known to protect animals from neoplastic processes (Lotzova, 1993); thus in Wistar rats, severe suppression of the GH-IGF-1 axis might promote neoplastic processes due to dysfunction of the immune system, because GH and IGF-1 are required for normal development of the immune system (Dorshkind and Horseman, 2000). In this regard, however, it is intriguing that Snell mice, which show the same phenotypes as Ames mice, including a lengthened lifespan, achieve normal immune responsiveness even if GH is almost deficient (Cross *et al.*, 1992).

#### Glucose, Insulin and Related Parameters

A distinctive feature of long-lived mice, in which the somatotrophic axis is suppressed, is a reduced serum insulin concentration (Hsieh *et al.*, 2002; Shimokawa *et al.*, 2003). As noted above, diminished insulin-like signaling by reduction-of-function mutations favors longevity in invertebrates, in which insulin and IGF-1 signal pathways are not clearly separated. Similar manipulations of insulin signal genes in mammals, however, resulted in metabolic disorders and shortened lifespans; there was only one exception, a strain of mice whose insulin receptor gene was disrupted exclusively in white fat tissues (Blucher *et al.*, 2003).

#### SERUM GLUCOSE AND INSULIN UNDER NOT-FASTING AND FASTING CONDITIONS

During the feeding cycle in our laboratory, blood glucose levels did not statistically differ among (-/-)-AL, (tg/-)-AL, and (tg/tg)-AL groups, although the number of rats examined was limited (Table 31.1). In the CR groups, (-/-) and (tg/-) rats, blood glucose levels tended to be slightly decreased, although this difference was statistically

insignificant. Serum insulin concentrations were significantly decreased in (tg/-)-AL and (tg/tg)-AL rats compared with (-/-)-AL rats (Table 31.1). In the CR groups, serum insulin was not significantly increased even in the CR1 phase even though (-/-)-CR and (tg/-)-CR rats consumed the same amount of food as each AL group overnight.

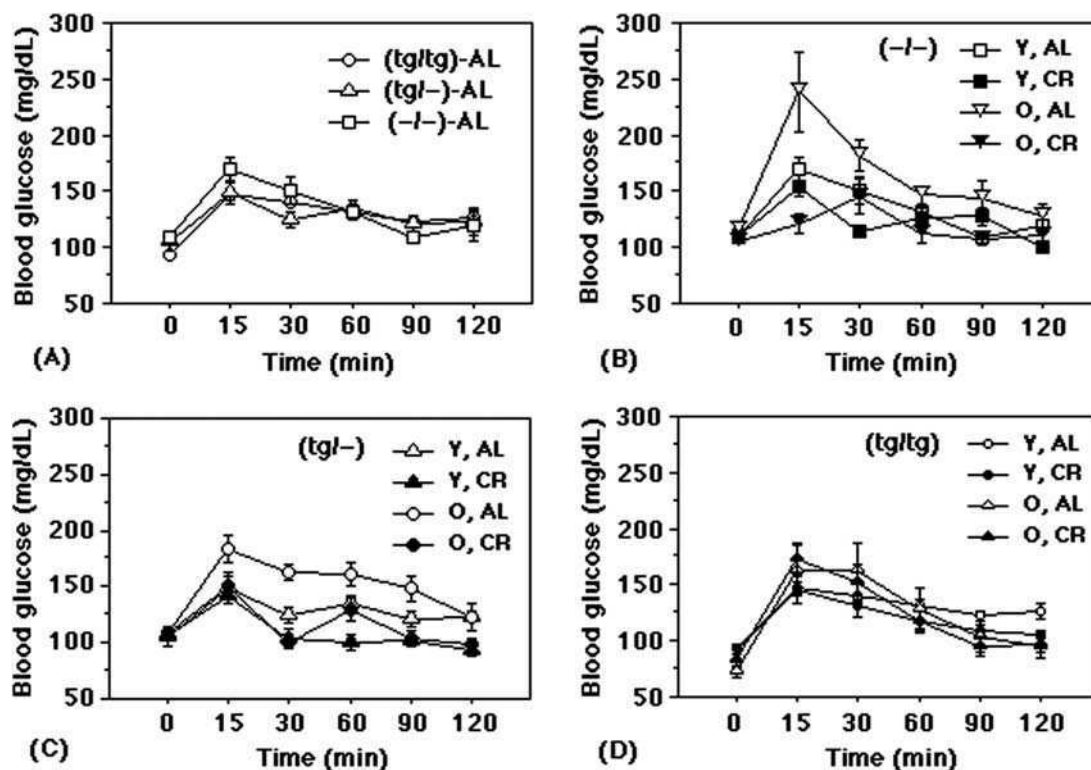

Data on fasting blood glucose and insulin concentrations were obtained by glucose tolerance tests. The blood glucose concentration in the tail vein after overnight fasting did not differ between (-/-) and (tg/-) rats, although it was slightly reduced in (tg/tg) rats, particularly at the age of 24 or 25 months (Table 31.5). Neither CR nor age affected blood glucose levels. Serum insulin concentrations were slightly, but significantly, lower in (tg/-) rats than (-/-) rats. This concentration significantly increased in the old group, but was insignificantly altered in the CR group. These data indicate that insulin resistance is already apparent in (-/-) and (tg/-) rats at old age, even if subjected to CR. It remains to be elucidated whether CR delays the occurrence of insulin resistance in middle age.

#### GLUCOSE TOLERANCE

At a young age, time-dependent alterations in blood glucose in the glucose tolerance test (GTT) were similar among (-/-), (tg/-), and (tg/tg) rats when fed ad libitum (Figure 31.3A).

In (-/-) rats, aging impaired glucose tolerance, particularly in the AL group (Figure 31.3B); in the CR group, it was mostly inhibited. In (tg/-) rats, glucose intolerance was also observed in the AL group at old age (Figure 31.3C); CR inhibited aging-related impairment. In (tg/tg) rats, time-dependent changes in blood glucose did not differ between young and old or AL and CR groups (Figure 31.3D).

Serum insulin concentrations during the GTT were measured in (-/-) and (tg/-) rats using samples drawn

**Figure 31.3.** Glucose tolerance of transgenic rats; the effect of calorie restriction and aging. Values represent the mean  $\pm$  SE of 4 to 7 rats. Y represents an age of 6 to 7 months, and O represents an age of 24 months. 2-f ANOVA was used to analyze the main effects of rat group and time and their interaction (A) or age and time and their interaction (B–D) on blood glucose tolerance.

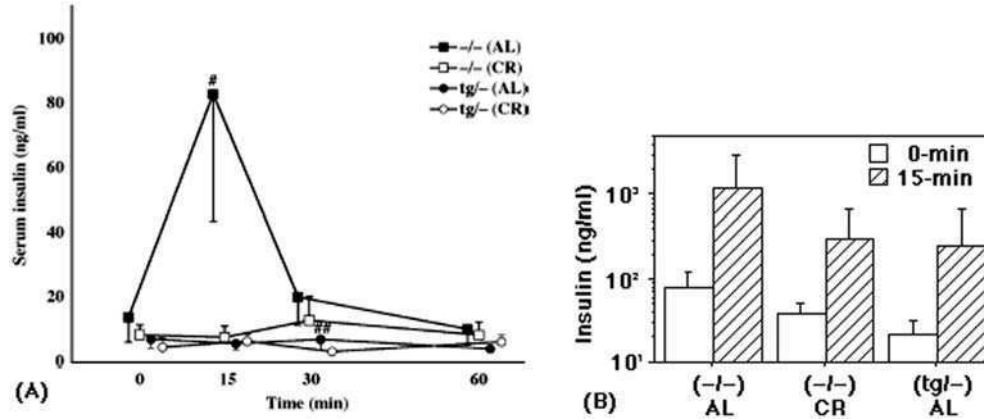

from the tail vein (Yamaza *et al.*, 2004). Serum insulin concentrations were transiently elevated at 15 min in  $(-/-)$  rats at young age (Figure 31.4A); there was no insulin surge during the GTT in  $(tg/-)$ -AL,  $(tg/-)$ -CR or  $(-/-)$ -CR rats.

If serum samples were prepared from trunk blood after decapitation, insulin levels at 15 min after glucose load were increased in  $(-/-)$ -CR and  $(tg/-)$ -AL rats as in  $(-/-)$ -AL rats, but the level was significantly lower by 75–80% in  $(-/-)$ -CR and  $(tg/-)$ -AL rats (Figure 31.4B), although values fluctuated. Serum insulin concentrations during the GTT fluctuated largely in old rats (data not shown, but refer to Shimokawa (2005)) and no transient increases were detected. On a whole, however, serum insulin levels were greater in  $(-/-)$ -AL rats compared with  $(tg/-)$ -AL and  $(-/-)$ -CR rats.

The data described here indicate that in transgenic rats, glucose is effectively transported into tissues with lower concentrations of insulin as in CR rats, and the islet cell insulin response to a rise in blood glucose is blunted in transgenic and CR rats. Similarly, this suggests that CR modulates glucose metabolism and insulin responses through a reduction in the GH-IGF-1 axis.

Glucose disposal occurs as a result of both insulin-mediated and non-insulin-mediated glucose uptake (IMGU and NIMGU, respectively (Baron *et al.*, 1988)).

By definition, IMGU can occur only in insulin-sensitive tissues, such as skeletal muscles and fat tissues, while, in the absence of insulin, NIMGU can occur in both insulin-sensitive and non-insulin-sensitive tissues including the central nervous system, peripheral nerves, visceral organs, and blood cells (Ferrannini *et al.*, 1985). A study conducted by Wetter *et al.* (1999) demonstrated that glucose uptake during the period before feeding, at which point serum insulin levels are lowered, is not reduced in most tissues of CR rats; in contrast, white and brown fat tissues showed increased glucose uptake rates. In the period after feeding—that is, postprandially, at which point the serum insulin concentration is increased—insulin-sensitive tissues such as skeletal muscles and fat tissues displayed an increase in glucose uptake in the AL and CR groups, while in some skeletal tissues and mesenteric fat, the glucose uptake tended to be greater in CR rats. GLUT4, the predominant glucose transporter expressed by skeletal muscle, seems to account for most of the insulin-stimulated glucose transport in muscles (Rodnick *et al.*, 1992). In the epitrochlearis muscle, CR increases the amount of cell surface GLUT-4 in response to insulin (Dean *et al.*, 1998). In human placental GH-overexpressing mice that exhibit severe insulin resistance, insulin-stimulated GLUT-4 translocation to the plasma membrane was shown to be reduced (Barbour

**Figure 31.4.** (A) Serum insulin concentrations during the glucose tolerance test. Serum samples were prepared from blood drawn from the tail vein. Values represent the mean  $\pm$  SD of 3 to 6 rats. Reproduced from (Yamaza *et al.*, 2004) by copyright permission of Elsevier. (B) Blood glucose concentrations after glucose load using the same amount of glucose as in the glucose tolerance test. Blood glucose was measured in serum samples prepared from trunk blood at decapitation. Values represent the mean  $\pm$  SD of 4 to 5 rats. 2-f ANOVA was used to analyze the main effects of rat group and time and their interaction. (C) Serum insulin concentrations after glucose load. Serum samples were the same as those in (B). Values represent the mean  $\pm$  SD of 4 to 5 rats. 2-f ANOVA was used to analyze the main effects of rat group and time and their interaction.

*et al.*, 2004), suggesting that the somatotrophic axis has an inhibitory effect on cell surface translocation of GLUT4. Therefore, we speculate that CR enhances the GLUT4 translocation machinery in insulin-sensitive tissues by reducing the inhibitory effect of the GH-IGF-1 axis. The effect of the reduced GH-IGF-1 axis and CR on non-insulin-mediated mechanisms of glucose uptake remains to be assessed.

Glucose is the prime modulator of insulin secretion, although the precise mechanisms and factors involved in the insulin secretion process are not fully understood. The findings described above suggest that CR and the reduced GH-IGF-1 axis suppress the islet insulin response to a blood glucose rise. The mechanisms of glucose rises and the islet response in long-lived rodents remain to be elucidated.

### Body Fat, the Blood Lipid Profile, Leptin and Adiponectin

GH deficiency affects lipid as well as carbohydrate metabolism, resulting in fat accumulation in the body (Gola *et al.*, 2005) and inducing insulin resistance and related disorders. As described above, the transgenic rats exhibited a number of characteristics indicating increased insulin sensitivity. The following section describes selected parameters related to fat metabolism in transgenic rats.

#### BODY FAT CONTENT AND BLOOD LIPID PROFILES

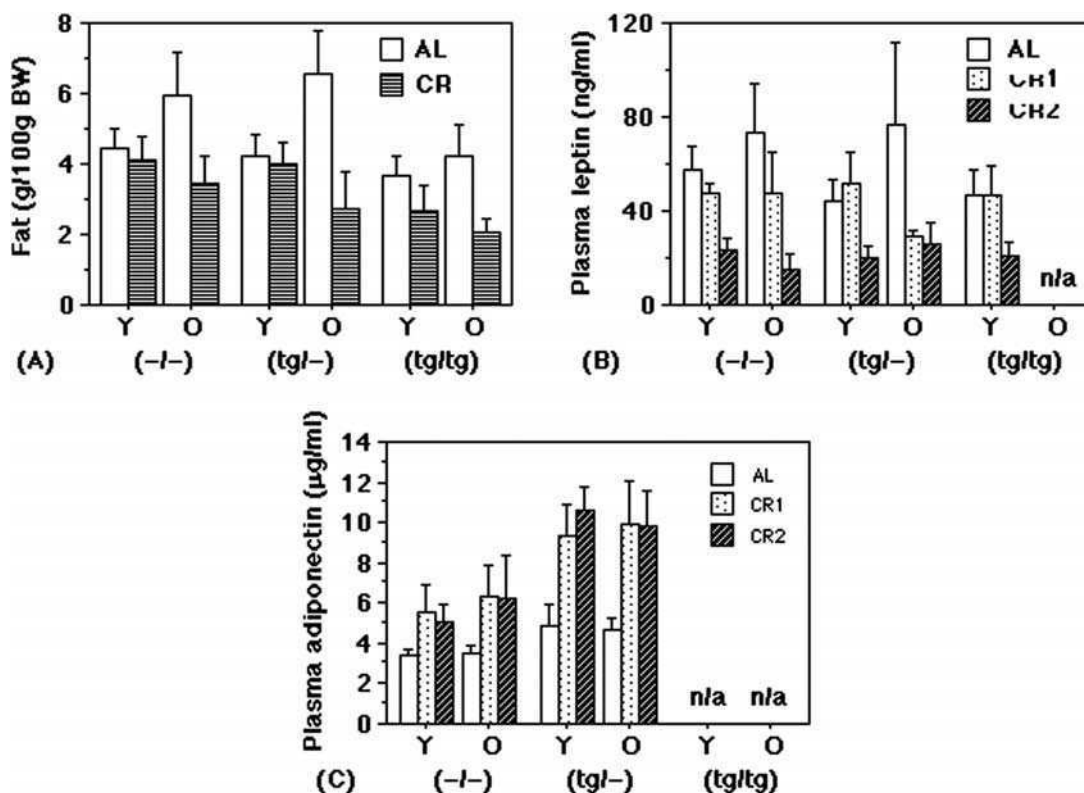

The fat content, when normalized by body weight, was slightly but significantly reduced in (tg/tg) rats, but there was no difference between (-/-) and (tg/-) rats (Figure 31.5A).

Aging tended to increase the fat content of the AL groups; however, when subjected to CR, the fat content was expectedly reduced. The aging-related increase was therefore prohibited in CR groups, but not in transgenic rat groups fed ad libitum.

The serum triacylglycerol (TG) concentration was reduced in (tg/tg) rats, but statistically insignificant between (-/-) and (tg/-) rats. CR reduced the serum TG concentration, but there was no difference between the CR1 and CR2 groups. Total serum cholesterol levels did not differ among rat groups, although CR resulted in a slight reduction (Table 31.6). HDL-cholesterol was greatest in (tg/tg) rats followed by (tg/-) and (-/-) rats, respectively. Correspondingly, serum concentrations of LDL-cholesterol were slightly greater in (-/-) rats compared with (tg/-) and (tg/tg) rats. HDL-cholesterol levels were slightly but significantly greater in CR1 compared to CR2 phase rats. As a result, LDL-cholesterol levels were particularly reduced in CR1 phase rats. The serum free fatty acid concentration did not differ among rat groups, but was reduced in CR1 phase rats and elevated in CR2 phase rats. Thus, transgenic rat strains, either (tg/-) or (tg/tg), exhibited no deleterious lipid metabolism profile; rather, the slightly lower concentration of total cholesterol and higher concentration of HDL-cholesterol in (tg/tg) rats suggested that a suppressed GH-IGF-1 axis yields some beneficial effects in animals.

#### PLASMA LEPTIN

Plasma leptin concentrations are known to reflect body fat content (Niswender and Schwartz, 2003). At the age between 6 and 8 months, plasma concentrations did not significantly differ among rat groups, although the fat content was slightly lower in (tg/tg) rats compared with

**Figure 31.5.** (A) Body fat content, and (B) plasma leptin and (C) adiponectin concentrations. The body fat content represents the combined wet weights of perirenal and epididymal fat normalized by body weight (g/100 g body weight (BW)). Fat content did not significantly differ between the CR1 and CR2 phase rats; thus data were combined into the CR group. Plasma samples were prepared from trunk blood collected at decapitation. Plasma leptin and adiponectin data was unavailable for  $(tg/tg)$  rats. "Young" represents an age of 6 to 8 months, while "Old" represents an age of 24 to 25 months. The numbers of rats examined were 7 to 24 for body fat content, 3 to 8 for plasma leptin, and 3 to 7 for plasma adiponectin. 3-f ANOVA was used to analyze the main effects of rat group, diet, and age and their interaction.

$(-/-)$  and  $(tg/-)$  rats (Figure 31.5B). The CR regimen in the present study reduced plasma leptin levels only in the CR2 phase rats. However, in our previous study using F344 rats, leptin levels were consistently lower in the CR group during the 2-day feeding cycle (Shimokawa and Higami 1999). The plasma leptin findings paralleled the altered fat content resulting from CR.

With aging, plasma leptin concentrations were slightly increased in the AL group, staying constant or slightly decreased in the CR group. These aging-dependent changes were also comparable with the changes in fat content.

#### PLASMA ADIPONECTIN

Plasma adiponectin concentrations are inversely correlated with body fat content (Havel, 2004); that is, they are lowered in obese patients and animals. Adiponectin exerts an antidiabetic effect by sensitizing insulin action and augmenting fatty acid oxidation in the muscles. It also exhibits an antiatherosclerotic effect by attenuating inflammatory insults in the vascular wall. These metabolic and anti-inflammatory effects are also thought to be some of the beneficial effects of CR (Masoro, 2003). Indeed,

recent reports demonstrated a higher plasma concentration of adiponectin in CR animals (Berg *et al.*, 2001; Combs *et al.*, 2003; Zhu *et al.*, 2004), and in long-lived dwarf animal models, plasma adiponectin concentrations have been shown to be increased (Berryman *et al.*, 2004).

In this study, plasma adiponectin levels were increased in  $(tg/-)$  rats, when fed ad libitum (Figure 31.5C). Levels were also increased in  $(-/-)$ -CR rats. In addition, CR of  $(tg/-)$  rats additively increased plasma adiponectin concentrations. The increased concentration with CR was slightly greater in  $(tg/-)$  rats.

This increased adiponectin concentration might be linked to the increased sensitivity of insulin or lower concentration of plasma insulin after glucose load. Recent studies have indicated that adiponectin could facilitate glucose uptake into skeletal muscle and adipocytes independent of insulin action, through activation of AMP-activated protein kinase (AMPK) (Tomas *et al.*, 2002; Wu *et al.*, 2003). The adiponectin-AMPK pathway might act as the insulin-independent pathway for glucose metabolism in long-lived dwarf and CR animals. The level of phosphorylated AMPK, the active form of the enzyme, is increased in GHRKO mice (Al-Regaiey *et al.*, 2005),

TABLE 31.6  
The serum lipid profile in the transgenic rats at 6 or 7 months of age

	(-/-)			(tg/-)			(tg/tg)		
	AL	CR1	CR2	AL	CR1	CR2	AL	CR1	CR2
Triacylglycerol	329 ± 106	137 ± 57	144 ± 90	229 ± 79	146 ± 44	143 ± 28	144 ± 47	91 ± 20	87 ± 28
Total cholesterol	93 ± 6	84 ± 11	82 ± 4	94 ± 7	84 ± 6	88 ± 4	102 ± 4	81 ± 5	89 ± 6
HDL-cholesterol	30 ± 3	41 ± 8	32 ± 4	36 ± 3	47 ± 4	41 ± 6	47 ± 2	52 ± 3	49 ± 4
LDL-cholesterol	11 ± 1	7 ± 2	8 ± 1	10 ± 1	7 ± 1	8 ± 2	8 ± 1	8 ± 1	7 ± 1
Free fatty acid	0.66 ± 0.20	0.35 ± 0.16	0.74 ± 0.20	0.75 ± 0.34	0.39 ± 0.13	0.79 ± 0.51	0.79 ± 0.24	0.30 ± 0.05	0.89 ± 0.19

Serum samples were prepared from trunk blood at decapitation between 9:00 and 12:00. Data represent means ± SD (mg/dL) of 3 to 7 rats. 2-f ANOVA analyzed the main effects of rat group and diet and their interaction. AL, groups of rats fed ad libitum. CR1 and CR2, groups of rats subjected to 30% calorie restriction, while sacrificed in the first day and the second day of 2-day feeding cycle, respectively (see the rat husbandry for the CR regimen, a modified alternate-day-feeding, used in the present study).

while not in CR rats. Our preliminary experiment did not confirm the upregulation of phosphorylated AMPK in transgenic rats (data not shown).

## Stress response

Stress resistance is linked to retardation of aging and an extended lifespan. CR rodents exhibit resistance to many types of stressors including toxic substances, inflammatory stimuli, ambient temperature, and surgery (Masoro, 2003). Some long-lived mice also show high survival rates after intraperitoneal injection of paraquat, a herbicide that generates reactive oxygen species (ROS) (Migliaccio *et al.*, 1999; Holzenberger *et al.*, 2003).

We therefore examined the resistance of the transgenic mice included here to lipopolysaccharide (LPS)-induced inflammatory challenge, which causes cellular injury by generating ROS and reactive nitrogen species (RNS). Six-month-old male Wistar ( $-/-$ ), ( $tg/-$ ), and ( $tg/tg$ ) rats fed ad libitum were administered LPS (1.6 mg/kg body weight) through the tail vein, then sacrificed 0-, 1-, 4-, and 8-h later. A preliminary study indicated that this dose of LPS induced necrotic foci in the liver at 8-h in 50% of ( $-/-$ ) rats. Serum aspartate aminotransferase (AST) levels, an index of LPS-induced tissue damage, were consequently measured. The preliminary results at 4- and 8-h (Figure 31.6) indicated that serum AST levels were greater in ( $-/-$ ) rats compared with ( $tg/-$ ) and ( $tg/tg$ ) rats, with no difference between ( $tg/-$ ) and ( $tg/tg$ ) rats.

Our previous study using a similar experimental protocol with F344 rats showed that CR rats resisted LPS-challenge (Tsuchiya *et al.*, 2005). Thus, common stress response machinery is thought to be elicited with reduced GH-IGF-1 and CR, respectively.

**Figure 31.6.** Stress response to lipopolysaccharide (LPS)-induced inflammation. Rats were sacrificed 0-, 1-, 4-, and 8-h after intravenous injection of 1.6 mg/kg body weight (BW) of LPS. Serum aspartate aminotransferase (AST) levels were measured as an index of LPS-induced tissue injury. Values represent the mean  $\pm$  SD of 3 to 10 rats. AST levels at 0- and 1-h are not shown because levels were not significantly elevated. 2-f ANOVA was used to analyze the main effects of rat group and time and their interaction on AST levels.

## Conclusions

When fed ad libitum, transgenic ( $tg/-$ ) rats displayed several phenotypes similar to those of wild-type rats subjected to CR. For example, profiles of blood glucose, insulin and other hormones during the feeding cycle or after glucose load and an enhanced stress response were seen in both. These findings suggest that this rat model is suitable for analyses of the mechanisms underlying the effect of CR, particularly with regard to the role of the somatotrophic axis in the regulation of lifespans and aging. Another merit of this model is that the reduced level of the GH-IGF-1 axis was moderate and less severe than in Ames or GHR/BP-KO mice whose GH-IGF-1 signaling was almost totally deficient. Thus, experiments using the transgenic mini rats can be conducted within physiological ranges.

The ( $tg/tg$ )-AL rats resembled ( $tg/-$ )-AL rats as well as ( $-/-$ )-CR rats with regard to glucose and insulin levels and the stress response. However, these ( $tg/tg$ ) rats died earlier of neoplastic diseases. Although immunological dysfunction was noted in ( $tg/tg$ ) rats, further studies are needed to determine whether severe suppression of the somatotrophic axis results in negative effects on aging and longevity, because mice models with deficient GH signals were shown to live longer.

# Rat Models of Age-Related Cognitive Decline

Jennifer L. Bizon and Michelle M. Nicolle

*Naturally occurring rat models can be useful for studying age-related cognitive decline. Long-Evans rats trained on the Morris water maze have been used to model individual differences in cognitive abilities that depend on the medial temporal lobe system. This approach has yielded a great deal of new information including the unexpected lack of neuronal loss in the hippocampus in aged rats with pronounced cognitive impairment. Despite this absence of neuron death, aged rats with impaired memory can be distinguished from those with intact memory at the neurobiological level. Cellular and molecular changes include alterations in the electrophysiological properties involved in synaptic plasticity, alterations in gene and protein expression, and efficacy of cell signaling pathways.*

*The prefrontal cortex and cognitive abilities supported by this brain region are also subject to age-related decline. The rat prefrontal cortex performs certain aspects of what is conventionally known as "executive function" in primates. This includes the ability to alter behavior in the face of changing environmental contingencies. Recently, an attentional set-shifting task has been designed for assessing executive function in rats. Individual differences in attentional set shifting have been described in aged rats, and this task is currently being combined with neurobiological studies to yield information regarding the underlying causes of behavioral impairment. The use of these two tasks assessing age-related cognitive impairment and the general approaches described in this chapter should yield informative data regarding our understanding of the neurobiology of age-related cognitive decline and should be useful for guiding therapeutic approaches targeting such deficits in humans.*

## Introduction

Age-related cognitive decline is a substantial problem, particularly based on the growing population of elderly in the United States and in other developed nations. The number of people over 65 living in the United States is expected to increase from 35 million in 2000 to

71.5 million by the year 2030, comprising almost 20% of the U.S. population (U.S. Census Bureau, 2004). It has further been estimated that 7–8% of individuals in the United States have severe cognitive impairment (Freedman *et al.*, 2002). This cognitive disability contributes a significant burden with regard to reduced individual quality of life as well as financial strain on the healthcare system and society—a burden that can only be expected to escalate. Understanding neurobiological factors that contribute to cognitive decline with aging is the initial step in combating this health problem. Animal models of aging complement human studies and can be advantageous for investigating the neurobiological changes that underlie age-related cognitive decline. Ultimately, the use of animal models will contribute to the discovery of efficacious treatment options for humans with cognitive impairment.

## Using Rats to Model Aging

### THE UTILITY OF A RAT MODEL

Rats provide an excellent and reproducible system in which to study age-related cognitive decline. There are surprising similarities between rodents and humans in the anatomy of brain systems, including those that are particularly vulnerable to cognitive decline during aging (e.g., the medial temporal lobe system). In addition, the availability of rodent subjects, as well as ethical concerns regarding the invasive procedures necessary for neurobiological research in humans, necessitates the use of animal models. Rats afford particular advantages because researchers can employ relatively large sample sizes and tightly controlled experimental conditions. Rats can also be used for invasive procedures that are important for uncovering the neurobiology responsible for age-related cognitive decline. In contrast to transgenic or knock-out mouse models of cognitive impairment and dementia, many aged rats strains provide a naturally occurring model of age-related impairment in which some rats demonstrate cognitive decline, whereas others have mnemonic abilities on a par with young rats. Making use of such naturally occurring rat models circumvents some of the challenges associated with transgenic mouse studies, including

developmental abnormalities, thereby providing a rich model for uncovering the neurobiological factors responsible for age-related cognitive loss.

### COMPARABILITY TO HUMAN AGE-RELATED COGNITIVE DECLINE

There is substantial evidence that specific factors that adversely impact cognition in rat models also correlate with age-related cognitive impairment in primates, including humans. For example, assessment of the degree of atrophy of the medial temporal lobe in humans is an effective predictor for the development of dementia in patients with mild cognitive impairment (Korf *et al.*, 2004), and medial temporal lobe atrophy in stroke patients predicts poor cognitive performance (Jokinen *et al.*, 2004). Likewise, lesions of medial temporal lobe structures induce memory impairments in rodents (reviewed by Jarrard, 1993). Moreover, age-related changes such as alterations in the glucocorticoid system and increases in oxidative stress are found among aged rat and human populations (Bizon *et al.*, 2001; Nicolle *et al.*, 2001; de Quervain *et al.*, 1998; Roozendaal, 2002; de Quervain *et al.*, 2003; Lupien *et al.*, 2005).

Finally, as discussed in more detail below, the absence of frank neural loss among aged rats with memory impairment has now been replicated in aged monkeys and humans. It should be emphasized that although parallels exist between behavioral deficits observed in the rat models of aging discussed here and both rodent experimentally induced brain lesions and human age-related disease, the models we employ are not intended to represent human neurodegenerative disease such as Alzheimer's or Parkinson's disease. Rather, we consider these naturally occurring rat models a tool for understanding the normal aging process in the absence of disease. Some have suggested that the cognitive decline seen in these rat models is akin to what is referred to as nonprogressive mild cognitive impairment in humans, although additional research on neuronal atrophy and other defining characteristics in both rats and humans are needed to support the use of this terminology (Gallagher *et al.*, 2003).

### RAT AGING MODELS—STRAIN SELECTION

There is a plethora of rat strains commonly used in neurobiological research today, but special considerations need to be taken into account when choosing a rat strain in which to conduct cognitive aging research. The most popular strains used for aging research include Sprague Dawley, Fisher 344 (F344), Long-Evans, Brown Norway, and F344 × Brown Norway F1 (Bizon and Gallagher, 2005; Merrill *et al.*, 2003; Drapeau *et al.*, 2003; Kasckow *et al.*, 2005; Lichtenwalner *et al.*, 2001). Some critical factors to consider when selecting a rat strain include variability in health and lifespan inherent to the strain, strain-specific

and sex-specific differences in cognition, and supplier availability. For example, certain strains may be more prone to tumors of the pituitary gland, a factor that can cause variability in circulating hormone levels and blindness through compression of the optic nerve. Such factors can impact cognitive performance and neurobiological data if behavioral tests are not carefully designed and aged rats are not properly screened for such tumors at sacrifice. Another consideration is the sex of rats chosen; the endocrine system certainly can influence memory and brain function, and it is well established that the endocrine system in rats, as in humans, is modified with aging. When using aged female rats one must therefore take into consideration circulating hormone levels in young and aged rats, as the estrous cycle in females is cyclic in young rats, becomes erratic at middle ages, and ceases at later ages (Savonenko and Markowska, 2003). Finally, availability must be a consideration for those wishing to conduct cognitive aging research. Indeed only three rat strains (F344, Brown Norway and F344 × Brown Norway F1 hybrids) are currently available for funded research from the National Institutes for Aging at the National Institutes of Health. Although we use the Long-Evans strain, which must be purchased as retired breeders (10–12 months of age) and then housed in the home institution, the latter can be an expensive and time-consuming option, as *per diem* expenses and long-term health monitoring for pathogens can become costly. Nevertheless, if the weaknesses of each strain are known (tendency for tumors, etc.), the behavioral characterization is soundly conducted, and aged rats are properly excluded due to poor health, the approach we describe below with Long-Evans rats should hold across strains.

### THE LONG-EVANS HOODED RAT

As mentioned above, we have chosen male Long-Evans rats for our cognitive aging research. This strain has good visual acuity even at advanced ages and is out-bred, such that genetic variability is consistently introduced into the population. Thus their general physical health and eyesight tend to be excellent well into old age, and we find very few pituitary tumors (<5%) in these animals upon sacrifice. Our animals are obtained as retired breeders from Charles River Laboratories, Inc., Cambridge, MA at approximately 10–12 months of age and are individually housed for another 12 months before behavioral testing. During this time, water and food intake assessments and frequent screenings for pathogens are conducted to constantly monitor their health. Extreme measures are taken to maintain a healthy and pathogen-free colony for our Long-Evans rat model of cognitive aging. Individual differences in cognitive decline described in detail below are routinely observed in this model in rats 24–25 months of age.

## Aging and the Medial Temporal System

### ANATOMY AND FUNCTION

One brain system that is particularly vulnerable to age-related decline is the medial temporal lobe system (Barnes, 1979; Barnes and McNaughton, 1985; Gallagher *et al.*, 1993). The anatomy of this system can be contrasted in human versus rat brain, seen shaded in light blue in Figure 32.1.

As can be observed in the circuit diagram shown in Figure 32.1, information flow in the system is multi-directional. Memory processing involves the hippocampal formation and entorhinal cortex, and information flows bi-directionally between these structures. Both of these brain regions receive direct projections from other brain areas, including the neocortical regions and subcortical structures. Communication with the hippocampus to other cortical regions is through the entorhinal cortex that receives input from and sends output to the parahippocampal gyrus (which includes the perirhinal and postrhinal cortices). Cellular regions of the hippocampus can be observed in the lower diagram (Figure 32.1), which highlights circuitry in a coronal section of rat hippocampus. The entorhinal cortex provides input to the dentate gyrus granule cells via the perforant path. The subgranular zone is a site of new neuron generation throughout the lifespan, a phenomenon that is the focus of considerable current aging research (Bizon and Gallagher, 2003; Bizon *et al.*, 2004; Merrill *et al.*, 2003; Litchenwalner *et al.*, 2001; Cameron and McKay, 1999). Granule cells project to the pyramidal neurons of CA3 and CA1 in turn. Finally, information is sent out of the hippocampus via projections through the subiculum to neocortical regions. This interaction of the medial temporal system with the neocortex underlies specific types of learning, consolidation, and retrieval of memories. This system is specifically important for processing explicit or declarative memory in humans, including conscious memories of events, people and places. Compromised function of the medial temporal system has been extensively studied across species, and contributes to specific memory deficits in normal aging, as well as in neurodegenerative conditions such as Alzheimer's disease.

### AGE-RELATED IMPAIRMENT

Individual differences in age-related decline of the medial temporal lobe system have been observed in both humans and rodents (Gallagher *et al.*, 1993; Bizon and Gallagher, 2005; Wilson *et al.*, 2002). Across species, some aged subjects maintain mnemonic abilities well into advanced ages, whereas others experience loss of cognitive capacities relative to younger individuals. The basis for these individual differences in age-related cognition is a compelling focus of neurobiological research. Indeed, focusing on such variability among aged populations

allows the investigator to compare neurobiological changes in the brain not only between young and aged subjects but also among aged rats that differ with respect to cognitive ability. For many years, we have used male Long-Evans rats trained on the widely used Morris water maze task to model individual variability in the function of the medial temporal lobe system among the aged human population.

### MODEL FOR THE AGE-IMPAIRED MEDIAL TEMPORAL SYSTEM

The Morris water maze is a hippocampus-dependent task that has been described in detail in numerous publications (e.g., Morris, 1984; Gallagher *et al.*, 1993; Bizon *et al.*, 2001). Rodents use visual cues around a circular pool in order to learn the location of a platform submerged 2 cm below the surface of the water's surface (see Figure 32.2).

In our training procedure, rats receive three trials each day for eight consecutive days. All cognitive testing occurs during the light cycle. At each training trial, rats are placed in the water and permitted to swim until they locate the platform, or for 90 seconds, at which time they are placed on the platform. Animals remain there for 30 seconds, and then they are removed from the maze area. The next trial begins again after a 60-second interval.

For spatial learning assessment, the platform stays in one maze quadrant with a randomized starting position for each trial. On every sixth trial, the platform is retracted to the bottom of the pool (probe trial) for the first 30 seconds of the 90-second trial. Our primary measures of hippocampal function are obtained by proximity measures both on the training trials and interpolated probe trials described in detail below. Very importantly, on the ninth day of training, we test sensorimotor skills and escape motivation independent of spatial learning by giving the rats a training session with six trials of cued training. During cued training trials, rats are trained to escape to a visible platform that protrudes above the water and that varies in position on each trial. On each trial, a rat is started in a novel location and has 30 seconds to reach the platform at which point it remains there briefly prior to a 30-second intertrial interval. Cue training is an extremely important control to conduct when characterizing aged rats. It can identify those subjects that are ill (and perhaps not motivated to swim), that have physical impairments that hinder swimming ability, or that have visual acuity problems. Each of these concerns can be alleviated with a proper cue training session incorporated into the water maze protocol. Any rat that fails cue training (i.e., performs worse than the young rat distribution of scores) is eliminated from further experimentation in our model.

Accuracy of performance in the water maze is assessed using a cumulative search error calculated from training

**Figure 32.1** Schematic of the medial temporal lobe system, including the hippocampus and associated structures in human and rat brain. The top left diagram shows a mid-sagittal view of the human brain. The general area of the medial temporal lobe is identified and the hippocampal formation is shaded dark gray. The top right panel shows a circuit diagram, and demonstrates the flow of information within this system. Structures that are part of the medial temporal lobe in this system are seen in light gray boxes. Generally, the neocortex sends afferent projections to the hippocampus from the entorhinal cortex via parahippocampal structures. Other subcortical structures (e.g., cholinergic projections from the basal forebrain) also project to hippocampus and entorhinal cortex. The lower diagram shows the rat brain, with the hippocampus highlighted in dark gray. An enlarged coronal section through hippocampus illustrates the basic cellular circuitry within this region. Projections from entorhinal cortex (perforant path) carry information to the granule cell layer (thick black line in C-shape). The hilus is the region encompassed on either side by the granule cell layer of the dentate gyrus. General information flow in the hippocampus entails granule cell projections to the pyramidal neurons of hippocampus proper (i.e., CA3 and CA1, in turn), before exiting the structure via the subiculum and sending information back to the neocortex.

trials and a learning index score calculated from probe trials. This method was originally described and is detailed in Gallagher *et al.*, 1993. Specifically, these proximity measures take into account deviation from

an optimal search (i.e., a search that leads the rat directly to the platform). Using computer tracking (HVS Image, UK), the rat's location relative to the platform is sampled in the maze 10 times per second, which gives

**Figure 32.2** This figure shows a photograph of a young male Long-Evans rat in the Morris water maze standing on a submerged atlantis platform (HVS Image, UK). Distal visual cues, used to locate the hidden platform, are placed around the periphery of the pool (white geometric figures). Performance in this task is a well-established indicator of medial temporal lobe and, specifically, hippocampal function.

a measurement of the rat's distance from the platform in one second averages. For both probe and training trials, a correction is made for the optimal path based on any given start position, to alleviate bias on trial performance created by variations in the distance to the platform from the different start locations. After this correction is made, the cumulative distance for training trial performance can be summed across trials (see large panel on Figure 32.3) and the average distance from the goal calculated on probe trials (see inset panel of individual Learning Index Scores on Figure 32.3).

Search error has some advantages over traditional measures of water maze like latency (i.e., time to reach platform) or path length (i.e., distance swum to reach platform), particularly for aged rats. By considering the proximity of the rat during the entire trial, one can assume that the most accurate measure of spatial bias is being achieved. For example, one rat may be swimming in close proximity to the platform for 25 seconds, while another rat may be swimming randomly throughout the maze for 25 sec. Although the first rat in the aforementioned example apparently had some appreciation of the platform's location, neither a latency nor path length measure would detect it.

It is also noteworthy that probe trials are critical for the spatial learning assessment of aged rats. Aged rats have a tendency to develop a strategy of "circling" the pool at a given distance from the wall, which might result

in short latencies and path lengths that are based entirely upon a nonhippocampal dependent strategy. Probe trials are therefore a better means by which to test rats' spatial knowledge, as rats with a good memory of the spatial location will consistently search in the area where the platform had been for at least 30 sec. Probe trials longer than this included throughout the protocol could lead to some extinction of learning. To minimize this problem, we employ an HVS atlantis platform (HVS Image, UK) that can be lowered to the bottom of the tank for the first 30 seconds of the probe trial and then raised again for the last 60 seconds of the trial. We find that this approach minimizes extinction that could be a concern with interpolated probe trials.

The data from these four interpolated probe trials are our main source of individual scores of spatial learning ability. The spatial learning index score is calculated from performance on all four of the interpolated probe trials. Performance on these trials is summed and weighted such that earlier trials receive greater weight (as age differences are generally larger earlier in training). As such, the Spatial Learning Index Score is an individual measure of spatial learning performance that takes acquisition and total spatial performance into account, and provides a single number that can be used to correlate with individual neurobiological data.

Figure 32.3 shows representative data from animals trained in this protocol. Note that as a whole, aged male

**Figure 32.3** This graph shows typical performance in the Morris water maze of young (6-month-old) and aged (25-month-old) male Long-Evans rats. Note that both young (open circles) and aged rats (closed circles) performed comparably on the very first trial, demonstrating similar sensorimotor and motivational abilities. As shown in the large panel, both groups learn over the course of time, but the aged rats were significantly impaired in this task in comparison to young adult rats. However, the inset graph in the upper right corner shows that despite an overall impairment in the aged group compared to young, there was substantial individual variability among aged rats such that some aged rats performed on par with young rats and others performed outside the range of young, demonstrating impairment on this task. Note that a higher Learning Index Score indicates poorer performance. About half of the aged rats (A) performed outside the range of the young rats (Y) and were considered aged-impaired, and about half of the aged rats performed as well as the young rats and were considered aged-unimpaired.

Long-Evans rats are consistently impaired relative to young subjects; however, when individual performance (spatial learning index) is calculated, notice that there is much greater variability among aged rats than in young. About half of the aged rats perform on a par with young, and about half perform outside the distribution of young subjects. Assuming that these latter animals are healthy and perform comparably to young rats on cue training, we may interpret that this latter subset of rats is spatially impaired.

#### MEDIAL TEMPORAL LOBE-BASED COGNITION: CORRELATIONS WITH NEUROBIOLOGICAL CHANGES

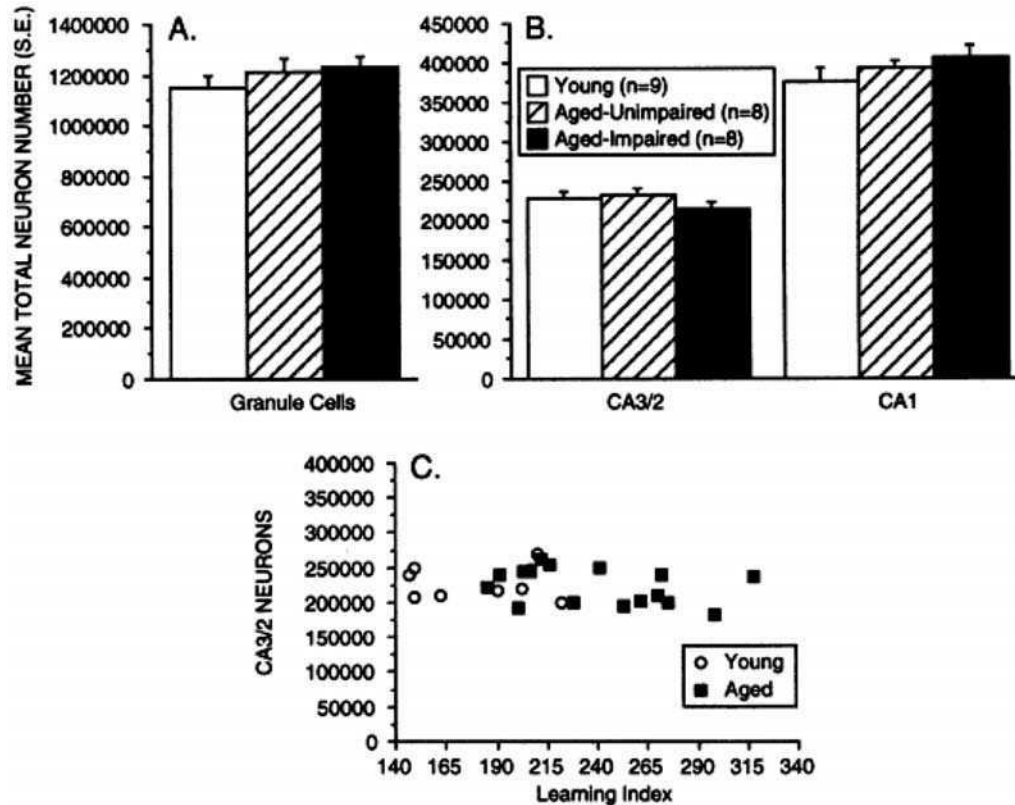

Using the derived spatial Learning Index Score, one is then able to correlate a variety of neurobiological and neuroanatomical data with spatial learning performance among aged rats. Figure 32.4 shows data obtained using the behavioral model described above. In this study, the total number of neurons in the hippocampal region was assessed in behaviorally characterized rats using quantitative unbiased stereology, as many theories of age-related memory loss at the time regarded cell loss as the endpoint for age effects on cognition. However, as shown

in Figure 32.4, Rapp and Gallagher (1996) found that frank neural loss in the hippocampal formation is not pervasive in the Long-Evans rat model, even though a considerable number of rats included in that study were spatially impaired.

This finding now has been documented for the principal neurons of the hippocampal formation, the entorhinal cortex, and the parahippocampal region, including the perirhinal and postrhinal cortices (Rapp *et al.*, 1996; Rapp *et al.*, 2002; Figure 32.1). The lack of frank neurodegeneration in normal aging has also been confirmed in other rodent models and primates, including humans (Merrill *et al.*, 2003; Rasmussen *et al.*, 1996; West *et al.*, 1994). Additional data supporting the lack of pervasive neurodegeneration in this model are provided by the absence of hypertrophied astrocytes (personal observation; Bizon and Rapp) and other markers such as OX-6 (Nicolle *et al.*, 2001), which are generally associated with widespread degeneration. These data challenge the long-standing view that neurodegeneration is a necessary condition of age-related cognitive impairment, and warrant further consideration.

Certainly, this absence of frank neuronal death has redirected our thinking about age-related neural impairment and focused our efforts toward identifying changes

### 32. Rat Models of Age-Related Cognitive Decline

**Figure 32.4** These graphs demonstrate a stereological analysis of neuronal number in all subfields of dentate gyrus and hippocampus proper in young and aged Long-Evans rats previously characterized on the Morris water maze task. Note in panels A and B that the total neuron number is not significantly different between young, aged-unimpaired, and aged-impaired animals for the granule cell layer (A), CA3/2 and CA1 (B). Moreover, no correlation between individual learning index (higher scores indicate greater impairment) and number of neurons in CA3/2 is observed (lower graph). This finding was consistent in both young (open circle) and aged (closed square) animals in hippocampus proper shown here and for the granule cells of the dentate gyrus (data not shown).

within and communication between neurons that are associated with neuronal plasticity as the main contributors to cognitive deficits. In other words, our current hypotheses are that suboptimal cell functioning and connectivity, rather than frank neuronal death, are likely to underlie the decline of many cognitive abilities that occur with age. Such cellular deficits have in fact been identified in the Long-Evans rat model. For example, differences have been found in the neurophysiological properties of place cells in aged-impaired rats versus young and aged unimpaired (see Chapter 33 by Nancy L. Nadon). Other findings, including changes in gene and protein expression and deficits in certain cell signaling pathways have been revealed using the Long-Evans rat model.

For example, using young and old Long-Evans rats behaviorally characterized on the Morris water maze as described above, our group has found that metabotropic glutamate receptor (mGluRs) and muscarinic cholinergic receptor signaling in the hippocampus is dysfunctional in the aged, learning-impaired rat (Nicolle *et al.*, 1999; Chouinard *et al.*, 1995). Both mGluR

and muscarinic M1 receptor stimulation of phosphoinositide (PI) turnover is blunted in aged rats, and the magnitude of the decrease in signaling correlates with the severity of cognitive impairment. Figure 32.5 shows a correlation between the Learning Index and the PI turnover response that occurred as a consequence of stimulating Type 1 mGluR receptors with the agonist 1S,3R ACPD.

The magnitude of this deficit in PI turnover significantly correlated with the decline in age-related spatial memory ( $R = -.67$ ,  $p < .01$  when young and aged grouped together;  $R = -.53$ ,  $p < .05$  when the aged are considered alone). This study illustrates the general approach and power of using naturally occurring rat models to identify age-related neurobiological changes that could underlie memory impairment in the medial temporal lobe system. Further work in this rat model and in aged primates should help confirm that this signaling pathway is a contributor to age-related mnemonic impairment and whether therapeutic interventions directed at this pathway would be beneficial in the reversal of such deficits.

**Figure 32.5** This graph shows the relationship of mGluR-mediated phosphoinositide (PI) turnover in the hippocampus in relation to spatial learning ability. Data points represent individual values for young and aged rats. The Learning Index is on the X-axis and the  $^{125}\text{I}$ -ACPD EMAX, a measure of PI turnover, on the Y-axis. The linear regression between PI turnover and the Learning Index for young and aged rats grouped together can be seen (solid line). A significant negative correlation was observed ( $R = -0.67$ ,  $p < .01$ ), with more impaired learning (higher learning index value) related to decreased turnover (lower disintegrations per minute [dpm] of [ $^3\text{H}$ ]-IP1). Overall, mGluR-mediated PI turnover decreased with increasing chronological age and was most blunted in the aged rats with the most severe cognitive impairment, indicated by a significant correlation in the aged group alone ( $R = -.53$ ,  $p < .05$ ).

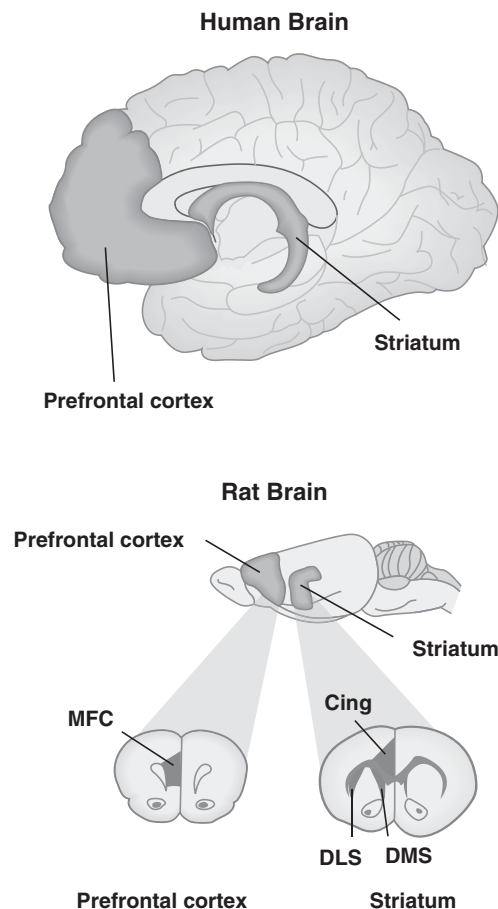

## Aging and the Frontal Cortical–Striatal System

### ANATOMY AND FUNCTION

Although a large body of literature has focused on the medial temporal lobe and the well-described age-related deficits in explicit or declarative memory that are dependent on this system, it is notable that other brain systems are also affected at advanced ages and contribute to losses in cognitive function. Frontal cortical and/or striatal circuitry is strongly affected in both normal aging and in pathological conditions associated with the aging process (i.e., Alzheimer's and Parkinson's disease). Subjects with prefrontal dysfunction are deficient in their ability to alter a behavioral response in the face of changing contingencies. This type of cognitive deficit may be caused by a disruption of striatal outflow resulting in frontal cortex dysfunction in circuitry connecting the prefrontal cortex, striatum and thalamus.

Figure 32.6 highlights the frontal cortex and striatum in the human and rat brain.

The frontal cortex (including infralimbic, prelimbic and anterior cingulate cortices) sends its major output to

**Figure 32.6** Schematic showing the prefrontal cortex and striatum in human (top) and rat brain. In both instances, these regions are shaded in dark gray and labeled respectively. The bottom sections show coronal sections through rat brain in which medial prefrontal cortex (MFC), cingulate cortex (Cing), and dorsolateral and dorsomedial striatum (DLS and DMS, respectively) are highlighted in dark gray. Although there is behavioral and molecular evidence to suggest the diagrammed circuitry is critical for executive function in rodents, clarification of the precise functional system in rats that supports cognition associated with "executive function" in humans is the subject of ongoing experiments.

terminate throughout the striatum (McGeorge and Faull, 1989). Subregions of the striatum have been shown to have different functions in learning and memory. In particular, the dorsomedial striatum (DMS) has been implicated as a necessary structure to enable behavioral flexibility (Ragozzino *et al.*, 2002). The anterior cingulate cortex, highlighted in the coronal section of the rat brain, receives afferents from the subiculum (Finch *et al.*, 1984) and subsequently sends efferents to the striatum (Wang and Pickel, 2000).

The prefrontal cortex mediates executive function, cognitive processes particularly vulnerable to the effects of aging. Executive function is complex; it can be defined as choosing and implementing a strategy to achieve

## 32. Rat Models of Age-Related Cognitive Decline

goal-directed behavior, coordinating the execution of the strategy, and disabling it afterwards (Band *et al.*, 2002). This combination of factors enables one to effectively alter one's behavior in response to changing environmental contingencies. Hence, executive function can be evaluated using tasks designed to assess a subject's ability to inhibit a previously learned rule in order to replace it with a new, more effective rule. Attentional set shifting is such a task. Set shifting is the ability to shift attention (attentional "set") from one perceptual feature of a stimulus (e.g., shape) to another, previously irrelevant and disregarded feature of a stimulus (e.g., color). The Wisconsin Card Sort Test (WCST) is often used to evaluate set shifting in humans. During the shift phase of the WCST, Positron Emission Tomography (PET) imaging has demonstrated an increase in activity of the prefrontal cortex (Nagahama *et al.*, 1997). Older adults display more perseverative behavior in the WCST and also show reduced prefrontal activation in response to task demands (Ridderinkhof *et al.*, 2002; Nagahama *et al.*, 1997). In a similar test, aged Rhesus monkeys were also impaired in set shifting, reflected by an increase in perseverative errors (Moore *et al.*, 2003).

### AGE-RELATED IMPAIRMENT

The prefrontal cortex is particularly susceptible to the effects of aging at the morphological and molecular level. Although the neurons within the prefrontal cortex of primates are resistant to cell death with aging (O'Donnell *et al.*, 1999; Peters *et al.*, 1994), morphological evidence indicates that these cells may be effectively disconnected from communication due to a loss of synapses, dendritic reduction and a loss of insulating myelin. Decreases in the density of synapses and dendrites in the prefrontal cortex in aged monkeys have been reported, particularly in layer 1. The decrease in synapses in layer 1 may be due to the loss of subcortical cholinergic and dopaminergic projections to the prefrontal cortex (Herzog *et al.*, 2003; Stemmelin *et al.*, 2000; Kaasinen and Rinne, 2002). In addition to a loss in synaptic connections, degeneration of myelin sheaths of nerve fibers also occurs in the prefrontal cortex of aged monkeys, and this loss significantly correlates with the magnitude of cognitive impairment in the aged group (Peters *et al.*, 2002). Although the prefrontal cortex, particularly the dorsolateral prefrontal cortex in primates, has been most strongly implicated in executive functions, some data indicate that the dorso-medial striatum may also factor in this ability (Ragozzino *et al.*, 2002).

### MODEL OF AGE-RELATED FRONTAL CORTICAL-STRIATAL IMPAIRMENT

Although the existence of a prefrontal cortex in rats analogous to the primate prefrontal cortex is a matter of controversy, it is generally accepted that the rat medial frontal cortex (infralimbic and prelimbic subregions) performs functions that are typically referred to

as executive function in primates (Uylings *et al.*, 2003). Birrell and Brown (2000) adapted an attentional set shifting task used in monkeys and humans (Owen *et al.*, 1991; Dias *et al.*, 1996) for use in rats. This task was subsequently used to investigate the effects of aging on prefrontal function in the same study population as that used for the investigation of medial temporal lobe function described above (Barenese *et al.*, 2002).

The rat version of the attentional set shifting task involves digging in a pot for a food reward (see Figure 32.7).

Two perceptual dimensions vary: the odor of the pot (e.g., lemon vs. cinnamon) and the digging medium that is contained within the pot (e.g., confetti vs. gravel). By manipulating the combinations of the dimensions, several types of discriminations can be evaluated, including simple discriminations, compound discriminations, reversals of both simple and compound discriminations, and intra- and extradimensional shifts. The simple

**Figure 32.7** This photograph shows a Long-Evans rat sitting on a pot used for digging in the attentional set-shifting task. This task that is detailed in the text has been shown to be sensitive to cortical regions believed to be analogous to human dorsolateral prefrontal cortex. Individual differences in cognitive abilities that are supported by this system have been observed among aged male Long-Evans rats. As shown in this figure, rats are trained to dig in pots containing different types of media (such as the beads shown here) and different odors (e.g., lemon) for a food reward. Throughout the course of training, the rule required to successfully find the food is altered, and the ability of the rats to switch to the new rule is evaluated. *Photo credit: Steve Kim, laboratory of Dr. Mark Baxter.*

discriminations (SD) require identifying the rewarded pot that contains only a single relevant perceptual dimension (e.g., odors are relevant, and the digging medium is the same in both pots). The compound discriminations (CD) present combinations of both perceptual dimensions (the pots contain both a unique odor and a unique digging medium; either the odor or medium can be the relevant, rewarded stimulus). The reversal discriminations change the valence of the previously rewarded stimulus; e.g., the previously unrewarded pot (–) becomes rewarded (+). Discrimination reversals can occur with both compound (CD-Rev) and simple (SD-Rev) discriminations. An intradimensional (IDS) shift is a new discrimination using the same perceptual dimension as what was previously relevant; for example, if the previous discrimination consisted of a relevant odor stimulus (e.g., lemon and cinnamon), the IDS would be a comparison between two new odors (e.g., peppermint and sage). The extradimensional (EDS) shift requires changing the rule that was used previously and shifting attention to the previously irrelevant stimulus. For example, if the previous comparison was between a lemon/sawdust pot and a cinnamon/confetti pot and the subject had learned that the odor, in this case lemon, was the positive exemplar, then EDS would require inhibiting the “odor” rule and creating the “digging medium” rule, e.g., the subject now needs to pay attention to the digging medium in order to accurately identify the pot containing the reward.

The set shifting task described above has advantages in that it contains within-subject measurements that can be used for control data. The ability of the animal to perform simple discriminations to an equal degree across dimensions (e.g., for odors and for digging media) is crucial, and pilot studies must be performed to assure comparable trials to criterion using different odor or medium pairs and/or to eliminate stimuli that cause a natural aversion. Performance on the simple discrimination must be at a baseline level prior to beginning the subsequent phases of the task, and this may vary depending on species (rat or mouse) and even strain.

Because of the neuropsychological and neurobiological evidence that the prefrontal cortex is vulnerable to the effects of normal aging, Dr. Mark Baxter’s group (Oxford, UK) examined attentional set shifting using the Birrell and Brown task in young and aged Long–Evans rats (Barense *et al.*, 2002). Performance of the aged rats on the EDS phase was significantly impaired compared to the young rats: the aged rats required significantly more trials to criterion to learn this discrimination (Figure 32.8).

The individual differences in EDS ability in the aged rats were not correlated with impaired spatial learning ability in the Morris water maze. These results indicate that the effects of age may be different in individuals not only within a specific brain region but also across brain regions that subservise different functions. The rat data obtained by Barense *et al.* (2002) parallels

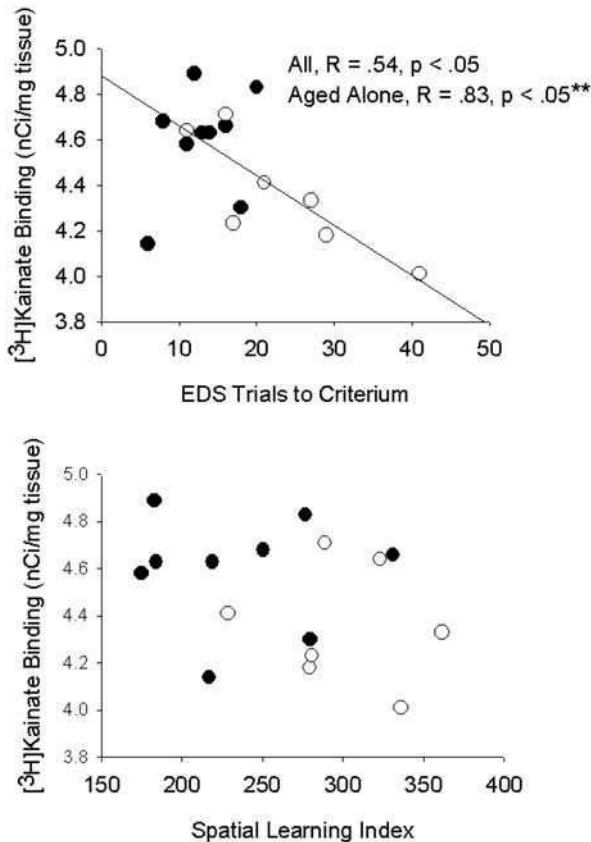

**Figure 32.8** This graph shows the performance of both young and aged animals on the attentional set-shifting task. The aged rats require more trials than young rats to be proficient at the extradimensional phase (EDS) of the task ( $p < 0.05$ ), while performing comparably to young on other discriminations in this task (SD = simple discrimination, CD = compound discrimination, IDS = intradimensional shift, REV = reversal). Extradimensional shifts are those that are most directly related to performance on human tasks that identify subjects with cognitive deficits and damage to the prefrontal cortex.

a neuropsychological study in healthy aged humans that also demonstrated a lack of correlation between deficits on tests traditionally associated with prefrontal function (including the WCST) and deficits on tasks traditionally associated with hippocampal/medial temporal lobe dysfunction (delayed cued recall) (Glisky *et al.*, 1995).

#### FRONTAL CORTICAL–STRIATAL–BASED COGNITION: CORRELATING AGE-RELATED DIFFERENCES

Attentional set shifting appears to be sensitive to the effects of aging on the prefrontal cortex, analogous to the sensitivity of spatial learning in the water maze to medial temporal lobe dysfunction in aging. Investigations of the neurobiological basis of age-related deficits in attentional set shifting are just beginning but have proven informative. For example, an analysis of ionotropic glutamate receptor binding in the aged Long–Evans rats assessed for attentional set shifting and spatial learning (described above) revealed that a decrease in binding to a glutamate-receptor subtype (kainate receptors) in the cingulate region of the prefrontal cortex was significantly correlated with poor performance in the EDS phase (Figure 32.9, top panel) but not spatial learning (Figure 32.9, bottom panel) (Nicolle and Baxter, 2003).

In that same study, decreases in NMDA receptor binding in the dorsomedial striatum of the aged group were shown to correlate with preserved memory ( $R = +.79$ ,  $p < .05$ ), perhaps indicating a neurobiological response that is compensatory in nature (Nicolle and Baxter, 2003). We hope that this model of age-related

**Figure 32.9** This graph shows the correlation between high-affinity [ $^3\text{H}$ ]kainate binding in the cingulate cortex and trials to criterion on the extradimensional shift (EDS) phase of the attentional set-shifting task (top panel) or the spatial Learning Index (bottom panel) in young and aged Long-Evans rats. Lower levels of [ $^3\text{H}$ ]kainate binding significantly correlated with more trials to criterion (poorer learning) in the cingulate cortex of the aged rats,  $R = -.83$ ,  $p < .05$ . There was no correlation between [ $^3\text{H}$ ]kainate binding in cingulate cortex with spatial learning index.

cognitive impairment will provide a rich source of neurobiological data that will be revealing as to the nature of frontal-cortical cognitive deficits in aging.

## Conclusion

Overall, these studies demonstrate that rodent models of cognitive aging can provide a rich resource for uncovering neurobiological alterations associated with age-related cognitive deficits. Findings that some aged rat populations naturally differ in their maintenance of cognitive function with age affords the opportunity to model individual differences in cognitive abilities in the human population. Importantly, rat models are convenient and can be easily manipulated, and the results from such models have broadly paralleled findings observed in humans and nonhuman primates.

As described, there is now an extensive literature using spatial learning ability as a functional measure of the output of the hippocampus/medial temporal system in aged rats. This individual variability in spatial learning in the aged population has been capitalized upon by using subsequent neurobiological assessments to identify the cellular and molecular contributors to age-related impairments. Neurobiological alterations continue to be identified in this model, and it remains a challenge to integrate the current and future findings so that they can provide a comprehensive picture of the range and complexity of alterations that occur during aging. The complexity of normal aging is illustrated by consideration of two different neural systems, the medial temporal lobe and the frontal cortical-striatal system, and how these each relate overall to cognitive function in aging. Individual vulnerability may exist (and probably does) that predisposes some subjects to frontal dysfunction and others to medial temporal lobe dysfunction. There may also be a subpopulation of aged individuals that are vulnerable to deficits in cognitive decline associated with both brain systems. How to identify and how to push these findings to the next level will depend upon sensitive behavioral assessment of these neural systems that are vulnerable to the effects of aging.

The newly devised attentional set shifting task developed for rats shows real promise as a behavioral measure of the integrity of the frontal cortical system, a brain system that is adversely affected by normal age and in numerous pathological age-related diseases. As this model is further developed and refined, the hope is to yield data regarding both molecular and cellular contributors to cognitive impairments associated with frontal cortical-striatal circuitry. In this latter case, the specific circuitry responsible for "executive functions" is not yet fully elucidated, and we are just beginning to uncover the neurobiological underpinnings of the widely reported age-related deficits associated with this brain system in the human population. Over the next several years, refinement of this protocol along with a gained understanding of the neural and molecular circuitry should garnish important new data in this arena. This approach will be necessary to identify the neurobiological etiology of individual differences in cognitive deficits in the aged population and will be necessary when trying to reverse age-related cognitive deficits in the human population.

The general approach described here in terms of relating neurobiological changes to individual differences in cognitive abilities among aged rodents should help uncover the underlying brain mechanisms responsible for age-related deficits. Ultimately, this combination of behavioral and neurobiological assessment in the same animals will help direct future therapeutic approaches to combating cognitive decline in the human aged population.

# Aged Rodents for Biogerontology Research

Nancy L. Nadon

*Studies in animal models have provided much of our understanding of the changes that occur in normal aging and in age-related diseases that humans encounter in their journey through life. Even lower organisms such as flies and worms have contributed to our understanding of human aging. But the rodent has been the most valuable model for biogerontology research because of the similarity between rodent physiology and that of humans and the low cost to maintain them. This chapter will discuss the advantages of the rodent model for aging research, provide some examples of the types of investigations made possible with the rodent model, discuss the special issues and concerns to be considered when using aged rodents, and describe resources available to facilitate studies with rodents.*

## Introduction

Human aging is the result of a complex interaction between biological changes and environmental/social influences. Healthcare throughout life, diet, and habits such as smoking, alcohol consumption and physical activity can all impact the rate of biological aging and complicate the study of the biology of aging in human populations. The rodent provides a venue for modeling the biological changes with age and investigating the genetic and physiological basis of aging and age-related diseases while controlling intrinsic and extrinsic influences. The genetic background, diet, environment, and health status of the rodent can be strictly controlled. Rodents are similar to humans in much of their physiology, cellular function, and to a lesser degree, even their anatomy. The musculoskeletal system, immune and endocrine systems, and gastrointestinal tract are very similar in both function and architecture between rodents and humans. Cardiac function has been modeled in rodents, as have age-related changes in the liver. While the rodent brain is more primitive than the human brain on the organ level, at the cellular level there are many similarities between rodent and human central nervous systems that can be exploited.

Rodents provide a good model for testing potential therapeutics, combining the value of a mammalian system

with a low-cost test subject. Longitudinal studies are more feasible in a short-lived rodent model than in a human population. The ability to analyze tissue at all stages of the process, be it normal aging or disease development, is one of the major benefits of working with the rodent model. In addition, the rodent model is amenable to manipulation at the genetic level, allowing us to test the role of gene products and pathways in age-related changes.

An example of an area of current emphasis where the rodent has made a vital contribution is the interaction of obesity with normal aging and age-related diseases. Obesity has become a serious public health concern—one that is the product of both biological and environmental/social contributions. It is a polygenic trait, with multiple genetic pathways contributing to the phenotype. Rodent studies allow for the dissection of the genetic contributions and the role of the environmental/behavioral interventions, and also the testing of potential therapeutic interventions. Many chromosomal regions (quantitative trait loci or QTL) have been identified as influencing obesity, and each contributes only a small percent of the overall phenotype (reviewed in Brockmann and Bevova, 2002). There are not only additive effects of different genes but also gene–gene interactions and gene–environment interactions, demonstrating the complexity of this phenotype.

Insulin resistance is a problem common to aging and obesity, and there are strain differences that can be exploited for studies in rodent models. Figure 33.1 compares the insulin resistance response to a high-fat diet in DBA/2J and C3H/HeJ mice, illustrating not only strain differences but also gender differences in the response by DBA/2J mice.

There are also many mutant and genetically engineered rodent models that address one or more aspects of obesity and the role of insulin resistance in aging, reviewed elsewhere (Tschop and Heiman, 2001; Mauvais-Jarvis *et al.*, 2002; Carroll *et al.*, 2004). One mutant mouse model of obesity, the leptin-deficient (*ob/ob*) mouse, exhibits obesity and increased insulin resistance. When leptin deficiency (*ob/ob*) was combined with the knockout of the adipocyte fatty acid binding protein *aP2* gene,

**Figure 33.1** Homeostasis model assessment of insulin resistance at 6 months of age, after 18 weeks on an atherogenic diet. These findings illustrate both strain differences and gender differences (Naggert *et al.*, 2003).

to create *ob/ob*, *aP2<sup>-/-</sup>* mice, these mice showed an even greater obesity than *ob/ob* mice, but had significantly less insulin resistance (Uysal *et al.*, 2000). This finding suggests that *aP2* functions in the insulin pathway independent of adiposity and hints at the complexity of the interactions leading to the altered physiological state in obese and aged individuals.

Sarcopenia, degeneration of the skeletal musculature with resulting weakness, is another serious problem in the elderly population being studied with the aid of rodent models. Investigations with the rodent model have illuminated some of the mechanisms behind age-related muscle loss and pointed to potential pathways for therapeutic interventions. For example, one cause of age-related muscle loss is the decreased ability of the muscle progenitor cells, the satellite cells, to divide and differentiate. Satellite cells in young muscle respond to cell death or injury by proliferating and differentiating into myoblasts, but in aged muscle that response is blunted. One involved pathway identified through rodent studies is the Notch pathway, a key signal pathway in muscle development and regeneration (Conboy *et al.*, 2002). The ability to regenerate muscle was restored in aged mice by directly activating Notch expression, suggesting that this is a candidate pathway for therapeutic interventions (Conboy *et al.*, 2003).

And one last example, Alzheimer's Disease (AD) provides a vivid illustration of both the potential of the rodent model and the challenges of modeling human disease in rodents. Rodents do not get AD, but do show decreases in cognition and memory that reflect changes seen in much of the aged human population (reviewed in Ingram *et al.*, 1994). There have been many attempts to make transgenic mouse models of the neuropathology of AD (plaques and tangles), too numerous to recount, but very few have successfully recapitulated even a portion

of the disease process (reviewed in Ashe, 2001; Phinney *et al.*, 2003; Lee *et al.*, 2005). Simply engineering in the mutations found in familial AD is not sufficient to recreate the disease. Tg2576 carries the Swedish mutation of APP and shows early-onset learning deficits, but not the morphological hallmarks of the disease (Hsiao *et al.*, 1996). TgCRND8 has a double mutant form of APP and shows plaque formation and some cognitive deficits, but no tangles (Chishti *et al.*, 2001). Modeling AD has required combining mutant amyloid precursor protein (APP) genes with other components of the neuronal pathways involved in the disease, and the most faithful recapitulation of AD pathology is found in a triple transgenic mouse carrying mutant forms of three genes involved in AD, amyloid precursor protein, presenilin-1 and tau protein (Oddo *et al.*, 2003). The ability to make multiple genetic alterations in a mouse holds promise for modeling complex diseases.

## Genetic Background

### INBRED STRAINS

One of the most important considerations in choosing a rodent model is the genetic background. There are advantages and disadvantages of different genetic backgrounds that must be weighed equally. Inbred strains have the advantage that all individuals of the strain are genetically identical, providing a uniform population for study. Small sample sizes are sufficient for most studies because of the genetic homogeneity. Care must be taken to note the substrain being used, as there can be genetic differences between substrains, particularly those that diverged a long time ago. Most laboratory strains of mice originated 80 to 100 years ago, and because embryo cryopreservation is a relatively new technology, for most of their existence they were maintained by constant breeding. Roderick *et al.* (1985) illustrate the pitfalls of breeding the strains in different laboratories for many generations, describing the many substrains of BALB/c mice in existence now. For example, BALB/cJ and BALB/cByJ share most alleles, but there are some genetic differences and some biological differences between them. BALB/cJ mice are more aggressive than BALB/cByJ, have larger brain weights, and different susceptibility to induced diabetes. While these differences are minor considerations for most studies, they illustrate the need to understand the genetic background.

While no one strain is a perfect model for all aspects of human aging, different strains have characteristics valuable for modeling specific aspects of human physiology or disease, and the use of inbred strains allows the investigator to choose a model with characteristics pertinent to the questions at hand. For example, DBA/2 mice are useful for modeling epilepsy and related seizure disorders, as they are very sensitive to audiogenic and electrogenic seizures, while C57BL/6 mice are resistant

### 33. Aged Rodents for Biogerontology Research

to both audiogenic and electrogenic seizures (Seyfried *et al.*, 1986). F344 female rats have very low femoral bone strength compared to other inbred rat strains and have been used to model age-associated bone loss (Turner *et al.*, 2001).

There are also disadvantages to using inbred strains, notably strain-specific pathologies that can reach very high levels of incidence, confounding interpretation of results. F344 rats, for example, develop tumors in a large proportion of the population by old age, as well as a high incidence of nephropathy (Lipman *et al.*, 1999). Some strains of mice, particularly the albino strains, experience degeneration of visual acuity with age, as reported for 129 mice by Hengemihle *et al.* (1999), rendering them unsuitable for studies requiring the use of visual cues, such as maze training. And some strains have extremely short lifespans due to susceptibility to specific diseases. AKR mice develop T cell lymphoma and die by about a year of age, because of interactions between retroviruses that the strain carries (Brayton *et al.*, 2001). Clearly this strain would not be useful for aging studies.

Other strain-specific pathologies are unrelated to the biology of aging but nevertheless may impact aging studies by causing losses in the study population. One commonly encountered problem is the ulcerative dermatitis found in C57BL/6 mice, one of the most popular strains for aging research. Many factors play a role in the development of this pathology, including genetics, diet and husbandry. The etiology of this problem has been reported to be an immune complex-induced vasculitis (Andrews *et al.*, 1994). While the incidence of ulcerative dermatitis is low in young C57BL/6 mice, it increases with age. Andrews *et al.* analyzed 300 C57BL/6N<sup>nia</sup> mice that were barrier-raised and negative for ectoparasites and bacterial and fungal diseases. They found an incidence of ulcerative dermatitis of about 20% in the aged mice, with an average age of onset of 20 months. Males and females were affected approximately equally. It is important to take this condition into consideration when using C57BL/6 for aging studies because severe cases require euthanasia, and sample sizes must be large enough to allow for such losses. Aggression is another factor that can lead to losses in group-housed rodents, such as with BALB/c males where fighting leads to some losses in the population due to serious wounds requiring euthanasia.

#### HYBRID STRAINS

Hybrid mice and rats are the offspring of two dissimilar parents and tend to be more robust than the parental strains, with longer lifespan and fewer, or lower incidence of, strain-specific pathologies. F1 hybrid rodents are the first generation bred from two inbred strains, and like the inbred strains, F1 hybrids still have the advantage that all individuals in the population are the same at the genetic level, allowing small sample sizes to represent the population. The genetic variation contributed by the two

TABLE 33.1

F344BNF1	640 gm	350 gm

<sup>a</sup>From Turturro *et al.* (1999).

different parental alleles at many loci produces the pay-off of improved health. Tables 33.1 and 33.2 compare the median lifespan and the average maximum body weight of some of the inbred and hybrid mouse and rat strains included in the NIA's aged rodent colonies.

Genetically heterozygous (HET) mice are another alternative to inbred strains. HET mice are mixtures of four (F2 generation) or eight (F3 generation) strains of mice. They have more genetic diversity, with individuals in the population differing from each other at a portion of the loci. That genetic diversity makes the population more reflective of the human population than an inbred strain, but also necessitates use of larger sample sizes due to the differences between individuals. HET mice are a valuable resource for mapping and identifying genes that influence or modify traits, by exploiting differences in characteristics specific to the parental strains. For example, Lipman *et al.* (2004) identified genetic regions that influence the types and prevalence of pathologies present at death. HET mice were also used to identify QTLs that influence the severity of age-related cataracts (Wolf *et al.*, 2004). Mice are a good model for age-related cataracts, as the timing and location of cataracts in mice are similar to what is observed in elderly humans. QTLs were identified on three chromosomes, and statistical analysis indicated that the effects of the three QTLs were additive—the more at-risk alleles a mouse had, the greater its risk for severe cataracts. Further description

of HET mice can be found in Chapter 4 of this book and other references (Miller and Nadon, 2000; Miller and Chrisp, 2002).

### Genetic Manipulations

The genetic makeup of rodents is easily manipulated by selective breeding and by genetic engineering. Table 33.3 summarizes types of rodent models produced by standard breeding protocols, selecting at each generation for chromosomal markers or phenotypic traits. They exploit strain-specific characteristics and are listed in descending order from the least amount of recombination between the strains to the most recombination between the strains. An example of the use of selective breeding models is found in Mountz *et al.* (2001), a review of recombinant inbred strains derived from a cross between C57BL/6 and DBA/2 mice that were used to identify genomic regions influencing immune response in young and aged mice.

Genetically engineered models have become an essential tool for identifying biochemical and genetic pathways involved in disease processes (summarized in Table 33.4). Transgenic mice are valuable for studying the effects of

increased expression of a protein, expression of dominant-negative proteins, and replacement of defective proteins. Transgenic rats are also produced, but they have not caught on as well as mice as they are more costly and difficult to produce. Knockout mice are used to model diseases based on deficiency and to study the function of individual gene products in a pathway. A good review of both selective breeding models and genetically engineered models is provided in Brockmann and Bevova (2002). Genetic background is just as important when working with genetically engineered models as it is when working with inbred strains, because the phenotype of the genetic alteration can vary on different backgrounds. For example, the expression of an amyloid precursor protein transgene in FVB mice showed unexpected phenotypes, including premature death and seizures, not observed when the same transgene was expressed on other genetic backgrounds (Ashe, 2001).

Mutations, whether spontaneous or induced, have also contributed greatly to our understanding of aging. The Snell Dwarf mouse, first identified in the 1950s, was the first mutant to show an extended lifespan. There have been over 100 publications on the Snell Dwarf since then,

TABLE 33.3  
Rodent models produced by selective breeding

Model	Description
Chromosome Substitution Strain (CSS)	An entire chromosome is moved to a different genetic background.
Congenic strain	One region of one chromosome is moved onto a different genetic background by backcrossing an F1 hybrid to one parental strain to inbreed.
Recombinant Congenic Strain (RCS)	Large regions of chromosomes moved onto another background by backcrossing an F1 hybrid to one parental strain for a few generations and inbreeding by brother-sister matings.
Recombinant Inbred Strain (RIS)	Large number of smaller recombination units made by creating an F2 hybrid and inbreeding by brother-sister matings.
Advanced Intercross Lines (AIL)	Multiple (F10 or more) intercrosses between two strains. They are not inbred, hence are heterozygous at many loci.

TABLE 33.4  
Genetically engineered rodent models

Model	Description
Transgenic	A genetic element is added through DNA injection into the embryo, resulting in a gain-of-function at the genome level.
Inducible transgenic	Expression of a transgene is induced by exogenous compounds.
Knockout	Expression of a genetic element is eliminated by homologous recombination with a construct that prevents transcription of intact mRNA.
Knock-in	Homologous recombination creates a change in the mouse genome, replacing the wild-type mouse sequence with a mutation, human gene sequence, etc.
Conditional Knockout	Knockout of a genetic element is controlled in a temporal, developmental, or tissue-specific manner.

### 33. Aged Rodents for Biogerontology Research

reporting on various aspects of aging in this mutant (reviewed in Bartke and Brown-Borg, 2004). It has been a key player in studies that demonstrate the importance of the insulin-signaling pathway in aging. The Ames Dwarf mouse is another spontaneous mutation with increased lifespan and a reduction in both total neoplastic load and total disease burden at death (Ikeno *et al.*, 2003). An in-depth discussion of the dwarf mouse models is presented in Chapter 34 of this book.

Liang *et al.* (2003) review seven mouse models with extended lifespan, three mutations (Snell and Ames Dwarf mice and Little mice [ $Ghrhr^{lit/lit}$ ]), and four gene knockouts ( $GHR/BP^{-/-}$ ,  $p66^{shc-/-}$ ,  $Igf1R^{+/-}$ , and FIRKO). All of the models are loss-of-function changes at the genetic level. Six of the seven models (with the exception of  $p66^{shc-/-}$ ) share many characteristics in spite of involving different genes: growth retardation and reduced body weight, altered metabolism, and alterations in the insulin signaling pathway. This concordance of phenotypes speaks to the importance of metabolism and the insulin-signaling pathway in lifespan determination.

There is some difference of opinion on the value of mutations that shorten lifespan rather than extend it. There are now several mouse mutants that have shortened lifespans, many of them based on mutations identified in human diseases. Clearly it is important when using models that shorten lifespan to distinguish between those that cause premature death due to a specific disease, such as cancer, and those that accelerate many aspects of the aging phenotype. Hasty and Vijg (2004) provide a good discussion of the pros and cons of the mutant rodent models with accelerated aging.

#### Caloric Restriction

An exciting field in biogerontology research is the emphasis on finding interventions that delay the onset of aging phenotypes or slow the process of aging. While many compounds have some beneficial effects in lower organisms or cell culture, the only intervention proven to extend lifespan and health span in mammals is caloric restriction (CR). When rodents are fed a nutritionally complete diet limited to 60–70% of their ad libitum food intake, they generally live longer, have a reduced disease burden, and show delayed onset of many of the common phenotypes of aging (reviewed in Masoro, 2000). Understanding the mechanisms by which CR extends lifespan and health span will likely lead to new therapeutic interventions to delay the negative aspects of aging. The insulin-signaling pathway is clearly one candidate pathway, as CR reduces age-associated insulin resistance. The action of CR appears to be independent of body weight reduction, as mice subjected to every-other-day fasting did not reduce their total food intake or body weight, yet still experienced the beneficial effect on glucose

TABLE 33.5  
Effect of caloric restriction on lifespan of selected mouse strains<sup>a</sup>

Mouse Strain	Median Lifespan	Maximal Lifespan
C57BL/6	+24%	+24%
DBA/2	-7%	-9%
B6D2F1	+26%	+31%

<sup>a</sup>Data is presented as percent increase (+) or decrease (-) in lifespan of caloric restricted mice as compared to ad libitum fed mice. From Forster *et al.*, 2003.

and insulin levels as seen in standard CR protocols (Anson *et al.*, 2003).

The CR effect is not universal, however, and different strains show different levels of response to CR. Table 33.5 shows the survival response to CR by male C57BL/6 mice, DBA/2 mice, and the F1 hybrid between them (Forster *et al.*, 2003). Note that while C57BL/6 showed a robust response to CR, with a 24% increase in both median and maximum lifespan, DBA/2 mice showed the opposite response, with a decrease in both median and maximum lifespan. The F1 hybrid, which lived longer than either parental strain under ad libitum (AL) feeding, showed a response to CR similar to the C57BL/6 parental strain. Willott *et al.* (1995) also reported that CR decreased lifespan in DBA/2 mice while increasing it in C57BL/6 mice, and Turturro *et al.* (1999) reported a similar result with male DBA/2 mice showing a 5% increase in lifespan. In the latter study, female DBA/2 showed a 30% increase in lifespan, illustrating a potent gender difference in this strain. In Turturro *et al.*'s study, both male and female C57BL/6 mice showed a similar increase in lifespan of about 40%. While these three studies gave similar results, the differences in lifespan changes due to CR (for example, 24% increase versus 40% increase for C57BL/6) illustrate that other factors, such as substrain, health status, diet formulation and environment, can affect experimental outcomes even when using inbred mice.

Most CR protocols are maintained from young adulthood through the rest of life, and there are conflicting reports on the benefits of CR when it is initiated later in life. Weindruch and Walford (1982) reported that CR initiated in mice in midlife produced beneficial results, while Forster *et al.* (2003) found that when CR was initiated at old age (22–25 months of age), mortality in the first 3 months was actually increased over that seen in the AL controls in 3 strains of mice studied (C57BL/6, DBA/2, B6D2F1). A study in F344BNF1 rats found no significant effect on lifespan and tumor burden when CR was initiated at midlife (17 months) or old age (24 months) (Lipman *et al.*, 1998). However, a study in B6C3F1 hybrid mice, in which CR was initiated at 19 months, produced a 4-month increase in median lifespan

over the AL controls (Dhahbi *et al.*, 2004). While CR and AL groups had the same incidence of neoplasms, there was a delay in the onset in the CR group. These findings suggest that CR, or therapeutic targeting of the pathways altered by CR, may have potential for improving health in old age, even when the intervention is begun at midlife.

The effect of long-term CR on health varies by strain and also by pathology. While the general trend is that CR reduces the incidence of, or delays the onset of, most age-related pathologies, there are exceptions to the rule. For example, pancreatic atrophy is common in aged F344 and Brown Norway (BN) rats under AL feeding. Under CR, the incidence of pancreatic atrophy decreases in F344 rats but increases in BN rats (Lipman *et al.*, 1999). CR delays the onset of cataracts in BN rats, but by old age, the incidence of cataracts was the same in CR and AL controls (Wolf *et al.*, 2000). In F344 rats, the age of onset was the same in CR and AL but as the rats aged, the incidence of cataracts increased more in the AL rats than in the CR rats, so that the CR F344 rats showed a reduction in the incidence of cataracts at old age. And CR does not appear to moderate age-related hearing loss in most strains of mice (Willott *et al.*, 1995). These findings serve to illustrate the complexity of biological aging and also the importance of genetic background on the rate of aging and the modulation of the rate of aging through interventions such as caloric restriction.

## Husbandry and Environment

One of the advantages of the rodent model is that the health, housing and environment of the colony can be strictly controlled. This is an important consideration because diseases in the experimental population could confound interpretation of results or give misleading results. Specific pathogen-free (SPF) barriers are the norm for commercial rodent breeders for research purposes, but investigators should be aware of the health status of their institution's vivariums, as exposure to new pathogens could affect the immune status and physiological responses. Susceptibility to infectious diseases varies greatly. Mites pose only a minor problem in some strains, but in C57BL/6 mice, mites exacerbate the ulcerative dermatitis common in this strain (Andrews *et al.*, 1994). *Helicobacter* species, first identified in the early 1990s and still endemic in some commercial colonies, cause little or no response in most strains of mice, but can cause inflammatory bowel disease, hepatitis, and hepatocellular cancer in some strains (Brayton *et al.*, 2001). Ward *et al.* (1994) examined 20 strains of mice for *Helicobacter hepaticus*-induced pathology and found only six strains that showed susceptibility to liver disease, with BALB/c mice highly susceptible and C57BL/6 resistant. Hepatic lesions increased with age in both incidence and severity in susceptible strains, and the chronic hepatitis is very persistent. While rats are believed to be resistant to most

*Helicobacter* species, there may be effects that surface with more rigorous study.

The aged rodent has special health concerns unrelated to infectious disease, and extra vigilance is required even when they are raised under barrier conditions. Many strains of rodents are prone to developing tumors as they age. Tumors on the feet, jaw and joint areas may cause pain, loss of ambulatory function or difficulty eating even when they are relatively small (Nadon, 2004). Malocclusion, overgrown teeth, resulting from the lack of hard substrates on which to chew, is another problem in aged rodents (Nadon, 2004). Aged rodents should be checked weekly for evidence of tumors or other problems such as malocclusion.

Another consideration is the housing configuration. Rodents are social animals, and most do better in group housing because of the social enrichment. However, group housing can cause stress in rodents due to territorial behavior and aggression. Long-term group housing may lead to some losses due to fight wounds, so this should be taken into consideration when determining sample sizes. Aggression is quite variable between strains, and males are usually more aggressive than females. In the NIA aged rodent colonies, significant aggression is only found in the male BALB/cBy and DBA/2 mice. DBA/2 mice responded with a significant reduction in aggression when provided with Shepherd Shacks<sup>®</sup>, pressed paper huts that provide a nest environment. Male BALB/cBy mice did not respond favorably to the introduction of Shepherd Shacks<sup>®</sup>—they shredded them and went back to fighting. This experience illustrates the differences between strains, in that even a basic behavior like aggression has different causes and different solutions. Rats tend to be less aggressive than mice in general, and male F344 rats can even be group housed after being retired from a breeding program.

There are many forms of environmental enrichment available for rodents, including huts, tunnels, chew sticks, and nesting materials. The inclusion of some sort of enrichment appears beneficial under any circumstances, and there is abundant literature that shows that rodents prefer an enriched environment (reviewed by Olsson and Dahelborn, 2002). However, it is important to house experimental and control groups under the same conditions to avoid confounding the interpretation of experimental results. For example, environmental enrichment has positive effects on the brain, including increased plasticity and neuroprotective effects, so in studies of brain aging and cognitive changes it is essential that all groups are housed in identical environments to ensure that changes observed are due to the experimental protocol and not to differences in the environment.

One last concern must be noted when using rodents in biogerontology studies. There are important decisions to be made regarding the appropriate ages to be used, the number of time points required to accurately define age-related changes, and sample sizes that will provide
