There are two kinds of low-turnover bone disease: osteomalacia and adynamic bone disease. In both, PTH is typically not elevated,^{9,10} but other serum bone markers like alkaline phosphatase and osteocalcin are in the normal range. Serum calcium may be normal or increased in patients with adynamic bone disease because of the lack of buffering capacity in bone when an oral calcium load is given.¹¹ In osteomalacia, there is usually aluminum deposition at the mineralization front, which blocks mineralization of osteoid. Osteomalacia is typically symptomatic, whereas adynamic bone disease is not. Adynamic bone disease is due to paucity of both osteoclasts and osteoblasts and is more prevalent in peritoneal dialysis patients than in hemodialysis patients. The disease can also occur in CKD (predialysis) patients.¹² Treatment options include avoiding oversuppression of PTH, which occurs with excessive doses of active vitamin D sterols or calcimimetic agents. Other factors have been implicated, including excessive oral calcium from high doses of calcium-containing phosphate binders.¹³ If present, an evaluation for aluminum toxicity by history, examination, and blood tests should be done, and if aluminum toxicity is confirmed, then treatment involves deferoxamine 5 mg/kg/wk post-dialysis or intraperitoneally. The duration of therapy is typically 6 months to a year. Adverse effects associated with therapy include hearing loss, retinal damage, and infection with mucormycosis. Once-weekly dosing is associated with fewer adverse effects compared with administration three times per week.

PREVENTION OF PHOSPHORUS RETENTION AND HYPERPHOSPHATEMIA

Several large retrospective studies of patients on hemodialysis showed that patients with elevated phosphorus or calcium \times phosphorus product had an increase in mortality^{14,15}; 39% of dialysis patients had hyperphosphatemia. Those with serum phosphorus greater than 6.5 mg/dL had a 27% increase in mortality after adjustment for other comorbid conditions. The goal should be to maintain serum phosphorus in all stages of CKD at levels recommended by the K/DOQI guidelines (Table 69-1). The available options for decreasing phosphorus accumulation in patients at all stages of CKD include (1) decreasing dietary phosphorus intake, (2) preventing the absorption of phosphorus with phosphorus binders, and (3) enhancing the removal of phosphorus by dialysis. It can be more complicated with severe secondary HPT because some compliant patients can develop hyperphosphatemia due to mobilization of phosphorus from bone.

Dietary Phosphorus Restriction

Dietary phosphorus restriction should always be the first step in treating CKD–bone and mineral disease, especially in predialysis patients.^{16–18} The phosphorus intake of normal adults is 1.0 to 1.8 g/day with the variation depending primarily on consumption of meat and dairy products. Poultry,

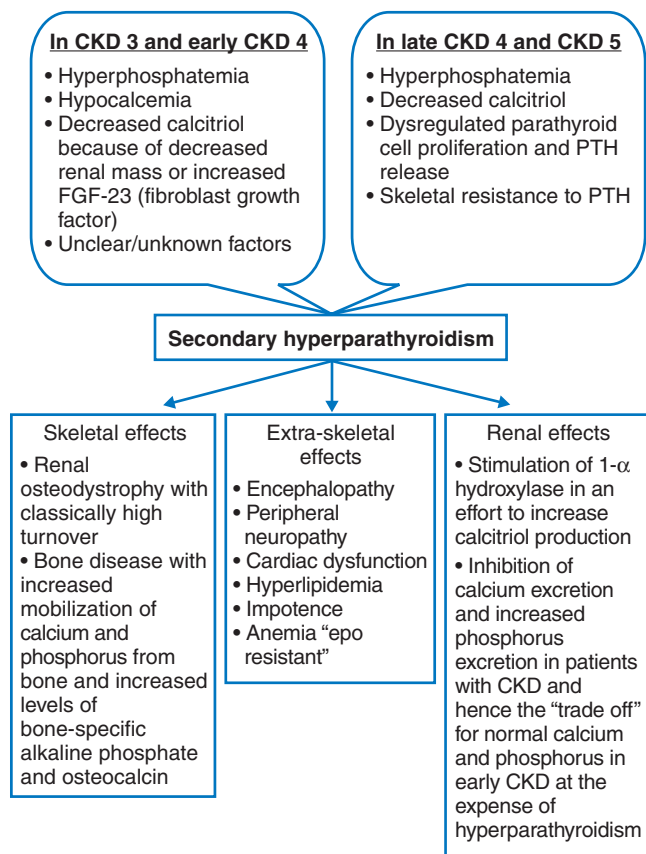

Figure 69-1 Pathogenesis and effects of secondary hyperparathyroidism in chronic kidney disease (CKD).

Table 69-1 Goals and Therapeutic Options for Chronic Kidney Disease–Mineral and Bone Disorder

Therapeutic Options	TARGETS			CKD stages
	Phosphorus	Calcium	PTH	
Restrict dietary phosphorus Correct low 25-dihydroxy vitamin D levels Phosphate binders, e.g., calcium acetate or calcium carbonate with meals Avoid oversuppression of PTH Avoid hypercalcemia	2.7–4.6 mg/dL (0.87–1.49 mmol/L)	Normal range for laboratory, e.g., 8.4–10.3 mg/dL	35–70 pg/mL	CKD 3: GFR 30–59 mL/min/1.73 m ²
All the above treatments Aggressive control of phosphorus with diet and binders (use of sevelamer HCl and lanthanum carbonate as phosphate binders is not FDA approved for use in patients with CKD stages 3 and 4. Consider active vitamin D sterol if above not sufficient (e.g., calcitriol 0.5 µg PO on M/W/F or 0.25 µg every day or paricalcitol or doxercalciferol; paricalcitol is preferred)	2.7–4.6 mg/dL (0.87–1.49 mmol/L)	Normal range for laboratory, e.g., 8.4–10.3 mg/dL	70–110 pg/mL	CKD 4: GFR 15–29 mL/min/1.73 m ²
Dietary phosphate restriction but liberalize protein intake to 1.0–1.2 g/kg Use vitamin D sterols with hemodialysis, e.g., paricalcitol 4 µg IV with hemodialysis. For peritoneal dialysis, administer PO every day or higher dose three times/week Use of noncalcium-based phosphate binders if hypercalcemia or any signs of vascular calcification, e.g., sevelamer 1600 mg with meals and large snacks Adequate dialysis to target kt/v. Consider cinacalcet to keep PTH at target if vitamin D sterol not adequate. Monitor serum calcium. PTX when, despite the above-mentioned options, PTH is very high, e.g., PTH > 1000 pg/mL and calcium or phosphorus limit other therapies	3.5–5.5 mg/dL (1.13–1.78 mmol/L)	Normal range for laboratory (preferably towards the lower half)	150–300 pg/mL	CKD 5: GFR < 15 mL/min/1.73 m ²

CKD, chronic kidney disease; FDA, U.S. Food and Drug Administration; GFR, glomerular filtration rate; M/W/F, Monday/Wednesday/Friday; PTH, parathyroid hormone; PTX, parathyroidectomy.

fish, liver, most soft drinks (especially colas), whole-grain breads, and some cereals, nuts, and legumes are rich in phosphorus. With elimination of dairy products and limiting the diet to 60 g of protein per day, the dietary intake of phosphorus is 750 to 1000 mg/day. Once a patient is on maintenance dialysis and dietary protein increases, the phosphorus may be increased. The National Cooperative Dialysis Study suggested that with commencement of dialysis therapy, a patient should eat at least 0.8 to 1.0 g/day of protein, which would increase daily phosphorus intake to a range of 920 to 1200 mg/day. Therefore, it can be difficult to achieve a balance between nutritional demands and limiting phosphorus intake in dialysis patients. In contrast, restriction of dietary phosphorus intake can be the sole measure needed to avoid phosphate retention in patients at the predialysis stage of CKD.

Phosphate Binders

Phosphate binders are broadly divided into calcium based (calcium carbonate, calcium acetate) and noncalcium based (sevelamer hydrochloride, lanthanum carbonate, aluminum hydroxide, and magnesium carbonate).

Calcium-Based Phosphate Binders

The use of calcium-based phosphate binders is limited to a total calcium intake of 2 g of elemental calcium per day because vascular calcification is present in many CKD patients, and hypercalcemia from calcium-based phosphate binders is a factor contributing to the progression of vascular calcification.³ Because the average daily intake of elemental calcium is 500 mg with meals, 1500 mg of elemental calcium can be

taken as calcium-based binders. It should be pointed out, however, that calcium-based binders have been associated with progression of vascular calcification even at a dose of 1100 mg of elemental calcium per day.¹⁹ The two types of calcium-based phosphate binders routinely used are calcium acetate and calcium carbonate: calcium acetate is available as 667-mg tablets providing 167 mg of elemental calcium per tablet and calcium carbonate is available in several sizes (tablets of 500 mg of calcium carbonate contain 200 mg of elemental calcium). The usual starting dose of these binders is one to two tablets with meals. Consequently, the 2-g limit of elemental calcium per day is exceeded if a patient takes approximately nine 667-mg calcium acetate tablets or seven 500-mg calcium carbonate tablets daily. It should be emphasized that calcium-based phosphate binders do not necessarily cause hypercalcemia if they are used judiciously.

Another important observation is that a sizable number of patients with CKD stage 4 or 5 have vascular calcification evident on plain radiographs, echocardiograms, or computed tomography scans. These patients will develop progressive vascular calcification irrespective of the type of binders used. However, calcium-based binders appear to aggravate and accelerate the vascular calcification, so calcium-based phosphate binders for these patients should be avoided. Patients who have no evidence of calcification when they begin dialysis will likely never develop calcification, and it seems reasonable to use calcium-based phosphate binders in these patients, but the 2 g/day limit should not be exceeded. Serum calcium must be monitored during the therapy to avoid hypercalcemia. Note that some patients will also be taking vitamin D therapy. Vitamin D avidly stimulates the adsorption of calcium and phosphorus from the gut. Another caveat is that calcium ingested when the stomach is empty or between meals can facilitate calcium absorption. For this reason, calcium-based binders should only be taken with meals. K/DOQI guidelines recommend using non-calcium-based phosphate binders in patients on dialysis if the serum PTH is less than 150 pg/mL and if there is evidence of vascular calcification or hypercalcemia. With other CKD patients, phosphate binders should be determined by patient preference, compliance, comorbid illnesses, side effects, cost, and the ability to control serum phosphorus levels while avoiding hypercalcemia (and limiting the total calcium intake).

Sevelamer Hydrochloride

Sevelamer hydrochloride is a non-calcium-based phosphate binder.²⁰ The usual effective dose is 2 to 8 g/day, given in divided doses with meals and with large snacks. Sevelamer is available as 400- and 800-mg tablets. It can be used in combination with other calcium- and non-calcium-based phosphate binders and active vitamin D sterols. Since its approval by the U.S. Food and Drug Administration in 1998, sevelamer has been used across the United States for CKD stage 5 patients on hemodialysis and peritoneal dialysis; it has not been approved for use in predialysis CKD patients. The binder is unique because it also lowers total cholesterol levels, principally by sequestering bile salts and lowering low-density lipoprotein levels.²¹ The efficacy of this phosphate binder was compared with calcium-containing phosphate binders in a randomized, controlled year-long study. Both treatments reached target levels of serum phosphorus and the calcium \times phosphorus products, but sevelamer treatment was associated

with less hypercalcemia and less oversuppression of PTH levels. In addition, the calcium-containing phosphate binders (both calcium acetate and calcium carbonate), but not sevelamer, led to progressive calcification of coronary arteries and the aorta.¹⁹ The average amount of elemental calcium associated with vascular calcification was only 1.1 g/day, which is far less than the recommended K/DOQI maximum of 1.5 g/day. Treatment with sevelamer has also been associated with a survival benefit compared with the use of calcium-containing phosphate binders. The adverse side effects of sevelamer are gastrointestinal distress, bloating, and flatulence, and there are case reports of intestinal obstruction.

Lanthanum Carbonate

Lanthanum is a heavy metal ion, and lanthanum carbonate is an effective phosphate binder.²² Unlike sevelamer hydrochloride, which is nonabsorbable by the intestines, a small amount of lanthanum is absorbed, and over a period of time, lanthanum can be found in various body tissues including bones and liver. To date, no adverse outcomes from this accumulation have been identified. The advantage of lanthanum carbonate is that it is chewable, which may improve compliance. In 2005, it was approved by the U.S. Food and Drug Administration for use in hemodialysis patients with CKD stage 5. The usual starting dose is 750 mg to 1 g, to be taken with meals or with meals and snacks. Lanthanum carbonate can be taken in combination with calcium- and noncalcium-based phosphate binders and vitamin D sterols.

Aluminum Hydroxide and Aluminum Carbonate

Aluminum is a very potent phosphate binder, yet it is potentially toxic. It was widely used around the world until the mid-1980s, when it was identified as a cause of a fatal neurological syndrome (seizures, dyspraxia, abnormal electroencephalogram); later, it also was implicated in causing fractures, myopathy, and microcytic anemia. The routine use of aluminum-based phosphate binder is not recommended because of these toxicities and because it can cause osteomalacia.²³ However, a course of aluminum hydroxide for a few days can be used to bring the serum phosphorus down acutely when the phosphorus or calcium phosphorus product in the serum is very high and traditional methods alone are insufficient to correct the abnormality.

Magnesium Carbonate

Magnesium carbonate is an effective phosphate binder but causes hypermagnesemia in renal failure patients. Hypermagnesemia can be treated with low- or magnesium-free dialysates. This poses a difficult logistic problem for outpatient dialysis units.

Vitamin D Deficiency

Vitamin D deficiency is prevalent in the general population and especially in patients with CKD. K/DOQI guidelines recommend measuring 25(OH) vitamin D levels and if low, correcting the level for patients with CKD stages 3, 4, and 5. The measurements should be made annually in CKD 3 and quarterly in CKD 4 and 5 patients. The level of 25-dihydroxyvitamin D (25-OH-D) considered normal is a value greater than 30 ng/mL. If there is severe vitamin D deficiency, a patient should be treated with weekly doses of 50,000 units of oral

ergocalciferol for 12 weeks followed by the same dose given monthly for another 6 months. Milder degrees of deficiency can be treated with monthly oral doses of 50,000 units. CKD patients, especially those with heavy proteinuria, can develop vitamin D deficiency because of urinary losses of vitamin D binding protein. Consequently, 25-OH-D levels should be checked in these patients at regular intervals. There is evidence that repletion of a low 25-OH-D level in vitamin D-deficient CKD patient decreases PTH,²⁴ especially in CKD stage 3 patients. Even if there is no beneficial effect on PTH levels, we recommend measuring 25-OH-D in all patients with CKD stages 3, 4, and 5 with or without preexisting secondary HPT; vitamin D should be replaced if the plasma levels are low. Vitamin D deficiency should be considered as an independent condition with adverse outcomes that include aggravating secondary HPT, depressing the immune system, increasing cancer prevalence, and decreasing overall survival.

Use of Active Vitamin D Sterols

Some patients with CKD stage 3 or 4 and the majority of patients with CKD stage 5 will continue to have PTH levels above the goal even after bringing serum calcium, serum phosphorus, and 25-OH-D levels into the target range. These are the patients who will benefit from one of the many available active vitamin D sterols.

Calcitriol

Calcitriol is available as a pill or an intravenous (IV) formulation. Oral calcitriol effectively decreases PTH levels, decreases bone resorption, improves endosteal fibrosis and mineralization, and to some extent helps in the bone pains associated with renal osteodystrophy. Calcitriol has a direct inhibiting effect on PTH synthesis. In predialysis patients (CKD stages 3 and 4), the usual starting dose is 0.25 µg every day or every other day. In dialysis patients, the dose can be titrated upward. The unfavorable effects associated with calcitriol are hypercalcemia and hyperphosphatemia, mainly due to increased intestinal absorption of calcium and phosphorus. Intravenous calcitriol is given to hemodialysis patients and is associated with less hypercalcemia and a more profound decrease in PTH levels. The usual starting dose of intravenous calcitriol is 0.5 to 1.0 µg per dialysis session, and it can be increased to 4 µg or more if hypercalcemia does not occur. Hypercalcemia with oral or intravenous calcitriol requires a decrease in the dose by 25% to 50% and rechecking calcium and PTH levels.

Paricalcitol

Paricalcitol or 19-nor-1,25(OH)₂D₂ is a vitamin D analogue that decreases PTH secretion while minimizing hypercalcemia and hyperphosphatemia.^{25,26} It does not appear to induce the vitamin D receptor in the intestine and hence does not promote calcium or phosphorus absorption from gut. Paricalcitol is available in oral and intravenous formulations; oral capsules are available as 1, 2, and 4 µg. The usual starting dose is 1 µg every day or 2 µg every other day in CKD stages 3 and 4 patients; the dose is titrated upward in CKD stage 5 patients treated by hemodialysis or peritoneal dialysis. Hemodialysis patients are usually treated with intravenous formulation, and the starting dose of intravenous paricalcitol is 0.04 to 0.1 µg/kg IV per dialysis session; it is increased as required. In

retrospective studies, paricalcitol appears to have a potential survival advantage over calcitriol in patients with CKD stage 5.²⁷ Overall, paricalcitol is safe and effective in dialysis patients with secondary HPT and causes fewer changes in serum calcium and phosphorus levels than calcitriol.

Doxercalciferol

Doxercalciferol is a vitamin D₂ derivative, 1-(OH)-D₂, and must undergo 25-hydroxylation in the liver to become biologically active. In a randomized study of doxercalciferol 4 µg/day or 4 µg three times per week was effective in decreasing the PTH to the K/DOQI target range. However, the serum calcium increased from 8.8 mg/dL to 9.5 mg/dL along with a significant incidence of hyperphosphatemia.²⁸ Other studies have also revealed significant hypercalcemia that is associated with doxercalciferol, so there is little evidence of selectivity of action of doxercalciferol (i.e., PTH suppression without inducing hypercalcemia or hyperphosphatemia).²⁹

Dialysis Adequacy

For hemodialysis patients with CKD stage 5, a single hemodialysis treatment can remove approximately 800 mg of phosphorus from the blood. Initially, there is a sharp gradient for phosphorus removal with increased removal in the first half of hemodialysis; removal decreases during the second half of the treatment because phosphorus is predominantly stored in the intracellular compartment and is not rapidly mobilized. Hence, a single session of dialysis, no matter how long, can only remove a limited amount of phosphorus. Emerging data from patients treated by daily hemodialysis indicate that they have far better serum phosphorus control with far fewer oral phosphate binders than patients treated with hemodialysis three times per week.³⁰ For hemodialysis patients, dialysis adequacy must be ensured and recirculation in the dialysis access excluded to be sure dialysis helps decrease the uremic and phosphorus burden of CKD patients.

Calcimimetic Agents

Calcimimetic agents are the newest addition to the armamentarium for treating secondary HPT. The available drug is cinacalcet hydrochloride in 30-, 60-, and 90-mg tablets.³¹ The usual starting dose is 30 mg and is titrated upward depending on the PTH level. The maximum dose is 180 mg, but most patients will respond well to 90 or 120 mg. Two things must be kept in mind about calcimimetic agents: First, the drug is very effective in lowering PTH and is akin to chemical parathyroidectomy, and, second, the drug can cause significant hypocalcemia so serum calcium must be monitored.

Calcimimetic agents stimulate the calcium-sensing receptor so the parathyroid gland senses a higher ionized calcium, which decreases the secretion of PTH. A high concentration of calcium-sensing receptor is present in parathyroid cell membrane, the kidney, bone, brain, and lungs, and small changes in the extracellular ionized calcium level will activate this receptor. In fact, decreased secretion of PTH by parathyroid cells occurs within seconds of increasing blood ionized calcium. However, the calcium-sensing receptor is also sensitive to magnesium, trivalent elements, and gadolinium. Consequently, stimulation of the calcium-sensing receptor in the kidney increases urinary calcium and

magnesium. Interestingly, concomitant treatment with vitamin D sterols often given to hemodialysis patients not only acts to decrease PTH but also helps by ameliorating the hypocalcemic effects of calcimimetic drugs. Currently, cinacalcet hydrochloride is not approved for treating patients with CKD stages 3 and 4.

Parathyroidectomy

Parathyroidectomy (PTX) for secondary HPT is indicated only if it is severe despite adequate medical management. There is no absolute PTH value signifying the need for PTX, but the presence of persistently elevated intact PTH levels greater than 1000 pg/mL plus high serum calcium \times phosphorus products (typically $>55 \text{ mg}^2/\text{dL}^2$) despite therapy and physical problems such as bony aches and pains or fractures suggests consideration of surgical PTX. It was recommended to perform a bone biopsy before performing a PTX because some of the CKD patients will have adynamic bone disease, and removing the parathyroid gland in such patients would prove catastrophic. A routine bone biopsy before PTX is no longer recommended because aluminum is rarely used as a phosphate binder. Because the exact location of all parathyroid glands in the neck is not consistent, a sestamibi nuclear scan can help locate the glands before surgery. Most experienced surgeons do not require a routine preoperative sestamibi scan. If a patient has persistent secondary HPT after renal transplantation or if a parathyroid adenoma is suspected, then sestamibi scan can help locate the culprit gland. The different surgical procedures are (1) subtotal PTX, (2) total PTX with autotransplantation of parathyroid tissue in the forearm, and (3) total PTX without autotransplantation. The number of surgical PTXs in the United States decreased between 1992 and 1998, but then steadily increased to the previous level in 2002. This probably reflects changes in the indications for PTX.

Postparathyroidectomy Management

PTX is usually performed as an inpatient surgery because of the immediate postoperative development of hungry bone syndrome. With chronic and severe secondary HPT, patients who undergo PTX can develop rapid recalcification of bones that have been demineralized by secondary HPT. This constitutes the hungry bone syndrome because serum calcium and phosphorus decrease sharply due to uptake into the bones. It requires a prompt and meticulous treatment plan. Postoperative management of such patients includes a concentrated calcium gluconate solution, usually prepared as 20 or 40 g of calcium gluconate dissolved in 1000 mL of 5% dextrose in water and administered at 20 to 30 mL/hr and adjusted by $\pm 5 \text{ mL/hr}$ depending on serum calcium levels measured approximately every 6 hours. As soon as the patient is able to take oral medications, oral calcitriol 0.5 to 2.0 $\mu\text{g/day}$ is given along with calcium carbonate 1 to 3 g/day on an empty stomach and at night to maximize intestinal calcium absorption. The calcium gluconate drip must not be stopped abruptly when there is a single high or normal reading for calcium because the bones may take up calcium very slowly. Removing the calcium infusion can precipitate tetany and prove fatal. Once the calcium gluconate drip is discontinued and the patient is taking a stable dose of oral calcium and calcitriol, outpatient therapy is planned and the patient is instructed to contact the physicians if perioral numbness or tingling develops. This could indicate incipient tetany. Other laboratory abnormalities

associated with postoperative PTX are hypophosphatemia, hypomagnesemia, and hyperkalemia; the first two require repletion because these minerals are also being taken up by the hungry bone and the latter requires standard therapy for hyperkalemia.

PERSISTENT SECONDARY HYPERPARATHYROIDISM AFTER RENAL TRANSPLANTATION

Persistent secondary HPT after renal transplantation is a frequent occurrence and rarely needs therapy. The usual recommendation is to wait as long as 1 year to let the parathyroid levels come back into the normal range. If therapy is needed, there are three ways to deal with the problem: (1) use bisphosphonates to block the osteoclastic effects of a persistently high PTH and wait for the serum PTH levels to normalize, (2) use calcimimetic agents to bring PTH levels into the normal range, and (3) surgically remove parathyroid gland tissue. In patients with persistent secondary HPT, a 24-hour urine specimen should be collected to measure calcium, phosphorus, and sodium excretion. If a patient is hypercalciuric ($>200 \text{ mg/dL}$) while eating a normal salt diet, then the patient is most likely to benefit from bisphosphonates.³² Conversely, if calcium excretion is low, then cinacalcet can be considered while serum calcium is measured at regular intervals.³³

CALCIPHYLAXIS

Calciphylaxis is a rare but devastating disorder. Its pathogenesis is poorly understood, and emergency PTX was once considered to be definitive therapy for calciphylaxis. Subsequent reports of poor outcomes after PTX and the presence of calciphylaxis in patients who have had a PTX have changed this practice.³⁴ Calciphylaxis is synonymous with calcific uremic arteriopathy and obliterative calcific vasculopathy, but none of these terms describes the abnormality adequately. Calciphylaxis involves mural calcification, endovascular fibrosis, and thrombosis of small arterioles, venules, and capillaries, so an arteriopathy label is incomplete. Unfortunately, both calciphylaxis and calcific uremic arteriopathy are used to describe the disorder.

Risk factors associated with the development of calciphylaxis are obesity, female gender, white race, high serum calcium and phosphorus levels, a high serum PTH and calcium \times phosphorus product, and coumadin treatment. Whether local trauma is a risk factor for calciphylaxis is not clear; in rodent models of calciphylaxis, sensitization with high calcium, phosphorus, and PTH levels followed by local trauma is usually required before the animal develops characteristic nonhealing ulcers. Moreover, many patients will report local trauma before developing the typical nonhealing ulcer.

The clinical features of calciphylaxis include painful subcutaneous nodules and dense plaques with an erythematous or violaceous color that progresses to necrotizing, nonhealing ulcers. A common site of involvement is the medial aspects of thighs, lower abdomen, and lower extremities. The diagnosis is based on characteristic nonhealing lesions. A bone scan is a modern way to diagnose and monitor the progression/regression of the disease. A skin biopsy should not be performed because nonhealing wounds can develop and progress to large gaping wounds requiring multiple débridements. This is particularly worrisome

because the major morbidity and mortality are wound infection and sepsis. There is no definitive therapy for calciphylaxis/calcific uremic arteriopathy, and the prognosis is generally poor with a 1-year mortality rate as high as 85%. Therapeutic options include the following possibilities.

Daily Dialysis

Daily dialysis for a few weeks using a low calcium bath (2 mEq/L) can help reduce serum phosphorus and mobilize deposited calcium while correcting uremia.

Sodium Thiosulfate

There are case reports of using sodium thiosulfate (STS) with apparent healing of the ulcers.^{35,36} STS is an antidote for cyanide and cisplatin toxicity and has antioxidant properties. The solubility of calcium thiosulfate in aqueous solutions can mobilize calcium from ectopic sources. The success of removing ectopic calcium is monitored by changes in bone scans. Investigators have given 25 g of STS/1.73 m² over 60 minutes after each dialysis session for 35 to 92 weeks. Intraperitoneal instillation of STS can also be used to treat calciphylaxis in peritoneal dialysis patients. Adverse effects associated with STS are nausea, vomiting, and metabolic acidosis.

Parathyroidectomy

PTX should not be considered in treating calciphylaxis because of poor healing. However, if serum PTH levels are very high despite medical management, then PTX could be a valid therapy.

Phosphate Regulation

Noncalcium-based phosphate binders should be used to cause a negative phosphate balance. Active vitamin D sterols should be avoided because they can increase calcium and phosphate absorption from the gut leading to hypercalcemia and hyperphosphatemia to aggravate the disorder. Daily dialysis helps decrease serum phosphorus to the K/DOQI target of 3.5 to 5.5 mg/dL. Dietary phosphorus restriction must be strictly followed because lowering serum phosphorus is probably the most important aspect in the treatment of this disorder.³⁷

Pain Management

The pain associated with calciphylaxis/calcific uremic arteriopathy is considered to arise from the combination of ischemic and neuropathic pain. Pain control is often a challenge with options including nonsteroidal anti-inflammatory drugs (ketorolac), narcotics (fentanyl), ketamine, and in some severe cases even spinal anesthesia. In studies of STS, most patients reported marked pain relief within days of initiating STS therapy.

Wound Care and Antibiotics

Although wound débridement might seem tempting, it is important not to be aggressive with débridement as it can increase the size of wound and the potential for infection. Close attention should be given to appropriate antibiotics; the

cause of death in these patients is usually sepsis from polymicrobial-resistant wound infection.

Other

There is evidence of osteoblastic transformation of vascular smooth muscle in CKD patients. The presence of bone matrix protein in blood vessels when there is calciphylaxis suggests that bisphosphonates will help. There is a case report that the first-generation bisphosphonate, etidronate disodium, given at 200 mg/day for 14 days led to dramatic improvement in skin ulceration.³⁸ Other therapeutic modalities that have had apparent success are cinacalcet hydrochloride (30–60 mg/day), and hyperbaric oxygen.^{39,40} Further studies are needed to determine the most useful treatment in these patients.

BACKGROUND

In patients with end-stage renal disease before (chronic kidney disease [CKD] stages 4 and 5) and after the start of dialysis treatment (stage 5D), angina pectoris, myocardial infarction, dysrhythmia, heart failure, stroke, and peripheral vascular disease are markedly more frequent than in the background population. The risk of death in dialysis patients is 15 times higher than in the background population. Age is a very prominent risk factor with a 3% risk increase per year in patients between 60 and 80 years old.¹ The cardiovascular risk (Box 70-1) starts to increase even in the earliest stages of CKD and increases exponentially with progressive loss of glomerular filtration rate (GFR).²

TREATMENT GOALS FOR UREMIC PATIENTS

In the distant past, it had appeared plausible that one should aim in uremic patients and in dialysis patients for the same treatment target values (Table 70-1) as in the general population. For a number of interventions, however, it has recently been suggested, unfortunately usually based on observational evidence, that targets for patients with end-stage renal disease should be different from those recommended in the general population, for example hemoglobin (Hb), parathyroid hormone (PTH), and blood pressure. Little controlled prospective evidence is available for patients with CKD, mainly because in the past patients with renal disease had deliberately been excluded from major cardiovascular intervention trials.

Further complexity has been created by some intervention trials documenting that mechanistically plausible interventions that had effectively improved cardiovascular outcome in nonrenal patients failed to yield significant benefit or yielded only marginal nonsignificant improvement in patients with

end-stage renal disease, for example, lowering of low-density lipoprotein cholesterol with statins in patients with type 2 diabetes on hemodialysis,³ lowering homocysteine concentrations with folate,⁴ and administration of angiotensin-converting enzyme (ACE) inhibitors in dialysis patients.⁵

The absence of intervention trials with information on the efficacy and safety of treatments makes it often difficult to make definite statements so that recommendations and guidelines for patients with end-stage renal disease are mainly based on expert opinion or low-grade evidence from observational data. The absence of controlled evidence has led to definite deficits in the prescription of treatments particularly for cardiovascular disease, as suggested by comparisons of the use of aspirin, statins, β -blockers, ACE inhibitors or AT₁ receptor blockers in renal patients compared with nonrenal controls. Such deficit is deplorable because, conversely, observational data suggest that risk reduction by intervention in this extremely high-risk population may be particularly rewarding. As a result, there remains a need for intervention trials to provide convincing evidence; the Cochrane group has shown that among several specialties in internal medicine, nephrology was the one where the least number of controlled trials had been performed.⁶

Healthy Lifestyle

A healthy lifestyle is routinely recommended to end-stage renal disease patients.

Smoking

Smoking accelerates the progression of renal disease and increases the cardiovascular risk substantially by a factor of as much as 10-fold,^{7,8} both in diabetic and nondiabetic patients.^{8,9} There are conflicting reports whether smoking aggravates the cardiovascular risk in patients on dialysis, but analogy to nonrenal patients suggests that this assumption is

Box 70-1 Cardiovascular Risk Factors and Cardiovascular Events for Uremic Patients**Risk Factors**

Smoking, glycemia, lack of exercise
 Dyslipidemia
 Anemia
 Hyperphosphatemia
 Lifestyle changes (metabolic syndrome)
 Additional cardiovascular risk factors (obstructive sleep apnea, depression)
 Dialysis modality

Cardiovascular Disease

Coronary heart disease
 Sudden death
 Heart failure

sensible. The proportion of smokers with early stages of CKD who stop smoking is disappointingly low, in our experience approximately 15%, although with the onset of ESRD, many smokers stop smoking.

The smoker with renal disease (and his or her partner) should be given advice, possibly nicotine replacement therapy or bupropion, but there is not sufficient safety information available to recommend nortriptyline, varenicline, rimonabant, or monoamine and selective serotonin reuptake inhibitors.

Normoglycemia

There is increasing (although not uniform) evidence that near-normal blood glucose levels as assessed by HbA1c or glycated albumin^{10,11} are associated with decreased cardiovascular events and improved survival of diabetic patients on dialysis,¹² although the relationship is confounded by several factors.¹³ For several reasons, HbA1c is not a perfect reflection of glycemic control, mainly because of the confounding influence of erythrocyte half-life and the measurement of carbamylated Hb in some assays.

Physical Exercise

Physical exercise has been shown to have beneficial metabolic and psychological effects,¹⁴⁻¹⁷ but in today's elderly dialysis population, this intervention is, unfortunately, very difficult to implement.

Obesity

Among further lifestyle changes, weight reduction is an important issue for which there is currently no definite answer available. The presence of metabolic syndrome¹⁸ and obesity¹⁹ increases the risk of CKD and end-stage renal disease.^{20,21} It would, therefore, appear rational to decrease the risk by weight reduction. Against this, one has to balance the recent observation that—for partially unclear reasons—survival on dialysis is better for those with a high body mass index, even in the range of morbid obesity.²² However, when adequately corrected for duration of follow-up using an adequate control group, the effect of a high body mass index on better survival dissolves. Due to wasting, it is not advisable to recommend weight reduction in those with far advanced CKD, for example, CKD stage 4 or 5.²³

Blood Pressure

In patients on long slow dialysis protocols, it has been shown that impressive survival rates are achieved with dialysis schedules resulting in normalization of blood pressure, primarily by low dietary salt intake, ultrafiltration to achieve dry weight, and prolonged dialysis sessions (8 hours).²⁴ Furthermore, a correlation was noted between blood pressure values (mostly in the normotensive range) and survival in the dialysis centers practicing long slow dialysis (e.g., Tassin²⁵). Strict normotension by decreased dietary salt intake and aggressive ultrafiltration has even led to reversal of left ventricular (LV) hypertrophy without antihypertensive medication.²⁶

Similarly, impressive blood pressure control with less need for antihypertensives has recently been achieved by protocols with daily short dialysis^{27,28} or daily nocturnal dialysis schedules,²⁹ which are not universally available, however. Improved blood pressure control is presumably the combined result of better control of hypervolemia, the potential removal of pressor agents (e.g., asymmetric dimethyl L-arginine), and a decrease in sympathetic overactivity.³⁰ There is a large trial ongoing to evaluate the clinical value of this modality.

The situation is much less clear in patients on the usual schedule of three times weekly short dialysis sessions ($3 \times 3-3 \times 5$ hr/wk). Initial analyses showed that high blood pressure values^{31,32} were associated with no or minor increase in risk, whereas the risk was highest in patients with low blood pressure. This finding is now commonly interpreted as the result of reverse causality, that is, reversal of the normal blood pressure-survival relationship because of the presence of heart disease or autonomic dysfunction. In the 4D study in patients with type 2 diabetes receiving hemodialysis,³ we found no correlation whatsoever between blood pressure and short-term patient survival.

Episodes of hypotension during dialysis carry a particularly adverse prognosis: Once blood pressure decreases below the threshold of coronary autoregulation of approximately 95 mm Hg systolic, the risk of cardiovascular death is significantly increased.³³

In almost all studies, correct assessment of the impact of blood pressure on target organs is rendered difficult because of the absence of ambulatory blood pressure measurements. Because the circadian blood pressure profile is abnormal and particularly because nighttime blood pressure values tend to be high, the blood pressure burden on target organs is underestimated by the office blood pressure.

A further confounder is the situation that brachial artery blood pressure may markedly underestimate central (aortic) blood pressure to which the target organs are exposed (heart, brain, kidney).³⁴

The frequently present high blood pressure amplitude is the result of increased aortic stiffness. Aortic stiffness, indirectly assessed by pulse wave velocity, is an independent predictor of adverse cardiovascular outcome.³⁵ A high blood pressure amplitude implies a low diastolic blood pressure, which exposes the patient to the risk of coronary underperfusion because coronary flow occurs only during diastole.

Recommended Blood Pressure in Dialysis Patients

Which blood pressure should one aim for? Little well-documented long-term evidence is available, but the following strategy appears sensible for patients on the usual dialysis schedules of three times for 3 to 5 hours per week.

Table 70-1 Basis for Treatment Targets in Uremic Patients According to Current Kidney Disease Outcome and Quality Initiative Guidelines

Parameter	Target/Goal	Evidence
Smoking	Cessation	Observational, strong opinion, no pharmacotherapy studies ¹
Physical activity	30 min/day, moderate intensity	Observational for hospitalizations and death ¹ Intervention for surrogate outcomes (clinical chemistry) ¹
Healthy weight	Uremia (BMI < 18.5 kg/m ² avoid)	Observational ²
	Diabetes and CKD stage 1–4 (BMI 18.5–24.9 kg/m ²)	Observational ³
Glycemia	Normoglycemia ³	
	Preprandial capillary plasma glucose 90–130 mg/dL (5.0–7.2 mmol/L)	
	Peak postprandial capillary plasma glucose 4 < 180 mg/dL (10.0 mmol/L)	
	Hb _{A1c} < 7%	Observational ³ One observational study ⁴
Blood pressure	Pre-dialysis < 140/90 mm Hg	Interventional, post hoc observational ⁵
	Post-dialysis < 130/80 mm Hg	Observational (avoid hypotension) ⁵
LDL cholesterol	<100 mg/dL (mmol/L)	CKD stage 4–5D observational retrospective ^{3,6} CKD stage 1–3 meta-analysis of RCTs post hoc = observational ^{1,3}
	<70 mg/dL (mmol/L) (option)	CKD stage 1–4 KDOQI opinion ³
Hemoglobin	Normalization	Observational, opinion ⁷
	11–12 g/dL	Interventional ⁸
	>13 g/dL, avoid	Interventional ⁸
S-phosphorus	3.5–5.5 mg/dL (1.10–1.80 mmol/L)	Observational ⁹

- BMI, body mass index; CKD, chronic kidney disease; Hb_{A1c}, hemoglobin A1c; KDOQI, Kidney Disease Outcome and Quality Initiative; RCTs, randomized, controlled trials.

In low-risk relatively young patients with potentially long life expectancy, one should aim for normotension according to Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure.

In contrast, standards may have to be relaxed in the elderly polymorbid patient with poor ultrafiltration tolerance and

predisposition to intradialytic hypotension, which by itself is a predictor of and contributor to an adverse cardiovascular outcome.

Dietary salt restriction, as originally recommended by Scribner and colleagues^{36,37} is certainly the most neglected and underused aspect of dialysis patient management.³⁸

Reduction of dietary salt intake, combined with modest lowering of dialysate sodium concentration (~ 135 mmol/L) and effective ultrafiltration, normalized blood pressure not only in centers with long slow dialysis but also centers with 3×5 hr/week dialysis.^{26,39}

Why is salt intake so important for blood pressure control? Ingestion of 9 g of salt by an anuric patient increases the osmotic pressure, which forces the patient to drink 1 L of water to maintain osmolality. Although some salt is stored in a non-osmotic form,⁴⁰ daily intake of the usual amount of 13 to 14 g of salt in the Western diet increases body weight by 1.5 kg/day and causes hypervolemia, the most potent cause of hypertension in anuric patients. Furthermore, salt intake increases the plasma concentration of endogenous digitaloids,⁴¹ which increase blood pressure.⁴² Such blood pressure increase can be reversed by ouabain antagonists in experimental studies⁴³ documenting their causal role. In experimental studies, a salt-induced increase in the concentration of cardiotoxic steroids reproduced the features of uremic cardiomyopathy.⁴⁴

The majority of dialysis patients require antihypertensive therapy. Are there differences between the different antihypertensive agents?

There is recent controlled evidence from a small study in dialyzed patients with heart failure that the β -blocker carvedilol reduces cardiac mortality by approximately 50%.⁴⁵ In dialysis patients, the use of β -blockers was also associated with less onset of heart failure.⁴⁶ Furthermore, observational studies documented less mortality in dialysis patients treated with β -blockers.^{33,47}

Recent preliminary studies suggest that angiotensin-receptor blockers on top of alternative antihypertensive medication improve survival of dialysis patients, although the study sizes were quite limited. The effect of ACE inhibitors examined in one study on elderly dialysis patients failed to document a statistically significant benefit, but showed a tendency for some improvement of outcomes.⁵

Calcium channel blockers are very effective in dialyzed patients and in some analyses of the most frequently used antihypertensive drug.⁴⁸

In contrast to the dialyzed patient, the situation is entirely different in the patient with CKD. There is consensus that high blood pressure, particularly systolic blood pressure, is the key factor that promotes progressive loss of renal function. There has been much discussion concerning whether it is more important to lower blood pressure or to block the renin-angiotensin system (RAS).⁴⁹ There is no doubt that lowering blood pressure per se is of overriding importance, as illustrated by one striking comparison: Before the availability of antihypertensive treatment, the patient with diabetic nephropathy lost approximately 10 mL/min/1.73 m² GFR per year. In the RENAAL (Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan) trial, the rate of loss of the estimated GFR was 5.24 mL/min/1.73 m² per year in the placebo arm and 4.4 mL/min/1.73 m² per year in the Losartan arm (Bakris, personal communication), illustrating the respective relative potencies for these two interventions. Controlled prospective evidence for this statement is somewhat weak, however. The Modification of Diet in Renal Disease study compared routine (target 107 mm Hg mean arterial pressure) and intensified (target 91 mm Hg mean arterial pressure) lowering of blood pressure. Intensified blood pressure lowering was associated with a GFR loss of

1.9 mL/min/1.73 m² compared with 3.4 mL/min/1.73 m², but this was not statistically significant.⁵⁰ In the long-term follow-up observation, the difference in the occurrence of end-stage renal disease was significant but small.⁵¹

Based on a number of observations, current guidelines recommend in patients with CKD a lower target blood pressure than in essential hypertension; most recommend 130/80 mm Hg. Such low blood pressure target is justified not only by the consideration of renal protection but also because of the high cardiovascular risk of CKD patients: Lewington and colleagues⁵² had shown in individuals without renal disease that if systolic blood pressure was lowered by 20 mm Hg, the rate of cardiovascular events was lowered by 50%.

A specific benefit from blockade of the RAS using ACE inhibitors or angiotensin receptor blockers has been documented in a series of head-on comparisons between RAS blockade and blood pressure lowering without RAS blockade. Even in studies, for example, the Ramipril Effect in Nephropathy study, in which blood pressure values in the ACE inhibitor and non-ACE inhibitor arms were identical, a benefit, that is, less decrease in GFR, was seen with RAS blockade,⁵³ and this has been confirmed by a meta-analysis of further controlled trials.^{54,55}

The beneficial effect of RAS blockade is particularly pronounced in patients with proteinuric renal disease and less certain in patients with CKD and proteinuria less than 1 g/24 hr.⁵⁶ One difficulty in interpretation relates to the fact that office blood pressure measurements are a poor reflection of the 24-hour blood pressure profile and may also substantially underestimate the level of central blood pressure (to which heart and kidney are exposed).

One drawback of RAS blockade is the phenomenon of escape, that is, gradual return of proteinuria to baseline values despite treatment after several years of RAS blockade. Modern approaches include dose escalation of ACE inhibitors and/or angiotensin receptor blockers, combination of ACE inhibitors and angiotensin receptor blockers.⁵⁷ Currently further approaches, for example, mineralocorticoid receptor blockade (which in patients with impaired renal function carries the substantial risk of hyperkalemia and is not advisable in such patients) and renin blockers are under investigation.

When lowering blood pressure, one caveat is the J-curve phenomenon. At low diastolic pressures, coronary perfusion is endangered as recently shown in the INVEST (International Verapamil SR/Trandolapril) study.⁵⁸ Because of the high frequency of coronary heart disease, it is advisable to not lower diastolic pressure to values less than approximately 70 mm Hg.

The single most neglected aspect of antihypertensive treatment is decreasing the dietary salt intake and adequate diuretic treatment. The current discussions of which antihypertensive drug reduces progression of renal disease best is entirely academic because mostly three to six antihypertensive classes are necessary to achieve the target blood pressure.⁵⁹

Lipid Abnormalities

Two decades ago, Degoulet and colleagues⁶⁰ made the counterintuitive observation that, in dialysis patients, the lower serum cholesterol is, the higher the mortality rate.⁶⁰ This observation has since been amply confirmed and does of course not imply that in end-stage renal disease high cholesterol is protective. Rather it is explained by so-called reverse causality,

that is, confounding the relationship between serum cholesterol and cardiovascular death by factors such as inflammation. This interpretation gains credence from the study of Liu and colleagues⁶¹ that documented that in CKD patients with high C-reactive protein low low-density lipoprotein cholesterol was associated with a high mortality rate, whereas in CKD patients with low C-reactive protein, the usual continuous positive relationship between serum cholesterol and cardiovascular risk was observed.

The contribution of lipids to the elevation of cardiovascular risk in renal patients cannot be fully assessed by routine laboratory measurements, particularly not by total cholesterol and low-density lipoprotein cholesterol. In CKD the typical constellation is low HDL cholesterol and high triglycerides. A number of further atherogenic lipid abnormalities are not measured routinely,^{62–64} for example, accumulation of remnants (chylomicrons, intermediate-density lipoprotein, small dense low-density lipoprotein); inflammatory high-density lipoprotein; covalent modification of apo-lipoproteins by carbamylation, glycation, and oxidation; increased lipoprotein(a).

In view of the strikingly increased cardiovascular risk in renal patients,⁶⁵ the question arises whether statin treatment is indicated in CKD patients even when cholesterol values are not frankly increased, that is, whether CKD (analogous to diabetes) should be considered a coronary equivalent with a 10-year mortality of more than 20%.⁶⁶ Controlled information on this point is currently not available, but post hoc analyses of study participants with a decreased estimated GFR in the trials on cardiovascular disease showed that statins reduced cardiovascular events in patients with CKD stages 2 and 3.⁶⁷ There is no information available on patients with CKD stage 4.

In patients on dialysis, observational studies had suggested a lower mortality rate in patients on statins,⁶⁸ but in diabetic patients on hemodialysis, the prospective controlled 4D study failed to show significant benefit for a composite cardiovascular endpoint, although a trend of benefit was seen for adjudicated cardiovascular death, nonfatal myocardial infarction, bypass, percutaneous transluminal coronary angiography, which was less frequent by 18% per 1 mmol/L lower low-density lipoprotein cholesterol, exactly what had been seen for coronary death in trials on nonrenal patients.⁶⁹

The prevailing opinion is currently that statin treatment should be started early in CKD and not stopped when patients go on dialysis, but the data do not justify de novo start of statin treatment for primary prevention in dialysis patients without clinical evidence of coronary heart disease. It is our opinion, however, that dialysis patients with established coronary heart disease should receive statins, although admittedly definite evidence on this point is currently lacking.

Anemia

In CKD, anemia is mainly the result of reduced plasma erythropoietin concentration, although additional factors such as chronic microinflammation, gastrointestinal blood loss, and iron deficiency play a role; in dialysis patients, blood loss through the dialysis procedure, blood sampling for laboratory investigation, etc. may further contribute. In the past, it was thought that anemia usually appears at an estimated GFR of approximately 30 mL/min, but more recent studies show that anemia may appear much earlier,⁷⁰ particularly in diabetic patients.⁷¹ In observational studies, Hb and hematocrit are

powerful predictors of mortality and adverse events.⁷² This appeared plausible because the circulatory adaptation to anemia is maladaptive, that is, vasodilatation, increased venous return, cardiac enlargement, and increased cardiac output.⁷³ It had therefore been widely anticipated that correction of anemia including normalization of Hb values was beneficial.

Undoubtedly, in the past, several small studies suggested that correction of severe anemia with Hb 7 to 10 g/dL did not improve only the quality of life, but also objective surrogate parameters such as LV hypertrophy.⁷⁴ It was therefore extrapolated that normalization of Hb was a promising goal. For several reasons, this concept has recently been questioned. In the study of Besarab and colleagues,⁷⁵ dialysis patients with cardiac disease were randomized to erythropoietin treatment with the goal of achieving predialytic target hematocrit values of 42% versus 30%. The study was prematurely stopped when an excess of adverse events was seen in the high hematocrit patients. This was primarily because of more frequent thromboses of the vascular access. In a prospective study of dialysis patients with concentric LV hypertrophy or LV dilatation, the changes in the cavity volume index were similar in both targets in patients with LV dilatation, whereas in patients with an initially normal LV volume, an inverse relationship was seen between the change in the LV volume index and the mean Hb level, potentially implying that normalization of Hb was better in preventing than in reversing LV dilatation.⁷⁶ With respect to LV hypertrophy no significant effect of full Hb correction was seen in nondiabetic incident hemodialysis⁷⁷ and diabetic patients with CKD.⁷⁸ Furthermore, in the CREATE (Cardiovascular Risk Reduction with Early Anemia Treatment with Epoetin Beta) study, patients with advanced CKD and anemia were randomized to achieve an Hb of 10.5 to 11.5 g/dL and 13 to 15 g/dL, respectively.⁷⁹ There was no difference in cardiovascular outcomes and a suggestive shortening of the time to the start of dialysis, but the quality of life was significantly better in patients with a higher Hb. More recently, in the CHOIR (Correction of Hemoglobin and Outcomes in Renal Insufficiency) study, increased rates of cardiovascular events were observed in the arm with higher target hematocrit values.⁸⁰ As a result, much concern has been raised whether normalizing Hb is safe.⁸¹ The definite answer will have to wait until the results of the ongoing TREAT (Trial to Reduce Cardiovascular Events with Aranesp) study in diabetic patients with CKD, in which normalization and incomplete normalization with erythropoietin beta are compared, are available.⁸²

At the same time, it appears that current recommendations (European Renal Association guidelines) go the middle road between the undoubted adverse effects of Hb less than 10g/dL on surrogate markers such as LV hypertrophy,⁷⁴ on the one hand, and a potential (although currently not proven) cardiovascular risk of normalization of Hb.⁸¹ Indeed, theoretically, mechanisms are conceivable regarding how renal failure may promote adverse effects of Hb normalization: Experimental work points to the importance of normal endothelial function to prevent adverse effects of erythropoietin and endothelial function is frequently disturbed in uremia.⁸³

Calcium Phosphate Metabolism

In the past, the only known adverse effects of hyperparathyroidism and abnormal plasma concentrations of calcium and phosphate were bone disease and soft-tissue calcification. The

treatment target was normalization of the PTH concentration by administration of active vitamin D (1,25-dihydroxycholecalciferol or its congeners) to prevent bone disease and to lower plasma phosphate by oral phosphate binders, mainly oral calcium carbonate or acetate.

It was recently recognized that both low- and high-turnover bone disease promote vascular calcification including coronary calcification⁸⁴ and that vascular calcification is closely related to adverse cardiovascular events as a result of arterial stiffening, increased blood pressure amplitude with decreased diastolic blood pressure, decreased coronary perfusion, and other factors.⁸⁵ The targets for treating abnormal mineral metabolism have therefore been broadened to include reduction of cardiovascular risk. The term CKD–metabolic bone disease has been coined to emphasize the link between metabolic bone disease and cardiovascular complications of CKD.⁸⁶

Hyperparathyroidism has an impact on survival as illustrated by improved long-term survival after parathyroidectomy,^{87,88} but, conversely, low immunoreactive PTH concentrations are associated with low bone turnover and increased risk of vascular calcification.⁸⁴

Treatment of elevated immunoreactive PTH includes reduction of plasma phosphate, administration of active vitamin D (1,25-dihydroxycholecalciferol or its congeners) at doses that avoid hypercalcemia and/or hyperphosphatemia, the calcium receptor agonist (calcimimetic) cinacalcet,⁸⁹ and parathyroidectomy.⁹⁰

Improved achievement of treatment targets with cinacalcet has been documented,⁹¹ but evidence of a positive effect on hard endpoints is still lacking.

The rationale for the administration of active vitamin D (i.e., 1,25-dihydroxycholecalciferol or its congeners) may go beyond the inhibition of elevated immunoreactive PTH concentrations. Several observational studies on dialysis patients documented better survival of patients given active vitamin D, particularly the congener paricalcitol, independent of immunoreactive PTH, plasma calcium, and phosphate.^{92,93} Although prospective controlled evidence is still lacking, an explanation for this unexpected finding may be the fact that active vitamin D inhibits renin secretion in the juxtaglomerular apparatus⁹⁴ and exerts PTH independent effects on the heart.^{94–96}

It has been well documented that hyperphosphatemia affects patient survival⁹⁷ so that currently serum phosphate concentrations of 5.5 mg/dL are recommended as a therapeutic target, which is admittedly difficult to achieve with current dialysis schedules. Even lower serum phosphate values are associated with a higher risk of cardiovascular events in CKD patients⁹⁸ and even in coronary patients without CKD.⁹⁹

The recognition that a positive calcium balance facilitates vascular calcification, including coronary calcification, has led to the introduction of noncalcium-containing phosphate binders for the prophylaxis of hyperphosphatemia. Although the phosphate binder sevelamer decreased vascular calcification,¹⁰⁰ thus far, despite suggestive trends,¹⁰¹ definite evidence that it also decreases hard cardiovascular endpoints is absent. The latter is also true for lanthanum carbonate.

Currently used phosphate binders include calcium acetate or calcium or magnesium carbonate, lanthanum carbonate,¹⁰² sevelamer,¹⁰⁰ and inhibition of intestinal phosphate absorption by nicotinamide.¹⁰³

Finally, it was only recently recognized that patients with CKD tend to have low 25(OH) vitamin D₃ concentrations,¹⁰⁴ which has been shown to be related to a number of functions unrelated to mineral metabolism, for example, impaired infection control (specifically tuberculosis), impaired insulin secretion and insulin sensitivity, and altered immune response. It has therefore been recommended to normalize 25(OH)D concentrations by administration of native vitamin D₃ (or D₂) to achieve a target 25-dihydroxyvitamin D of 30 ng/mL.

Dialysis Modality

Uremia is a state of intoxication by retention not only of urea, but also the number of more or less hypothetical low molecular weight, water-soluble substances, which are not very effectively removed with current dialysis strategies.¹⁰⁵ There has been much recent interest in strategies to modify the dialysis procedure.

On the one hand, the relative value of removal of urea (Kt/V) versus hypothetical higher molecular weight substances was assessed in the HEMO (Hemodialysis) Study, which failed to provide a clear-cut result,¹⁰⁶ although the currently unpublished results of the European MPO (Membrane Permeability Outcomes) trial show that high-flux membranes improve hard endpoints in dialysis patients.

Even more spectacular are observations on dialysis procedures other than the routinely used 3 × 3 to 3 × 5-hours per week schedule, for example, daily short-term dialysis (2–3 hours), on the one hand^{28,107} and daily nighttime dialysis.²⁹ Such modified schedules reduced hypertension and permitted reduction or omission of antihypertensive agents, facilitated phosphate removal, improved anemia, and decreased or eliminated the use of erythropoietin, improved sleep and sleep apnea syndrome as well as many other facets of the uremic syndrome. Ongoing controlled trials will provide information on the true real-life value of these alternative procedures.

CORONARY ARTERY DISEASE

Coronary artery disease is extremely common in the population of uremic patients. Its morphology differs from that of nonuremic individuals by the high prevalence of calcification¹⁰⁸ and higher degree of inflammatory changes and intraplaque hemorrhage.¹⁰⁹ Myocardial infarction accounts for approximately 9% of deaths of patients on dialysis, which, as a percentage of total death, appears low, but compared with absolute rates in the general population, it is high. The prognosis of myocardial infarction in dialysis patients is abysmal.¹¹⁰ Observational studies suggest, despite higher perioperative risk, superior long-term survival with coronary artery bypass graft compared with percutaneous transluminal angioplasty with stent placement.¹¹¹ It is important that even minor reductions in renal function accelerate atherogenesis in experimental models¹¹² and that in observational studies, the risk of coronary heart disease increases progressively with decreasing GFR.¹¹³ Unfortunately, patients with CKD tend to be undertreated with respect to interventions such as aspirin, β-blockers, and statins, although undertreatment alone does not fully account for the more adverse prognosis of coronary heart disease in CKD patients.

In patients with end-stage renal disease, the symptomatology of CHD is frequently atypical (dyspnea without precordial pain) and the exercise electrocardiogram usually cannot be performed because of muscular weakness. The best option is to perform coronarography if there is a high suspicion of coronary heart disease (particularly before renal transplantation) and if intervention by percutaneous transluminal angioplasty or bypass surgery is possible.

SUDDEN DEATH

Sudden death is the most common modality of death in dialysis patients.¹¹⁴ In contrast to the general population, it occurs most frequently at night (patients are found dead in bed). Pathogenetic factors include myocardial fibrosis, repolarization disturbances, electrolyte changes, and possibly medication-induced QT prolongation. There is no documented prophylaxis, but medications causing QT prolongation should be avoided.¹¹⁵ Although there is no formal proof, β -blockers are apparently helpful.¹¹⁴

HEART FAILURE

Heart failure is common in dialysis patients and is found in as many as 50% of patients if sophisticated techniques are used. Structural heart disease is common (aortic and mitral valve calcification/stenosis, coronary heart disease, cardiac hypertrophy and fibrosis, cardiac underperfusion because of microvessel disease). The role of endogenous cardiotoxic digitaloids in the genesis of hypertension and organ damage of uremia had been postulated by Ahmad and colleagues¹¹⁶ and was recently documented in the genesis of uremic cardiomyopathy by Kennedy and colleagues.⁴⁴

A major correctable factor is overhydration by volume control (see earlier). Impressive results have been obtained by the prophylactic administration of β -blockers,⁴⁶ particularly carvedilol in trials involving a limited number of patients.

CONCLUSIONS 789

In men with chronic kidney disease (CKD), quality of life is significantly affected by erectile dysfunction (ED).¹ The cause is often multifactorial. Uremia, medications, associated comorbid conditions, physiologic changes with dialysis, and the causative pathophysiology leading to the patient's CKD should be considered before initiating treatment (Box 71-1).

INCIDENCE

Is the incidence of ED greater than in normal men? Masters and Johnson² reported that the incidence of ED in normal men younger than the age of 50 years was less than 5%. The Massachusetts Male Aging Study reported that 5% of men at age 40 years have complete ED; and this increases to 50% among men aged 70.³ Rodger and colleagues⁴ reported on 100 uremic men with a significantly higher prevalence. In a current study, Rosas and colleagues⁵ found that 82% of patients on hemodialysis had ED. ED was much more prevalent in the dialysis patients older than 50 years (63% in those younger than 50 compared with 90% in those older than 50).

Karacan⁶ observed that rapid eye movement sleep was associated with penile tumescence, using a nocturnal penile tumescence (NPT) monitor. If psychological factors predominate, the NPT results should not be affected. Thus, these studies showed that organic disturbances or pharmacologic

alteration of physiology correlated with altered NPT and impotence. Karacan reported that 50% of patients on hemodialysis had abnormal NPT.

CAUSES OF ERECTILE DYSFUNCTION IN CHRONIC KIDNEY DISEASE: AN OVERVIEW

Physiologic factors in the evaluation of ED include alterations in venous and arterial flow patterns, altered smooth muscle tone, hormonal aberrations, neurogenic abnormalities, and structural damage secondary to infection, trauma, or associated diseases. In addition, chronic fatigue, depression, and psychosocial stress may result from chronic indolent illnesses that can contribute as psychological components of ED.⁷

PHYSIOLOGIC ALTERATIONS IN CHRONIC KIDNEY DISEASE PREDISPOSING TO ERECTILE DYSFUNCTION

In evaluation of a patient with CKD who presents with erectile problems, several physiologic processes must be considered: endocrine abnormalities, neurological compromise, vascular

insufficiency, venous incompetence, pharmacologic manipulations, psychological disturbances, and associated chronic diseases (such as hypertension, diabetes mellitus, anemia, and electrolyte abnormalities).

ENDOCRINE ABNORMALITIES

CKD leads to abnormal hormonal balances throughout the hypothalamic-pituitary-gonadal axis. Semen quality is also affected and correlates with decreased testosterone levels.⁸ The decrease in serum testosterone results from increased

elimination, with maintained testicular hormone-binding capacity. Not all patients, however, have abnormal serum testosterone levels. Thus patients with CKD are likely to have a deficiency in hormone production and secretion as the primary mechanism for their hypogonadism, as well as an element of end-organ failure. Interestingly, giving exogenous testosterone to CKD patients with diminished levels of circulating testosterone does not improve erectile function or fertility.⁹

Men with CKD have abnormal secretion of luteinizing hormone, follicle-stimulating hormone, and prolactin. Luteinizing hormone levels are generally increased in response to low testosterone levels and because of a decrease in the metabolic clearance of luteinizing hormone.¹⁰ Follicle-stimulating hormone is also elevated in those men with suboptimal spermatogenesis. The increase in serum luteinizing hormone and follicle-stimulating hormone correlates well with the pituitary response to hypothalamic stimulation by gonadotropin-releasing hormone, which is preserved in the CKD patient. Thus, if the luteinizing hormone response to low testosterone levels is inadequate, a pituitary abnormality may be present.

The frequently elevated prolactin levels in men with CKD may cause sexual dysfunction. Medications that induce hyperprolactinemia include methyl dopa, digoxin, cimetidine, and metoclopramide. Patients with hyperprolactinemia often have ED. Once the hyperprolactinemia is treated, erectile function improves, as does fertility.

Diabetes mellitus is a common cause of ED. The autonomic and sensory neuropathic dysfunction resulting in ED is not amenable to medical therapy. This is especially difficult for the young patient who has adequate vascular and venous function but insufficient neurological ability to produce a sufficient erectile response.¹⁰

Secondary hyperparathyroidism is a common manifestation of CKD. Massry and associates¹¹ suggested in 1977 that the excess blood levels of parathyroid hormone in uremic patients might contribute, at least partly, to the disturbance in hormones of the hypothalamic-pituitary-gonadal axis and in the genesis of the impotence of uremia.

NEUROGENIC ALTERATIONS

In the flaccid state and during detumescence, sympathetic neural activity predominates. Norepinephrine activates postsynaptic α_{1a} , α_{1b} , and α_{1b} receptors, and its activity is modulated by presynaptic α_2 receptors (Fig. 71-1).¹² Erections are mediated through the parasympathetic system via acetylcholine. Activation of muscarinic receptors liberates nitric oxide, which relaxes smooth muscle and causes erection. There are also nonadrenergic, noncholinergic neurons that release nitric oxide (Fig. 71-2). Nitric oxide increases cyclic guanosine monophosphate production, which relaxes cavernous smooth muscle.¹³

In studies of 12 CKD patients with ED, an abnormal Valsalva maneuver correlated with abnormal NPT and diminished ability to achieve erections suitable for intercourse.¹⁴ Peripheral neuropathy in CKD is frequent. Evaluation of patients with suspected neurogenic causes of impotency must rely on clinical judgment.¹⁴

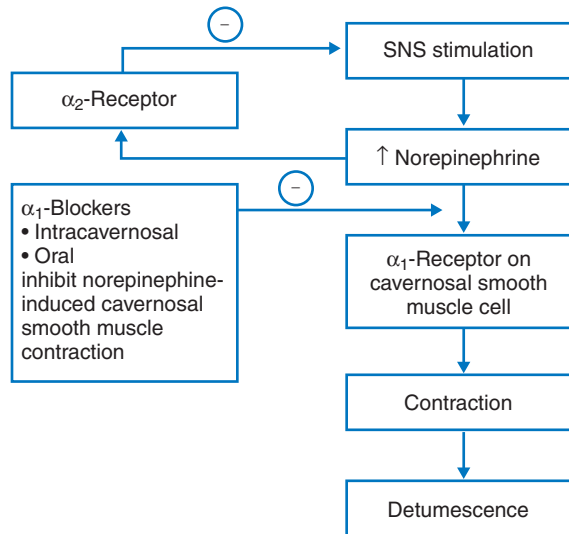

Figure 71-1 Sympathetic nervous system (SNS) effect on cavernosal smooth muscle.

VASCULAR COMPROMISE

Sexual stimulation releases nitric oxide, which relaxes smooth muscle and dilates the arterioles, thus increasing blood flow. Blood trapped in the expanding sinusoids compresses the venous system, increasing the pressure within the cavernosal bodies to approximately 100 mm Hg. Contraction of the ischiocavernosus muscle further increases pressure in the penis leading to a rigid erection.

Acceleration of atherosclerosis leads to vasculogenic ED by occluding large vessels and their arterial tributaries. Therefore, regardless of age, vasculogenic ED occurs even in younger

men with CKD. Kaufman and colleagues¹⁵ reported that 78% of impotent CKD patients had significant occlusive disease of the cavernosal artery.

Techniques to identify venous outflow abnormalities in ED include dynamic infusion studies, pharmacocavernosometry, and pharmacocavernosography.¹⁶ In a series by Kaufman and colleagues,¹⁵ 90% of CKD patients had venous occlusive incompetence.

MEDICINAL AGENTS IMPLICATED IN ERECTILE DYSFUNCTION

Medications frequently associated with ED are listed in Box 71-2. Reductions in libido are seen with centrally acting agents like clonidine and reserpine, as well as drugs that increase prolactin levels. ED has been associated with virtually all antihypertensive agents. Calcium channel blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and α -adrenergic antagonists are least likely to cause iatrogenic ED. Conversely, β -blockers, sympatholytics, and vasodilators are strongly associated.¹⁷ These drugs, if causing ED, may be changed to α -adrenergic blocking agents such as terazosin, prazosin, or doxazosin, or angiotensin-converting enzyme inhibitors and calcium channel blockers.

ANEMIA AND DIMINISHED OXYGEN DELIVERY

Low partial pressure of oxygen (PO_2) causes impotency by impairing cavernosal nitric oxide synthesis. Kim and colleagues¹³ found decreased nitric oxide synthesis and elevated

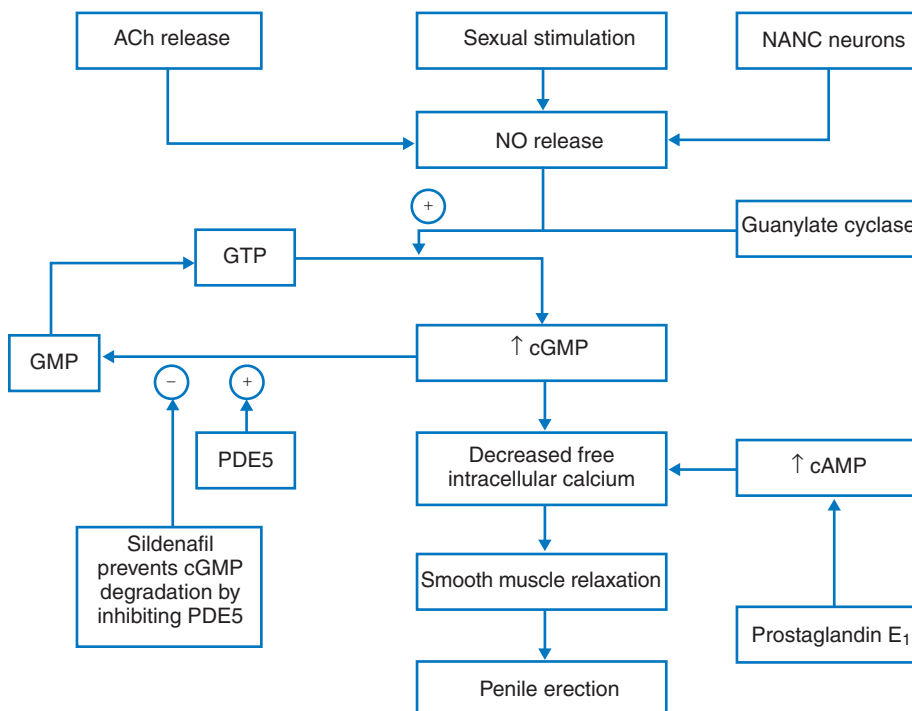

Figure 71-2 Nitric oxide (NO)-related neurogenic alterations. The primary pathway is cyclic guanosine monophosphate (cGMP) mediated, whereas cyclic adenosine monophosphate (cAMP) acts secondarily. Both decrease intracellular calcium, thus causing relaxation of smooth muscle. ACh, acetylcholine; GTP, guanosine triphosphate; NANC, nonadrenergic, noncholinergic; PDE5, phosphodiesterase-5.

smooth muscle tone in patients with low PO_2 at the corpora cavernosa. Luscher and colleagues¹⁸ found increased endothelium-derived contracting factors, which could further increase smooth muscle tone and inhibit erection. Finally, metabolites that inhibit nitric oxide synthase accumulation of CKD patients possibly contribute to ED.

EVALUATION OF ERECTILE DYSFUNCTION IN MEN WITH CHRONIC KIDNEY DISEASE

ED in men with CKD should proceed systematically as outlined in Box 71-3. The use of NPT monitors can identify patients with a true organic cause of their ED whose vascular problems are suggested. Doppler screening studies, pharmacocavernosometry, pharmacocavernosography, dynamic infusion studies, and color Doppler response studies may be helpful. Finally, hormonal studies, including testosterone, luteinizing hormone, follicle-stimulating hormone, and prolactin, should be obtained. These may be supplemented by serum glucose, hemoglobin A_{1C} , lipid profile, and thyroid function studies.

TREATMENT OPTIONS

Treatment options for ED are reviewed in Box 71-4.

Box 71-3 Evaluation of Erectile Dysfunction in Men with Chronic Kidney Disease

Physical examination
General examination
Genitourinary examination: testicles, scrotum, phallus, meatus, prepuce, and glans
Digital rectal examination
Neurological examination: S2 to S4 sensation, bulbocavernosus reflex, anal wink, anal tone, and penoscrotal sensation
Laboratory evaluation to assess general and specific causes of erectile dysfunction
Serum testosterone
Luteinizing hormone
Follicle-stimulating hormone
Prolactin
Complete blood count
Serum glucose or hemoglobin A_{1C} and baseline electrolytes
Lipid profile
White men older than 50 years and black men younger than 40 years should have a prostate-specific antigen test
Further referral to a urologist if considering:
Doppler screening studies
Color Doppler ultrasonography for flow
Pharmacocavernosography
Pharmacocavernosometry
Dynamic infusion studies
Nocturnal penile tumescence studies
Biothesiometry
Injection therapy
Surgical therapy

Medical Management of Erectile Dysfunction

Hormone Regulation

Patients who have low testosterone levels may respond to replacement therapy, which normally improves libido without a significant impact on potency or fertility. Data on the effects of testosterone replacement in end-stage renal disease are scant. There have been several small studies suggesting that testosterone therapy does not improve erectile function in the majority of hemodialysis patients for which it was prescribed.^{19–21} Effective replacements include injectable preparations, transdermal delivery systems, or sustained-release products. However, 100 to 200 mg of testosterone weekly by injection produces only small and variable responses in erectile function.²²

Clomiphene citrate, which is a partial agonist of the estrogen receptor, increases secretion of gonadotropins and increases plasma testosterone in CKD. One study that found increased testosterone levels from the hypogonadal range to the high end of normal range in five uremic men using clomiphene citrate reported uniform increases in libido and sexual function.²³

If hyperprolactinemia is found, chromophobic tumors of the anterior pituitary must be excluded because men may present with ED or decreased libido. Methyldopa and reserpine interfere with dopamine secretion and therefore lead to

Box 71-4 Treatment Options in Men with Chronic Kidney Disease and Impotence**Medical****Medications**

- Hormone replacement therapy
- Oral medications to improve arterial flow
- Intracavernosal injection therapy
- Transurethral therapy
- Dopaminergic agonists
- Erythropoietin

Devices

- Vacuum constriction device
- Constriction bands

Surgical

- Revascularization techniques
- Penile prosthetic devices

Psychiatric

- Posttransplantation

Other Issues

- Adjust medications where appropriate
- Control comorbid disease states
- Evaluate for psychosocial stresses
- Discuss expectations with patient
- Routinely evaluate efficacy of therapy and patient satisfaction
- Realize the changing patterns of erectile dysfunction and need to change therapy or modality
- Consider early referral to a urologist

hyperprolactinemia. If these causes are excluded, dopaminergic agonists may be of benefit.^{24,25} Bromocriptine (1.25–5.0 mg/day) and lisuride hydrogen maleate (0.05–0.2 mg/day) decrease prolactin and increase testosterone. Bromocriptine can induce hypotension, nausea, vertigo, and dizziness, side effects that are intolerable to many patients. These side effects are less prominent with lisuride hydrogen maleate.

For patients with symptomatic secondary hyperparathyroidism, it was recently found that sexual function of male patients can be improved by parathyroidectomy and autotransplantation. The report also demonstrated a decrease in the levels of prolactin in association with decreasing levels of calcium, phosphorus, and immunoreactive parathyroid hormone.²⁶

Phosphodiesterase Inhibitors

Since 1998, the U.S. Food and Drug Administration has approved three selective type 5-phosphodiesterase inhibitors (PDE-5Is): sildenafil (Viagra, Pfizer), tadalafil (Cialis, Lilly), and vardenafil (Levitra, Bayer). Each of the three PDE-5I registration programs involved more than 2000 patients. In the United States, sildenafil was approved in 1998 and both vardenafil and tadalafil were approved in 2003.

Erectile function depends on the neuronal pathways (non-adrenergic, noncholinergic neurons) and release of nitric oxide.^{27,28} PDE-5Is inhibit the breakdown of cyclic guanosine monophosphate, thereby allowing continued relaxation of

smooth muscle in the corpus cavernosum.²⁹ All three drugs in this class have similar pharmacokinetic and pharmacodynamic profiles, and each is effective for patients with ED of all ages, severities, and causes.

In patients with CKD, sildenafil has the longest patient experience and the most robust data confirming its activity, safety, and tolerability. The best results in the initial human trials were obtained with 100 mg of sildenafil; however, as many as 24% of men responded effectively on the 50-mg dose schedule. Also significant was the increase in frequency of intercourse, with those receiving sildenafil making on average 5.9 successful attempts per month compared with 1.5 in those receiving placebo.³⁰ Sildenafil studies in patients on dialysis show a good response rate (66.7%–80%). The majority of sildenafil responders had success with the 50-mg tablets.^{31,32} Sildenafil has been shown to be effective in patients with difficult-to-treat ED and the Sildenafil Diabetes Study Group³³ showed that 56% of men with ED and diabetes mellitus who received sildenafil (25–100 mg) treatment for 12 weeks reported improved erections, in contrast to 10% of patients receiving placebo ($P < .001$).

Sildenafil given to transplant recipients does not perturb plasma levels and has a 60% satisfactory response rate.³⁴ The most commonly reported side effects are headache (16%), flushing (10%), and dyspepsia (7%).³⁵ Hypotensive side effects occur particularly with concomitant nitrate administration. It is unclear how long the patient must wait until nitrates can be safely administered. Sildenafil decreases systolic and diastolic blood pressures by 10 and 7 mm Hg, respectively. Nitrate use leads to a synergistic increase in cyclic guanosine monophosphate levels, which can cause excessive hypotension and occasionally ischemic cardiac events or strokes.²⁸ Sildenafil can be safely administered in CKD if there is no serious cardiac disease. Sildenafil is primarily metabolized in the liver, but there is some renal excretion; lower doses are recommended initially (25 mg) in CKD patients.

In vitro studies have shown that the potency of vardenafil in inhibiting PDE-5 purified from the human corpus cavernosum tissue was approximately 25 times greater than that of sildenafil and 48 times greater than that of tadalafil.³⁶ In a study by Hellstrom and colleagues,³⁷ many patients returned to normal erectile function after treatment with vardenafil. For example, 89% of patients with mild ED at baseline return to normal function after treatment with 10 mg of vardenafil. Forty percent of patients with severe ED at baseline returned to normal function after treatment with 20 mg of vardenafil, compared with only 4% who received placebo. There is limited evidence that a small percentage of sildenafil nonresponders can be salvaged with vardenafil.³⁸ A starting dose of 5 mg of vardenafil should be used in men with severe renal impairment.³⁹

Recent double-blind, placebo-controlled, multicenter trials have assessed the efficacy and safety of tadalafil in the treatment of ED. Significant improvements from baseline in the International Index of Erectile Function erectile frequency domain score, successful penetration attempts, successful intercourse, and overall satisfaction compared with placebo have been reported with an on-demand schedule of the drug.^{40–42} Tadalafil has a terminal half-life of 17.5 hours, which is consistent with a broad window of clinical responsiveness.^{42,43} Tadalafil enhances erectile frequency in men with ED for as long as 36 hours. Thus, tadalafil may be associated with less planning or pressure to have sexual intercourse after

dosing. Unlike sildenafil and vardenafil, meal intake has no effect on the absorption of tadalafil.

The cytochrome P-450 system is the chief metabolic pathway for sildenafil, vardenafil, and tadalafil. All three agents are substrates for the cytochrome P-450 pathway P3A4, and concomitant administration of P3A4 inhibitors such as ritonavir, indinavir, ketoconazole, and erythromycin can increase plasma levels of the PDE-5Is.⁴⁴⁻⁴⁶ Because these drugs potentiate the vasodilator/hypotensive effects of nitric oxide, treatment with any PDE-5I is contraindicated in patients taking organic nitrates.⁴⁴⁻⁴⁶ According to United States prescribing information, coadministration of α -blockers with sildenafil, vardenafil, and tadalafil is listed as a precaution.⁴⁴⁻⁴⁶ None of the three agents are dangerously associated with prolongation of the corrected QT interval on the electrocardiogram.

The recent advent of vardenafil, which has the highest in vitro potency of all available PDE-5Is, and tadalafil, which has a prolonged half-life that may enable couples to have sexual activity with less planning, represent further advances. However, although there are clear pharmacokinetic differences among these agents, the data on preference trials, head-to-head clinical trials, and selection trials are few.⁴⁷

Intracavernosal Injection Therapy

Alprostadil (Caverject, Edex), an exogenous form of prostaglandin E₁, administered by intracavernosal injection is the only approved agent. Alprostadil causes smooth muscle relaxation, vasodilation, and inhibition of platelet aggregation. Approximately 96% of alprostadil is locally metabolized within 60 minutes. No change in peripheral blood levels occurs because of extensive pulmonary metabolism.⁴⁸ Linet and Neff⁴⁹ concluded that alprostadil produced full erections in 70% to 80% of patients. Side effects include pain (17%), hematoma or ecchymosis (1.5%), and priapism or prolonged erection (1.3%).

Other agents used alone or in combination with prostaglandin E₁ include papaverine and phentolamine mesylate (Regitine, CIBA Pharmaceuticals). Papaverine inhibits phosphodiesterase, leading to increases in cyclic adenosine monophosphate, elevated nitric oxide, and eventual relaxation of cavernosal smooth muscle and arterial dilation. Kapoor and colleagues⁵⁰ reported on the use of papaverine in men with spinal cord injuries, who obtained satisfactory erections capable of successful penetration in 98%. Papaverine, however, causes priapism and fibrosis in as many as 35% and 33% of men, respectively, with an increased incidence in young and neurogenic patients.⁵¹

Phentolamine mesylate is a competitive nonselective α -adrenergic receptor antagonist. It has been used in combination with papaverine to increase blood flow. Side effects include hypotension, reflex tachycardia, and nasal congestion.

These agents can be used successfully in CKD patients with vascular compromise, diabetic microangiopathy, moderate atherosclerosis, and partial arterial dysphasia, although higher doses may be necessary. Patients with venous occlusive disease may also benefit from increased engorgement of the corpora, leading to increased compression of the tunica albuginea and therefore occlusion of the emissary veins. It is interesting to note that patients with neurogenic and hormonal causes also do well with this therapy (as do older patients), without increased side effects. Long-term use of these injection therapies is effective, with few complications in transplant recipients.⁵² No major complications on transplanted kidneys have been noted. The only contraindications to therapy are sickle cell

anemia, severe psychiatric disorders, severe venous incompetence, and severe systemic disease.

Transurethral Suppositories

The transurethral delivery system, medicated urethral system for erection (MUSE), allows for delivery of alprostadil to the corpora by direct venous communication.⁵³ The mechanism of action of alprostadil has been discussed earlier. Success has been variable.

Erythropoietin, Anemia, and Erectile Dysfunction

The treatment of anemia with recombinant human erythropoietin in men with CKD improves sexual performance and elevates levels of follicle-stimulating hormone and testosterone.⁵⁴

Devices

Vacuum Constriction Devices and Constriction Bands

Vacuum constriction devices work by engorging the penis with blood by negative pressure. A constriction band is placed at the base of the penis for no longer than 30 minutes to avoid injury. These devices have local side effects such as pain from the constriction band, entrapment of ejaculation by the constriction band, cold and dusky penis, numbness of the penis, and local irritation. Many men use these devices, but they can be difficult for men with a short penis or an extensive suprapubic fat pad. In those who need pharmacologic manipulation for an adequate erection but who have evidence of venous incompetence, a constriction band alone may be used to sustain rigidity of the penis that is suitable for intercourse.

Surgical Treatment of Erectile Dysfunction

Vascular Procedures for Erectile Dysfunction

As most patients with renal failure have small-vessel disease, the use of revascularization techniques and venous occlusive surgery is not commonly employed. These judgments are best left to the urologist.

Penile Prostheses

Implantation of a penile prosthesis is safe and usually successful, with low morbidity. Renal transplant recipients commonly benefit from the device.⁵⁵ Such procedures should be performed after renal transplantation, if possible, because many men have improved sexual function, fertility, and potency after transplantation surgery. In immunocompromised patients, the risks of implanting an artificial device include prosthetic infection.⁵⁶ Cuellar and Sklar⁵⁷ examined their own cohort of 46 patients who had undergone pelvic organ transplantation before placement of a penile prosthesis. The risk of infection after insertion of penile prostheses in patients with a pelvic organ transplant was similar to that in nontransplant patients.

IMPROVEMENT IN ERECTILE DYSFUNCTION AFTER RENAL TRANSPLANTATION

After renal transplantation, patients report improved erectile function and libido. Testosterone levels return to normal

within 2 to 3 months, as do luteinizing hormone, follicle-stimulating hormone, and prolactin. Sperm counts normalize in 9 to 16 months. Patients who receive human chorionic gonadotropin stimulation show improved responses with higher testosterone levels. Salvatierra and colleagues⁵⁸ found pre-transplantation potency to be 22% while on dialysis; however, after renal transplantation, 84% of men resumed levels of potency comparable with those of a time before the onset of uremia. Posttransplantation psychological disturbances, except for anxiety, appear to diminish.

Although data are limited, studies evaluating commonly used immunosuppressive agents such as cyclosporine, azathioprine, tacrolimus, and prednisone suggest that these agents do not have significant effects on the sex hormone profiles of renal transplant patients.^{59–62} Sirolimus, a new immunosuppressive, has been found to lower total testosterone and increase luteinizing hormone and follicle-stimulating hormone in renal transplant recipients; however, this has not proven to result in a change in sexual function.⁶³

It is important to remember that a significant proportion of men after transplantation will continue to have ED despite normalization of hormone values and improved physiology.⁶⁴ Many of these patients suffer from vasculogenic ED. These patients should be evaluated in a way similar to that for pre-transplant recipients; treatment plans should be generated for their specific needs.

CONCLUSIONS

ED includes a vast array of organic, anatomic and psychosocial elements, which make evaluation and treatment complex. However, a practitioner who observes a good history, physical examination, and laboratory evaluation can provide a great service to the quality of life of his or her patient with CKD. The physician must address the topic and make the patient feel comfortable with his changing physiology and anatomy. Renal transplantation has the potential to normalize hormone profiles and subdue some of the physiologic changes, although it may not solve the problem in men because of associated comorbid conditions. Psychological, medical, and surgical therapies can be highly effective in correctly evaluated patients. A multidisciplinary approach to care should be employed that involves the primary care physician, a nephrologist, urologist, psychiatrist, and psychologist.

METHODS OF TREATING OF OBSTRUCTIVE SLEEP APNEA 793

Patients with chronic kidney disease (CKD) have a greater incidence of sleep-disordered breathing than the general population. Sleep-related disorders in this population can include insomnia,¹ nocturnal myoclonus, obstructive sleep apnea (OSA), and restless legs syndrome. A high prevalence of untreated sleep disorders results in diminished quality of life secondary to symptoms including but not limited to irritability, excessive snoring, daytime somnolence, and decreased concentration. Studies on the relationship between poor sleep quality and renal dysfunction have suggested a high correlation between the two, although the precise pathophysiologic relationship remains to be elucidated.²

We focus on OSA with special attention to (1) some of the available effective treatments, (2) benefits of treatment in improving quality-of-life issues associated with OSA, and (3) the association between OSA and common comorbid conditions in CKD, in particular, hypertension and cardiovascular disease.^{3,4} Unfortunately, identifying patients with CKD and OSA may be made more difficult due to the overlap in symptoms between OSA and uremia. However, recognition of these symptoms and their underlying cause can afford patients the benefit of symptom-improving treatment. It can also have beneficial therapeutic implications related to other comorbidities.

SLEEP APNEA

Sleep apnea may be separated into central sleep apnea and OSA, although overlap between the two often exists. The severity of the OSA syndrome is defined by the number of apneic or hypopneic episodes per hour during sleep as well as the presence of symptoms. Apnea is defined as more than 10 seconds without airflow plus associated desaturation or arousal from sleep. Hypopnea is defined by a more than 50% reduction in airflow over the same period of time. The presence and severity

of OSA may be partly defined by the apnea-hypopnea index (AHI) or by the number of apneic or hypopneic episodes per hour of sleep. When the AHI is greater than 15, patients are considered to have moderate to severe sleep apnea. However, even when the AHI is 15 or more and there is associated daytime sleepiness, OSA can be pathologic. The AHI may point toward a diagnosis of sleep apnea but not whether the cause is primarily central or due to obstruction to air flow.

PREVALENCE AND DIAGNOSIS OF OBSTRUCTIVE SLEEP APNEA

It is estimated that as many as one in four Americans may be at risk of OSA.⁵ In CKD patients, the prevalence ranges from 16.4%⁶ to 66%.⁷ However, most reports have concentrated on patients treated by hemodialysis so the prevalence may be less in CKD patients who are not being treated with dialysis. A recent study of dialysis-independent patients concluded that patients with more severe renal dysfunction had higher AHI values.⁸ Other studies have suggested that the quality of sleep as assessed by a survey is most diminished in the early stages of renal dysfunction and that there is no correlation with the severity of renal dysfunction.² There does appear to be a strong association between OSA and CKD, even based on the lowest estimate of the prevalence of OSA. Given the association and the potential for effective treatment, OSA evaluation of patients with renal dysfunction is warranted. This may be achieved by asking questions about sleep habits (snoring or apneas noted by the patient or the patient's bed partner), the quality of sleep (is the patient refreshed after a night's sleep), and daytime symptoms (daytime somnolence, irritability, decreased concentration, frequent falling asleep during performance of activities). Another means of identifying CKD patients who may have concomitant OSA is by observation during dialysis. Witnessed episodes of snoring or apnea/hypopnea or frequent

or prompt falling asleep during dialysis should raise suspicions about undiagnosed OSA.

In patients who have signs suggestive of OSA, the initial screening may be achieved via overnight pulse oximetry to record the magnitude and number of periods of oxygen desaturation. Obstructive patterns with nocturnal desaturation are usually associated with sawtooth patterns in the oxygen saturation tracing. However, the actual diagnosis of OSA is best achieved via polysomnography, during which oxygen saturation, heart rate (electrocardiogram), and sleep stages by an electroencephalogram in addition to limb movements, changes in body position, airflow, and respiratory effort are monitored. Use of polysomnography helps to determine, first, the presence of sleep apnea, second, whether it is of central or obstructive origin, and, third, the type and efficacy of treatment.

PATHOPHYSIOLOGY

Patients with CKD and OSA do not necessarily follow the typical profile of OSA. For example, end-stage renal disease patients with OSA are not consistently obese.^{7,9} This finding suggests that there may be other mechanisms at play in the evolution of OSA.^{10,11} In addition to obesity, sleep apnea and other sleep disturbances may result from a combination of uremia, metabolic derangements, hematologic abnormalities, neuropathies, and fluid imbalances.

Uremia

Uremia may cause symptoms similar to those of sleep apnea, including somnolence, decreased ability to concentrate, and confusion. Uremia may also affect the central respiratory drive as well as airway muscle tone.^{10,12,13} A possible role for uremia in OSA is supported by one recent study that suggests that the AHI score correlates with the urea concentration in diabetic and nondiabetic CKD patients who are not by treated by dialysis.⁸

Metabolic Derangements

CKD is associated with the development of chronic metabolic acidosis. Metabolic acidosis can affect the chemoreflex drive, which in turn affects respiratory drive. For this reason, chronic metabolic acidosis can lead to a decreased apneic threshold resulting in worsening frequency or number of apneic episodes.

Hematologic Abnormalities

In CKD and end-stage renal disease patients with anemia, full correction of the anemia with erythropoietin is associated with improvement in arousals from sleep, sleep fragmentation, and daytime alertness.¹⁴ This suggests that treatment of the underlying anemia may improve quality of life secondary to sleep disturbances in these patients.

Neuropathies

Neuropathies can occur in CKD secondary to the underlying cause of the renal failure (e.g., diabetes) or to metabolic derangements. Neuropathy can affect the normal neurologic input to the respiratory system, resulting in periodic breathing via effects on the respiratory drive.

Volume Overload

Volume overload may lead to edema of the upper airway, which can contribute to a mechanical obstruction of normal airflow. Reduction in the radius of the airway would result in exponentially increasing resistance to airflow. This resistance, in combination with other risk factors, can cause worsening or more frequent apnea or hypopnea. The role for fluid overload in OSA is supported by evidence that dialysis can help reduce apnea severity.

TREATMENT OF CHRONIC KIDNEY DISEASE: EFFECTS ON OBSTRUCTIVE SLEEP APNEA

Treatment of CKD may possibly alternate sleep apnea and thus may result in an improvement of quality of life. Case reports and results from formal studies suggest that effective dialysis¹² or kidney transplantation¹⁵ can improve sleep apnea. For example, Hanly and Pierratos⁹ suggest that nocturnal hemodialysis may attenuate sleep apnea. They studied 14 patients and 57% (8 of 14 patients) had OSA. Patients began an intensive program of daily nocturnal hemodialysis, and there was a significant reduction in their apnea/hypopnea index from 46 ± 19 /hr to 9 ± 9 /hr. In contrast, an earlier small study of 11 long-term hemodialysis patients did not show any reduction in sleep apnea with standard daytime hemodialysis.⁶ There was no difference in their apneic episodes on the nights after dialysis compared with the nights during the interval between dialysis treatments. Sabbatini and colleagues¹ examined a series of 694 surveyed hemodialysis patients and concluded that the prevalence of insomnia was still very high, but the incidence of OSA was not determined. Tang and colleagues¹⁶ also suggest that nocturnal peritoneal dialysis may have a therapeutic edge over continuous ambulatory peritoneal dialysis in treating sleep apnea based on their study of 46 stable patients with documented sleep apnea using the overnight polysomnography method. The prevalence of sleep apnea was reported to be 4.2% during the treatment with nocturnal peritoneal dialysis but 33.3% when patients were treated with continuous dialysis. The change in AHI was substantial: AHI was 3.4 during nocturnal dialysis and 14.0 during continuous dialysis.

These studies suggest there can be potential benefit for CKD patients with sleep apnea, but it should be recognized that there is a higher prevalence of sleep apnea among hemodialysis patients compared with the general population. Specifically, nocturnal dialysis appears to have a benefit over conventional dialysis. It is possible that any improvement in sleep apnea may be related to improved control of uremia, but the mechanism has not been defined.¹⁷ In future studies, it would be important to relate the degree of improvement in metabolic, uremic, and volume parameters to changes in sleep apnea indices to clarify how treatment of uremia might improve sleep apnea.

TREATMENT OF OBSTRUCTIVE SLEEP APNEA: EFFECTS ON RENAL FUNCTION

Although the evidence suggests that OSA may improve after successful treatment of uremia, it is unclear whether treatment of OSA will improve renal function. OSA is a known risk factor for hypertension^{18,19} by mechanisms that include increasing

pressor and sympathetic activation responses to repetitive nocturnal hypoxemic episodes.²⁰ In this case, treatment of OSA could improve OSA-mediated pressor stress and the increased filtration that causes maladaptive architectural changes and proteinuria and kidney damage. Some reports suggest that proteinuria is associated with sleep apnea.^{21–23} Other studies with a small number of patients indicated that proteinuria disappeared with treatment of OSA.²⁴ Kinebuchi and colleagues²⁵ suggest that continuous positive airway pressure (CPAP) can ameliorate glomerular hyperfiltration in sleep apnea patients. More recent reports, however, suggest that clinically significant proteinuria cannot be directly attributed to OSA alone.^{26,27} Further studies are necessary to elucidate any potential etiological role in the association of sleep apnea and a decrease in renal function.

METHODS OF TREATING OBSTRUCTIVE SLEEP APNEA

Treatment of OSA can improve the quality of life for CKD patients. The mainstay of treatment for OSA is to use CPAP when patients are sleeping.²⁸ However, there are other treatment options for patients who cannot tolerate CPAP.²⁹ Methods to improve sleep apnea include weight loss, position changes in bed, (e.g., lying on one's back can worsen obstructive physiology), and avoiding alcohol. In some patients with OSA, mandibular devices, such as the anterior mandibular positioner, may be useful to prevent posterior displacement of the tongue during sleep and thereby alleviate obstruction of the airway. These devices are sometimes uncomfortable and generally are effective in patients with only mild to moderate airway obstruction. Patients with OSA associated with CKD appear to have a combination of central and obstructive components, making these devices less useful. They are not as effective as nasal CPAP in comparison studies.³⁰ The benefits of anterior mandibular positioner treatment is that it is sometimes more tolerable than CPAP and is more portable.

In patients with obesity, weight loss may require surgical intervention and gastric bypass. Gastric bypass is not a benign procedure, and for CKD patients, in whom obesity does not appear to have as common an association with OSA, this option may be useful for only a subset of patients. One report, however, concluded that gastric bypass in obese CKD patients may lead to a decrease in comorbid conditions.³¹

In patients with OSA secondary to craniofacial abnormalities, ear, nose, and throat procedures may prove beneficial; again, these procedures will not relieve the central nervous system causes of sleep apnea. The most widely used surgery is uvulopalatopharyngoplasty, but it is not very effective in decreasing the AHI over the long term, even in patients with pure OSA.³² Other ear, nose, and throat procedures include genioid advancement with hyoid resuspension, maxillo-mandibular advancement, tongue suspension via the repose system, or base-of-tongue somnoplasty. It is difficult to assess which patients will benefit from these invasive procedures; they probably should be reserved for patients in whom less-invasive treatments fail.³²

CPAP works by directly applying Poiseuille's law to maintain an open airway via positive pressure; the pressure prevents collapse or obstruction during inspiration. In patients who can tolerate CPAP, it is highly effective, but many patients

will have difficulty sleeping with a mask on their face or with the noise of the machine. Some patients may also experience claustrophobia or suffocation from the mask, drying of their mucosa, or nasal congestion. As a result, CPAP may be useful for only a subset of CKD patients. Before giving up, a smaller mask that covers only the nose should be tried because it relieves some of the complaints of claustrophobia and mucosal drying. Another option is an Adams Circuit, which uses a prong in each nostril with applied positive pressure (these options may not be as effective for mouth breathers). Typically, CPAP settings are titrated to each patient's needs based on symptoms and polysomnographic findings. There are machines capable of autotitrating CPAP to adapt settings over the course of the night automatically.

A last resort for treatment of OSA consists of tracheostomy. This is considered definitive treatment but should be used only in patients with OSA that is refractory to CPAP and who have significant complications, such as cardiac arrhythmias. It is used as a last resort.

The benefits of other treatment modalities, such as nocturnal hemodialysis, are still controversial but can be tried. Likewise, vigorous treatment of uremia should always be tried. Future studies of the effects of hemodialysis on sleep apnea should be directed at understanding the pathophysiology of the disorder. This is the first step for designing effective treatment strategies.

INITIAL NEUROPSYCHIATRIC ALGORITHM	814

Neuropsychiatric disorders are common in patients with end stage renal disease (ESRD). They include “hardware” disorders that are primarily neurological in their presentation and “software” disorders that would more often be in the clinical province of the psychiatrist. This chapter is intended to help the treating nephrologist recognize, classify, and initiate treatment for commonly encountered, ESRD-associated neuropsychiatric issues. The following are several essential clinical points that should be kept in mind while reading the chapter.

1. A large array of pathologic processes associated with chronic kidney disease (CKD) can cause neuropsychiatric disorders in ESRD patients. In addition, many commonly used nonpsychiatric medications are psychoactive and can produce iatrogenic complications. When confronted by mental status changes, look to the disease itself and to the unintended side effects of its treatment.
2. Treatment of neuropsychiatric disorders in ESRD patients favors a selected subset of the psychotropic agents used in non-ESRD patients, with dosing and titration adjusted for the altered pharmacokinetics of renal failure. The ESRD population is elderly, has multiple comorbidities, has often lost protein stores, and is prone to marked fluid and electrolyte shifts. These problems often translate into lower starting points and slower titration toward standard, non-ESRD target doses.
3. Drug absorption may be impaired by gastric fluid alkalization.
4. Volume of drug distribution may be increased by edema and ascites, necessitating larger initial doses of some hydrophilic medications. Conversely, dehydration and muscle wasting may decrease the apparent volume of distribution, with the opposite effect on dosage requirements.

5. Most psychotropic medications are preferentially protein-bound. In the protein-deficient/uremic ESRD state, the free fraction of drug is often increased, boosting both therapeutic and toxic effects.
6. Nevertheless, standard psychotropic drugs can in general be used safely in ESRD patients. Most are lipophilic and easily penetrate the blood-brain barrier. Most are not removed by dialysis and are dependent on hepatic metabolism and enterohepatic elimination.
7. Research data to support clinical conventions in the employment of psychotropic drugs is far from solid, and future double-blind psychopharmacologic trials are sorely needed to assess pharmacologic measures in CKD patients.
8. Pharmacotherapy is not a substitute for skilled individual and family psychotherapy. Most counseling is provided by renal social workers, and their availability is a legally mandated requirement for dialysis programs. It is also advisable to have backup by consulting psychiatrists and a good working relationship with local hospital-based mental health units.

Figure 73-1 is a general clinical algorithm to direct treatment of common neuropsychiatric issues in the ESRD patient. Box 73-1 describes common neuropsychiatric syndrome etiologies. Table 73-1 describes commonly used neuropsychiatric drugs. Finally, several timely and helpful references are recommended to the interested nephrologist.

PRIMARY NEUROLOGICAL PROBLEMS AND THEIR MANAGEMENT

Patients with CKD frequently suffer from neurological symptoms. For elderly dialysis patients, central nervous system disorders rank prominently as a cause of hospitalization.¹ Chances of

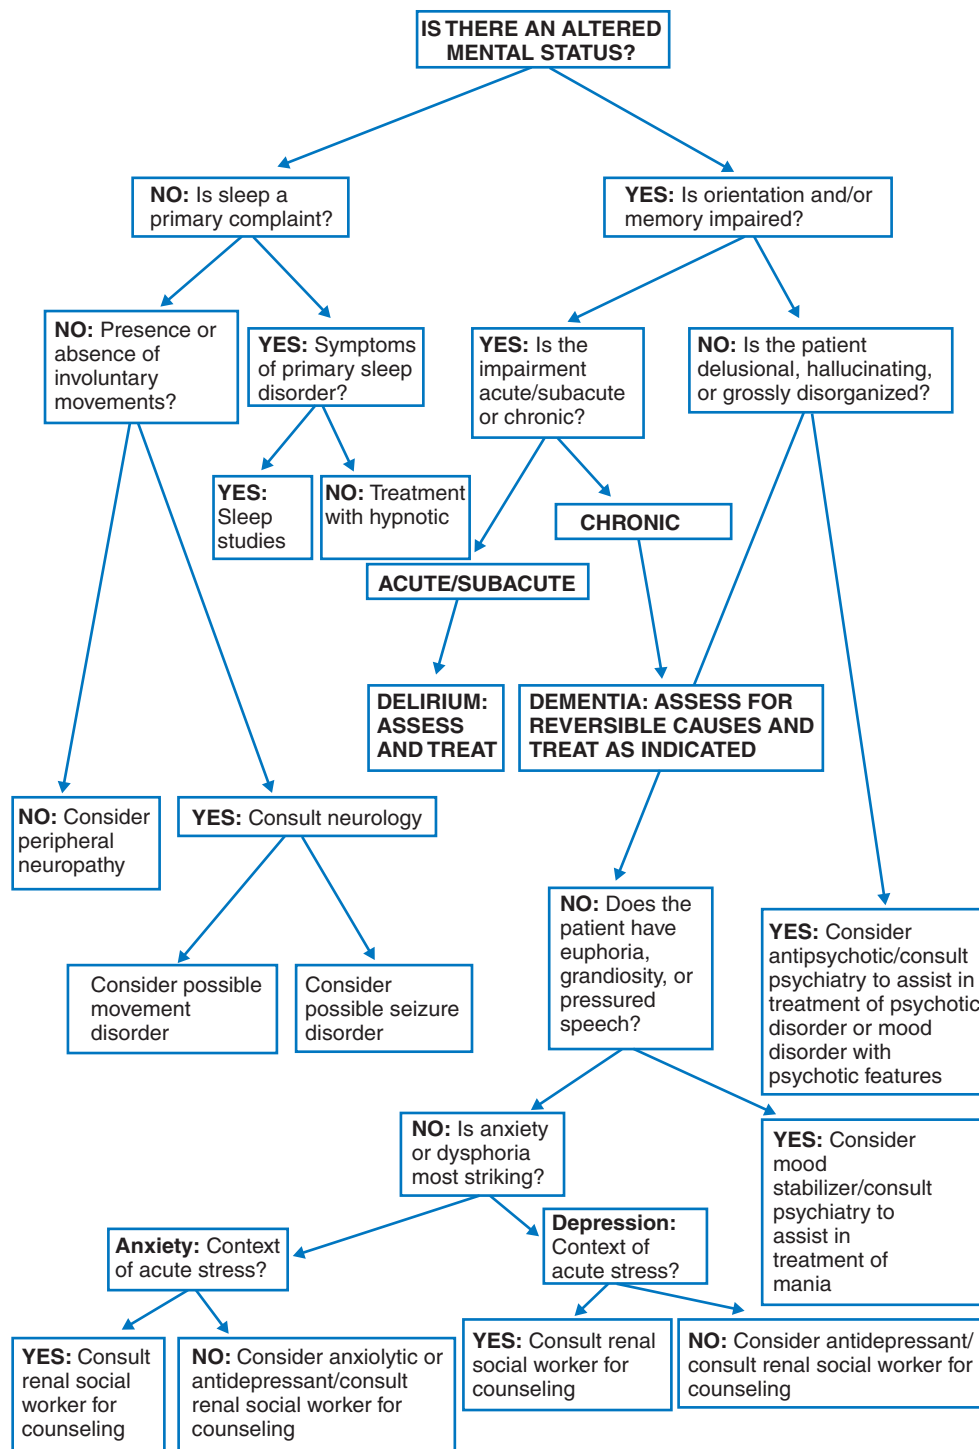

Figure 73-1 Algorithm to direct treatment of common neuropsychiatric issues in the patient with end-stage renal disease.

neurological problems increase parallel to the decline in renal function, classically appearing late in its course.^{2,3} Causative factors include medication side effects, primary effects of the uremia itself, iatrogenic dialysis and transplantation pharmacotherapy effects, other comorbid conditions, and electrolyte disturbances. There is a multiplicity of chemical species on the list of possible uremic toxins, including homocysteine, β_2 -microglobulin, glycosylated end products of metabolism, carbamylated proteins, myo-inositol, so-called middle molecules, indoles, phenols, parathyroid hormone, transketolase products, electrolytes, trace minerals, and water.³ Subtle deficits in cogni-

tive function on neuropsychological testing can be found in CKD patients with moderate renal impairment and in adequately dialyzed patients as well as in uremic patients. As renal failure supervenes, delirium becomes apparent with confusion, lethargy, and progression to coma.⁴ Seizures can occur in severe neuropathic states. If the alteration in mental status is solely due to uremia, encephalopathy may respond to dialysis. Paradoxically, dialysis itself, particularly in the first session or in patients with predisposing vulnerabilities of age, metabolism, or comorbid central nervous system disease can result in a disequilibrium syndrome that may progress to coma or status epilepticus.³

Box 73-1 Etiology of Neuropsychiatric Syndromes in Chronic Renal Disease

1. Common drugs leading to neuropsychiatric effects
 - a. Psychotropic drugs
 - b. Narcotics
 - c. Illicit drugs
 - d. Metoclopramide
 - e. Antiseizure medications
 - f. Cardiac medications, such as digoxin and amiodarone
 - g. Transplant medications: calcineurin inhibitors, rapamycin, prednisone
2. Uremia
 - a. Inadequate dialysis
 - b. Glomerular filtration rate <12
3. Dialysis related
 - a. Disequilibrium syndrome
 - b. Dialysis dementia
4. Metabolic disturbance
 - a. Hypoxemia
 - b. Hypo- and hyperglycemia
 - c. Sepsis
 - d. Malignant hypertension
5. Structural neurological lesions
 - a. Subdural hematoma
 - b. Multi-infarct dementia
 - c. Cerebral vascular accident
6. Electrolyte disturbances
 - a. Hyper- and hypocalcemia
 - b. Hypophosphatemia
 - c. Hypermagnesemia
 - d. Hyper- and hyponatremia
7. Anemia
8. Hyperparathyroidism
9. Heavy metal intoxications
 - a. Lead
 - b. Aluminum (dialysis dementia)
 - c. Mercury
 - d. Cadmium
10. Vitamin and mineral deficiencies
 - a. Carnitine
 - b. Zinc
11. Miscellaneous
 - a. Hyper- and hypothyroidism
 - b. Normal pressure hydrocephalus
 - c. Sleep apnea
 - d. Central pontine myelinolysis

Peripheral Neuropathies

The peripheral nervous system is vulnerable to uremia, with 65% prevalence of peripheral neuropathy in ESRD patients beginning dialysis; cranial neuropathies, including uremic amaurosis, have been described, and autonomic neuropathies are common.^{3,5,6} Large nerve fibers are most frequently involved, with attendant impaired nerve conduction and dysautonomia, and patients may present with sensory or motor peripheral neuropathy as prominent aspects of their subjective illness burden. There is evidence that sensory neurons are in a state of axonal depolarization in predialytic CKD patients, with an increase in refractoriness of the affected nerves correlating with hyperkalemia.⁶ In addition, the arteriovenous fistula used for hemodialysis may cause focal neuropathy as the result of a “steal syndrome.” Carpal tunnel syndrome may be caused by the accumulation of β_2 -microglobulin with resultant amyloidosis. Treatment options range from the prophylactic to the symptomatic. Dialysis itself leads to improvement in peripheral nerve excitability, with normalization of resting membrane potential after treatment.⁷ Fistula-related neuropathy can be addressed by banding or tying off the offending vessel, whereas carpal tunnel syndrome may be helped by more intense dialysis with large surface area dialyzers to promote β_2 -microglobulin clearance, by daily hemodialysis, wrist splints, or surgery.³ Postural hypotension is addressed with compression stockings and/or midodrine, whereas sertraline, 50 mg predialysis, may prevent intradialytic hypotension. Metoclopramide can be prescribed as symptomatic treatment for gastroparesis

and other neuropathic bowel motility disorders. Antidepressants and anticonvulsants are commonly used to treat polyneuropathic discomfort. Low-dose tricyclics can be effective, but the prescriber must be concerned about potential cardiac effects, given the common pairing of cardiac disease and CKD. In addition, tricyclics can promote confusion, worsen constipation, and lower the seizure threshold. It is worth knowing that desipramine and protriptyline substantially depend on renal elimination and can accumulate in patients with CKD or ESRD and that these drugs are not dialyzable. Of the commonly used anticonvulsants, gabapentin is renally excreted in unchanged form, and its dose must be decreased in tandem with a decrease in creatinine clearance. Posthemodialysis doses are also necessary with gabapentin. Carbamazepine and free valproic acid are subject to variable pharmacokinetics in renal failure, necessitating close monitoring of levels. Duloxetine is coming into wider use for diabetic neuropathy, but is contraindicated in renal failure because it is eliminated by the kidney.

Seizures

Seizures, including generalized tonic-clonic, partial motor, partial complex, and absence episodes are common in patients with CKD, particularly among those requiring dialysis (among whom the incidence has been estimated at 2%–10%), and nonconvulsive status epilepticus may be unrecognized.^{8–10} Seizures may be predialytic as a result of uremia or be intra- or postdialytic in context of changes in hemodynamics and abrupt shifts in electrolytes.¹¹ Blood

Table 73-1 Neuropsychiatric Drugs with Comments on Likely Effects for Patients with Renal Failure

Drugs	Active Metabolites	Neurologic/ Psychiatric Adverse Reaction	Typical Adult Dose	t _{1/2}	Adult Dose in ESRD	t _{1/2} in ESRD	Removed by Dialysis?	Comment	Ref.
Anidepressants (SSRIs)									
Escitalopram (Lexapro)	(S+)-Desmethylcitalopram (SDMC) (S+)-Didesmethylcitalopram	Insomnia Somnolence	10–20 mg/day	22–32 hr SDMC: 59 hrs	10 mg/day (20 w/ caution)	Likely simi- lar to normal renal function	H: no	ESRD likely has minimal impact on escitalopram (similar to cital- opram)	89,90
Citalopram (Celexa)	Desmethylcitalopram Didesmethylcitalopram Citalopram-N-oxide	Anxiety Agitation Hallucinations Somnolence	20–60 mg/day	33–37 hr	10–40 mg/day	43–49 hr	H: no	ESRD has minimal impact on cital- opram kinetics	27,89
Fluoxetine (Prozac, Sarafem)	Norfluoxetine: NF	Anxiety Agitation Asthenia Insomnia Somnolence	20 mg/day	1–4 days NF 7–15 days	20 mg/day	1.8 days	H: no	No significant dif- ferences in fluoxetine and NF levels in renal failure	22,28,91
Fluvoxamine (Luvox)	No active metabolites	Anxiety Agitation Asthenia Insomnia Somnolence	50–300 mg/day	15–22 hr	50–300 mg/day	Similar to normal renal function	H: no to modest (levels decreased by 22%)	No significant dif- ferences in re- nal failure; manufacturer recommends lower initial doses	Case re- port of venous throm- bosis 28,29,92
Paroxetine (Paxil)	No active metabolites	Anxiety Agitation Asthenia Insomnia Somnolence	20–60 mg/day	17.3–25.1 hr	10–30 mg/day	10.9–54.8 hr	H: unknown	Increased AUC for paroxetine in ESRD (β related to metabolite that is inhibitor of CYP2D6); Re- duced dose rec- ommended; 10 mg effective in ESRD ¹⁰⁴	28,30,93

Sertraline (Zoloft)	Desmethylsertraline	Anxiety Agitation Insomnia Somnolence	50–200 mg/day	24 hr	50–200 mg/day	42–96 hr	Hi: minimal	Minimal changes in kinetics in ESRD. Conflicting data on benefit in hemodialysis-related hypotension	31,32,94–97
Antidepressants (Tricyclic)									
Amitriptyline (Elavil)	Nortriptyline Hydroxyamitriptyline Hydroxynortriptyline	Sleep disturbance Confusion Delirium Hallucinations Paranoia Forgetfulness Asthenia	25 mg q8h (10–25 mg/hs for neuropathic pain)	32–40 hr	25 mg q8–12h	Active metabolites likely prolonged	Hi: no CAPD: no	Elevated conjugated metabolites observed in renal failure; probably no difference in dosing. Use of therapeutic drug monitoring (TDM) with level of 75–175 ng/mL may guide therapy if used for depression	28,98,99,102
Clomipramine (Anafranil)	Desmethylopramine (DMC)		25–250 mg/day	19–37 hr DMC 54–77 hr	No data	No data		Few data in ESRD	28
Desipramine (Norpramin)	2-Hydroxydesipramine (2OHD)	Sleep disturbance Confusion Delirium Depression Forgetfulness Hallucinations Paranoia	100–200 mg/day	12–54 hr 2OHD: 22 hr	75–125 mg/day	Active metabolites likely prolonged	Hi: no CAPD: no	Effective in small trial for depression. Use of TDM with level of 100–160 ng/mL may guide therapy if used for depression. Unconjugated amine and OH metabolites not removed by dialysis	28,99,100

Drugs	Active Metabolites	Neurologic/ Psychiatric Adverse Reaction	Typical Adult Dose	t _{1/2}	Adult Dose in ESRD	t _{1/2} in ESRD	Removed by Dialysis?	Comment	Ref.
Doxepin (Sinequan)	Desmethyldoxepine (DMD)	Dizziness Somnolence	25 mg q8h	8–25 hr DMD: 30–80 hr	25 mg q8h	10–30 hr	H: no CAPD: no	Few data in ESRD	28
Imipramine (Tofranil)	Desipramine	Sleep distur- bance Confusion Delirium Hallucinations Paranoia Forgetfulness	25 mg q8h	6–20 hr See Desipra- mine	25 mg q8h	See Desip- ramine	H: no CAPD: no	See Desipramine TDM with levels ≥200 ng/mL may guide ther- apy if used for depression	28,99
Nortriptyline (Aventil, Pamelor)	10-Hydroxynortriptyline E 10-hydroxynortriptyline Z 10-hydroxynortriptyline	Asthenia Somnolence	25 mg q6–8h	18–93 hr	25 mg q6–8h	15–66 hr Active me- tabolites likely	H: no CAPD: no	Use of TDM with level of 50–150 ng/mL may guide therapy if used for depres- sion	28,33, 98, 99, 101, 102, 113
Antidepressants (Other)									
Bupropion (Wellbutrin, Zyban)	Hydroxybupropion (HB) Threobupropion (TB)	Hallucinations Insomnia Agitation Headache Seizures	100 mg q8h	10–21 hr	Limited data; use only with caution. ? Reduce to 1/3 of usual dose. SR may be less epi- lepto- genic	HB: ele- vated TB: ele- vated	H: minimal	Risk of seizures with elevated levels of bupro- pion or metabo- lites. Use of TDM of bupro- pion (level 10–50 µg/L), HB (<1200 µg/L), and TB < 400 µg/L may guide therapy to avoid toxicity	28, 114

Duloxetine (Cymbalta)	4-Hydroxy-D-glucuronide (4OHD) 5-Hydroxy-D-sulfate (5OHD) 6-Hydroxy-D-sulfate (6OHD) (See comments)	Dizziness Insomnia Somnolence Suicidal ideation	20–60 mg/day (often in divided dose)	12 hr	Not recommended	AUC: Duloxetine: ↑ 100% 4OHD: ↑ 700%– 900% 5OHD: ↑ 700%– 900% 6OHD: ↑ 700%– 900%	Pharmacologic activity of metabolites may be minimal	105, 106
Maprotiline (Ludomil)	Desmethylmaprotiline Maprotiline-N-oxide	Asthenia Headache Somnolence	75–150 mg/day	48–51 hr	37.5–100 mg/day	Minimal data	May have more cardiovascular risk in ESRD. Elevated seizure risk of concern	107, 108
Mirtazapine (Remeron)	Demethylmirtazapine (DMM)	Somnolence Dizziness Asthenia	15–45 mg/day	20–40 hr DMM 25 hr	7.5–22.5 mg/day	Clearance reduced by 50% in ESRD	No clear role for TDM	34
Trazodone (Desyrel)	Metachlorophenylpiperazine	Hypomania Dizziness Confusion Somnolence Headache Priapism	150–400 mg/day (50 mg in PM for insomnia)	4–11 hr	Few data	No data	Predialysis levels of 50 mg/mL; post-dialysis level 29–40 ng/mL. No clear role for TDM. Parkinsonism: case report	36, 109, 110
Venlafaxine (Effexor)	O-Desmethylvenlafaxine (ODV)	Asthenia Disturbed sleep Dizziness	37.5–225 mg/day XR	4 hr ODV 4 hr	37.5–112.5 mg/day XR	6–11 hr ODV 9 hr	No clear role for TDM. Half usual dose in dialysis patient; withhold until post-dialysis	37

Drugs	Active Metabolites	Neurologic/ Psychiatric Adverse Reaction	Typical Adult Dose	t _{1/2}	Adult Dose in ESRD	t _{1/2} in ESRD	Removed by Dialysis?	Comment	Ref.
Antimanic Agents									
Lithium (Eskalith, Lithobid, Lithonate)	None	Multiple	900–1200 mg/day	14–28 hr	200–600 mg/day	40 hr	H: considerable CAPD: variable reports	Single dose after dialysis. Titrate dose to level/response 25%–50% standard dose in ESRD	38,111
Lamotrigine (Lamictil)	Inactive metabolites	Dizziness Headache Ataxia	Dose dependent on indications/concurrent interacting drugs	13–30 hr	Conflicting reports. Reduced dose recommended by manufacturer	43–58 hr	H: moderate		145,146
Valproic acid/divalproex (Depakene, Depakote)	Unclear whether active metabolites	Somnolence Dizziness Headache	15–60 mg/kg/day	6–17 hr	15–60 mg/kg/day		H: modest	‡ Increased risk of pancreatitis with ESRD. Increased free levels in ESRD. Use free VPA levels with TDM	39,112
Antipsychotics (Typical)									
Chlorpromazine (Thorazine)	Chlorpromazine-N-oxide CPA sulfate 7-OH-CPZ Nor-1-CPZ Nor-2-CPZ Nor-2-CPZ sulf 3-OH-CPZ	EPs Somnolence Dizziness	50–400 mg/day	11–42 hr	Few data. No longer in common use	Few data	H: no	Accumulation in ESRD in case report. No longer in common use among psychiatrists	40,110, 113, 114
Haloperidol (Haldol)	Hydroxyhaloperidol plus other metabolites (activity not clear)	Dizziness EPs ↑QT interval	1–2 mg q8–12h	14–26 hr	1–2 mg q8–12h	Similar	H: no	<1% excreted in urine	41,115

Antipsychotics (Atypical)

Drug (Brand)	Chemical Name	Headache Insomnia Somnolence	10–15 mg	75–146 hr DHA: 94 hr	10–15 mg	Unknown	H: unknown	Few data	117
Aripiprazole (Abilify)	Dehydroaripiprazole (DHA)		10–15 mg	75–146 hr DHA: 94 hr	10–15 mg	Unknown	H: unknown	Few data	117
Clozapine (Clozaril)	N-Desmethyloclozapine (NDC)	Dizziness Somnolence Vertigo Delirium and psychosis on withdrawal	12.5–450 mg slowly titrated. Monitoring ANC weekly per manufacturer's guidelines	8–12 hr NDC 13.2 hr	Titrate to response and use TDM	Large interindividual variation	H: probably minimal	Best left to psychiatrists TDM may assist dosing in unclear circumstances. Avoid levels > 400 µg/L. Risks are multiple, including seizures, agranulocytosis, thromboembolic events, cardiac myopathy	42,116
Olanzapine (Zyprexa)	N-Desmethyloclozapine Olanzapine-10-N-glucuronide (activity may be minimal)	Somnolence Dizziness Abnormal gait	5–20 mg/day	32–38 hr	5–20 mg	32–38 hr	H: no CAPD: no	Dose adjustment not necessary in renal failure per manufacturer	43
Quetiapine (Seroquel)	7-Hydroxyquetiapine N-Dealkylated quetiapine	Dizziness Somnolence	50–800 mg/day in divided dose	6 hr	50–800 mg/day in divided dose			Dose adjustment not necessary in renal failure per manufacturer	118
Risperidone (Risperdal)	9-Hydroxyrisperidone (9ROH)	EPSs Dizziness Somnolence	1–3 mg bid	3–30 hr 9ROH 19 hr	0.5–1.5 mg bid	9ROH: 25 hr	H: no CAPD: no	Wide variation in clearance noted between poor and extensive metabolizers. Clearance of sum of risperidone and 9ROH are reduced by 60% in renal failure	44, 119

AUC, area under the curve; CAPD, continuous ambulatory peritoneal dialysis; CPZ, chlorpromazine; CrCl, creatinine clearance; CVWH, continuous venovenous hemofiltration; EPs, extrapyramidal symptoms; ESRD, end-stage renal disease; hs, at bedtime; MRx1, may repeat once; SSRI, selective serotonin reuptake inhibitor; VPA, valproic acid; XR, extended release.

pressure fluctuations; derangement of calcium, magnesium, sodium, and glucose; intradialytic air emboli fever; hypoxia; and occult alcohol or sedative withdrawal may all participate in precipitating seizures.¹⁰ Seizures may be induced by toxic accumulations of drugs (e.g., penicillins, cephalosporins, amantadine, intravenous contrast agents, acyclovir) or their metabolites (e.g., normeperidine). Lacerda and colleagues⁹ have reviewed the clinical literature describing convulsive and nonconvulsive status epilepticus in renal failure patients on β -lactam penicillins, cephalosporins, quinolone antibiotics, and carbapenems. Even intended drug effects can have epileptiform consequences, for example, a rapid increase in hematocrit with epoetin alfa. Seizure treatment and prophylaxis are made more difficult by altered anticonvulsant pharmacokinetics. Drug levels can be decreased by dialysis, whereas interdialytic accumulation of unexcreted waste products and hypoalbuminemia can lead to unintended accumulation of anticonvulsants, including valproic acid, gabapentin, vigabatrin, levetiracetam, topiramate, and phenytoin.⁹ The risk of metabolic and hemodynamically related seizures with the first dialysis treatment can be decreased by a gradual decrease in blood urea nitrogen by low blood flows (200 mL/min) and by short dialysis (2–3 hours), a small surface area dialyzer, and lower dialysate flow rates. Dialysis disequilibrium with its attendant seizure risk can be prevented by phenytoin prophylaxis early in dialysis by administering intravenous mannitol (12.5 g of 25% solution) midway through sessions and by careful infusion of hypertonic saline if symptoms emerge.³ The theoretical effects of idiogenic osmoles on intracranial pressure can be countered by gradually adjusting the dialysate sodium concentration from hypernatremic early in the session to normal levels as the session finishes. Hypertension should be controlled, and epoetin doses should initially be low to prevent a rapid increase in hematocrit (see Chapters 60 and 67).

Management of intradialytic seizures should be standardized; dialysis must be halted and the airway secured, intravenous glucose is given as indicated, and then a series of anticonvulsant medications is used if the seizure has not promptly resolved. Intravenous lorazepam 4 mg over 2 minutes is a first step in ending seizure activity; a repeat dose can be given after 10 to 15 minutes if required. Phenytoin is then loaded via a large-bore intravenous catheter, at no more than 50 mg/minute to avoid hypotension; then a total dose should be 10 mg/kg rather than the standard 18 mg/kg loading dose for adults with intact kidney function. Once the seizure has ended, maintenance anticonvulsants may not be necessary, particularly if the seizure is thought to have been triggered by uremia or the dialysis procedure. Abou Khaled and Hirsch¹⁰ have published a generic, polydrug treatment protocol for status epilepticus in the critically ill patient, along with remarks particularly relevant to seizure management in renal failure. Where feasible, free serum levels of anticonvulsants should be monitored in patients with epilepsy. On maintenance anticonvulsant treatment with phenytoin, free serum levels of 1.0 to 2.5 mg/L should be maintained. Consideration should be given to using lower doses of renally eliminated anticonvulsants (specifically topiramate), whereas carbonic anhydrase inhibitors require caution because of enhanced risk of nephrolithiasis. Dialyzable agents, including gabapentin, phenobarbital, topiramate, levetiracetam, ethosuximide, pregabalin, and (to a lesser extent) lamotri-

gine can require postdialysis supplementation.¹⁰ This is less likely to be required for highly protein-bound agents such as carbamazepine and valproic acid.⁹

Insomnia

Sleep disruption is present in 50% to 90% of patients,^{12,13} and primary sleep disorders are common, including restless legs syndrome (RLS), periodic leg movements in sleep, and sleep apnea.^{1,14–16} Studies of nonpharmacologic and pharmacologic treatments of this problem are limited, and much of the treatment is by inference from the non-ESRD population.¹⁷

RLS is found in more than half of patients treated with long-term dialysis and manifests itself with predominantly nocturnal lower extremity “jitteriness,” necessitating frequent leg movement and, often, pacing. Periodic leg movements in sleep are found in most patients with RLS, whereas RLS is found in a minority of patients with periodic leg movements in sleep. Nonpharmacologic treatment with heat packs and exercise can be effective. Dopaminergics are first-line pharmacologic agents for both conditions, with carbidopa/levodopa, pramipexole, and ropinirole among the most commonly used agents; the ergot dopamine agonists are problematic because they can induce cardiac valve regurgitation.¹⁸ Narcotics, benzodiazepines, and gabapentin follow dopaminergics as RLS/periodic leg movements in sleep treatments. Although dopaminergics, gabapentin, clonidine, and (subsequently) opioids are used in uremia-associated RLS,^{1,19,20} the efficacy of these standard treatments in uremic patients is not yet clear.^{21,22} Uremic patients are vulnerable to neuropsychiatric respiratory and gastrointestinal side effects with medications, and tachyphylaxis may necessitate dose escalation and drug class rotation. Sloand and colleagues²³ reported double-blind, placebo-controlled data on the successful use of intravenous iron dextran in uremic RLS. Sleep apnea also occurs in patients with ESRD and is likely underdiagnosed and potentially precipitated by hypocarbia, metabolic acidosis, and uremic toxins in the bloodstream.^{16,24} There are reports of intensive dialysis, nocturnal dialysis, and renal transplantation reversing sleep apnea.^{25–28} Optimal dialysis, modification of the usual risk factors and continuous positive airway pressure and biphasic positive airway pressure are used in uremia-associated sleep apnea. Sleep hygiene methods, including avoidance of caffeine and nicotine, are recommended for sleep disorders, and relaxation therapy, biofeedback, stimulus control therapy, and cognitive-behavioral therapy can also be considered.¹⁷ Pharmacotherapy with sedative hypnotics can be considered in patients without sleep apnea, including newer generation benzodiazepine-receptor agonists (e.g., zolpidem), benzodiazepines, and sedating antidepressants. Of these, the benzodiazepine-receptor agonists seem promising, with good tolerability and low liability to cause residual sedation, withdrawal, dependence, or tolerance.¹⁷ Antihistamines should be avoided, as they are likely to aggravate problems such as xerostomia and to contribute to cognitive impairment. Nocturnal melatonin levels are decreased in dialysis patients, but melatonin and the melatonin agonist ramelteon have yet to be investigated as primary hypnotics in ESRD.^{17,29}

Sleep-onset insomnia may be best addressed with short-acting agents such as benzodiazepine-receptor agonists and triazolam. Triazolam's potential for inducing rebound insomnia,

anterograde amnesia, and behavioral disinhibition at low doses is likely no greater than that of other benzodiazepines,^{30,31} but its potential for inducing delirium is a concern. Zaleplon is more rapidly eliminated than zolpidem and zolpiclone, and there is evidence that adverse effects may be shorter or milder than those found in benzodiazepines and the other benzodiazepine-receptor agonists.^{17,32} There is a small, randomized, double-blind crossover study available on zaleplon's use in hemodialysis patients with insomnia, in which it was well tolerated and performed well, with improved sleep quality and reduced sleep latency.³³ Zaleplon does have significant renal elimination and although there is no recommended dose adjustment for mild to moderate renal impairment, caution is indicated in severe renal disease. Difficulty in maintaining sleep may be best dealt with by using medium half-life agents like temazepam or lorazepam, although the longer pharmacokinetics of zolpidem and zolpiclone may also make them appropriate for maintaining sleep.^{17,30} Longer acting hypnotics like flurazepam present a potential problem with residual daytime effects. Antidepressants are commonly pressed into service as sedatives and agents such as amitriptyline, trazodone, and mirtazepine may be of some use. However, tricyclics have significant drawbacks, as noted in the subsequent section on treatment of depression, whereas the use of trazodone in dialysis patients may be limited by its tendency to cause hypotension and by the risk of trazodone-associated arrhythmias in patients with comorbid cardiac disease.^{17,34}

Delirium

Delirium implies one or more identifiable etiologies and should prompt a vigorous search for reversible causes, including dyspnea related to volume overload, adverse medication reactions, inadequately treated pain, and fever. There is some evidence implicating older age and longer term therapy as risk factors for delirium in hemodialysis patients.³⁵ As always, medications are frequent offenders, and there are some common, potentially neurotoxic agents that require monitoring in this respect (see Box 73-1). Acyclovir can cause delirium as can meperidine's excitotoxic normeperidine metabolite.^{36,37} Clarithromycin has precipitated visual hallucinations in peritoneal dialysis.³⁸ Many patients have multifactorial causes.

Delirium can be accompanied by agitation when waste products accumulate,³⁹ and treatment of agitation in uremic delirium follows the general delirium approach, with considerations attendant to renal failure. Antipsychotics are the usual "platform" upon which regimens for the treatment of agitation are built. There are 14 prospective studies and various case reports to support the use of haloperidol, chlorpromazine, olanzapine, risperidone, ziprasidone, quetiapine, and aripiprazole in delirious patients. However, there are limited prospective studies to go on; there are no randomized, double blind, placebo-controlled data for any of the antipsychotics in delirium. At this point, haloperidol remains the mainstay psychotropic for agitated delirium.⁴⁰ The drug is documented to be effective and metabolized in the liver, and its metabolites are not active. It is often used at initial doses of 0.5 to 1 mg PO/SC/IM/IV hourly, titrating to effect.³⁸ There are several more aggressive haloperidol regimens for severe agitation; a recent guideline lists the episodic use of 5 to 10 mg haloperidol,⁴¹ whereas another protocol calls for a starting dose of 5 mg, doubling the dose every 20 minutes until the patient is tranquilized, but arousable.³⁸ Although commonly used, intravenous haloperidol is not

formally approved by the FDA, and there have been rare cases in which torsade de pointes developed, as noted later. Haloperidol-induced akathisia, dystonia, and parkinsonism can be dealt with by using diphenhydramine 25 to 50 mg IV every 4 to 6 hours in the usual manner, although the use of this agent will likely worsen cognitive decline. Psychiatric units often medicate severely agitated patients using alternating doses of haloperidol and a benzodiazepine (e.g., lorazepam 1 or 2 mg) every 30 minutes to 1 hour, but the treating nephrologist should be alert for paradoxical disinhibition and accelerated confusion when using benzodiazepines in the neuropsychiatrically compromised patient. Olanzapine, ziprasidone, and aripiprazole are now available in intramuscular form and in the future may come into more common use in agitated delirium.

Dementia

Dementia is common in the ESRD population and may be the result of uremia with associated metabolic and physiologic disturbances or comorbid neurodegenerative or cerebrovascular disorders. A single study available did not find a significant difference in the prevalence of dementia between patients on hemodialysis and those on peritoneal dialysis.⁴² Dialysis dementia is accompanied by facial grimacing, myoclonus, asterixis dyspraxia, and convulsions.³ It has been divided into three categories: an epidemic form that is often associated with aluminum, a sporadic form, and a type that is associated with congenital or early childhood renal disease. Dialysis dementia related to aluminum toxicity has decreased with the use of aluminum-free dialysate. It can be treated with deferoxamine, large surface area dialyzers, or charcoal hemoperfusion. Dialysis patients can become thiamine deficient, and this should be suspected in patients presenting with cognitive impairment. Thiamine deficiency can present as a cryptogenic delirium or rapidly progressive dementia, accompanied by chorea, loss of vision, myoclonus, convulsions, and coma; it is potentially reversible with intravenous supplementation.⁴³ Other sporadic causes of dialysis-associated dementia include vascular lesions, such as cerebrovascular accidents precipitated by ultrafiltration-related hypotension, hemorrhagic stroke, and subdural hematoma.^{44,45} There is at least one case report involving the use of donepezil in a patient with comorbid renal failure and Alzheimer's disease, but the use of acetylcholinesterase inhibitors as a treatment for uremic or dialysis dementia is not substantiated.⁴⁶ It should be noted that the most commonly employed acetylcholinesterase inhibitor, donepezil, is predominantly excreted in the urine. The manufacturer's information does not indicate a decrease in its clearance in patients with moderate to severe renal impairment. It may be administered safely at the 5-mg dose to Alzheimer's patients with mild to moderate renal impairment.⁴⁷

PRIMARY PSYCHIATRIC PROBLEMS AND THEIR MANAGEMENT

Adjustment Disorders

All renal replacement therapies and procedures place patients in a position of forced passivity and unaccustomed dependence.¹⁴ Loss of autonomy is stressful, and prolonged dependence can

promote regression; dependency issues are particularly brought out in hemodialysis patients. Personality and the patient's ability to withstand the dependent position should be considered in making choices between treatment options. Decisions must be flexible and the staff must be aware of the possibility of a poor fit for the chosen dialysis method and be willing to shift to a different modality.

Most chronic illnesses afford at least some periods of respite. This is not the case in ESRD. Its victims are continually involved in the management of their disease and its symptoms. Multiple medications, fluid and dietary restrictions, dialysis schedules, and vascular procedures all ensure that the patient has very little opportunity to escape a continual dialogue with the disease. Treatment alters the individual's appearance with skin discoloration, surgical scars, and fistula sites. Peritoneal dialysis distorts the patient's body shape and may be punctuated by episodes of peritonitis. Work, normally a source of identity and self-esteem, is no longer possible for many patients because of age or illness. Financial stress increases in this context, and increased expenditures for care, diet, and transport are often unmet by social resources and available insurance coverage. The strain on the family of the ESRD patient may be accentuated by the patient's increased caretaking needs and by role reversal required for spouse and/or children.⁴⁸

Subjective adequacy of social supports has been reported to be a significant factor in the survival of dialysis patients. Discrepancy between a patient's expectations and available levels of support has been found in a recent study to be associated with increased mortality in both peritoneal dialysis and hemodialysis populations.⁴⁹ The connection does not appear to be mediated by clinical depression and may reflect the effects of stress and anxiety attendant to dialysis, particularly when inadequately buffered by significant human attachments.

Short-term, reversible changes in emotional state due to proximal stressors are defined as adjustment disorders and can be characterized by predominant depression, anxiety, disturbances in behavior, or any combination thereof. Treatment of an adjustment disorder involves supportive, cognitive, and psychoeducational therapy, along with group and individual peer support and family intervention as indicated. Most psychotherapy is provided by renal social workers, with referral to the local mental health resources or consultants as needed. Pastoral counseling may also be beneficial. Advance preparation, appropriate support, and judicious treatment can, along with time, help the patient's recovery. If the patient's symptoms are protracted, disabling, or complicated by mania, psychosis, or lethal ideation, the diagnosis of adjustment disorder is no longer appropriate.

Anxiety Disorders

Anxiety is commonly encountered in ESRD patients and may present in multiple forms. Fears can center on prognosis, the ability to adjust to the demands of the disease and its treatment, or sexual performance or may be fueled by anticipated effects of the disease on the family and the patient's place within it.⁵⁰ Anxiety may be triggered by the dialysis experience, with its attendant fluid shifts, electrolyte disturbances, and gastrointestinal upset and cramping. Needles and blood can provoke phobic reactions, and the methodical draining of

the patient's blood from the body can be subjectively terrifying.¹ Panic attacks can be the vector result of psychological, physiologic, and familial stress.

Pharmacologic management is symptomatic and can be directed at persistent generalized anxiety, acute panic episodes, or a combination of the two (see Table 73-1). Because benzodiazepines are metabolized in the liver, a decrease in dose is generally not necessary in ESRD, with the exceptions of midazolam and chlordiazepoxide. Diazepam, lorazepam, alprazolam, and clonazepam can be used as needed before or during dialysis sessions. In recent years, antidepressants have become first-line treatments for most anxiety disorders. Selective serotonin reuptake inhibitors (SSRIs) are used increasingly to treat panic and generalized anxiety disorders in the general population and are also helpful in CKD patients. Venlafaxine, a serotonin-norepinephrine reuptake inhibitor and its metabolite *O*-desmethylvenlafaxine are subject to decreased clearance and elimination in renal disease; the manufacturer recommends decreasing the dose by 25% to 50% in patients with renal impairment and 50% in hemodialysis-dependent patients (dose is withheld until 4 hours post-dialysis). Mirtazepine, another dual neurotransmitter antidepressant, may also need to have its dose adjusted downward for decreased clearance and elimination in ESRD.

Depression and Manic Depression

Depression is quite common in the dialysis population. The 1997 review of O'Donnell and Chung⁵¹ found major depression in 5% to 22% of ESRD patients and subclinical depression in an additional 25%. Major depression may be driven by losses of autonomy, productivity and sexual function. Depression in dialysis patients often goes unrecognized and untreated,⁵² and suicide rates are elevated.^{53,54} The traditionally quoted 500-fold increase in suicide among dialysis patients is a gross overestimate,¹ but dialysis-dependent patients can, with unconscious intent, take their own lives by missing treatments or not complying with dietary and fluid restrictions. Depression and mortality in ESRD have been associated in several studies but not in all.^{55,56} In one study,⁵⁶ low scores on the Beck Depression Inventory were associated with 85% 2 year survival rate, whereas high depression scores were associated with a 25% survival rate. A 2000 study by Kimmel and colleagues⁵⁵ found that depressive indices predicted survival at 1 year and that higher levels of depressive affect were associated with increased mortality. Diagnosis of depression begins with suspecting it. The diagnostic inquiry starts with a simple question about mood (though patients may be unable to recognize changes in their emotional state). It makes sense to follow the initial mood question by additional questions about psychiatric symptoms. Characteristics used to classify major depression can be found in the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV)* (http://psyweb.com/Mdisord/DSM_IV/jsp/dsm_iv.jsp). If patient and clinician then believe that "the shoe fits," additional relevant history can be explored, including personal and family history of depression, history of substance abuse, and (especially important) past suicide attempts.⁵³

Treatment of depression involves both psychotherapy and pharmacotherapy. Most psychotherapy in the ESRD/dialysis setting is provided by renal social workers; there also should be access to more specialized psychotherapists

in the community for patients with particularly complicated or intensive needs. Pharmacotherapy relies on antidepressants, often in combination with or augmented by other agents such as thyroid hormone, buspirone, or stimulants. The nephrologist should refer for psychiatric consultation those depressed patients for whom antidepressant monotherapy is ineffective.

Double-blind, placebo-controlled trials of pharmacotherapy in ESRD depression are needed, but the available data consistently support the use of both SSRIs and tricyclic antidepressants in this population.^{57,58} As the oldest generation of antidepressants, tricyclics have accumulated the most data and experience. They are prone to cause anticholinergic and antihistaminic side effects, can precipitate or aggravate postural hypotension, will lower seizure threshold, and lengthen cardiac conduction intervals. Nortriptyline, a secondary amine tricyclic, is particularly useful because of a meaningful therapeutic window in its serum levels and a relatively lower side effect burden, at least in terms of anticholinergic effects and sedation. Imipramine and amitriptyline, tertiary amines, have hydroxylated metabolites that contribute to both therapeutic and toxic effects. Tricyclics can be used adjunctively in the treatment of neuropathic pain, commonly found in ESRD. Although useful and well established, tricyclics are cumbersome, with a low therapeutic index and potential lethality in overdose. At this point, they have been superseded as the first-line of treatment by newer agents and are best reserved for treatment-resistant depression in ESRD.

SSRIs are the first-line treatment of depression in the general population. They are also beneficial in ESRD-related depression, although they are not as well researched as tricyclics. Fluoxetine is the best studied SSRI and appears to be both effective and well tolerated.⁵⁹ Fluoxetine is metabolized hepatically; the kinetic profile of single doses of fluoxetine is unchanged in renal failure, even in anephric patients. Renal function does not significantly alter either fluoxetine or norfluoxetine serum levels. Sertraline is also widely used as it too is metabolized hepatically, and urinary excretion of the unchanged drug is insignificant. Subjects with mild to severe renal impairment and matched controls show no significant differences in pharmacokinetics. As noted, sertraline can be used to help prevent sudden hemodialysis-related hypotension.⁶⁰ Citalopram kinetics follows the SSRI pattern and is minimally changed in patients with ESRD; dose adjustment is probably not necessary.⁶¹ Paroxetine is unusual among SSRIs in that its blood level is sensitive to renal impairment; in patients with severe renal insufficiency, it should be started at 10 mg or half the usual starting dose.⁶²

There are several non-SSRI new-generation antidepressant medications that should be used with caution or avoided in ESRD patients. Careful dose adjustment for patients with renal impairment is necessary with venlafaxine, as noted.⁶³ With this drug, hypertension can be a risk, and regular blood pressure monitoring on venlafaxine is indicated. Bupropion is contraindicated in patients with seizure disorders and must be used with caution in patients with lower seizure thresholds. In ESRD patients, proconvulsive metabolites may accumulate and predispose to seizures, along with the electrolyte disturbances caused by the disorder. Duloxetine, another nontricyclic serotonin-norepinephrine reuptake inhibitor, has been used as a treatment for diabetic neuropathy as well as for depression and anxiety. It is, however, eliminated by the kidneys, and its use is

contraindicated in patients with renal failure. Mirtazepine is an atypical noradrenergic/serotonergic antidepressant often used for depression with prominent insomnia, anorexia, and anxiety. Single-dose oral clearance of mirtazepine is decreased by 33% in moderate and by 50% in severe renal failure. There is inadequate documentation of its use in patients with renal failure.^{64,65} Little is known about the use of nefazodone for depression in the ESRD population; its potential hepatotoxicity and cytochrome P-450 3A4 inhibition argue against its use.⁶⁶ As a rule, care must be taken when prescribing antidepressants to patients on cytochrome-dependent drugs, as many of the antidepressants, particularly the SSRIs, will inhibit selected isoenzymes of the P-450 system. 3A4 inhibition can be particularly common and problematic, affecting multiple drugs used in the renal failure/transplant population (e.g., tacrolimus, cyclosporine, sildenafil). Inhibitors of the 3A4 subsystem include nefazodone, fluoxetine/norfluoxetine, fluvoxamine, paroxetine (weakly), sertraline, and valproic acid (weakly). In patients with unexplained toxicities, including delirium, careful examination of the use of antidepressant drugs and their interactions with other drugs is critical.^{67,68} The pharmacologic management of mania and of depression in the context of a bipolar disorder is considerably more difficult than the management of unipolar depression. Use of polypharmacy by psychiatrists is the rule, and combinations of mood stabilizers, antipsychotics, antidepressants, and other agents are commonly used. In addition, the risk of switching a bipolar patient from a depressed state to mania when antidepressant therapy is required complicates the treatment of bipolar depression. Lithium has traditionally been the primary mood stabilizer used in bipolar disorder. There are many years of experience with the use of lithium, and it has demonstrated efficacy in acute episodes and in prevention of relapses. In the past decade or two, it has been gradually displaced by anticonvulsant medications, particularly valproic acid, carbamazepine, and, more recently, lamotrigine. These drugs are effective, and lamotrigine has particular efficacy in patients with bipolar depression. These useful anticonvulsants can have drug interactions with each other, with antidepressants, and with nonpsychiatric medications, and they are eliminated by the kidneys. The latter property requires dosing adjustment for lamotrigine alone. Titration of the lamotrigine dose is slow and must be carefully monitored to minimize the risk of rapid increase in drug level precipitating Stevens-Johnson syndrome or toxic epidermal necrolysis. For those bipolar disorder patients with ESRD who require lithium, treatment involves administration of a single dose (usually 600 mg) after each dialysis. Lithium is removed by dialysis and a single dose should result in a steady serum level,⁶⁹ but serum lithium levels obtained before and after dialysis sessions can help adjust the dose. Lithium levels should be obtained immediately before dialysis and 2 hours after its completion; the immediate level after dialysis is misleadingly low and will increase with subsequent redistribution.

Lithium can be nephrotoxic, and other mood stabilizers are preferable in patients with renal insufficiency. A long-term follow-up study found that when the drug is discontinued, renal function may improve.⁷⁰

Electroconvulsive therapy can also be used as an antidepressant strategy in patients with renal failure. Individual case reports in the literature document successful treatment of bipolar depression in ESRD patients with electroconvulsive therapy.^{71,72} Salient issues include renal osteodystrophy with

attendant increased fracture risk, hyperkalemia with potential cardiotoxicity when using succinylcholine in the uremic patient, altered pharmacokinetics of anesthetic induction agents, and adverse effects of metabolic acidosis and of changes in volume status complicate the treatment. Careful attention to both muscle relaxation and potassium level is necessary; the use of a nondepolarizing paralytic rather than succinylcholine may also be a consideration.

Schizophrenia and Psychotic Disorders

Pharmacologic treatment of schizophrenia has been shifted away from the reliance on traditional neuroleptics with the advent of the atypical antipsychotics, including clozapine, risperidone, ziprasidone, aripiprazole, and olanzapine. Unlike traditional neuroleptics, this new generation of antipsychotics does not rely primarily on D₂ receptor blockade for efficacy and so is less prone to aggravate negative symptoms of the disease, such as emotional blunting and apathy. Before the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) in 2005, atypical antipsychotics were largely uncontested as the standard of care for the treatment of psychotic disorders. In CATIE, the atypical antipsychotics did not seem as a class to show improved tolerance or better results than a standard neuroleptic (perphenazine), but there was much greater cost. CATIE has left the field in doubt as to any reflexive preference for atypical agents and may reshuffle existing treatment guidelines in the coming years. For example, there may be a renewed appreciation for traditional neuroleptics like haloperidol.⁷³

There are few data concerning the use of atypical agents in the ESRD population and peer-reviewed data to guide their use in psychotic patients with comorbid renal failure is scanty. There has been a re-emergence of tics in an adolescent treated with risperidone when the patient was switched from peritoneal to hemodialysis; this may have been due to altered gut absorption, as the level of the water-soluble 9-OH metabolite was unaffected by dialysis.⁷⁴ In a study of healthy young and elderly subjects compared with patients with cirrhosis or moderate and severe renal insufficiency, the elimination and clearance of risperidone and 9-OH risperidone were decreased in patients with renal disease. This implies there should be a reduced dose and slower titration of risperidone in patients with renal failure.⁷⁵ Ziprasidone pharmacokinetics have been studied; mild to moderate renal insufficiency did not alter pharmacokinetics of ziprasidone and hemodialysis did not significantly alter ziprasidone pharmacokinetics.⁷⁶ Single-dose data for quetiapine showed no pharmacokinetic difference between nonpsychotic healthy subjects and subjects with renal impairment.⁷⁷ There is a case study describing the development of protracted hypothermia in a hemodialysis patient after a single dose of olanzapine, possibly due to an enhanced hypothalamic effect. However, product information for olanzapine indicates no change in pharmacokinetics with severe renal insufficiency, leaving the issue unresolved.⁷⁸ Finally, there have been cases of acute renal failure associated with clozapine treatment, including a documented case of acute renal failure due to interstitial nephritis.⁷⁹ These reports leave the prescribing physician somewhat at sea in dosing these agents, and caution is warranted. The traditional neuroleptics are still used in the management of schizophrenia and other psychotic disorders and may see a resurgence in future use.

Emerging data show a significant increase in mortality among the demented elderly treated with atypical antipsychotics. Initially recognized and quantified with Risperdal (risperidone) results, the association appears to be a class effect. An increase in stroke risk was also postulated, but this has not been borne out in larger meta-analyses of randomized, controlled trials. Development of the metabolic syndrome is another growing concern with the use of atypical antipsychotics. Clozapine and olanzapine appear to be the worst offenders in this regard, whereas aripiprazole has a more favorable profile in terms of diabetes and hyperlipidemia. Regardless, hemoglobin A1c, weight, blood pressure, and lipids should be monitored when any atypical agent is prescribed.

In vulnerable CKD patients, dopamine-blocking drugs, especially higher potency neuroleptics and risperidone, can cause hyperprolactinemia, affecting gonadotropin levels and bone metabolism.

Cardiac conduction effects and the potential for lethal arrhythmias have become a prominent source of concern in the treatment of medically ill patients with both typical and atypical antipsychotics. In CKD patients and especially ESRD patients who are subjected to disturbances in electrolytes, this is of particular concern. Antipsychotics can cause QTc prolongation, presumed to be related to drug antagonism of the I_{kr} delayed rectifier current. There are reports of the development of torsade de pointes with haloperidol, pimozide, droperidol, sertindole, thioridazine, chlorpromazine, ziprasidone, risperidone, and quetiapine. In terms of QTc prolongation, ziprasidone and thioridazine are the most problematic, with ziprasidone midway between thioridazine and a number of other, more modestly prolonging antipsychotics, including haloperidol, risperidone, quetiapine, and olanzapine.⁸⁰ Aripiprazole may be preferable in this regard, with a low propensity for QTc prolongation.⁸¹ After a U.S. Food and Drug Administration review, thioridazine was found to be contraindicated when other drugs that prolong QTc or that interfere with thioridazine's metabolism or elimination are used. The potentially offending drugs include fluvoxamine, propranolol, paroxetine, and fluoxetine. Thioridazine is no longer a widely used agent, but the consideration of increased cardiac risk with pharmacodynamic or pharmacokinetic drug interactions should be reflexive on the part of the prescribing clinician. On general principles, alternatives to thioridazine (other low-potency neuroleptics such as chlorpromazine) should be preferred for the patient with renal impairment.⁸²

Sexual Disorders

Sexual dysfunction in CKD patients has multiple causes, including vascular disease, malnutrition, anemia, hormonal abnormalities, iatrogenic drug effects, and psychiatric disorders. It is found in both men and women, is significantly distressing, and can precipitate lapses in treatment compliance. A recent study has demonstrated an independent association between sexual dysfunction and depression in male hemodialysis patients; the association may be bidirectional.⁸³

A majority of patients on dialysis experience a decrease in sexual interest or frequency. Levy and Cohen⁵⁷ state that approximately 70% of men have partial or total impotence, that the majority of women are amenorrheic or infertile, and that even successful kidney transplantation does not always restore a patient's sexual function. Dialysis also does not seem to ameliorate sexual dysfunction.⁸⁴ SSRIs and other psychiatric

medications can be significant offenders. Treatment addresses underlying causes (e.g., correction of anemia and secondary hyperparathyroidism, hormone replacement therapy).⁸⁵ Behavioral psychotherapies may be helpful and treatment of clinical depression is indicated, with recognition that antidepressants have side effects that impair sexual performance. Sildenafil is highly effective in the treatment of many cases of erectile dysfunction found in CKD patients,⁸⁶ but is contraindicated in people taking nitrates for coronary artery disease (these drugs can cause fatal hypotension). They may not be as effective in diabetic dialysis patients⁸⁷; apomorphine was far less effective than sildenafil in a study comparing the two drugs in the treatment of erectile dysfunction in dialysis patients.⁸⁸

For patients with ESRD who have not developed significant hypotension during dialysis and are not receiving cytochrome P-450 3A4-inhibiting drugs, a low dose of sildenafil (25 mg) may be considered. Men may need surgical intervention to preserve sexual function (see Chapter 71).

INITIAL NEUROPSYCHIATRIC ALGORITHM

Making sense of an array of neuropsychiatric symptoms can be a confusing and unsettling task for the nephrologist. Diagnostic categories and treatments frequently overlap, and comorbidities are routine. This chapter's algorithm should be taken with an "osmole of sodium"—it is simplified and generalized and will apply in some cases far better than in others. An algorithm must not be substituted for informed clinical judgment, and the threshold for referring patients for psychiatric consultation should be low, particularly if problems are persistent, severe, or refractory to initial attempts at management. It should also be emphasized that suicidal or homicidal ideation or threats represent emergent situations requiring an immediate response from the treating physician. If the safety of the patient or others is in doubt, prompt assessment, rapid psychiatric consultation, and careful consideration of inpatient treatment are indicated. Local crisis resources should be identified and emergency contact numbers easily accessed by all clinical personnel.

In more routine situations, a good starting point is to ask whether neuropsychiatric problems involve the mental status of the patient and whether they have an impact on awareness, cognition, mood, thought, or perception.

FACTORS ASSOCIATED WITH DIFFERENCES IN QUALITY OF LIFE IN END-STAGE RENAL DISEASE 819

RECOMMENDATIONS 819

BACKGROUND

Health outcomes in end-stage renal disease (ESRD) have traditionally been measured in terms of morbidity and mortality. The focus has broadened in recent years to an increase in emphasis on patient-reported outcomes. In addition to sustaining life, the success of renal replacement therapy may now be considered in terms of maintenance and improvement of health status and quality of life (QOL).¹⁻³ The change in emphasis is based on the principle that health is “a state of complete physical, mental and social well-being and not merely the absence of disease and infirmity.”⁴

Health is, therefore, a personal and abstract concept, influenced by both medical and nonmedical factors.⁵ It can neither be measured directly nor can its essence be captured using single variables such as physiologic measures of organ function.⁶⁻⁸ Multidimensional assessment of health is required, and the patient’s own perception of well-being and QOL is a vital component.^{6,9,10}

DEFINING QUALITY OF LIFE

QOL is a difficult concept to describe, with no single operational definition. This causes difficulties when interpreting results and comparing studies.^{7,11} The terms functional status, health status, and QOL are often used interchangeably and are (incorrectly) considered by many sources to define similar constructs.¹² Measures of functional status are largely concerned with physical health, based on measurement of disability. Health status and QOL are far broader concepts, encompassing both the physical, psychological, and social dimensions of health.^{13,14} QOL includes the personal beliefs, values, perceptions, and responses that are exclusive to each individual within the context of his or her unique social environment.⁷

The term health-related QOL is used to refer specifically to the physical, psychological, and social dimensions of health.¹⁵ For the purpose of this text, QOL is defined as a concept that takes account of the multidimensional nature of a person’s well-being, reflecting the physical, psychological, and social

dimensions of health, which is influenced by personal beliefs, experiences, and expectations as well as socioeconomic and cultural factors. This definition is consistent with the World Health Organization’s International Classification of Functioning, Disability and Health.¹⁶

MEASURING QUALITY OF LIFE

Personal subjective perceptions are key to QOL assessments, which should evaluate daily-life performance in physical, psychological, and social dimensions.^{9,15,17-19} Numerous QOL scales exist. Selection (generic vs. disease specific, self-report vs. interview, single item vs. battery, preference-based or utility indices) should reflect the purpose of measurement and the target patient group, and the validity, reliability, and responsiveness of the instrument should be established. Disease-specific instruments are generally more sensitive to changes in the target population and may be more useful for sequential monitoring of individual patients or in clinical trials; generic instruments are of greater value when comparing groups of patients with different conditions and when relating results from patients to characteristics of the general population.¹⁴ Single-index, preference-based, and utility scores are useful for multivariate and economic analyses,²⁰⁻²⁴ but multi-item profiles emphasize the diverse aspects of QOL and allow a broader personal and clinical perspective.^{8,14,23}

QOL instruments are thus useful for characterizing patient groups, discriminating between groups at one point in time, monitoring change over time, predicting outcomes, and economic analysis.⁶

QUALITY OF LIFE IN END-STAGE RENAL DISEASE

Studies reporting QOL in renal patients were first published in the 1980s,²⁵⁻²⁷ and interest in QOL outcome measurement for predialysis, dialysis, and transplant groups has grown dramatically since then.^{17,28-36} PubMed searches for “Dialysis AND Quality of Life” and “Renal Transplant AND Quality of

Life” currently produce 1997 and 926 citations, respectively. The variation in the type and number of instruments used is notable; some studies have focused on one dimension only, whereas others consider global QOL.²⁹ Commonly reported multidimensional measures include the Short Form 36 health survey,³⁷ and the Kidney Disease Quality of Life Questionnaire.^{38,39} The Kidney Disease Quality of Life Questionnaire is an increasingly widely used instrument; in particular, it has been rendered into 24 language/cultural translations and been validated in a range of countries.

There is unequivocal evidence that QOL is impaired in dialysis patients compared with the general population.^{40–48} Transplant recipients also demonstrate impaired QOL, although this is not as marked as in dialysis groups.^{34,35,49–52} Limitations are most marked in the physical and social dimensions, whereas mental health scores tend to remain comparable with those in healthy individuals.^{46,53,54} The maintenance of high psychological well-being in the majority of ESRD patients may result from an alteration in health values and expectations with chronic disease.^{54–56} However between 20% and 30% of ESRD patients report significant psychological distress and depression.^{43,57}

FACTORS ASSOCIATED WITH DIFFERENCES IN QUALITY OF LIFE IN END-STAGE RENAL DISEASE

Factors associated with differences in QOL in ESRD have been identified mainly by cross-sectional studies, which allow comparisons between groups based on existing clinical and sociodemographic characteristics. Many of these report univariate relationships only, whereas others have used multivariate analysis to identify independent associations with QOL. Several prospective single-group and case-control studies using QOL indices as outcome measures have been conducted, and the number of randomized, controlled trials is growing. Problems arise when comparing studies because of the considerable diversity in methodology, definition of QOL, choice of measurement instrument, and sample characteristics. Direct relationships between measures of clinical status and QOL may not always exist, and variables affecting QOL are often interrelated. Broadly speaking, these may be divided into sociodemographic variables, clinical variables, and comorbid medical variables.

Relationships between these characteristics and the multidimensional Short Form 36, and Kidney Disease Quality of Life questionnaires are summarized in Table 74-1, and a sample of randomized, controlled clinical trials reporting QOL outcomes in predialysis and ESRD groups is presented in Table 74-2.

The main sociodemographic factors associated with QOL are age, gender, socioeconomic status, income, employment, and educational level, whereas the relationship with ethnicity is variable. Aging of the ESRD population is a worldwide trend, and this phenomenon brings older patients with greater comorbidity to renal replacement therapy.⁵⁸ In general, older age is associated with declining physical function, but when combined with the physical sequelae of chronic renal insufficiency (cardiovascular, neurological, myopathic, and skeletal), the physical dimension of QOL is especially compromised in this older ESRD group.^{40,59} Physical limitations are, however, universally reported in ESRD patients of all ages, to varying degrees. There is now a significant body of evidence that

strongly supports exercise as an effective therapy to ameliorate the physical impact of ESRD and improve QOL for dialysis and transplant cohorts.^{60,61}

Renal transplantation is associated with improved QOL, but this in part reflects patient selection. There are conflicting reports regarding the benefit of peritoneal dialysis over hemodialysis. A 2004 Cochrane review concluded that there was not enough evidence to indicate significant differences in QOL between dialysis modalities.⁶² Early referral for specialist treatment, adequacy of dialysis, maintenance of nutritional indices, correction of anemia, management of symptoms, and prescription of exercise are the main clinical factors associated with better QOL. Severity of comorbid illness is a strong predictor of poorer QOL. Other factors affecting QOL are perceived burden of illness and the degree of social support.

RECOMMENDATIONS

QOL measurement is a valuable adjunct to objective clinical assessment in ESRD and recent Cochrane reviews have highlighted the need to include QOL outcomes in clinical trial design.^{62–64} Close relationships exist between self-reported QOL and morbidity and mortality outcomes,^{65–73} and these subjective measures may even be better predictors of outcome than clinical parameters.^{43,74} There is also growing evidence that self-assessed physical and psychosocial well-being influences compliance and survival.^{64,73,75,76}

The inclusion of QOL assessment in the routine management of ESRD patients offers several advantages. Specific patient problems may be identified, thus directing clinical intervention to alleviate the symptom burden affecting the patient’s life. For example, older patients and those reporting specific physical problems will benefit from referral for physical therapy and targeted physical rehabilitation.

Through formal QOL assessment, nonmedical factors such as patient satisfaction, personal beliefs, and social and environmental issues affecting QOL may be highlighted and ways of improving quality of care identified. QOL assessment fosters more patient-centered treatment, enhancing communication between the patient and the health care team, and there is evidence that patient empowerment results in better outcomes.⁷⁷ Serial QOL measurement is valuable for patient surveillance over time, and QOL assessment may direct health care planning and quality assurance initiatives.

Factors to consider when attempting to improve QOL are summarized in Figure 74-1, and these reflect the five Es of renal rehabilitation identified by the Life Options Rehabilitation Council: education, encouragement, employment, exercise, and evaluation.⁷⁸ Evaluation and regular reassessment are central to any initiative aimed at improving QOL, and early referral to specialist multidisciplinary nephrology services is crucial. Adequacy of dialysis, correction of anemia, careful management of comorbidity, maintenance of nutritional status, and exercise programs designed to enhance physical fitness are key factors in physical management. Exercise prescription is a routine part of patient management in some centers, aimed at improving physical function and QOL in addition to reducing cardiovascular risk,^{79–81} and exercise counseling of patients by nephrologists should be promoted.^{60,81–83} There is ongoing research on the optimal dose, duration, and setting for exercise, but the current consensus is that individually tailored,

Table 74-1 Factors Affecting Quality of Life in End-Stage Renal Disease

Sociodemographic Variables	
Age of patient	
Older	↓ Physical health scores ^{45,46,56}
Younger	↓ Mental health scores ^{45,46,48,65,96}
Sex: female	↓ Global QOL scores ^{65,97-99}
Lower educational level	↓ global QOL scores ^{45,50,65,66,96}
Lower socioeconomic group	↓ Global QOL scores ^{65,96,97}
Employment: unemployed	↓ Global QOL scores ^{46,66,100}
Higher income/health insurance	↑ Global QOL scores ^{66,100,101}
Social Support	
Living alone	↓ Mental health scores ⁴⁸
Married	↑ Social function scores ⁵²
Supportive relationship	↑ Global QOL scores ⁵
Race	
UK: Asian vs. European UK dialysis patients	↓ Global QOL scores ⁹⁷
US: African American vs. white	↑ Global QOL scores ¹⁰²⁻¹⁰⁶
International: Japan vs. Europe and US	↑ Physical QOL scores ¹⁰⁵ ↑ Disease burden
US: Native American vs. white	↑ Physical health scores ¹⁰⁶ ↓ Mental health scores
US: Hispanic vs. white	↑ Physical health scores ¹⁰⁶ ↓ Mental health scores
Clinical Variables	
Treatment modality	
Transplant vs. dialysis	↑ Global QOL scores ^{41,44,51,52,96,98,99,107,108}
Home HD and PD vs. in-center HD	↑ Global QOL scores ^{42,44}
HD vs. PD	Same global QOL scores ^{109,110}
PD vs. HD	↑ Mental health status ^{42,111}
APD vs. CAPD	Same QOL scores ^{112,113} Cochrane review APD ↑ psychosocial benefit ⁶³
CAPD vs. home or in-center HD	Cochrane review: same ⁶²
Preparation for dialysis: early referral	Better global QOL scores ^{100,114,115}
Time since transplantation: longer duration	↓ Global QOL scores ⁵¹
Low serum albumin	↓ Global QOL scores ^{45,48,65,66,116}
Nutritional status: low	↓ Physical health scores ¹¹⁷⁻¹¹⁹
Anemia: low hemoglobin/hematocrit	↓ Global QOL scores ^{42,51}
Dialysis dose and efficacy: better Kt/V/higher dose	↑ Global QOL scores ^{48,120-122}
Low serum creatinine	↑ Global QOL scores ¹⁰⁷

Table 74-1 Factors Affecting Quality of Life in End-Stage Renal Disease—cont'd

Comorbidity	
Complex comorbidity	↓ Global QOL scores ^{41,42,44,51,96,97}
Diabetes mellitus	↓ Global QOL scores ⁴⁵
Cardiovascular disease	↓ Global QOL scores ^{48,65}
COPD	↓ Global QOL scores ⁴⁸
Musculoskeletal disease	↓ Physical status scores ⁴⁶
Erectile dysfunction	↓ Global QOL scores ^{123,124}
Other	
Severe physical symptoms	↓ Global QOL scores ⁷⁴
Pain	↓ Global QOL scores ^{125,126}
Restless legs syndrome	↓ Global QOL scores ^{127–129}
Sleep disturbance	↓ Global QOL scores ^{47,127,128,130,131}
Dialysis symptoms	↓ Global QOL scores ⁴⁷
High burden of disease	↓ Global QOL scores ⁴⁷

APD, automated peritoneal dialysis; CAPD, continuous ambulatory peritoneal dialysis; COPD, chronic obstructive pulmonary disease; HD, hemodialysis; PD, peritoneal dialysis.

Table 74-2 Randomized Controlled Trials of Interventions to Improve Quality of Life

Intervention	Sample	Outcome in Intervention Group	Ref.
Erythropoietin			
EPO vs. placebo	Predialysis (N = 603)	↑ Physical function ↑ General health	Drueke et al ¹³²
EPO doses to achieve normal vs. subnormal Hgb	HD, PD, and predialysis (N = 416)	Dialysis patients ↓ Physical symptoms, fatigue, depression, and frustration in normal Hgb group	Furuland et al ¹³³
EPO doses to achieve high target Hgb vs. low target Hgb	Predialysis (N = 1432)	Same change in QOL both groups Higher risk of adverse events with high target Hgb	Singh et al ¹³⁴
EPO doses to achieve normal Hgb vs. low target Hgb	HD (N = 14)	↑ QOL normal target Hgb group	McMahon et al ¹³⁵
EPO vs. placebo	PD (N = 152)	↑ QOL EPO group	Nissenson et al ¹³⁶
EPO vs. control	Predialysis (N = 83)	↑ QOL in physical and vitality domains in EPO group	Revicki et al ¹³⁷
EPO doses to achieve normal vs. subnormal Hgb	HD: placebo (N = 40) Normalized Hgb (N = 40) Subnormal Hgb (N = 38)	↑ QOL both EPO groups vs. placebo	Canadian Erythropoietin Study ¹³⁸

Continued

Table 74-2 Randomized Controlled Trials of Interventions to Improve Quality of Life—cont'd

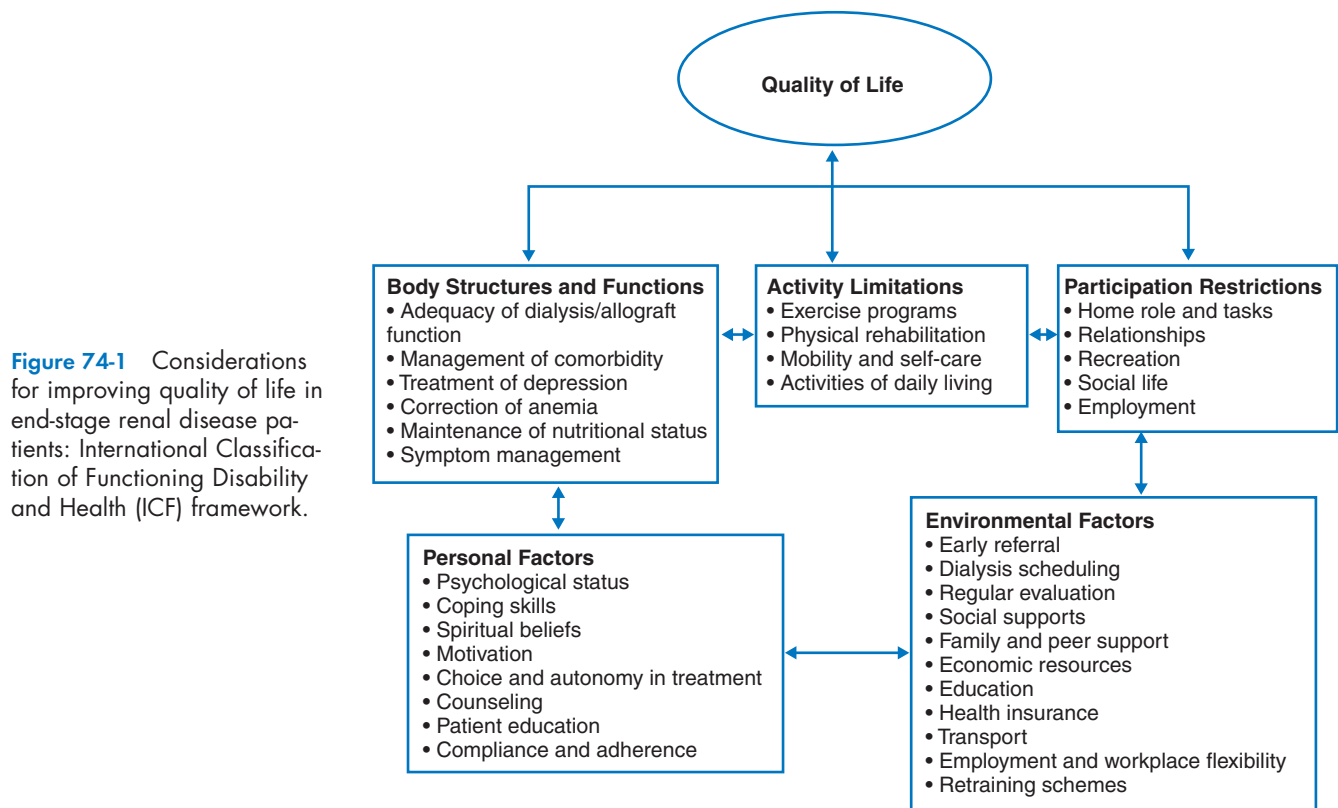

Intervention	Sample	Outcome in Intervention Group	Ref.
Carnitine			
Carnitine vs. placebo	HD (N = 50)	↑ QOL scores in physical domains in carnitine group	Steiner et al ¹³⁹
Carnitine vs. placebo	HD (N = 20)	↑ QOL scores in carnitine group	Rathod et al ¹⁴⁰
Gabapentin vs. Levodopa Restless Legs Syndrome	HD (N = 15)	↑ QOL scores in gabapentin group	Micozkadioglu et al ¹⁴¹
Glucose in Dialysis Fluid vs. Usual Care	HD (N = 34)	No change in QOL; decreased blood pressure decreased variability in blood glucose levels	Sangill and Pedersen ¹⁴²
Predilution Online Hemofiltration vs. Low-Flux HD	Dialysis (N = 40)	↑ QOL scores: hemofiltration	Beerenhout et al ¹⁴³
High-Dose HD	HD	High-dose HD: ↑ Physical QOL scores and ↓ pain	Unruh et al ¹²¹
Exercise Training			
Resistance exercise ± nandrolone decanoate	HD (N = 79)	↑ QOL scores in physical domains with exercise	Johansen et al ¹⁴⁴
Moderate conditioning exercise + counseling vs. control	HD (N = 96)	↑ QOL scores	van Vilsteren et al ¹⁴⁵
Outpatient vs. intradialytic exercise	HD (N = 48)	↑ QOL in both exercise groups	Kouidi et al ¹⁴⁶
Intradialytic exercise vs. control	HD (N = 13)	8-wk exercise program in high function patients: no effect on QOL	Parsons et al ¹⁴⁷
Exercise vs. control	HD (N = 33)	Exercise group ↑ QOL scores in physical domains	Molsted et al ¹⁴⁸
Progressive exercise vs. nonprogressive exercise	HD	12-wk exercise program high function patients: no effect on QOL	DePaul et al ¹⁴⁹
Exercise vs. usual care	Transplant recipients (N = 167)	Exercise group ↑ QOL scores in physical domains	Painter et al ¹⁵⁰
Exercise ± normalize hematocrit	HD (N = 65) 4 groups, 2 exercise	Exercise groups ↑ QOL scores in physical domains	Painter et al ¹⁵¹
Physical rehabilitation vs. control	HD (N = 82)	Exercise group ↑ QOL scores	Tawney et al ¹⁵²
Exercise coaching and counseling vs. control	Predialysis (N = 18) HD (N = 18)	Exercise group ↑ QOL scores Greater effect in predialysis	Fitts et al ¹⁵³
Exercise vs. control	HD (N = 31)	Exercise group ↑ QOL and depression scores	Kouidi et al ¹⁵⁴

EPO, erythropoietin; HD, hemodialysis; Hgb, hemoglobin; PD, peritoneal dialysis; QOL, quality of life.

submaximal exercise prescribed by a qualified health professional is safe, effective, and feasible for all ESRD patients and can be carried out both during dialysis as an outpatient and in the community.^{84–89} Sustained benefits require long-term commitment to exercise, so motivation through regular monitoring is necessary, and supervised settings generally demonstrate

greater improvement. There are, however, barriers to exercise for the patient and resource issues for the health care provider.⁶¹

The importance of diagnosis and management of depression is increasingly emphasized in the literature, and the role that that patient's own coping mechanisms and psychosocial status play is recognized.^{74,90–93} In this regard, education,

patient involvement in decision making, counseling, motivation, and the promotion of a positive ethos of rehabilitation are necessary components in psychological management and in ensuring compliance. Vocational rehabilitation is an important consideration in social well-being, and every effort should be made to keep patients employed or allow them to return to work. Efforts to enhance QOL therefore require a multidimensional and multidisciplinary approach, and this process should be started in the predialysis phase of CKD.^{94,95}

SYMPTOM ASSESSMENT	829	SUMMARY	834
SYMPTOM MANAGEMENT	829		
Management of Pain	829		
Management of Other Symptoms Common in End-Stage Renal Disease	829		

BACKGROUND

Despite technological advancements, more than 80,000 dialysis patients die each year in the United States with an unadjusted mortality rate of 22% to 25%.¹ The age- and sex-matched life expectancy is only 16% to 37% that of the general population. Cardiovascular complications account for at least half of the deaths, and the risk of death for a 45-year-old patient is 20 times that of a person of the same age not receiving dialysis. On average, a 50-year-old dialysis patient will live 5.2 additional years and a 75-year-old could expect to live 2.4 more years.¹ Symptom burdens are very high in this population,^{2–6} and the dying experience for patients with end-stage renal disease (ESRD) is less than optimal.^{7–10} For these reasons, the integration of modern palliative care principles into the care of patients with ESRD is essential to the practice of nephrology.¹¹

The World Health Organization defines palliative care as an approach that improves the quality of life of patients and their families faced with a life-limiting illness through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems—physical, psychosocial, and spiritual. As the dialysis population ages and experiences multiple comorbidities, it is becoming increasingly difficult to maintain a reasonable health-related quality of life (HRQOL) for these patients. Patients with diabetes represent more than one third of the ESRD population, and many of these patients experience amputations, neuropathies, blindness, and other complications. Other common comorbid disorders of incident patients include congestive heart failure (34%), coronary artery disease (25%), peripheral vascular disease (15%), and cerebrovascular disease (10%). Although dialysis supports life, it may not provide what many people consider to be an adequate HRQOL.

A systematic approach to palliative care in dialysis units, emphasizing shared decision making and advance care planning, is discussed in Chapter 84. This chapter focuses on symptom management and the logistics of end-of-life care for patients who withdraw from dialysis or who choose to not initiate dialysis.

SYMPTOM PREVALENCE AND IMPACT

Given the aging population and the increasing incidence of comorbidities, it is not surprising that dialysis patients experience multiple symptoms.¹² Until recently, little attention was paid to the prevalence of symptoms in ESRD and consequently, symptoms are frequently underrecognized and inadequately treated. The overall symptom burden in ESRD is extensive and matches or exceeds that reported by patients hospitalized in palliative care settings with cancer.^{13,14} For the following symptoms, the reported mean prevalence rates are fatigue/tiredness, 71%; pruritus, 55%; constipation, 53%; anorexia, 49%; pain, 47%; sleep disturbance, 44%; anxiety, 38%; dyspnea, 35%; nausea, 33%; restless legs syndrome, 30%; and depression, 27%.¹⁴ Chronic pain in this population is typically severe, with 82% experiencing moderate to severe pain.² The cause of pain is often multifactorial and may be due to comorbidity, the primary renal disease, or the dialysis procedure itself. There are also painful syndromes associated with chronic kidney disease such as renal osteodystrophy, calcific uremic arteriolopathy, and dialysis-related amyloidosis. Symptoms, both physical and psychological, are highly relevant patient outcomes in evaluating HRQOL. In fact, recent research suggests that dialysis patients' perceptions of symptom burden are more important than objective clinical assessments in determining HRQOL.^{4,15–19} A recent study showed that symptom burden in dialysis patients accounted for 29% of the impairment in physical HRQOL and 39% of the impairment in mental HRQOL.¹³ Moreover, a change in symptom burden accounted for 46% of the change in mental HRQOL and 34% of the change in physical HRQOL.²⁰ These results suggest that a palliative care focus on symptom assessment and management would greatly enhance the HRQOL of ESRD patients.

If there is a subgroup of ESRD patients who ought to receive quality palliative care, it is those whose dialysis has been withdrawn and who consequently have a mean of 8 days to live.²¹ Data are limited, but recent studies demonstrate an unacceptable degree of suffering of these patients in their last days

of life.^{8,10} The most common terminal symptoms following withdrawal of dialysis are confusion/agitation (70%), pain (55%), and dyspnea (48%); 24% of patients continued to have unrelieved symptoms at the time of death.¹⁰

There are patients with stage 5 chronic kidney disease (glomerular filtration rate < 15 mL/min) who are managed without dialysis, either through their own preference or because dialysis is unlikely to benefit them. This group of patients also has extensive palliative care needs. Although data on symptom prevalence in this population are limited, it appears that their overall symptom burden may approach that of dialysis patients.²²

SYMPTOM ASSESSMENT

Until now, laboratory tests have played a primary role in the assessment and care of patients with chronic kidney disease. However, it is increasingly becoming clear that the patient's symptoms should be the first priority. Regular comprehensive assessment of physical and emotional symptoms, together with proactive management of identified symptoms, is essential if efforts to improve HRQOL are to be successful. Although the most commonly used HRQOL instruments in dialysis patients, the Medical Outcomes Study 36-Item Short-Form Health Survey²³ and the Kidney Disease Quality of Life questionnaire,²⁴ have items pertaining to physical and psychological symptoms, they do not directly assess patient self-report of troublesome symptoms. In addition, these tools are time-consuming and difficult for patients to complete. Tools used to evaluate symptom burden must be simple and easily understood and take little time to complete. They must also be reliable, valid, sensitive, and responsive to change; yield useful information; and be self-reported because outcomes are dependent on the perceptions and lived experience of individual patients.

The Edmonton Symptom Assessment System is a simple, short, and self-completed measurement tool that was developed for symptom assessment in cancer patients and has been used extensively in palliative care settings. More recently, it has been modified and validated to assess physical and psychological symptoms in ESRD.^{3,13,20} The respondent burden is low, and the instrument can even be successfully completed by patients close to death (Fig. 75-1). In contrast to the use of HRQOL instruments, the resources required for data collection, analysis, and reporting of the Edmonton Symptom Assessment System are minimal.

SYMPTOM MANAGEMENT

Management of Pain

It has only recently been recognized that chronic pain is one of the most common and distressing symptoms for patients with ESRD. Medical management is complicated by the high incidence of comorbidity, polypharmacy, and advanced age. However, the greatest barrier to effective pharmacologic management of chronic pain is the altered pharmacokinetics and pharmacodynamics of analgesics in renal failure. More than 90% of most opioids are excreted by the kidneys, and many have active metabolites that accumulate

in chronic kidney disease, causing opioid toxicity. This difficult situation is worsened by a paucity of data on the use of analgesics in ESRD. Drug dosing is covered in greater detail in Chapter 91.

Given the lack of pharmacokinetic and pharmacodynamic data and systematically tested symptom treatment protocols, it is difficult to advocate specific pain management algorithms, but the basic principles of pain assessment and management can be adapted and integrated into the care of ESRD patients (summarized in Box 75-1). Research is needed to test the effectiveness of various interventions.²⁵ The World Health Organization analgesic ladder is advocated for the pharmacologic management of malignant and nonmalignant pain (Fig. 75-2) and relies on a stepwise approach with analgesics. There is limited evidence to support its use in ESRD patients,²⁶ and not all analgesics are recommended for patients with ESRD (Table 75-1). Although morphine is the mainstay of pain control for most palliative care programs,²⁷ active metabolites accumulate in ESRD. The metabolite morphine-6-glucuronide equilibrates very slowly across the blood-brain barrier, and patients may remain sedated for days after the drug is stopped. This may be beneficial if the patient is agitated or in intractable pain after the withdrawal of dialysis, but it could also deny an individual the level of alertness necessary to achieve spiritual and interpersonal goals. For these reasons, morphine is not recommended.

The essentials of opioid dosing are reviewed in Box 75-2. Adverse effects of opioids should be aggressively treated and ideally prevented with a prophylactic bowel regimen and a gradual titration of dose. When titrated slowly, most patients will develop tolerance to the adverse effects of opioids, allowing the higher dose often required for adequate analgesia. Patient and health care professional fears about opioid addiction remain a major barrier to the effective use of opioids. Fortunately, opioid addiction is extremely rare in patients being treated for chronic pain (Box 75-3). Adjuvant therapies are important components of an effective pain management strategy and often permit the use of lower doses of opioids. Tricyclic antidepressants and anticonvulsants are particularly beneficial in controlling neuropathic pain (Table 75-2). Future strategies will likely include cannabinoids.

Management of Other Symptoms Common in End-Stage Renal Disease

Table 75-3 lists some common ESRD symptoms and our suggested guidelines based on the available literature. We caution that these particular protocols have not been validated or tested with sufficient numbers of patients. They should be considered only as rough guidelines and may not be appropriate for those patients who withdraw from dialysis.

Withholding and Withdrawing Dialysis

Increasing numbers and percentages of patients are dying after dialysis withdrawal: 24% of patient deaths were due to discontinuation of dialysis in 2004.¹ Given that withdrawal from dialysis is an accepted and increasingly common treatment option, one might hope that ongoing discussions about terminal care preferences would be routinely occurring with staff, patients, and the families.²⁸ Instead, research has found that such communications are rare and that written advance directives are completed by only 7% to 35% of long-term

Modified Edmonton Symptom Assessment System:
Numerical Scale
 Northern Alberta Renal Program

Please circle the number that best describes:

No pain	0	1	2	3	4	5	6	7	8	9	10	Worst possible pain
Not tired	0	1	2	3	4	5	6	7	8	9	10	Worst possible tiredness
Not nauseated	0	1	2	3	4	5	6	7	8	9	10	Worst possible nausea
Not depressed	0	1	2	3	4	5	6	7	8	9	10	Worst possible depression
Not anxious	0	1	2	3	4	5	6	7	8	9	10	Worst possible anxiety
Not drowsy	0	1	2	3	4	5	6	7	8	9	10	Worst possible drowsiness
Best appetite	0	1	2	3	4	5	6	7	8	9	10	Worst possible appetite
Best feeling of well-being	0	1	2	3	4	5	6	7	8	9	10	Worst possible feeling of well-being
No itching	0	1	2	3	4	5	6	7	8	9	10	Worst possible itching
No shortness of breath	0	1	2	3	4	5	6	7	8	9	10	Worst possible shortness of breath
No insomnia	0	1	2	3	4	5	6	7	8	9	10	Worst possible insomnia

 Caregiver assisted

Please mark on these pictures where it is you hurt.

Box 75-1 The Essentials of Pain Management

1. Regular, systematic pain assessment
 - a. Believe the patient's report of pain
 - b. Assess pain in its site, character, intensity, extent, relieving and aggravating factors, and temporal relationships.
 - c. Use a simple assessment tool such as a numerical scale of 0–10, e.g., the Modified Edmonton Symptom Assessment System
 - d. Educate patients or their caregivers at home on pain assessment and charting
2. Patients may have more than one kind of pain; each pain syndrome must be independently diagnosed and treated.
3. Aim to achieve control at a level acceptable to the patient. It may not be necessary or possible to make the patient completely pain free.
4. Refer for nonpharmacologic interventions such as physical therapy (e.g., transcutaneous nerve stimulation, hot and cold therapy, exercise, and neuromuscular massage) where appropriate.
5. Educate patients and their caregivers on the goals of therapy, management plan, and potential complications. This will help minimize noncompliance.
 - a. Distress at and confusion about previous treatment has a powerful influence on patients' reactions to pain and disability.
6. Early and aggressive treatment of pain is important in minimizing progression to chronicity.

Concurrent Psychosocial Issues

1. Pain may be associated with and aggravated by concurrent psychological symptoms. The psychological state

of the patient must be assessed and treated appropriately with equal concern.

2. Use an interdisciplinary team to manage total pain. Total pain refers to any unmet need of the patient that may aggravate pain (e.g., financial, spiritual). Pain may not be controlled unless these needs are addressed. This may require a consultation to a palliative care team.
3. Psychological factors typically have a stronger influence on outcome than do biomedical factors.
 - a. Psychological response to acute pain is predictive of chronic incapacity.
 - b. Better management of psychological reactions at early stages of treatment has the potential for preventing unnecessary chronicity.

Guidelines to Be Followed When Using Opioids

1. Before initiating opioids, screen for risk factors for addiction using tools such as the Opioid Risk Tool (ORT) or the Screening Instrument for Substance Abuse Potential (SISAP).
2. Use a specific opioid for a specific type of pain.
3. Use adjuvants judiciously.
 - a. Adjuvants may be used with opioids to control side effects.
 - b. Adjuvants may be used for specific pains not responding well to opioids.
 - c. Adjuvants may be used as an opioid-sparing agent to decrease the dose of opioid when side effects of opioids become troublesome.

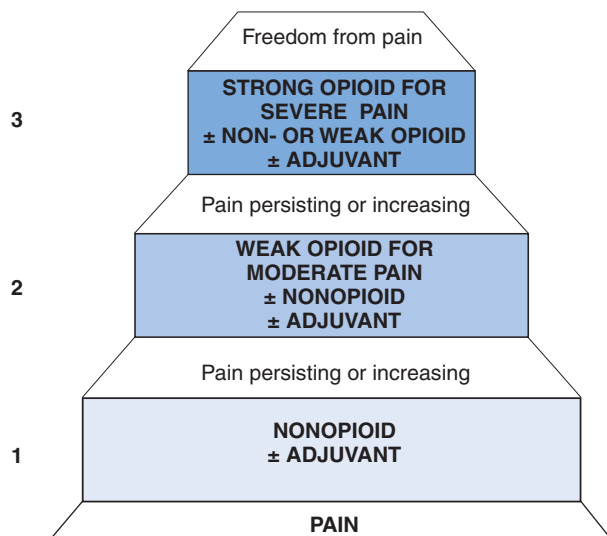

Figure 75-2 The World Health Organization analgesic ladder.

dialysis patients.^{29,30} Patients often do not know that they have the option of withdrawing from dialysis, and they frequently believe that their physicians would not support such a choice.³¹ Even the relatively simpler discussion around cardiopulmonary resuscitation is not consistently done well in dialysis units. Six months following cardiopulmonary resuscitation, only 3% of ESRD patients are alive: approximately 78% of successfully resuscitated dialysis patients die a mean of 4.4 days later, and 95% of these patients are on mechanical ventilation at the time of death.³² Despite the extremely poor chance of survival after cardiopulmonary resuscitation, relatively few dialysis patients choose do not resuscitate orders.³³ Issues around advanced care planning are discussed further in Chapter 84.

Less is known about the numbers of patients who choose not to initiate dialysis. In the United States, it is estimated that less than 5% of patients who present to a nephrologist elect to forgo dialysis. In Canada and Great Britain, as many as 15% to 20% of patients may choose to not start dialysis. For each patient, the decision to commence dialysis or have conservative management (without dialysis) is complex and involves discussions on prognosis, anticipated quality of life (with and without dialysis), treatment burden, and patient preferences. A recent retrospective analysis of the survival of all patients older than 75 years with chronic kidney disease

Table 75-1 Analgesic Use in End-Stage renal Disease

WHO Ladder	Analgesic	Recommendation	Comments
Step 1	Acetaminophen	Recommended	No dose adjustment required
	Nonsteroidal anti-inflammatories	Use with caution	Increased incidence of bleeding in CKD. More appropriate for acute pain management
Step 2	Tramadol	Use with caution	Maximum dose 50 mg q12h; associated with a lower seizure threshold
	Codeine	Avoid	Several case reports of profound toxicity, which can be delayed and unexpected
	Dextropropoxyphene	Avoid	Levels of parent compound and active metabolites increase in CKD and are associated with CNS and cardiac toxicity
Step 3	Fentanyl/alfentanil	Recommended	Should only be prescribed by a clinician experienced in its use
	Methadone	Recommended	Should only be prescribed by a clinician experienced in its use
	Hydromorphone	Recommended	Appears well tolerated in dialysis patients, but toxic metabolites rapidly accumulate in patients with stage 5 CKD being managed conservatively and should probably be avoided in this situation
	Oxycodone	Insufficient evidence	
	Buprenorphine	Insufficient evidence	
	Morphine/diamorphine	Avoid	Accumulation of metabolites; metabolite morphine-6-glucuronide is a more potent analgesic than morphine itself and accumulates in ESRD. It equilibrates very slowly across the blood-brain barrier. Thus, patients may remain sedated for days after the drug is stopped
	Meperidine	Avoid	Accumulation of normeperidine, which is only half as potent an analgesic as the parent compound, but is 2–3 times more likely to cause CNS toxicity (agitation, myoclonus, and seizures)

CNS, central nervous system.

stage 5 attending dedicated multidisciplinary predialysis care clinics showed that the survival advantage of dialysis may be lost in patients with high comorbidity scores, especially when the comorbidity includes ischemic heart disease.³⁴ Because dialysis is a demanding treatment associated with a tremendous symptom burden, data of this sort should help inform discussions for dialysis options including no dialysis.

INTEGRATING PALLIATIVE CARE

Palliative care can best be thought of as supportive care initiated at the time of diagnosis of a life-limiting illness and occurring throughout the illness, depending on the needs of individual patients (Fig. 75-3). All elements of a successful palliative care program require good patient-doctor communication. Specific

Box 75-2 The Five Essentials of Analgesic Dosing

By mouth:	Whenever possible, drugs should be given orally.
By the clock:	For continuous pain, schedule doses over 24 hours on a regular basis. Additional breakthrough medication should be available on an as-needed basis.
By the ladder:	Use analgesics stepwise according to the World Health Organization analgesic ladder.
For the individual:	There is no standard dose for strong opioids. The right dose is the dose that relieves pain without causing unacceptable side effects.
Attention to detail:	Pain changes over time; thus, there is the need for constant reassessment.

Box 75-3 Facts about Opioid Addiction

1. The incidence of addiction in patients receiving opioid therapy for acute pain relief is less than 1%. The incidence of addiction in patients receiving opioid therapy for chronic pain is less clear but is felt to be less than 5%.
2. Patients will become physically dependent when treated with opioids for a time and therefore will have effects of withdrawal if the opioid is stopped suddenly.
3. Physical dependency is easily managed by a slow taper of the opioid when pain has resolved.
4. Physical dependency is not synonymous with addiction.
5. Addiction is a psychological problem rather than a physical one and is characterized by patients engaging in manipulative behaviors to secure the drug.
6. Individuals who are addicted use opioids for reasons other than pain. Taking drugs for pain management is different from taking them for pleasure.

Table 75-2 Adjuvant Use for Neuropathic Pain in Stage 5 Chronic Kidney Disease

Class of Drug	Dose	Comments
Tricyclic Antidepressant		
Amitriptyline	10–100 mg od	Dose alteration not usually necessary in ESRD, although may be poorly tolerated due to common anticholinergic adverse effects; lowers seizure threshold
Desipramine	10–150 mg od	Less sedating and fewer anticholinergic adverse effects than amitriptyline
Anticonvulsants		
Carbamazepine	200 mg od, titrate weekly to effectiveness Maximum dose 1600 mg	No dose adjustment in ESRD
Gabapentin	100–300 mg od	Cases of neurotoxicity reported when using >300 mg od
Benzodiazepines		
		No dose adjustment required for most benzodiazepines

ESRD, end-stage renal disease; od, once daily.

Table 75-3 Symptom Guidelines

Symptom	Treatment	Dose	Comment
Cramps	Quinine	260–325 mg PO prn	Give before symptoms; limit to 3 doses/day
	Carnitine	1000–2000 mg IV during dialysis	Also used for myopathy, cardiomyopathy, refractory anemia
Restless legs syndrome	Clonazepam	0.5–2.0 mg hs prn	
	Carbidopa-levodopa	25/100 mg hs prn	
	Pergolide	0.05–0.2 mg qd	
	Pramipexole	0.3 mg qd	
Pruritus	Skin moisturizer		Limited effectiveness
	Hydrourea cream		
	Capsaicin	0.025% cream qid	Burning sensation may be problematic; expensive, therefore, not practical for generalized pruritus
	Antihistamines		Trial any H ₁ antagonist; inexpensive, safe, but often poor clinical response
	Clemastine	1–3 mg bid prn	
	Ketotifen	2 mg bid prn	
	UVB light	2–3 times/wk	Effective but potentially noxious in the long term, impractical, and often not available
	Ondansetron	2–4 mg bid	High cost, constipating
	IV lidocaine	100 mg IV during dialysis	Potential seizures
Activated charcoal	6 g qd × 8 wk	Impractical, poorly tolerated	
Plasmapheresis	3–4 exchanges	Impractical	

Continued

Table 75-3 Symptom Guidelines—cont'd

Symptom	Treatment	Dose	Comment
Hypotension, intradialytic or persistent	Alterations to the dialysis bath, temperature, sodium, ultrafiltration		
	Midadrine	1–10 mg tid prn or pre-dialysis	Oral α -adrenergic agonist
	Sertraline	25–50 mg pre-dialysis	
Anorexia	Megestrol	40–400 mg	Has been used in ESRD
	Dronabinol	2.5–5.0 mg bid/tid	Cannabinoid
Lethargy, fatigue	Methylphenidate	5–10 mg AM and noon	Psychostimulant, limited use and effectiveness in ESRD

ESRD, end-stage renal disease.

Figure 75-3 The World Health Organization model of cancer management.

key elements of a renal palliative care program would include regular symptom assessment and treatment protocols or guidelines available at clinics and dialysis units, advance care planning, enhanced referrals to hospice, morbidity and mortality conferences to review the deaths of recently deceased patients, and annual bereavement services for families, loved ones, and staff who wish to celebrate the memories of patients who died in the previous year. Memorial services, in particular, have been rated very highly by attendees and have been shown to markedly influence the culture in renal centers, making it more open to end-of-life care issues.³⁵ Hospice can also significantly enhance end-of-life care for patients with ESRD,³⁶ but United States Renal Data System data indicate that current hospice use is fivefold lower in dying dialysis patients when compared with nondialysis patients.¹ When death becomes imminent, end-of-life care should become the focus of our treatment. Principles of a good death can be seen in Box 75-4. However, achieving these goals takes time. Because death occurs quickly after withdrawal from dialysis, palliative care must be initiated well in advance. The key to end-of-life symptom management is aggressive symptom management before death is imminent. Early pain management is particularly beneficial in reducing the adverse effects of narcotics during the final days of life. Patients in pain who have not been exposed to opioids for some time are at a greater risk of depression, whereas respiratory depression is rare in most terminally ill patients receiving long-term treatment with opioids as long as the dose does not exceed the dose needed for pain relief. Although there remains great concern among health care professionals about using opioids in patients with ESRD or any dying patient for fear of hastening death, the most common form of narcotic abuse in the care of the dying is undertreatment of

Box 75-4 Principles of a Good Death

- Anticipate death and know what to expect
- Retain control of choices and have those wishes respected (advance care planning)
- Maintain dignity
- Control of pain and other troublesome symptoms
- Choose where death occurs
- Easy access to needed care and expertise (palliative care)
- Spiritual and emotional support as needed
- Access to hospice at all locations (home, hospital, nursing home)
- To have those present at death that one chooses
- To have time to say goodbye and choose the time of death (withdrawal from dialysis if appropriate)
- Bereavement services for those left behind

pain.³⁷ Although most symptoms associated with dying with ESRD can be managed before death is imminent, some symptoms such as agitation, twitching, nausea, and shortness of breath due to the accumulation of toxins may become more troublesome in the final days of life after withdrawal of dialysis and need to be anticipated and aggressively treated. Table 75-4 lists the treatment of the most troubling terminal symptoms.

SUMMARY

Expertise in pain and symptom management, psychological and spiritual support, and dealing with issues surrounding end-of-life care defines the specialty of palliative care. As tools for measuring patient symptoms and quality of dying are validated in ESRD, and treatment algorithms are developed and tested, the nephrology community will have the opportunity to incorporate these elements of modern palliative/supportive care into their facilities. Collaboration between renal and palliative specialists will likely help identify ways to achieve best care for these patients in the final phase of life.

Table 75-4 Symptoms at the End of Life

Symptom	Treatment
Retained secretions	Scopolamine
Shortness of breath	Fan, oxygen, patient position (upright), opioids
Agitation (includes involuntary twitching)	Ensure that pain and psychosocial issues addressed, haloperidol, methotrimeprazine (effective for anxiety, restlessness, nausea, and pain), and benzodiazepines
Nausea and vomiting	Metaclopramide, prochlorperazine, ondansetron
Hiccups	Chlorpromazine, haloperidol, metoclopramide

HEMODIALYSIS	837		

In 2004, nearly \$32.5 billion was spent on end-stage renal disease (ESRD) care in the United States.¹ The U.S. government, under the Medicare program, paid approximately 62% (\$20.1 billion), and private insurers and patients paid the rest. Medicare beneficiaries receiving treatment for ESRD represent less than 1% of the Medicare population, but in 2004, they accounted for nearly 7% of the Medicare outlays. Thus, a strikingly disproportionate share of Medicare expenditures is spent annually on Medicare ESRD beneficiaries: ESRD beneficiaries cost an average of at least five times more than beneficiaries in other categories (Fig. 76-1). This disproportionate spending will keep the economics of ESRD treatment under the close scrutiny of legislators and regulators.

The Medicare ESRD program has continued to grow in absolute terms (slightly more than 11.7% in 2003–2004).¹ There is a belief that care can be delivered for a lower cost while offering higher quality care to ESRD patients. In the United States, physicians are paid a monthly fee to care for dialysis patients (monthly capitation payment), and dialysis providers are paid a fixed amount per dialysis treatment per month (composite rate). As this amount has remained relatively stable over time, its value has decreased relative to inflation. Physicians and dialysis providers have had to find ways to increase their productivity by delivering the same or better quality care at a lower cost. To evaluate various measures to improve patient care as well as maintain the economic viability of a practice or dialysis unit, it is useful to understand the economic tools available and how they can be used.

METHODOLOGIES

There are several ways to evaluate the economic and clinical effects of changes in the treatment of ESRD patients.

Cost-Benefit Analysis

This technique compares the costs of an intervention or treatment protocol with the benefits, identified in terms of monetary units. The benefits are typically measured as the change

in medical expenditure and productivity. By converting the outcome to a monetary unit, interventions with a variety of outcomes can be compared. There are drawbacks to these types of analyses. They do not reflect changes in quality of life, and determining the impact on productivity among non-working people, such as the very old or young, is problematic. Although it is difficult to assign a value to a year of life that is free of disease, a standard benchmark is \$100,000.² Multiple interventions can be ranked by their cost-to-benefit ratios. Clearly, as the cost-to-benefit ratio approaches a value of 1, the intervention becomes less desirable.

Cost-Effectiveness Analysis

This technique compares the costs of an intervention or treatment protocol with a measure of effectiveness. It identifies the trade-offs involved in making decisions about care. The costs are monetary, and the effectiveness measure is reported in outcomes (life-years gained or episodes averted) that are adjusted to reflect a measure of quality of life. The results are reported as cost per quality-adjusted life years, or QALYs. The advantage is that it avoids placing a value on a year of life. A recent example is the cost-effectiveness of retransplantation, which was determined as \$9656 per QALY saved.³ Table 76-1 shows the cost per QALY of some treatments for ESRD.

Cost-Minimization Analysis

This technique analyzes two or more interventions or treatment protocols that are believed to be equal clinically, such that the only difference is the economic cost. An example of this type of study would be the cost consequences of using generic versus branded drugs.

Cost-Identification Analysis

This technique identifies and totals all the costs of a particular intervention or treatment protocol. It is useful when comparing a new treatment protocol with an existing one. An example would be the effect of increasing Kt/V (K is the clearance time,

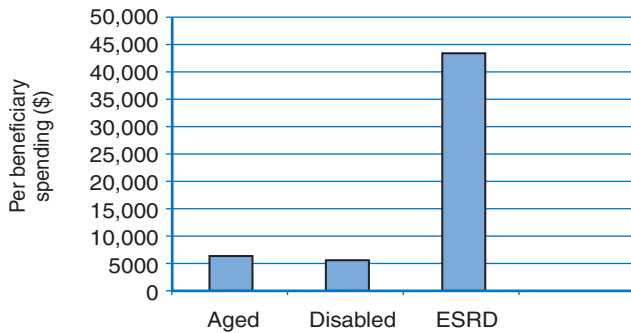

Figure 76-1 Medicare spending by type of beneficiary, 2003. ESRD, end-stage renal disease. (From the Medicare Payment Advisory Commission: A Data Book: Health Care Spending and the Medicare Program. Washington, DC: Medicare Payment Advisory Commission, 2006.)

t is the dialysis time, and V is the volume of distribution) to 1.2 for all Medicare dialysis patients who have a Kt/V of less than 1. This intervention would increase dialysis costs by approximately \$2340 per patient-year at risk, but would decrease nondialysis spending by approximately \$4670, a savings per patient-year at risk of \$2330.⁴ Patient-year at risk is a technique used to standardize reporting of data on patients with varying follow-up times. The expenditures for all patients are summed, and all patients receiving therapy during a given year contribute to the denominator based on the days during that year that they were in the program; thus, a patient who was alive and on hemodialysis (HD) for 30 days in 1999 contributes to the cost (numerator) and the time (denominator) for those 30 days. These economic studies are frequently lumped together under the heading of cost-effectiveness. However, it is important to understand a few methodologic characteristics of these studies.

Perspective

Economic studies consider one or more perspectives, such as patient, provider, and payer. For example, per-patient spending for a transplantation in 1996 was \$148,959, but Medicare

Table 76-1 Estimated Cost per Quality-Adjusted Life Year Gained by Investing in Different Treatments

Treatment	Cost per QALY (US\$)
Kidney transplantation	9099
Home hemodialysis	33,345
Continuous ambulatory peritoneal dialysis	38,387
Hospital hemodialysis	42,444
Erythropoietin for dialysis anemia (with 10% reduction in mortality)	105,057
Erythropoietin for dialysis anemia (with no increase in survival)	243,978

Adapted from Maynard A: Developing the health-care market. The Economic Journal 1991;101:1277-1286 with permission from the publisher.

spending per patient was \$141,968. The difference between Medicare spending and total spending is relatively small for transplantation (5%), and substantially larger for HD (17%).⁴ The difference is accounted for by payments that patients make, such as those relating to Part A (deductible) and Part B (copayments). Therefore, an analysis that ignores these costs would be appropriate from the perspective of the government, but not from the perspective of the patient.

In the example of cost identification cited previously, increasing Kt/V to 1.2 would increase costs to the providers of dialysis care, but would decrease total costs from the government’s perspective. Therefore, it would be cost-effective for Medicare, but not for providers. However, if providers were responsible for all the costs (as they would be under a capitated system), then it would become cost-effective for the provider as well.

The societal perspective measures the net effect of all these perspectives. Generally, health economic studies analyze interventions for their effect on the health care system and the benefits to patients. A truly societal view should also value the effect of interventions on the non-health-related aspects of society, referred to as indirect costs. For example, if daily HD enabled patients to continue to work and be productive members of society, then from a societal perspective, the increased productivity of those patients might well offset any increased costs.

To better understand how these economic tools can be used, we describe the economics of renal replacement therapies.

HEMODIALYSIS

Hemodialysis (HD) is the renal replacement treatment of choice for the majority of ESRD patients in the United States, as 91% of patients receiving renal replacement treatment use this modality compared with 6% for peritoneal dialysis (PD) and 2% for those who go directly to transplantation. Direct comparison of cost-effectiveness between HD and PD is not possible as no prospective study has satisfactorily determined differences in effectiveness between the two modalities. Differences in costs, as determined by Medicare payments, between the two modalities are well documented. In 2004, Medicare paid \$67,733 per patient-year at risk for HD patients and \$48,796 per patient-year at risk for PD patients.¹

Currently, routine payment for HD patients is composed of two main components: the monthly capitation payment made to physicians on a per-patient basis and the dialysis facility reimbursement, which consists of the composite rate payment plus separately billable items such as drugs and biologics.

The monthly capitation payment includes physician services related to all routine dialysis treatment in a given month. Services not covered include surgical services, interpretation of tests, training of patients to encourage self-treatment, services not related to patients’ renal disease, evaluation for renal transplantation, and physician services covered during a hospital stay as an inpatient. The monthly capitation payment was revised in 2004 to encourage physicians to see their patients more frequently and since that time has been based on the number of times that a physician visits a patient while on dialysis during a month. The rates for 2007 were published in

the Federal Register on December 1, 2006, and are displayed in Table 76-2. It is clear from this table that a physician is paid the same whether a patient is seen two or three times per month. It is not yet clear whether this change has resulted in physicians seeing patients two, three, or four times per month on average.

The dialysis facility reimbursement also changed in 2004 as a result of enactment of the Medicare Modernization Act in 2003. Previously, there was a composite rate payment for all necessary dialysis services, equipment, and supplies established in 1981 and effective in 1983. The composite rate has declined substantially on an inflation-adjusted basis. There was no increase in the composite rate between 1983 and 1991. In fact, there were decreases. Subsequent increases in 2000, 2001, 2005, and 2006 were less than half the inflation rate. Dialysis providers point out that the ESRD program is the only payment program in Medicare that does not have an annual inflation adjustment mechanism.

Some dialysis-related pharmaceuticals and supplies are paid as an add-on to the composite rate. These include erythropoietin, vitamin D injections, intravenous iron, and antibiotics. Payments for these ancillary services are an important component of dialysis facility revenues. For example, erythropoietin, iron, and vitamin D account for almost 90% of incremental payments above the composite rate. The Medicare Modernization Act changed the drug reimbursement to an average sales price methodology and added the estimated historical average wholesale price margins to the composite rate, such that the payment rate for most dialysis drugs decreased while the composite rate increased.

There is widespread expectation that some or all of ESRD care will move toward capitation in the near future. There are two ways to achieve this and both are under active consideration in the United States. The first method would capitate the entire cost of care for Medicare beneficiaries with ESRD. This methodology is currently being tested by several organizations, but the results are not expected for a number of years. The second method would only capitate the costs related to the dialysis procedure. It was the intent of the U.S. Congress that the latter would also be tested shortly after passage of the Medicare Modernization Act; however, constructing the test has proven to be difficult. A major concern is that patients require different levels of resources to provide optimal care, and the capitation amount therefore needs to be adjusted to reflect that variation from the average patient. This is called "case-mix adjustment and is an important analytical tool that is used to ensure that the variation (in dollars) that is attributable to patients' needs is accounted for. For example, erythropoietin, iron, and vitamin D account for almost 90% of the incremental cost to the composite rate, yet there is wide variability in the drug utilization from patient to patient and for a single patient over time. Constructing a case-mix adjustment

Table 76-2 The Monthly Capitation Payment: 2007

Visits/Month	Code	2007 Reimbursement Rate (National Average)
1	G-0319	\$184.94
2-3	G-0318	\$233.83
4	G-0317	\$283.09

Table 76-3 Estimated Increase in Dialysis Spending to Achieve 1.2 Kt/V Threshold for All Patients Based on 1997 Levels

	Kt/V VALUE			Total

system with no inherent incentives for overutilization has proven to be difficult. This is true not only in dialysis, but in all capitated systems. Ideally, in a capitated system, patients are provided optimal care and providers are rewarded for delivering optimal care.

Under the current payment scheme, the incentives to decrease use of high-cost health care may not rest with the individuals who have the greatest opportunity to affect change. For example, approximately 40% of total ESRD payments were for hospitalizations.¹ Decreasing hospitalizations would benefit both the Medicare program and the individual patient, but the cost of providing additional services to the patient would likely be borne by the facility. Dialysis adequacy provides a useful illustration of such costs. Increasing Kt/V from 0.82 to 1.33 is associated with a 32% decrease in hospital days, which translates to an average savings of \$5400 per patient.⁵ A recent study found that a 0.1 lower Kt/V was associated with an 11% increase in hospitalizations and \$940 more for Medicare inpatient reimbursement.⁶

Thus, a strategy to deliver an improved level of dialysis should decrease costs. This would require increasing treatment times or increasing the size of the dialyzer used.⁷ At present, however, most ESRD providers have little incentive to do so. An increase in spending by the dialysis facility or supplier of \$393 should increase the Kt/V value of all patients from less than 1.0 to 1.2 (Table 76-3).⁷ An increase in dialysis treatment time is a much less expensive means to increase Kt/V than a change in dialysis membrane (Table 76-4).

VASCULAR ACCESS

There are three types of vascular access used today: arteriovenous fistulas, arteriovenous grafts, and catheters. In 2004, 38% of patients had arteriovenous grafts, 36% had arteriovenous fistulas, and 26% had catheters. Although catheter use has

Table 76-4 Cost Estimates Using Three Methods of Increasing Dialysis Dose Based on 1997 Data

	Increase in Kt/V	Increase in Cost (%)
Increase in dialysis time (10 min)	0.05	1.4
Switch to synthetic membrane	0.05	5.3
Switch to modified cellulose membrane	0.05	20.7

remained relatively constant in this century, graft use has fallen by 30% and fistula use has grown by a third. Medicare has instituted an initiative called Fistula First with a goal of 66% of patients having their vascular access by arteriovenous fistula. A recent article used economic modeling to determine the effect of reaching this goal.⁸

If we reached the 66% goal, and the relative proportions of grafts and catheters remained constant, it is estimated that the shift would provide an additional 35,000 years of survival for the 2003 incident patient cohort, resulting in \$2.25 billion in additional Medicare expenditures. This is offset by the \$840 million savings in vascular access–attributed costs, yielding Medicare’s net additional expenditure of \$1.4 billion over the cohort’s lifetime. Relative to the current mix of access options, the shift to 66% fistula would be achieved at a cost-effectiveness ratio of \$40,000 per year of life gained (\$1.4 billion/35,000 years gained).⁸

It is believed that the current payment rate for creating a fistula discourages surgeons from performing the procedure, yet Schon and colleagues⁸ demonstrate that trebling the payment from approximately \$610 to \$1830 while achieving the 66% goal would only decrease Medicare savings from \$840 million to \$765 million over the life of the cohort and increase the cost-effectiveness ratio by only \$2000 per year of life gained.

PERITONEAL DIALYSIS

PD is the choice of only 8% of dialysis patients in the United States.¹ In the past 10 years, PD has declined by nearly 54% in some parts of the country; however, the highest prevalence of PD tends to be in areas with low population densities, suggesting that people choose PD if going to a facility poses a travel burden. Interestingly, its use has declined in recent years despite evidence that outcomes are generally similar and costs are lower than those of HD.^{9,10} However, there are no prospective, randomized trials that conclusively determine whether equivalent outcomes exist for morbidity and mortality.

Even if we assume equivalent efficacy between the two modalities and thus propose that PD is the least expensive (cost minimization) modality, it may still lag behind HD as the modality of choice. Traditional cost-effectiveness analysis reflects patient preferences and the perceived impact on

quality of life. For PD patients, it is possible that the impact of assuming responsibility for one’s treatment reduces quality of life and thus diminishes the benefits of the lower cost therapy.

TRANSPLANTATION

Transplantation is the most cost-effective renal replacement therapy (see Table 76-1). The high cost of surgery is offset by a “long” period in which the patient requires little medical care. It is the only therapy that, if successful, is curative. However, the number of people eligible for receiving a kidney transplant far exceeds the current supply of donor kidneys. In the prevalent population, the number of patients waiting to receive a kidney has grown at an annual rate of 7% to 12% over the past 3 years, and in 2004 numbered more than 60,000. In the same year, there were only slightly more than 10,000 deceased donor transplants as demand clearly outstripped supply. One way to increase the supply of available kidneys is to use expanded criteria donor kidneys. These kidneys are offered to those on the waiting list who have agreed, in advance, to accept them. In 2004, almost one in five deceased donor kidney transplants used an expanded criteria donor kidney.¹ The use of these donors is significantly more expensive than either cadaver or living-related transplants, although graft survival is similar.¹¹ Are the costs of expanded criteria donor transplants greater than, less than, or equal to alternate renal replacement therapies, assuming roughly similar clinical outcomes? Modeling data show that HD costs would be expected to exceed expanded criteria donor transplant costs after 6.6 years.¹² Therefore, it would be reasonable to proceed with the use of expanded criteria donor transplants, assuming a graft survival, on average, of at least 6.6 years, while collecting economic data to verify the modeling results.

Given the scarcity of kidneys available for transplantation, it is useful to understand the cost-effectiveness of offering retransplantation to patients with failed grafts. The question to be answered is whether improvement in QALYs from a second transplant is greater than the loss of QALYs from someone else having to wait longer for their first transplant. The answer is that this policy has a cost per QALY of \$9656.³ The policy is, not unexpectedly, better for younger patients, lowering costs while increasing QALYs; however, it remains cost-effective for older patients. Costs are lower because the patients would be on dialysis less often and, on average, would be healthier after receiving a transplant.

All payers would like to be able to predict, and therefore manage, their financial risks. A risk (or case-mix) adjustor model allows the payer to measure the degree to which its patient population may differ from a reference population. The risk adjustor may use demographic information, typically age or gender, or clinical information such as cause of renal failure. In patients receiving a transplant, one can construct a risk adjustor model using both demographic and clinical data (Table 76-5).⁴ The base or reference case is a 20- to 34-year-old white woman who has had ESRD as a result of diabetes for less than 1 year who lives in an average-cost city in the Midwestern United States and who will receive a living-related donor kidney for her first transplant. As can be seen in Table 76-4, various demographic factors can dramatically affect the

cost. For example, if she were 45 to 54 years old, as are almost one fourth of transplant recipients, costs would be expected to increase by \$6243. The cost would increase by an additional \$10,333 if she received a cadaver transplant rather than a living-related donor transplant.

It is necessary to understand how good the model is in predicting actual costs. Table 76-6 shows that the model's ability to predict cost is a function of the number of patients or sample size. Thus, for groups of 100 patients, the model would be $\pm 4\%$ to 5% of actual spending 90% of the time and 6% to 8% for 98% of the time. These models are generally useful for predicting costs for larger groups of patients, but they are

based on historical costs and treatment protocols. When new treatment protocols are used, both costs and outcomes change and the old paradigms are no longer valid. Newer immunosuppressive agents demonstrate this well.

The cost of immunosuppressive drugs is an important posttransplantation cost. In the United States, patients who are not at least 65 years of age or disabled have to pay for these drugs beginning 3 years after receiving their transplant. The U.S. Food and Drug Administration approved mycophenolate mofetil in 1995, 12 years after the approval of cyclosporine. Tacrolimus and sirolimus have also been approved. Economic analyses will be important in determining whether

Table 76-6 Percentage of Difference between Actual and Predicted Spending-within-Year Transplant Recipients

Group Size	Mean Predicted as % of Actual Spending*	90% of the Time, Predicted \$ Are within (of Actual Spending)	98% of the Time, Predicted \$ Are within (of Actual Spending)
10 patients	101%	16% to -13%	29% to -16%

these newer drugs alone or in combination with older therapies provide better clinical outcomes at equal or lower cost.¹³ In performing the analyses, the perspective will be especially important as outpatient drug costs 3 years after a successful transplant place a real burden on patients.

CONCLUSION

Applying the tools of economics to ESRD enhances the decision-making powers of patients, providers, and payers. This chapter has identified a variety of analyses and health care scenarios that show that proper use of economic analysis can result in changes in practice and policy that might achieve more efficient use of resources as well as better patient outcomes.

GENERAL PRINCIPLES

Hemodialysis is a complex process performed with apparent simplicity. By attaching an extracorporeal circuit to a patient, the procedure of hemodialysis effectively removes uremic toxins and corrects acid-base disturbances in a manner approximating some of the functions of a natural kidney. This chapter presents a discussion of dialyzers, dialysate composition, water treatment systems, and some of the technical aspects of hemodialysis.

THE HEMODIALYSIS PROCEDURE

Blood Circuit

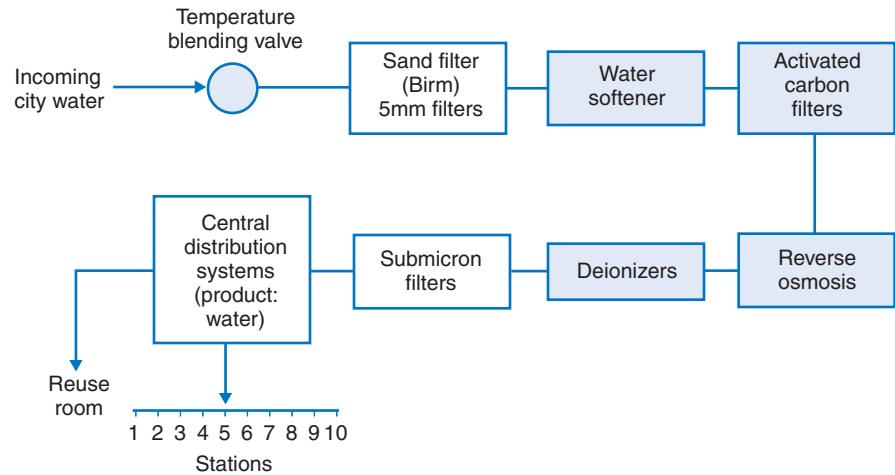

Blood in the extracorporeal circuit is contained within tubing that is connected to the venous and arterial sides of a patient's access (Fig. 77-1). Needles are inserted into the patient's blood access, and blood tubing is connected to the needle hubs. Blood is withdrawn from the arterial segment by the blood pump and pumped through the dialyzer back to the patient via the venous segment of tubing. Inadvertent entry of air into the dialysis circuit, *air embolism*, is a potentially lethal complication and is most likely to occur between the vascular access site and the blood pump. Air can enter the dialysis circuit from areas around the arterial needle, through leaky or broken tubing or tubing connections, and through the saline infusion set. Air traps are located in the blood tubing to trap air and prevent it from entering the patient's circulation. Air detectors are linked to a relay switch that automatically clamps the venous blood line and shuts off the blood pump if air is detected.

Blood pumps used for hemodialysis (HD) are roller pumps that use the principles of peristaltic pumping to move blood through tubing. A compressible part of the tubing (the *pump segment*) is occluded between rollers and a curved rigid track. Elastic recoil refills the pump tubing after the roller has passed over it. The flow rate of the blood pump is dependent on the stroke volume, the speed of rotation of the rollers, and the volume of the pump segment. The blood flow rate displayed on the dialysis machine is based on these three parameters, rather than an actual value from a blood flow probe. This can lead to significantly higher values for the displayed blood flow compared to the true blood flow rate. Incomplete occlusion of the pump segment due to a pump maladjustment leads to a reduced volume of blood with each pump rotation. This is a common cause of overestimation of blood flow and hence clearance. Careful maintenance of the pump is essential to ensure that the prescribed dialysis dose is actually delivered to the patient.

Pressure monitors are usually located proximal to the blood pump and immediately distal to the dialyzer. The proximal monitor, the *arterial monitor*, guards against excessive suction on the vascular access site by the blood pump; the distal monitor, the *venous monitor*, gauges the resistance to blood return to the venous side of the vascular access. Some machines place the arterial monitor distal to the blood pump and proximal to the dialyzer to detect clotting in the dialyzer and more precisely estimate pressure in the dialyzer blood compartment. To prevent blood clotting in the dialyzer, an anticoagulant such as heparin is often infused into the circuit. A peristaltic pump or syringe pump delivers the anticoagulant into blood in the circuit via a T-tube or T-fitting usually located between the blood pump and the dialyzer.

A blood leak detector is usually placed in the dialysis circuit in the dialysate outflow line. If a blood leak develops through

Figure 77-1 Components of a water treatment system. Deionizers are optional if reverse osmosis (RO) produces water of adequate quality. Granular-activated carbon filters are always placed before the RO system to reduce water hardness and prevent scaling of the RO membranes. Deionization does not remove bacteria or endotoxins and should always be followed by ultrafiltration or submicron filters. (From Ismail N, Becker BN, Hakim RM: Water treatment for hemodialysis. *Am J Nephrol* 1996;16:60–72. Reproduced with permission of S Karger AG, Basel.)

the dialysis membrane, the blood leaking into the dialysate is sensed by the blood leak detector and the appropriate alarm is activated.

Dialysis Solution Circuit

Two properties of the dialysis solution that require constant monitoring are conductivity and temperature. A proportioning system dilutes a concentrated dialysis solution with water. If this system malfunctions, patient blood can be exposed to a hyperosmolar dialysis solution, resulting in hypernatremia, or a hypo-osmolar dialysis solution, leading to hyponatremia and hemolysis. The primary solutes in the dialysis solution are electrolytes. Therefore, the concentration of the dialysis solution is reflected by the concentration of electrolytes and their electrical conductivity. Appropriate proportioning of water and the dialysis solution is monitored by a meter measuring conductivity of the dialysis solution fed into the dialyzer.

A temperature monitor prevents complications related to warm dialysis solution. In most situations, the dialysate temperature is higher than that of the patient, resulting in the transfer of thermal energy into the patient. The energy transfer may prevent a rise in total peripheral resistance as fluid is removed by ultrafiltration (UF), resulting in hypotension during hemodialysis. A cool dialysis solution (i.e., 35°C) can be uncomfortable for the patient and may be dangerous when the patient is unconscious. However, the use of cool dialysate otherwise may have therapeutic value in preventing hypotension. Overheated dialysis solution (>42°C), however, can lead to hemolysis. If the conductivity or the temperature is outside the normal range, a bypass valve diverts the dialysis solution around the dialyzer and directly to a drain.

On-line Monitoring

Dialysis machines function as more than just dialysis delivery systems. Built-in monitors assess the physical characteristics of the dialysis solution, as noted above, and accrue data ranging from patient blood pressure and heart rate to treatment parameters, medication data, measures of delivered dialysis dose, plasma volume, thermal energy loss, and even dialysis access recirculation. Computerized medical information systems have been linked with dialysis delivery systems to provide information networks that can control treatments at individual patient

stations while maintaining information and treatment records for future use. Some of these systems include the Smart Connection from Baxter Healthcare, RenalSoft, and a similar system designed by Fresenius Medical Care. Real-time information regarding treatment parameters and patient information also can be visualized during dialysis treatments with the Cobe Centry System 3, the Althin Drake Willock System 1000, and the Fresenius 2008H system. It is now possible to integrate data, such as comparing present and past dialysis treatments, into a real-time display to help gauge therapy, change prescription and ultrafiltration goals, and generate better immediate assessment of a patient's and unit's overall status.^{1,2} Such on-line monitoring that allows sensors from the machine to change treatment parameters has been termed a *biofeedback system* (Fig. 77-2). Automatic biofeedback systems have the potential to reduce adverse events such as hypotension, to monitor the state of the hemodialysis access, and to increase the efficiency of the hemodialysis treatment (Table 77-1).

Other monitoring systems have been developed and are used to monitor access flow and function during dialysis and to make accurate determinations of circulating blood volume during the dialytic procedure. Single- and dual-sensor systems using saline injections and sound velocity dilution calibration have been investigated as a method for accurately determining access flow during hemodialysis.³ Similar efforts have led to noninvasive optical hematocrit monitoring that continually measure hematocrit during dialysis to better determine circulating blood volume.⁴ As blood volume decreases, hematocrit increases. It is often possible to define a hematocrit above which hypotension is likely to occur in a patient. A critical hematocrit can be determined with these devices above which hypotension can be reliably predicted in up to 75% of patients.⁵

The measurement of on-line blood volume with these devices can identify patients who are not near their estimated dry weight. In 18% of hemodialysis patients, a less than 5% decrease in blood volume was noted during routine hemodialysis sessions. In subsequent treatments, increased volume was successfully removed without hypotensive episodes.⁶ The patients were able to have intradialytic fluid removal intentionally increased by 47% (average, 0.8 L). The change in blood volume can be determined noninvasively during hemodialysis with these devices.⁷ Thus, these devices provide an added on-line safety measure to the treatment.

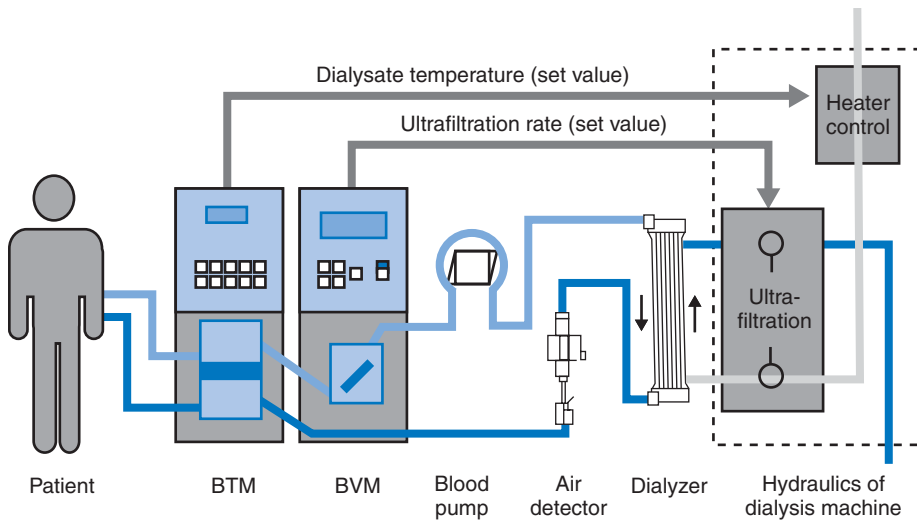

Figure 77-2 Elements of a hemodialysis biofeedback system. Patient input variables include blood pressure, plasma volume, sodium concentration, and plasma temperature. These inputs are measured by an on-line blood pressure monitor, a blood volume monitor (BVM), and a blood temperature monitor (BTM). The inputs lead to automatic adjustments by the hemodialysis machine of the ultrafiltration rate, dialysate temperature, and dialysate sodium concentration.

Table 77-1 On-line Features of the Hemodialysis Machine

Parameter	Consequence
Blood pressure	Changes in ultrafiltration rate, sodium modeling
Plasma volume by hemoglobin	Changes in ultrafiltration rate, sodium modeling
Thermal energy loss/gain	Change in dialysate temperature
Transient change in dialysate	Measurement of Kt/V sodium
Transient change in hemoglobin	Access blood flow, recirculation, cardiac output
Transient change in temperature	Access recirculation

CHARACTERISTICS OF DIALYZERS

The classical view of membranes as inert structures providing solely fluid, ion, and molecular transport is now obsolete. Modern dialysis membranes display numerous physical and adsorptive properties that contribute to the degree to which blood components are activated by them. Membranes that produce little interaction with blood components such as white blood cells and the humoral components of plasma are described as being *biocompatible*. The structural compounds comprising the dialysis membranes may be their simplest distinguishing feature, dividing dialyzers into cellulosic, semisynthetic, and synthetic membranes. Cellulose extracted from cotton lint is dissolved in sodium hydroxide and regenerated, and the membrane is then formed in an acid bath. Cuprophane is generated with an ammonium solution of copper hydroxide. Copper-ammonia-cellulose complexes are extruded into an acid bath, producing a membrane with cuprammonium radicals. This modification yields greater diffusion and UF capabilities for cuprophane membranes compared to straight cellulose. Increasing glycerine content in membranes (average content for cuprophane = 5%) also affects these

characteristics, as does membrane acetylation, yielding greater solute and flux capacities to the membrane.

Synthetic membranes differ from cellulose-based dialyzers in several ways. All cellulose membranes have hydroxyl radicals at the surface, which increase their hydrophilicity (membrane wettability). Techniques that mask hydroxyl radicals enhance hydrophobicity and increase protein adsorption.⁸ Most synthetic membranes are thicker than less permeable cellulosic membranes. Membrane permeability is inversely proportional to membrane thickness and directly proportional to the membrane's intrinsic diffusion coefficient. However, synthetic membranes also display greater intrinsic diffusion coefficients and maintain their thickness when wet. Cuprophane and cellulose acetate membranes swell when wet.^{9,10} A number of synthetic membranes also strongly bind blood proteins, causing decreases in their filtration efficiency.

Membranes can be symmetric or asymmetric. The smooth "skin" side of asymmetric membranes interacts with blood. Asymmetry, obtained by altering membrane precipitation during manufacturing,¹¹ allows for greater diffusive permeability. Hence, asymmetric membranes are very useful for hemofiltration. Polyacrylonitrile (PAN) and polysulfone (PS) membranes are commonly used asymmetric membranes. Polymethylmethacrylate (PMMA) membranes also manifest many of these characteristics. PAN, polyamide (PA), and PMMA membranes have low hydrophilicity and appreciable protein adsorption. Cellulose-based membranes have greater hydrophilicity and less adsorptive capacity.¹¹ Surface charge of the membranes also differs, which affects the sieving of charged solutes.¹²

Types of Dialyzers

Three forms of dialyzers have been used for hemodialysis. Plate dialyzers, used in the early days of dialysis, consist of sheets of membranes separated by a spacer in rectangular compartments that are placed in parallel. This arrangement allows for low blood flow resistance and controlled UF.

Coil dialyzers are constructed from one or several pieces of membrane tubing wound around a central core. A support screen maintains the tubing in position. Blood flows through the tubing while dialysate flows through the supporting screen.

Coil dialyzers are of historical interest only because they are rarely used today. They are highly compliant with high blood flow resistance and variable UF rates.

Hollow-fiber dialyzers are the most common dialyzers in use today (Table 77-2). They consist of 10,000 to 15,000 hollow fibers wrapped in a bundle inside a plastic jacket. Each fiber has a diameter of 200 to 300 μm . Blood flows through the fibers while dialysate flows outside the fibers, typically in a countercurrent fashion. Hollow-fiber dialyzers are easy to use and provide low blood flow resistance, excellent mass transfer, low compliance, and controllable UF. Thus, the extracorporeal blood volume is constant and remains independent of transmembrane pressures. They require low (100–200 mL) priming volumes and are easier to reuse than the other types of dialyzers. Problems associated with early hollow-fiber dialyzers include increased blood clotting, blood loss, and residual ethylene oxide or formaldehyde in the potting compound that anchors the fibers to the dialyzer. These problems have largely been overcome with newer dialyzers.¹³

Dialyzers are classified as conventional, high efficiency, or high flux, but with some imprecision surrounding these definitions. The blood flow and the length of treatment employed when using these dialyzers should not be part of the definition. Nor should urea clearance be used in the definition because clearance, or *dialysance*, varies with blood flow. Instead, the dialyzer is defined by the urea mass transfer coefficient (KoA_{urea}) of its membrane, its ultrafiltration coefficient (K_{uf}), and its degree of hydrophobicity or hydrophilicity (Table 77-3). The latter

parameter governs the permeability of the membrane to high-molecular-weight substances, its degree of biocompatibility, and its ability to adsorb plasma proteins and peptides to its surface.

The conventional dialyzer has a homogenous membrane that permits effective small-sized solute clearance, but its clearance of medium-sized solute is relatively low. Urea clearance at a blood flow of 300 mL/min is less than 200 mL/min. The relatively low hydraulic permeability of the membrane usually permits treatment with a dialysis machine that does not have an ultrafiltration controller. These membranes are cellulose-based and contain nucleophilic groups that permit complement activation unless they have been chemically modified. The blood flow and membrane structural limitations on urea mass transfer preclude their use in high-efficiency hemodialysis.

Both high-efficiency and high-flux dialyzers have membranes with a KoA_{urea} greater than 450 mL/min. Under standard operating conditions (blood flow of 400 mL/min), the urea clearance is more than 250 mL/min. The high-flux membranes are semisynthetic or synthetic thermoplastics that permit some passage of molecules exceeding 10,000 daltons with a clearance as high as 40 mL/min. In addition, significant adsorption of protein and peptides from the blood onto the membrane may occur with these membranes. When the high-flux membrane is chemically modified such that the hydraulic permeability and the permeability to high-molecular-weight substances is reduced, a high-efficiency membrane is created.

Table 77-2 Representative List of Commonly Used Hollow-Fiber Dialyzers

Rights were not granted to include this table in electronic media.
Please refer to the printed publication.

From Daugirdas JT, Blake PG, Ing TS: Handbook of Dialysis, 2nd ed. Boston: Little Brown, 1994, pp 30–52.

Table 77-3 Comparison of Different Dialyzers

Dialyzer	KoA_{urea} (mL/min)	Ultrafiltration Coefficient	Hydrophobic/Hydrophilic	Membrane Structure
Conventional	<450	<10 mL/mm Hg/hr	Hydrophilic	Symmetrical
High efficiency	>450	10–19 mL/mm Hg/hr	Intermediate	Intermediate
High flux	>450	>15 mL/mm Hg/hr	Hydrophobic	Asymmetrical

Thus, with respect to these low-molecular-weight substances, high-flux and high-efficiency dialyzers have similar performance characteristics. They differ in their respective clearance rates of high molecular substances.

Several reasons suggest use of high-efficiency and high-flux dialyzers. Each of these dialyzer types has a low-molecular-weight solute clearance rate far greater than that of conventional dialyzers. They are useful in large patients with high urea volumes to ensure delivery of an adequate level of therapy. In addition, high-flux dialyzers also clear higher-molecular-weight substances, including substances proven to produce toxicity, such as β_2 -microglobulin (MW 11,800 daltons). The surfaces of these membranes are more biocompatible; they cause less activation of complement, less neutropenia, and less immune cell dysfunction during dialysis. Several studies have suggested that biocompatible membranes have a favorable impact on morbidity and mortality in hemodialysis patients. However, the primary motivation behind the use of efficient dialyzers is often the facilitation of shorter dialysis times.

Each dialyzer includes a specification sheet that gives operating information for the dialyzer. The K_{uf} is a function of the hydraulic permeability of the membrane and is expressed as the number of milliliters per hour ultrafiltration achieved for every mm Hg of transmembrane pressure. For example, if the K_{uf} is 4.0, the transmembrane pressure required to remove 1000 mL/hr is 250 mm Hg. This pressure is assessed at the midpoint of the fibers. The values for K_{uf} supplied by manufacturers are derived from in vitro data and usually underestimate the actual clinical K_{uf} by 5% to 30%.¹⁴ Because most hollow-fiber dialyzers have pressure drops across the fibers, because blood is pushed by the blood pump at high pressures (generally 300–350 mm Hg) and exits the dialyzers at lower pressures (generally 100 mm Hg), a “natural” transmembrane pressure of 100 to 150 mm Hg is possible. Thus, with a K_{uf} exceeding 5 mL/mm Hg/hr there is an obligate loss of 500 mL/hr. Patients on these dialyzers may require fluid replacement if their UF requirements are less than 500 mL/hr. Because of this, with most synthetic membranes that have a K_{uf} of more than 6.0, monitoring is necessary to prevent hemodynamically significant errors in UF.

Solute clearance values for urea, creatinine, and vitamin B₁₂ are also often supplied on the specification sheet. Clearance of these substances varies directly with hydraulic permeability, and the normal K_{uf} of many synthetic dialyzers can be altered by the manufacturer without requiring relabeling of the dialyzer. Dialyzer urea clearance is usually reported at various blood flow rates (e.g., 200, 300, and 400 mL/min) but at a specific dialysate flow rate (e.g., 500 mL/min). Creatinine clearance approximates 80% of urea clearance. Vitamin B₁₂ clearance denotes the ability of the membrane to allow passage of solutes of larger molecular weight. High-flux and high-efficiency dialyzers significantly increase vitamin B₁₂ clearance (>100 mL/min at 200 mL/min blood flow) compared to conventional dialyzers (30–60 mL/min at 200 mL/min blood flow). For most dialyzers, in vivo clearance is 20% to 25% less than in vitro clearance.

Dialyzer Reuse

Dialyzer reprocessing for reuse of disposable dialyzers has been widely practiced in the United States, largely due to financial constraints. Dialyzer reuse may be performed manually or with an automated rinsing device. Sterility during reprocessing is maintained either by the use of a chemical disinfectant (such

as paracetic acid, glutaraldehyde, or formaldehyde) or via heat sterilization. After reprocessing, dialyzer adequacy is assessed indirectly by measuring the volume of the dialysis fiber bundle in the blood compartment (*fiber bundle volume*) and by pressurizing the dialyzer to evaluate the structural integrity of the fibers (*pressure test*). For a dialyzer to have acceptable reuse parameters, the fiber bundle volume must be greater than 80% of the initial value, the in vitro ultrafiltration rate must be greater than 20% of the manufacturer’s stated value, and the dialyzer should not leak at a pressure that is within 20% of the maximal operating pressure.

Reuse of dialyzer can impose its own direct effects on reactions during hemodialysis treatment as well as indirectly via alterations in membrane biocompatibility. During repetitive use, plasma proteins can coat dialysis membranes. The use of formaldehyde or glutaraldehyde without a bleach cycle fixes protein to the surface. This attenuates cuprophane-induced complement activation. However, many reuse procedures with these sterilants also include a bleach-containing cleansing cycle. This tends to restore the original surface of the membrane. Reuse with a mixture of peracetic acid and hydrogen peroxide also allows the surface of the membrane to become coated with protein, improving biocompatibility after reuse.

The increasing use of the newer synthetic membranes raises new issues with respect to reuse. Dialyzers manufactured with synthetic membranes have a favorable biocompatibility profile, even on first use. Therefore, there is no direct clinical benefit associated with reuse. However, the substantial cost of these dialyzers often means that reusing them saves costs. Reuse in this setting permits the introduction of these membranes into situations in which the cost would otherwise be prohibitive. A second issue relating to reuse of high-flux synthetic membranes involves changes to the fundamental characteristics of the membrane induced by the reuse procedure. A procedure using bleach increases porosity and makes the membrane more permeable to substances of larger molecular weight. This is obviously advantageous for removing injurious substances such as β_2 -microglobulin. However, if the membrane opens too much, losses of albumin can be substantial. If hydrogen peroxide or peracetic acid is used as the sterilant, an opposite phenomenon occurs, and the permeability of the membrane declines. This is clearly disadvantageous if removal of high-molecular-weight substances is deemed important.

The safety of dialyzer reuse practices has been closely scrutinized, and data concerning the practice have been controversial. Recent data suggest that overall, facilities that reuse dialyzers have a similar risk-adjusted mortality to facilities that do not reuse dialyzers. Most nephrologists believe that patients are not placed at increased risk if strict infection control precautions and quality assurance measures are implemented in dialyzer reprocessing. However, data compiled from the practice of a large dialysis organization suggest that outcome may be improved if dialyzer reuse is discontinued.

Permeability and Porosity

Synthetic high-flux membranes are being increasingly used in the United States. Advantages (or disadvantages) related to their use may result from improved biocompatibility, enhanced clearance or adsorption of large-molecular-weight substances, or both of these features. Even cellulose-triacetate membranes, cellulose-based high-efficiency membranes, have

a relatively good biocompatibility profile. The majority of membranes used for conventional or high-efficiency hemodialysis are cellulose or PMMA based. Polysulfone membranes, when configured as low-flux membranes for use without UF control (i.e., “biocompatibility” dissociated from “flux”), cause intermediate degrees of neutropenia and complement activation. The use of polyvinylpyrrolidone to accomplish this dissociation restores some hydrophilicity to the membrane and, thus, a tendency for complement activation.¹⁵

No large prospective long-term studies have attempted to differentiate effects related to high flux and effects related to biocompatibility. Potential benefits of high flux include enhanced middle-molecule clearance, removal of activated substances such as complement, clearance of β_2 -microglobulin, and better lipid control due to the removal of a circulating inhibitor of lipoprotein lipase.¹⁶ Potential disadvantages include albumin loss into the dialysate and the risk of introducing endotoxins or similar substances into the blood.

It is also apparent that reuse procedures may affect membrane properties. As mentioned, bleach may increase high-flux membrane permeability to substances with large molecular weights, whereas hydrogen peroxide or peracetic acid may decrease the permeability of the membrane. This alteration in permeability affects the membrane only when the membrane is configured as a high-flux membrane (e.g., polysulfone or PMMA), but it is unimportant when the membrane is configured as a low-flux membrane. Reuse procedures may also alter the surface charge, potentially resulting in elaboration of bradykinin.

Membrane Choice for Optimal Dialysis

In recent years, there has been a major shift away from the use of cellulosic membranes in favor of synthetic membranes. This is clearly due to the multiple lines of evidence describing the adverse blood-membrane interactions associated with cellulosic membranes. Membrane selection influences the frequency and number of adverse events related to hemodialysis therapy (Box 77-1). The membrane may also influence the response to vaccines or erythropoietin and injury to various organs, which may be mediated by inflammatory substances generated during blood-membrane interactions. Some recommendations have been suggested regarding membrane choice for optimal dialysis:

1. Newer synthetic membranes offer established and theoretical advantages over cellulosic membranes.
2. Synthetic membranes are beneficial when used in acute renal failure.

Box 77-1 Factors Influencing Membrane Choice

Adsorptive properties
Effect of reuse
Porosity/permeability
Diffusive and convective clearance

From Schulman G, Levin NW: Membranes for hemodialysis. *Semin Dialysis* 1994;7:251–256.

3. There is not enough information about the superiority of one synthetic membrane over another (one reasonable approach is to use the specific membrane found in a given study to ameliorate the particular adverse reaction of concern to the nephrologist); currently, the expense of the membrane should also factor in the decision.
4. Avoid the use of angiotensin-converting enzyme inhibitors when PAN membranes (specifically AN-69) are selected. Caution must also be applied with reused membranes.
5. In most cases, the absence of complement activation and of neutropenia is a useful marker of biocompatibility.

Future Developments in Dialyzers

Advances in membrane manufacturing techniques are likely to yield dialyzers better able to remove substances of larger molecular weight (*middle molecules*). Advances have been seen in techniques for regulating pore-size dimensions, distribution, and geometry; these advances have allowed for increased sieving coefficients for molecules such as β_2 -microglobulin but not larger substances such as albumin.^{17,18} Reducing the inner diameter of the hollow fibers has been shown to increase resistance in the blood compartment, which permits greater filtration of substances in the middle-molecule range.¹⁹ A sorbent system is being developed that also enhances the removal of larger substances; it will be placed in series with the dialyzer in the extracorporeal circuit.²⁰

DIALYSATE COMPOSITION

One of the major aims of hemodialysis is the restoration of normal ion concentrations. As such, the levels of individual ions in the dialysate can be set to their desired plasma levels; however, in some instances dialysate levels are set for the diffusible fraction of the ion found in plasma. Dialysis solutions have undergone substantial changes since the inception of hemodialysis.

Dialysate Glucose

In the early 1960s, high glucose concentrations in dialysis fluid were used to provide osmotic pressure for water removal. However, advances in hydraulic UF and the demonstration that high dialysate glucose (>320 mg/dL) increased the risk for hyperosmolar syndrome, postdialysis hyperglycemia, and hyponatremia²¹ rendered the use of high dialysate glucose obsolete. Contemporary dialysis fluids range from glucose-free to slightly hyperglycemic (up to 200 mg/dL).²² Most noninsulin-dependent diabetic patients tolerate dialysis with glucose-free dialysate well, despite losing 25 to 30 g of glucose across the dialyzer. However, this glucose loss may potentiate hypoglycemia^{23–25} and adversely affect hemodialysis catabolism, raising levels of free amino acids during dialysis²⁶ and increasing the intradialytic protein catabolic rate.²⁷ Ketogenesis and gluconeogenesis are usually sufficient to maintain serum glucose in the physiologic range despite reductions in plasma insulin, lactate, and pyruvate. By contrast, physiologic dialysate glucose (200 mg/dL) has few adverse effects,²⁸ aside from aggravating hypertriglyceridemia. Dialysate glucose can affect potassium removal, the risk of dialysis disequilibrium syndrome, and postdialysis fatigue. In general, an optimal dialysate glucose

concentration is 100 to 200 mg/dL. However, in diabetic patients, insulin doses may require adjustment to account for this dialysis-imposed *glucose clamp*, in which levels of plasma glucose may be kept constant during dialysis as a result of the concentration in the dialysate.

Dialysate Sodium

Investigators comparing hemodynamic changes induced by conventional dialysis, ultrafiltration, and sequential ultrafiltration dialysis found that plasma osmolality plays a pivotal role in maintaining hemodynamic stability during hemodialysis.^{29–31} Iso-osmolar fluid removal improved hemodynamic stability. During hemodialysis, the fall in extracellular osmolality is more rapid than corresponding changes in intracellular osmolality, resulting in extracellular to intracellular (ECF–ICF) fluid shifts, exacerbating volume depletion. This decline in plasma osmolality (P_{osm}) is more apparent with rapid solute removal that is not counteracted by sodium diffusing from dialysate into the blood. A low-sodium dialysate (<135 mEq/L) favors this ICF shift because plasma becomes more hypo-osmolar after sodium movement from plasma to dialysate.

The reduction in plasma volume with UF and HD also increases plasma oncotic pressure and decreases capillary hydrostatic pressure. Both forces mobilize extravascular fluid. The degree to which plasma volume decreases depends on the UF rate, fluid shifts, and the plasma refilling rate from the ICF and interstitial fluid compartments. By maintaining a constant P_{osm} , a high-sodium dialysate minimizes intracellular water movement during dialysis, preserving plasma volume.^{29,30} A stable P_{osm} during dialysis enhances blood pressure stability,^{31,32} especially when the dialysate sodium concentration is increased to at least 135 mEq/L.^{33–35} Hypo-osmolality impairs peripheral vasoconstriction during volume removal and exacerbates autonomic insufficiency. Hence, high-sodium dialysate, by maintaining stable P_{osm} , favorably influences compensatory mechanisms during volume removal.^{27,36} Improved hemodynamic stability is paralleled by a reduction in cramping, nausea, vomiting, and headache during dialysis.^{35–37} Furthermore, patients given higher dialysate sodium concentrations (144 mEq/L) appear to have fewer hypotensive episodes.³⁷ Thus, a dialysate sodium concentration of 140 to 145 mEq/L is reasonable, gauging the optimal concentration to the patient's blood pressure, weight gain, and symptoms on dialysis.

The use of dialysates with higher sodium concentrations may lead to higher interdialytic weight gain because of increased thirst stimulated by an elevated serum tonicity. In addition, higher dialysate sodium concentrations are associated with a net increase in total sodium shift into the patient. There was concern that hypertension or volume overload would be a consequence of this practice. Although higher dialysate sodium concentration is associated with increased interdialytic weight gain, the excess volume is able to be removed successfully by carefully and frequently assessing the patients' estimated dry weight and increasing the ultrafiltration rate as needed. Adverse symptoms such as hypotension are mitigated by the greater hemodynamic stability associated with the higher sodium concentration. Indeed, it can be argued that of all the changes in dialysate composition, the greatest improvement in intradialytic symptoms such as hypotension has been the result of the introduction of dialysate with a higher sodium concentration.

Sodium Modeling

A strategy combining high and low levels of dialysate sodium is known as *sodium-gradient hemodialysis*. A high-sodium dialysate of 150 mEq/L is used initially and is then reduced automatically and progressively toward isotonic levels in one of three patterns. A linear, ramp pattern lowers sodium concentration at a constant rate throughout the treatment. A step pattern maintains the high sodium level for three quarters of the treatment time and decreases it to 135 to 140 mEq/L for the rest. Finally, sodium is reduced from 150 to 140 mEq/L in an exponential pattern. Sodium modeling can be incorporated into the biofeedback system described in this chapter. Sodium modeling allows the greatest sodium influx to the patient when urea and solute flux from the body is greatest. Theoretically, this technique is associated with fewer symptomatic hypotensive episodes, although in reality it may not be any more advantageous than fixed high-sodium dialysate.^{38–41} However, a recent prospective, crossover study in hypotension-prone hemodialysis patients (used as their own controls) compared standard dialysis (138 mEq/L sodium) to step-sodium modeling, isolated ultrafiltration, cool dialysate, and constant high-sodium dialysate (144 mEq/L). The volume removed was similar throughout the study. Sodium modeling and cool dialysate were found to be of greatest benefit in reducing hypotensive events and preserving postdialysis blood pressure. High-sodium dialysate was also shown to reduce hypotensive events. The authors conclude that sodium modeling should be the first approach in patients with intradialytic hypotension.⁴² Sodium-gradient dialysis may be beneficial in the initial dialysis of patients with advanced renal insufficiency and urea concentrations higher than 200 mg/dL to decrease the risk of dialysis disequilibrium syndrome. Modeling may also be useful in patients with a low KoA_{urea} , who have delayed urea equilibration between ICF and ECF.^{29,43,44} Although sodium modeling has been of unquestionable benefit in selected patients with intradialytic hypotension, it should not be used indiscriminately because of the risk of volume overload and hypertension. The patient must be carefully monitored for symptoms of volume overload.

The concepts of sodium modeling can also be applied to UF, resulting in volume to be removed early in the dialytic session when the patient's intravascular volume is greatest. The UF rate can be gauged to decrease during dialysis as the intravascular volume declines: 50% UF during the first hour, 25% UF during the second hour, 15% UF during the third hour, and 10% UF during the fourth hour. Such a protocol, especially in combination with concurrent sodium modeling, may minimize cramping and symptomatic hypotension in patients prone to these complications.⁴⁵

Dialysate Buffer

Bicarbonate dialysis is the dialytic treatment of choice, conferring benefits over acetate dialysis, including a lower incidence of hypotension and hypoxemia and improved left ventricular stroke work.^{46–50} Metabolism of acetate occurs predominantly in skeletal muscle. Healthy people can metabolize acetate at a rate of up to 300 mM/hr, whereas for elderly people and those on chronic hemodialysis, who often have decreased muscle mass, the rate is approximately 3 to 3.5 mM/hr.^{51,52} If acetate accumulates due to its reduced rate of metabolism to bicarbonate,

reduced myocardial contractility and lowered systemic vascular resistance may occur. In addition, the low PCO_2 of the acetate buffered dialysate results in the net transfer of carbon dioxide (CO_2) from the blood to the dialysate, leading to hypoventilation and hypoxia. Thus, older patients, especially those with underlying myocardial dysfunction and low muscle mass, may benefit from bicarbonate dialysate. Dialyzers with a large surface area and increased blood flow rates enhance acetate transfer to the patient, thereby increasing the acetate load for patients to metabolize.⁴⁸

The hemodynamic instability associated with acetate dialysate buffer may be related to a number of factors, including adenosine production,²⁹ interleukin-1 release,⁵³ and hypoxemia as a result of myocardial hypoperfusion and dysfunction.⁵⁴⁻⁵⁷ Dialysate delivery systems also may play a role, because a change from a single-pass system to recirculation with cellulosic membranes can reduce hypoxemia during acetate dialysis.⁵⁸ In acetate dialysis, the transfer of CO_2 from blood to dialysate results in reflex hypoventilation and hypoxemia with a decrease in the respiratory quotient (CO_2 produced)/(O_2 consumed), producing hypocapnia and hypoventilation. Bicarbonate dialysate solutions with elevated PCO_2 levels reduce reflex hypoventilation and hypoxemia. However, when the dialysate bicarbonate concentration is more than 35 mEq/L, hypoventilation may result from metabolic alkalosis.

Higher dialysate sodium concentrations may improve hemodynamic instability related to acetate dialysis.^{33,57-59} Nonetheless, bicarbonate is the dialysate buffer of choice in critically ill patients. In chronic hemodialysis patients, bicarbonate buffer may not offer added hemodynamic benefit when the sodium dialysate is higher than 140 mEq/L. However, patients who metabolize acetate poorly tolerate bicarbonate dialysate better.⁶⁰

Dialysate Calcium

Because dialysate calcium equilibrates with the diffusible (ionized) fraction of plasma calcium, a dialysate calcium concentration of 2.5 mEq/L is equivalent to a serum calcium level of 10 mg/dL. High dialysate calcium (3.5 mEq/L) or low dialysate calcium (<2.5 mEq/L) has certain risks and advantages. Serum calcium level is often reduced in advanced renal failure as a result of reduced sun exposure, depressed production of 1,25-dihydroxyvitamin D_3 , and decreased absorption of calcium from the gastrointestinal tract. High dialysate calcium concentration can improve indices of metabolic bone disease and reduce parathyroid hormone levels.^{61,62} High dialysate calcium concentration can also improve hemodynamic stability during dialysis⁶³⁻⁶⁵ as well as echocardiographic measures of left ventricular function.^{66,67}

The main disadvantage of high dialysate calcium concentration is hypercalcemia. Calcium-based phosphate binders, used preferentially over aluminum-containing antacids and oral or intravenous 1,25-dihydroxyvitamin D_3 , are presently used in the management of hyperphosphatemia and to prevent uncontrolled secondary hyperparathyroidism.⁶⁸⁻⁷⁰ High dialysate calcium concentration can limit the effectiveness of this therapy by inducing hypercalcemia. To obviate hypercalcemia, lower dialysate calcium concentrations (2.5 mEq/L) have been combined with high doses of oral calcium-containing phosphate binders and vitamin D sterols to control hyperphosphatemia⁷¹ and secondary hyperparathyroidism.⁷² Mild hypotension was the only major adverse effect associated with such dialysate calcium

concentrations.^{66,71} Thus, a dialysate calcium concentration of 2.5 to 2.7 mEq/L is recommended for hemodynamically stable patients, particularly for those prone to hypercalcemia during treatment with vitamin D and calcium salts.

Dialysate Potassium

Dialysis is the primary route of potassium elimination for hemodialysis patients^{73,74} although the gastrointestinal tract also contributes to potassium excretion in individuals with end-stage renal disease. Typically, 50 to 80 mEq of potassium are removed with each dialysis treatment.⁷⁵ The rate of potassium removal during dialysis is largely a function of the concentration gradient between blood and dialysate. Blood and dialysate flow rates, dialyzer efficiency, and factors affecting transcellular potassium distribution, such as pH, insulin, and catecholamines, are also important.

The majority of dialyzed potassium originates intracellularly and must cross cell membranes before crossing the dialyzer membrane. Plasma potassium concentrations tend to rebound 4 to 5 hours after dialysis, averaging 30% greater potassium values than immediately postdialysis.⁷⁶⁻⁷⁸ This postdialysis rebound is important because an immediate postdialysis potassium value of more than 5.5 mEq/L is not considered safe, and supplementation for postdialysis hypokalemia is not warranted.

The potassium rebound after hemodialysis reflects a two-compartment model. Potassium transit across cell membranes is believed to be the limiting factor in its removal during dialysis. As a result, potassium dysequilibrium is established, with transfer from ICF to ECF compartments during dialysis failing to replenish external potassium transfer to the dialysate. Net internal transfer continues after the termination of dialysis until a new steady-state potassium gradient is established. Potassium transfer is affected by many factors. Acidosis promotes potassium efflux from cells, and alkalosis causes cellular potassium uptake; this is particularly important in hypokalemic patients with metabolic acidosis. Dialyzing patients with depletion of total body potassium can worsen hypokalemia when concurrent metabolic acidosis is corrected with parenteral bicarbonate during dialysis. Also, plasma tonicity can affect potassium distribution because tonicity favors movement of potassium into extracellular spaces and consequently its removal during dialysis. Hypertonic saline solution or mannitol, used to treat hypotension or muscle cramps during dialysis, thus favors potassium removal during dialysis. Glucose-free dialysate also promotes the dialytic removal of potassium by lowering plasma insulin concentrations.

Low dialysate potassium concentrations can precipitate atrial and ventricular ectopic beats, especially in patients with left ventricular hypertrophy or impaired left ventricular function or in patients taking digoxin.⁷⁹ The frequency of arrhythmias is greatest during the first 2 hours of dialysis, when potassium flux is greatest. Therefore, in some arrhythmia-prone patients, a "sequential" reduction in dialysate potassium level may be safer for potassium removal.

WATER TREATMENT

Hemodialysis patients are exposed to as much as 600 liters of dialysis water a week, and to all its potential contaminants. Although water treatment systems (WTS) used by dialysis

centers produce high-quality water for safe dialysis, WTS are susceptible to malfunction or to user error. Technical advances, such as high-flux and high-efficiency dialysis, reuse, and bicarbonate dialysate, have heightened awareness about water safety.

Hazards Associated with Dialysis Water

Numerous reports of patient injury or death have been linked to improperly treated or inadequately monitored water used for hemodialysis. High levels of aluminum sulfate in dialysate water have been linked to bone disease (osteomalacia and aplastic bone disease) and dialysis-associated encephalopathy (dialysis dementia).^{80–82} Limiting aluminum levels in dialysate water to 10 µg/L has resulted in a continued decline in the incidence and case fatality rate of dialysis dementia.^{83,84}

Chloramines, used as bactericidal agents in treatment of municipal water, denature hemoglobin by oxidation and inhibition of the hexose monophosphate shunt. Chloramine exposure during dialysis has been associated with hemolysis, Heinz body hemolytic anemia, and methemoglobinemia.^{85–87} Other compounds also have adverse effects in dialysis patients. Sodium azide, used frequently with glycerine as a preservative for WTS ultrafilters, has been associated with hypotension.⁸⁸ Fluoride, even at the recommended level of 1 mg/L, can cause osteomalacia and bone disease⁸⁹ as well as cardiac death.⁹⁰ Excess calcium and magnesium in dialysate water have been linked to the *hard water syndrome*, a constellation of symptoms that includes nausea, vomiting, weakness, flushing, and fluctuations in blood pressure.^{91,92} Untoward effects have also been reported with nitrates (methemoglobinemia with cyanosis and hypertension),⁹³ copper (hemolytic anemia),^{94,95} and zinc⁹⁶ in excess concentrations in dialysate water. Formaldehyde toxicity, secondary to improper disinfectant use and leaching from sediment filters, has caused hemolytic anemia and death.^{97,98}

Essential Components of Water Purification

The efficiency of a WTS depends on the capacity of the system, the nature of the water supply, variations in quality of municipal water, and the quality of product water. Figure 77-1 represents a WTS with temperature-blending valves, filters, water softening, carbon filters, reverse osmosis (RO), and deionizing stations. Temperature-blending valves mix incoming hot and cold water to provide an optimum water temperature for downstream components. Most RO membranes work with greatest efficacy at 77°F (26°C). Water temperature lower than 77°F reduces the flow rate of the RO system; water warmer than 100°F (38°C) may damage RO membranes. Filters remove particulate matter from the water. Sand filters remove particles of 25 to 100 µm, cartridge filters extract particles of 1 to 100 µm, and submicron filters remove particles as small as 0.25 µm. In general, 5-µm filters are accepted as adequate protection for equipment and water treatment.

Water softeners, often sodium-containing cation-exchange resins, can remove calcium, magnesium, and other polyvalent cations from the feedwater. Because calcium and magnesium are removed from water in exchange for sodium, the amount of sodium released can be problematic. Removing calcium and magnesium prevents these ions from depositing on the

RO system with resulting malfunction. Granular activated-carbon filters absorb chlorine, chloramines, and other organic substances from the water. Carbon filters are porous, with a high affinity for organic material. Granular activated-carbon filters can be contaminated with bacteria if they are not serviced properly or exchanged frequently. The size of the activated carbon bed depends on the empty bed contact time (EBCT). The EBCT calculation is:

$$\text{EBCT} = V \times 7.48 \text{ (gallons/cu. ft.)}/Q$$

where V = carbon volume required in cubic feet and Q = water flow rate in gallons/min. EBCT differs for different substances. Recommended EBCT values are 6 minutes for chlorine removal and 10 minutes for chloramine removal. The Food and Drug Administration recommends that two granular activated-carbon filter-filled tanks are used in series, with each tank having an EBCT of 3 to 5 minutes.

Reverse osmosis applies high hydrostatic pressure to a solution across a semipermeable membrane to prepare a purified solvent. RO rejects 90% to 99% of monovalent and divalent ions and microbiologic contaminants, producing water safe for dialysis. An RO device is often used as pretreatment to deionization, as an economic measure to provide longer service life for the deionization system. Subsequent deionization of permeate (product) RO water is usually unnecessary. Deionization removes all types of cations and anions. The cation-exchange resin exchanges hydrogen ions (H⁺) for other cations; the anion-exchange resin exchanges hydroxyl ions (OH⁻) for other anions. Deionizing efficacy is determined by measuring the resistivity of the effluent. Resistivity varies with temperature; therefore, resistivity monitors must be temperature-compensated. When the deionization system is exhausted, previously adsorbed ions can elute into the effluent, causing ion-related toxicities.^{94,99}

MICROBIOLOGY OF HEMODIALYSIS SYSTEMS

Water used by HD centers is usually obtained from the community water supply. Community water treatment can reduce bacteria and the concentration of endotoxins in the water, yet the dialysis WTS (apart from ultraviolet light) can still become contaminated with bacteria and endotoxins.^{100,101} The primary microbial contaminants in dialysis fluids are water bacteria, gram-negative bacteria, and nontuberculous mycobacteria (Box 77-2). Nontuberculous mycobacteria in particular are problematic. They do not produce endotoxins, but they are more resistant to germicides than gram-negative bacteria and are infectious, especially in the setting of inadequately disinfected dialyzers.^{102–105} They can survive and multiply in RO-treated water or deionization water that contains little organic matter.¹⁰⁰ Indeed, the Centers for Disease Control documented the presence of nontuberculous mycobacteria in the water of 83% of dialysis centers surveyed in 1984.¹⁰²

Sterilization destroys microorganisms, including highly resistant bacterial spores. Disinfection, in contrast, eliminates all but the highly resistant microorganisms.^{106,107} Disinfection can be high level, intermediate, or low level, depending on the germicidal activity. High-level disinfection inactivates all microorganisms except bacterial spores. Low-level disinfection

Box 77-2 Naturally Occurring Water Bacteria Commonly Found in Hemodialysis Systems**Gram-negative Bacteria**

Pseudomonas
Flavobacterium
Actinobacillus
Alcaligenes
Xanthomonas
Serratia
Achromobacter
Aeromonas

Nontuberculous Mycobacteria

Mycobacterium chelonae
M. fortuitum
M. goodii
M. scrofulaceum
M. avium

M. intracellulare

From Ismail N, Becker BN, Hakin RM: Water treatment for hemodialysis. *Am J Nephrol* 1996;16:60–72. Reproduced with permission of S. Karger AG, Basel.

reduces the bacterial population to a “safe” level. WTS disinfection generally utilizes low-level disinfection. High-level disinfection is more often used for dialyzer reprocessing.

PYROGENIC REACTIONS DURING HEMODIALYSIS

Pyrogenic reactions (PRs) often develop during or after dialysis treatment, with an incident rate of 0.5% to 12%.^{107,108} A *pyrogenic reaction* can be defined as chills (or rigors) and/or fever (oral temperature > 37.8°C [100°F]) in a previously afebrile patient with no recorded signs or symptoms of infection before dialysis.^{107,108} Hypotension is sometimes also included in the definition. Other signs of a PR are headache, myalgia, nausea, and vomiting. The symptoms usually begin 30 to 60 minutes into the dialysis treatment and stop shortly after, unless they are extreme. There appears to be little difference in rates of PRs between different hemodialysis modalities.¹⁰⁸

Three lines of evidence implicate endotoxin in the pathogenesis of PR: (1) antiendotoxin antibodies in dialysis patients,^{109,110} (2) *Limulus* lysate reactivity in plasma from patients experiencing PRs,^{111,112} and (3) an association of PRs with fluids contaminated with gram-negative bacteria.^{112,113} It is unlikely that microorganisms cross intact dialyzer membranes because of the diameter of their pores. Rather, it is endotoxins and other pyrogenic substances that probably gain access to the patient’s bloodstream across the dialysis membrane.^{112,114} Some of these substances are bacterial pyrogens released by gram-negative bacteria (see Box 77-2),¹¹⁵ including lipopolysaccharides (LPS), the A-layer LPS subunit, other LPS fragments, peptidoglycans, muramylpeptides, exotoxins, and exotoxin fragments.

Assays for determining the permeability of pyrogens include the *Limulus* amoebocyte lysate assay, the mononuclear cell

(MNC) assay, radiolabeled LPS fragments, and neutrophil activation. Many bacterial substances, such as endotoxin fragments, are small enough to penetrate tight cellulosic membranes. These fragments go undetected in the *Limulus* amoebocyte lysate assay. Thus, measuring in vitro cytokine production by MNCs may be more sensitive and specific, allowing detection of these low-molecular-weight substances.^{116–118}

The inability to detect passage of endotoxin across intact dialyzer membranes during conventional or high-flux dialysis^{119–121} suggests that additional factors are probably involved in PRs. Bacterial products such as endotoxins induce human MNC production of interleukin-1 and tumor necrosis factor alpha.¹¹⁵ Experimental data suggest that cultured MNCs increase interleukin-1 production in response to LPS, LPS fragments, or plasma proteins in the dialysate.^{118,121,122} Moreover, LPS-like fragments can cross dialyzer membranes.¹²² Interestingly, plasma must be present on the blood side for cytokine induction. LPS-binding proteins, complement, and other plasma proteins can be activated by regenerated cellulosic membranes¹²² and amplify MNC cytokine production.^{122–125} Evidence also suggests that endotoxin fragments can cross intact hemodialysis membranes and induce MNC cytokine production, particularly in the presence of plasma.

Additionally, severe PRs in hemodialysis patients appear to correlate with the extent of bacterial contamination in the dialysate.¹¹³ Recent studies have suggested that up to 35% of all water samples and 19% of all dialysate samples in the United States do not comply with AAMI (Association for the Advancement of Medical Instrumentation) standards (<200 colony-forming units [CFU]/mL in water, 2000 CFU/mL in dialysate). Presumably, bacteria adhere to and grow in the dialysis tubing, releasing endotoxin and endotoxin fragments into the dialysate.

Changing dialysis practices have had an impact on PRs, which have been reported with higher frequency in association with dialyzer reuse. Theoretically, use of RO and membrane integrity monitoring should lead to a decrease in the incidence of PRs.¹²⁶ The use of bicarbonate and high-flux dialysis have been linked with a higher risk of PRs.⁸⁴ In dialysis units that used bicarbonate dialysis, a higher frequency of PRs occurred only in centers that also performed high-flux dialysis. Centers that prepared their own bicarbonate dialysate also were more likely to report pyrogenic reactions than centers that used commercially prepared bicarbonate dialysate. The method for preparing bicarbonate dialysate entails potential contamination.¹²⁵ Acetate dialysate is prepared from a single concentrate at a concentration that prohibits bacterial growth (4.8 mol/L). However, bicarbonate dialysate must be prepared from two concentrates: an acid concentrate with a pH of 2.8 that is not conducive to bacterial growth and a 1.2 mol/L bicarbonate concentrate with a neutral pH. Bicarbonate concentrates can support halotolerant endotoxin-producing, gram-negative organisms. As many as 10⁵–10⁶ CFU/mL can develop in liquid bicarbonate in as few as 10 days after dialysate preparation. Because of this, active quality assurance should be exercised to use liquid bicarbonate concentrate as soon as possible after manufacture or receipt by the dialysis center. Tanks and distribution lines containing stored liquid bicarbonate concentrate should be disinfected at least twice weekly.

Finally, dialyzer reuse practices have been associated with PRs independent of high-flux dialyzer use.⁸⁴ Manual dialyzer

reprocessing has been associated with a higher incidence of PRs compared to automated reprocessing.¹⁰⁶ Manual reprocessing can allow defects in dialyzer membranes to go undetected because testing for integrity of the membrane is generally not performed with this technique.

Several outbreaks of patient infection and PRs have been reported in HD patients.^{127–130} Many of these involved substandard reprocessing or poor water quality.¹⁰⁷ Inadequate mixing of germicide or the use of a new germicide (e.g., chlorine dioxide) have been implicated in several of these outbreaks.^{108,131,132} Errors in the design and maintenance of a WTS were responsible for PRs and gram-negative bacteremia in another center.¹³² Damage to RO membranes contributed to this outbreak, leading to the recommendation of a thorough inspection for RO damage whenever the RO system removes less than 90% to 95% of total dissolved solids. Finally, although HD has been safely conducted outside the hospital or dialysis center setting, fatal endotoxemia has occurred in dialysis patients at summer camp,¹³³ illustrating the importance of dialysis WTS in different environmental conditions.

The formaldehyde content used for disinfection also may be important for PRs. Formaldehyde 2% does not effectively or reproducibly eradicate mycobacterial organisms within 36 hours.^{104,128} If the concentration of formaldehyde is increased to 4%, mycobacteria cannot survive at room temperature beyond 24 hours.¹³⁴ However, there is increasing evidence that lower concentrations of formaldehyde (e.g., 1%) can be effective if the dialyzers are kept at a temperature of 37° to 40°C.¹³⁵

Hemodialysis may be performed acutely to treat complications of acute kidney injury or remove dialyzable toxins or chronically to treat end-stage renal disease (ESRD). In either situation, to be effective hemodialysis requires a well-functioning access to the bloodstream. To serve this role, significant demands are placed on the vascular access. It must be easy to connect to the external hemodialysis blood circuit, capable of delivering the blood flows of up to 400 to 500 mL/min required for high-efficiency hemodialysis, and must remain patent and free of infection despite frequent, repetitive use—particularly in long-term maintenance hemodialysis. For acute hemodialysis the focus is on ease of creation and rapid access to the circulation. For chronic maintenance hemodialysis the access must be convenient to use and have a low incidence of long-term complications despite repetitive use.

The National Kidney Foundation/Kidney Disease Outcomes Quality Initiative (K/DOQI) established clinical practice guidelines for vascular access in 1997. The guidelines were updated and revised in 2006.^{1,2} These guidelines, based on published evidence and expert opinion, represent an excellent resource and an authoritative guide to direct clinicians in the choice and maintenance of the vascular access. They also serve as a source for clinical performance measures being developed by the Centers for Medicare & Medicaid Services (CMS) ESRD Quality Initiative. This chapter endorses most of the K/DOQI guidelines; the reader is referred to published recommendations for more discussion on the background and rationale for those guidelines.^{1,2}

VASCULAR ACCESS FOR ACUTE HEMODIALYSIS

Dual-lumen, noncuffed temporary catheters are best used for acute hemodialysis.³ These catheters are rigid at room temperature, thus aiding insertion, but become pliable when they achieve body temperature after insertion. Acute dialysis catheters may be

placed in one of three anatomic locations: the femoral, jugular, or subclavian vein.

In most patients, the femoral vein is the easiest site to insert a catheter; it is associated with the lowest risk of life-threatening complications. The major disadvantage of use of the femoral vein is that the patient generally must lie down while the catheter is in place, and there is a high rate of infection if the catheter is left in place for more than 5 days.⁴ Thrombosis is also a concern with femoral vein catheterization. A femoral catheter is particularly useful for short-term treatment of acute renal failure, emergent stabilization of a critically ill patient with a coagulopathy, or acute toxin removal when the patient will only need a few dialysis treatments. It is preferable to use femoral catheters 19 to 20 cm long, because recirculation in the femoral position is considerably lower than when shorter catheters (13–15 cm) are used.⁵

For patients who require longer periods of hemodialysis, the jugular approach is preferable.³ Catheters placed under aseptic conditions in either jugular vein may be left in place for up to 3 weeks. The complication rate associated with insertion into the jugular is higher than that associated with femoral-line insertion; complications include pneumothorax and arterial or great vein puncture with associated mediastinal, pleural, or pericardial hemorrhage.^{3,6} There is also the risk of introducing an air embolism when inserting these catheters, and patients should be maintained in the Trendelenburg position while the catheter is being inserted until the caps have been placed on the end of the catheter. The risk of perforation of the great vein is probably greatest in patients who have previously had many line insertions and have developed central vein stenosis. A chest radiograph is imperative after a jugular or subclavian line is inserted and before initiation of hemodialysis, both to exclude the development of a pneumothorax and to confirm that the catheter is positioned appropriately. If there is any doubt that the tip of the catheter is not within the great vessels, a vascular study should be performed by injecting a small amount of contrast into the catheter under fluoroscopic control.

Subclavian vein catheterization can also be performed, with a rate of immediate complications and catheter-life similar to that seen with jugular vein insertions. However, central vein stenosis—a late complication—occurs more commonly with subclavian than with jugular insertions.^{7–9} Thus, subclavian vein catheterization for hemodialysis should be avoided in patients with chronic renal failure who will need future arteriovenous access placement.

Use of ultrasound guidance for catheter insertion can decrease the rate of complications and is strongly recommended.^{3,10,11} Ultrasound is used before the procedure to localize the position of the vein and artery and exclude intramural thrombus. Use of real-time ultrasound while cannulating the vein can further enhance successful catheterization and reduce the incidence of inadvertent arterial catheterizations.

All temporary catheters carry the risk of bacterial infection due to contamination of the insertion tract or lumen.^{3,6} Strict adherence to aseptic technique in placement and care of the catheter is crucial (for details see www.cdc.gov/mmwr/preview/mmwrhtml/rr5110a1.htm and Posa and colleagues¹²). At the first sign of systemic infection or the development of fever, the catheter should be removed. The most common offending organism with jugular lines is *Staphylococcus aureus* or *S. epidermidis*.^{13–15} Any signs of systemic infection should be treated with antibiotics after appropriate cultures. Typically vancomycin (10–20 mg/kg, up to a maximum dose of 2 g) is given initially, pending bacteriologic identification of the organism and sensitivities. Patients with femoral catheters are also likely to become bacteremic from gram-negative organisms and should be treated with vancomycin and either a third-generation cephalosporin, quinolone, or an aminoglycoside, pending the results of blood cultures. The culture results should guide antibiotic therapy after the initial dose. Combinations of vancomycin and an aminoglycoside must be used with caution because of the risk of ototoxicity. These patients must be treated for 2 to 3 weeks when cultures are positive and to confirm adequate antibiotic levels. The trough level of vancomycin is 10 to 15 mg/mL. Patients with some residual renal function or those receiving continuous venovenous hemofiltration will have increased vancomycin clearance and require more frequent dosing.

Uremic patients who develop *S. aureus* bacteremia have a relatively high incidence of metastatic complications; these patients may develop infectious endocarditis, septic arthritis, or epidural abscess.¹⁵ Patients who develop a metastatic focus of infection should have any accumulation of pus drained and should be treated for up to 6 weeks with parenteral antibiotics.

VASCULAR ACCESS FOR MAINTENANCE HEMODIALYSIS

Three main classes of vascular access are currently used for maintenance hemodialysis: the autogenous arteriovenous fistula (AVF), arteriovenous bridge graft (AVG), and central venous catheter (CVC).¹⁶ Common types of AVFs include the radiocephalic fistula, brachiocephalic fistula, and basilic vein transposition to the brachial artery.^{17–19} Most current AVGs are composed of expanded polyfluorotetraethylene (ePTFE)

and are placed either in a loop configuration in the forearm (brachial artery to cephalic or basilic vein), straight configuration in the upper arm (brachial artery to axillary vein), or a loop configuration in the upper thigh (femoral artery to vein).²⁰ Compared to ePTFE, biografts have a lower infection rate but tend to degenerate quicker.^{21–23} Autogenous vessels also have other uses (e.g., coronary artery bypass), so they generally are not favored for AVGs over ePTFE. Tunneled central venous catheters (TCCs) are most commonly placed in the internal jugular vein but can be placed in the subclavian vein, femoral vein or, in exceptional circumstances, directly into the inferior vena cava via a transhepatic or translumbar approach.²⁴

Selection of a Permanent Vascular Access

An algorithm for the selection of a vascular access is shown in Figure 78-1. Each type of vascular access has advantages and disadvantages. An AVF placed in the most distal location possible in the arm is the preferred access.^{1,25} In our practice an AVF is preferred not only for the first, but also subsequent accesses even if the patient is already on dialysis.²⁶ Once mature, an AVF has the longest cumulative patency, lowest incidence of thrombosis or infection, lowest per patient per year cost, and is associated with prolonged patient survival (though reported differences in survival are admittedly confounded by indication).^{14,27–36} The main disadvantages of an AVF are a slower rate of maturation and a higher rate of primary access failure, leading to the increased need for CVCs and subsequent surgery for new access creation.^{37–43} Hence, early referral for access creation about 6 months before the expected need for hemodialysis is important to avoid the need for a central venous catheter.^{34,44,45} For patients already on hemodialysis, placement of an AVF can lead to longer CVC use with its attendant risks. In this setting, whether the long-term benefits of an AVF outweigh the short-term increased risks compared to an AVG has not been completely resolved.⁴² However, we prefer to use an AVF whenever possible and try to be proactive about assessing and facilitating AVF maturation and early catheter removal. The choice between using a basilic vein transposition fistula versus an AVG is debated, but we generally prefer to create the basilic vein transposition fistula before an AVG.^{46–53} An additional problem for AVFs is that they can be more difficult to cannulate, particularly when they are deep or not fully developed. The “graftula,” created by placing a piece of ePTFE around the adventitial side of the fistula, is a novel approach to the problem of a deep fistula that can be used in selected instances to provide an easier target to cannulate.

An AVG is preferred over a central venous catheter.^{30,35,36,54–56} In our practice an AVG is primarily a salvage procedure, reserved for situations in which adjacent vessels are not available to create a suitable AVF.²⁶ An AVG can typically be cannulated and used for dialysis within 3 to 6 weeks after creation and is often easier than a new AVF to cannulate.^{57–60} Grafts can also be used to create heroic types of vascular accesses, such as axilloaxillary arteriovenous grafts or arterioarterial grafts.^{61–63} However, AVGs have a significantly increased frequency of stenosis, thrombosis, and infections, leading to an increase in per patient per year costs and morbidity compared to an AVF.^{29,30,35,36,54–56,64} Frequent access

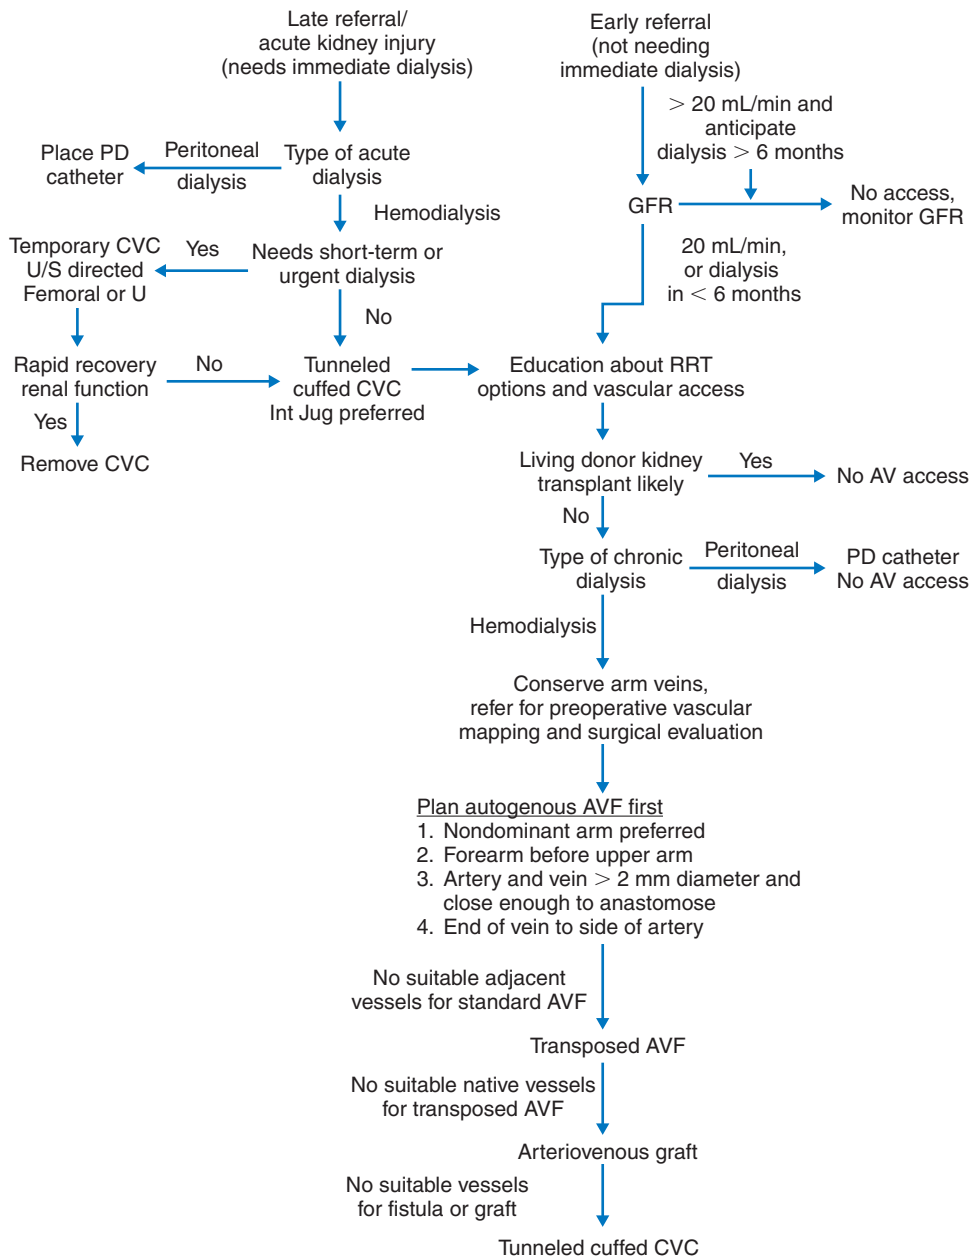

Figure 78-1 Algorithm for vascular access selection.

monitoring is also needed to detect and treat AVG stenosis before it leads to thrombosis.^{1,65}

Central venous catheters are discouraged. They should be reserved only for short-term bridging to a permanent AVF or AVG and in situations in which an AVF or AVG is contraindicated (e.g., severe congestive heart failure) or cannot be constructed.^{24,66} CVCs are appealing because of the ease and rapidity of creation, the absence of repetitive needle sticks, and lack of problems with postdialysis hemostasis.²⁴ These advantages are more than offset by the higher risk of infection, leading to increased hospitalizations, higher mortality, and the highest per patient per year costs of any access.^{29,34–36,41,44,54,67} Problems with catheter clotting and slow blood flow rates with CVCs also can limit adequate dialysis.^{24,55,68} CVCs carry the additional risk of developing central venous stenosis (particularly with subclavian catheters) that is difficult to treat and may prevent subsequent creation of an AVF or AVG in that arm.^{7,9}

Preoperative Evaluation and Vascular Mapping

Creation of a successful AVF is enhanced by careful preoperative evaluation.⁶⁹ In most cases this should include preoperative arterial and venous imaging.^{70–76} The preoperative history includes a review of any prior arteriovenous access surgeries, the location of any current or past CVCs or peripherally inserted central catheters, the presence of a transvenous pacemaker or other significant operations involving the extremities, and the presence of symptomatic organic heart disease. Symptoms and signs, such as swelling, atrophy, ulcers, skin lesions, surgical scars, catheters, pacemakers, and pain or ischemia of the extremity or central vessels, are noted.¹ Arterial pulses in the extremity should be palpated and an Allen's test performed to assess hand perfusion by the radial and ulnar artery.⁷⁵ Venous anatomy in the extremity is assessed using a tourniquet. However, given the age

and underlying vascular disease in the current ESRD population, the history and physical examination are usually not sufficient to determine the optimal site for AVF creation.^{70,77} Preoperative vascular mapping has been shown to increase the percentage of successful AVFs created.^{72–74,77} At this time no cross-center standardized protocol exists. Duplex ultrasonography is the current procedure of choice to look at the arterial and venous anatomy for significant stenoses, thrombosis, an atypical vascular pattern, and vessel size. It has a reported sensitivity of 80% to 90% and specificity of 90% to 100% for significant arterial and venous stenosis (>50% luminal narrowing) and other lesions in the distal extremity.^{70,78,79} However, duplex ultrasonography is less sensitive in detecting central arterial or venous stenosis.^{70,78} If this is suspected on clinical grounds or the patient has had a current or prior CVC (especially a subclavian catheter), further imaging by contrast-enhanced digital subtraction angiography or magnetic resonance angiography is recommended.⁷⁸ Both of these techniques have some risks, including contrast-induced nephropathy and nephrogenic systemic fibrosis, respectively.^{80–82} The risks need to be discussed with the patient before the procedure.

Vessel size is an important determinant of successful fistula creation.^{38,74} This appears to be a threshold effect: below a critical size the likelihood of a successful outcome is negligible, but above that threshold, size does not appear to be strongly predictive of outcome.^{83–86} The exact threshold has not been established and may vary with surgical expertise and measurement technique but is probably approximately 2 to 2.5 mm for both arteries and veins.^{69,74,85} Venous size should be measured using compression of 30 to 40 mm Hg. Some surgeons favor performing the examination themselves in the operating room just before access creation because vessel size may vary from preoperative assessment due to changes in ambient temperature or sympathetic activity. Studies have also reported that endothelial function, as measured by brachial artery flow-mediated dilation, or venous compliance, as measured by venous plethysmography, are predictive of AVF success.^{86,87} However, these are not routinely measured.

Unique Considerations

A number of unique situations influence the timing and choice of vascular access placement. Patients under consideration for kidney transplantation pose a challenge as to when to place a vascular access. Because deceased donor transplantation is unpredictable and may require that the patient wait for several years on dialysis, I recommend placement of an AVF in such patients. However, for patients with a high likelihood of receiving a living donor kidney before starting dialysis, it seems an acceptable risk to delay vascular access placement until that workup is completed. Patients with severe heart failure from organic heart disease are unique because they may decompensate after vascular access placement due to their inability to increase cardiac output sufficient to meet the demands of an arteriovenous shunt.^{88,89} A tapered AVG may be considered in such cases to limit the volume flow through the fistula, but most of these patients will likely need a CVC for dialysis. No well-defined parameters exist to predict this outcome. However, patients with organic heart disease who have significant dyspnea at rest or minimal exertion should probably start hemodialysis with a CVC rather than

an arteriovenous shunt. If their symptoms improve on dialysis, conversion to an AVF should be reconsidered. Similarly, patients whose remaining lifespan from comorbidities apart from ESRD is predicted to be very short (i.e., a few months) that nonetheless choose to go on hemodialysis may be suitable candidates for a CVC rather than AVF. However, given the uncertainty in predicting survival in any given person, it seems prudent to recommend placement of an AVF for most patients who are deemed suitable candidates for maintenance hemodialysis. Age, race, and gender should not deter placement of an AVF.^{18,69,90,91} With appropriate preoperative vascular mapping, an AVF can be constructed; it remains the first access of choice.

Process Improvement: Achieving Increased Fistula Prevalence

Whereas surgeons and radiologists are responsible for placement of most permanent hemodialysis accesses in the United States, the referring nephrologist plays a critical role in choosing the surgeon, educating the patient and primary care physicians, timing the referral, and communicating with the interventionalist and dialysis staff the type of access that he or she wants in their patients.^{38,69,92,93} The nephrologist, in concert with the access surgeon and dialysis staff, should establish access practice goals for the unit.^{25,94} Clinical practice guidelines for vascular access established by K/DOQI are a good source for these goals.¹ The CMS ESRD Quality Initiative has currently established three clinical performance measures for vascular access: (1) number of hemodialysis patients with an AVF, (2) number of hemodialysis patients with a catheter, and (3) monitoring of AVGs for stenosis.⁹⁵ Current targets are for at least 50% incident patients and 40% prevalent patients to have an AVF. The future goal of the CMS Fistula First Breakthrough Initiative is a 65% prevalence of AVFs by 2009. K/DOQI recommends that less than 10% of hemodialysis accesses should be permanent CVCs (those not used as a bridge to AVF).¹ These targets are challenging but achievable.^{91,96–99}

The Fistula First National Vascular Access Improvement Initiative has established 11 core strategies to increase fistula placements. These strategies are listed in Box 78-1. Additional information and resources for implementing these strategies can be found at the Fistula First website (www.fistulafirst.org/index.htm). Central to achieving these goals is the creation and maintenance of a vascular access database.^{69,100} At a minimum the database should contain the date, location, and type of each access placement; the surgeon who placed the access; and the date and reason the access was abandoned. Optimally, the database should also record the date of first use for hemodialysis and the date and description of each access study, complication, and intervention, along with the person who performed the intervention. (An electronic database program is available on request from the author.) A vascular access coordinator needs to be assigned to input the data into the database in a timely manner. The database then allows for ongoing continuous quality improvement to monitor progress toward achieving the clinical vascular access practice goals established by the unit. Periodic meetings with the surgeon and vascular access management group are needed to review the data and implement changes to achieve the established goals or to set new goals if prior targets have been attained.

Box 78-1 Core Strategies to Increase AVF Placements (Fistula First Initiative)

1. Routine CQI review of vascular access
2. Timely referral to nephrologist
3. Early referral to surgeon for "AVF only" evaluation and placement
4. Surgeon selection based on best outcomes, willingness, and ability to provide access surgeries
5. Full range of appropriate surgical approaches to AVF evaluation and placement
6. Secondary AVF placement in patients with AVGs
7. AVF placement in patients with catheters where indicated
8. Cannulation training for AVFs
9. Monitoring and maintenance to ensure adequate access function
10. Education for caregivers and patients
11. Outcomes feedback to guide practice

Most of the strategies listed in Box 78-1 to increase AVF prevalence are self-explanatory. Further details can be found at the Fistula First website, as well as in recent reviews.^{38,69,93,101} Early identification of patients with stage 4 chronic kidney disease when glomerular filtration rate is approximately 30 mL/min allows for timely education about types of dialysis and vascular access.⁶⁹ Preservation of vessels by avoiding intravenous or arterial catheters, particularly in the nondominant upper extremity, is important but admittedly often difficult to enforce. Choice of a surgeon with an interest in vascular access, who is willing to participate in continuous quality improvement and has expertise in creating all types of AVFs (as well as AVGs if needed), is critical. Early referral to the surgeon about 6 months before the expected time of starting hemodialysis is crucial to allow time for AVF maturation, particularly if a radiocephalic AVF is placed.^{45,97,102,103} Recommendation of arm exercises for 4 to 6 weeks before and after AVF placement may assist maturation, but this has not been conclusively proven.^{104–106} Most AVFs should be mature and safe to cannulate by 4 to 8 weeks after surgery.^{57,107,108} Re-evaluation of the AVF at this time allows earlier detection and intervention, if necessary, for AVFs that are slow to mature. If primary AVF failure occurs, there is time to create a second AVF before hemodialysis is needed (or minimize catheter use if already on dialysis). Utilizing the services of a nurse coordinator who assists in education and coordinating care for patients with stage 4 chronic kidney disease is an invaluable asset to help with vascular access education and referrals.^{69,100} Patients already dialyzing with CVCs should be routinely identified and considered for AVF (or AVG) placement. Patients with an AVG that fails should be evaluated by vascular mapping for conversion to an AVF.¹⁰⁹ We have had experience with converting failed AVGs to an upper arm AVF; the AVF survival in these cases is the same as in primary upper arm AVF placements.¹¹⁰ Finally, ongoing education and training of patients and hemodialysis staff in proper techniques of AVF cannulation and the benefits of an AVF for the patient and healthcare system is important to achieve acceptance of the change.¹¹¹

Fistula Maturation

Fistula maturation is the process of arterial and venous dilation that permits an increase in access blood flow sufficient to allow repetitive cannulation with two needles to support maintenance hemodialysis. It is the principal problem associated with AVFs.^{112,113} Primary failure due to impaired maturation occurs in approximately 25% to 50% of new AVFs.³⁸ However, maturation as currently defined in terms of clinical usability is an unsatisfactory criteria and leads to delays in detecting and treating the failing AVF. To promote earlier detection and salvage of a failing fistula, K/DOQI proposed the Rule of 6's (>600 mL/min flow rate, 0.6 cm vein diameter, and no more than 0.6 cm below the skin as measured by duplex ultrasonography by 6 weeks after access creation) as a working biologic definition of fistula maturation.¹ Failure to reach this goal should prompt a search for reversible etiologies. The goal is laudable, but the definition has not been validated and may be too aggressive, potentially leading to unnecessary investigations and intervention. More work is needed to establish the optimal criteria.¹¹⁴ Importantly, examination of the access by an experienced observer looking for how far the palpable thrill and bruit extend up the arm, as well as the diameter, depth, and length of usable vein, and a pulse augmentation test may be nearly as accurate at predicting maturation.^{113,114} However, the specific criteria to use have not been validated across centers.

The etiologies of impaired maturation include stenosis, impaired arterial and/or venous dilation, thrombosis, and the presence of accessory veins.^{112,113} Failure to mature as defined above should prompt a search for reversible etiologies. The physical examination (Table 78-1) and a duplex ultrasound can help to assess the likely etiology, but contrast angiography will be needed for any intervention.^{113,115,116} The most common etiology for impaired maturation is a focal venous stenosis,

Table 78-1 Physical Examination Characteristics of a Normal and Stenotic Access

Parameter	Normal	Stenosis*
Thrill	Present at arterial anastomosis and decreases along vein	Present at site of stenotic lesion (decreased at arterial anastomosis)
Pulse	Soft, easily compressible throughout access	Water-hammer upstream of stenosis Falls off after stenosis
Bruit	Low-pitched Continuous Diastolic and systolic	High-pitched Discontinuous Systolic only

*Abnormalities listed are for the two extremes: completely normal and severe stenosis. With lesser degrees of stenosis the findings will be between these two extremes.

From Beathard GA: Physical examination of the dialysis vascular access. *Semin Dial* 1998;11:231–236.

typically at or just downstream of the juxta-arterial anastomosis.^{40,117–119} This lesion can be treated successfully with angioplasty, although the lesion often recurs, requiring additional angioplasty.^{117,119–121} If angioplasty fails to correct the stenosis and improve maturation, consideration should be given to using the downstream good vein to create a new arteriovenous anastomosis at a more proximal site on the artery.¹²² Another cause of impaired maturation is accessory veins that divide the flow and limit maturation of a single superficial target vein. This has been treated successfully by ligating the accessory veins to increase flow through a single superficial vein.^{117,123} Finally, early thrombosis or a generalized impairment of arterial and venous dilation are reportedly less common but are difficult to treat and typically require creation of a new access. Careful attention should be paid to whether an upstream arterial stenosis is also present that is limiting access blood flow and fistula maturation.¹²⁴ An aggressive interventional approach to impaired fistula maturation has led to excellent results in some reports but more modest success in others.^{117,119–121} The important message is to not wait too long for a fistula to mature before identifying an etiology and working on a solution.

No pharmacologic strategies have been proved to improve AVF maturation. Several small studies have suggested that using an antiplatelet agent at the time of surgical creation may prevent early thrombosis and allow an AVF to mature.¹²⁵ Recently a large multicenter randomized controlled trial demonstrated that administration of clopidogrel for 6 weeks starting at the time of fistula creation decreased early thrombosis from 19.5% to 12.2% at 6 weeks. However, despite the impressive decrease in thrombosis, fistula suitability for hemodialysis, which was only 40% in the placebo group, was not improved by treatment with clopidogrel.¹²⁵ Small trials studying allogeneic endothelial cells or human elastase placed on the adventitial side of the vein and arteriovenous anastomosis are currently underway as possible novel therapies to improve fistula maturation.¹¹²

MAINTENANCE OF THE VASCULAR ACCESS

Stenosis and Thrombosis

Stenosis leading to impaired access flow and thrombosis is the most common etiology of arteriovenous shunt failure.¹²⁶ Median primary patency of an AVG is less than 1 year; and median secondary patency is about 2 years.^{27,47,64,110,127,128} In the absence of routine monitoring, approximately 70% to 95% of AVG failure is due to thrombosis (0.6–1.4 thromboses/access-year).^{64,129–131} Stenosis is found to underlie the thrombosis in approximately 85% of cases.^{126,132} Stenosis and thrombosis occur much less frequently in an AVF.^{27,64,110,127,128,130} Whereas median primary patency of a lower arm AVF is similar to an AVG (due to failed maturation), median secondary patency, particularly for an upper arm AVF, is typically longer and can exceed 3 to 4 years.¹¹⁰ Overall, the thrombosis rate in an AVF is approximately 0.25 per fistula-year when the initial maturation phase is included, but drops to approximately 0.1 per fistula-year in a mature AVF.^{130,133,134} Stenosis in an AVG typically occurs at the vein-graft anastomosis or downstream vein; stenosis in an AVF typically occurs at the arteriovenous anastomosis or in the immediate downstream vein.^{117,132} Importantly, stenosis

may also occur in the feeding artery, the graft itself, or the central veins.^{124,132}

Access Surveillance and Prophylactic Angioplasty

Observational studies have demonstrated that a regular vascular access surveillance program can detect stenosis and that early intervention with angioplasty can decrease the rate of subsequent thrombosis in grafts and fistulas.^{129,130,134–136} A recent small, randomized study has also reported that prophylactic angioplasty of hemodynamically significant stenosis increases survival in fistulas.¹³⁷ However, several recent small, randomized, controlled trials in AVGs found mixed results for preventing thrombosis; only one study found evidence for prolonging AVG survival.^{138–143} Nevertheless, routine surveillance and prophylactic angioplasty of hemodynamically significant stenoses is currently recommended to decrease thrombosis and prevent the resulting disruption of dialysis unit function and missed dialysis sessions that otherwise occur.⁶⁵

Development of access stenosis can be detected by various techniques (Box 78-2). Broadly, these techniques include a physical examination (Table 78-1); measurement of access recirculation, intra-access pressure (IAP), and access flow rate (Qa); and imaging studies for direct visualization of the stenosis.¹ The optimal approach would have a high sensitivity and specificity for the detection of access stenosis, be easy to perform on a frequent basis, and be inexpensive. Currently no surveillance technique has been shown to meet all of these criteria. A key principle of access surveillance, however, is that due to biologic and technical variability a single measurement of access flow or pressure has limited usefulness.^{144–148} Performing repetitive measurements over time, as well as trend analysis, can improve sensitivity and specificity.^{148,149} For AVGs, in which the risk for thrombosis is high, reliance simply on the physical examination and measurement of access recirculation is not sufficient; additional surveillance tools are needed.^{65,150} However, for AVFs the risk of thrombosis even at low flow rates is much lower. For AVFs, careful attention on a regular basis to the physical examination, measures of access recirculation (including adequacy of dialysis), and the ability to achieve the target blood flow rate may be sufficient to detect and correct stenosis before thrombosis.^{133,150} Regular measurements of IAP, Qa, or duplex ultrasonography (stenosis detection) have all been validated as surveillance tools with modest accuracy to detect stenosis.^{148,151–156} Measurement of IAP is better suited for detecting stenosis in an AVG, where the stenosis is typically downstream of the needles, than in an AVF, where the stenosis is typically upstream of the needles.^{157,158} Measurement of Qa or use of duplex ultrasonography is equally suited for surveillance of an AVF or AVG.

For measurement of IAP, the blood pump flow rate is set at zero and the blood line clamped proximal to the venous drip chamber.¹⁵⁹ IAP is then determined from the drip chamber pressure after correcting for the decreased hydrostatic pressure due to the height of the drip chamber above the access. The IAP is normalized for the mean arterial pressure (MAP) taken in the contralateral arm (IAP/MAP). An IAP/MAP ratio in an AVG consistently greater than 0.5 (venous drip chamber) or 0.75 (arterial chamber) is an indication to investigate for a downstream venous stenosis.⁹⁵ Alternatively, an equivalent IAP can be calculated from the drip chamber pressures measured at a fixed low blood pump flow rate. This is done using a computer algorithm

Box 78-2 Arteriovenous Access Surveillance Techniques and Criteria for Fistulogram**A. Clinical Criteria**

Recommended for both fistulae and grafts. Use of additional monitoring technique recommended for grafts (see below).

Trend analysis more specific than isolated measurement or event.

Examine access each dialysis (see Table 78-1)

Arm swelling (if persistent)

Inability to cannulate access

Aspiration of clot from access

Prolonged postdialysis bleeding at cannulation sites

Increased recirculation (trend data over time, measured at least monthly)

Indicator dilution techniques (e.g., UDT, GIT, K dilution) >0% is abnormal (if persistent)

Urea-based recirculation test not recommended, >10% abnormal if persistent or increasing

Inability to maintain target blood flow (trend Q_b over time)

Inadequate dialysis (trend monthly K_t/V or URR)

Increasing DVP or decreasing DAP (trend over time; *not* a substitute for IAP)

B. Additional Monitoring^{1,2}

Recommend using at least one of these three techniques for monitoring grafts; optional for fistulae.

1. IAP Monitoring (at least monthly; perform trend analysis)

Measurement:

IAP (mm Hg) = static drip chamber pressure at 0 pump speed with ultrafiltration off or line between dialyzer and drip chamber clamped (mm Hg) + height of drip chamber above access (cm) \times 0.74

Mean arterial pressure (MAP) = DBP + 1/3(SBP – DBP) measured in contralateral arm

Arterial pressure ratio (APR) = arterial IAP/MAP

Venous pressure ratio (VPR) = venous IAP/MAP

Criteria for AVG

Venous stenosis: APR > 0.75 or VPR > 0.5

Intra-access stenosis: APR \geq 0.65 and VPR < 0.5

Arterial inflow stenosis: APR < 0.3 and clinical criteria

Criteria for AVF (less sensitive for detecting upstream lesions most common in fistulae)

Venous stenosis: APR > 0.43 or VPR > 0.35

Intra-access stenosis: APR \geq 0.65 and VPR < 0.35

Arterial inflow stenosis: APR < 0.13 and clinical criteria

2. Access Flow (Q_a) Monitoring (at least monthly; perform trend analysis)

Measurement:

Various techniques.¹⁶² UDT using saline infusion in the reversed dialysis flow configuration is standard (e.g., HD01, Transonics Systems)

Criteria for AVG

Q_a < 600 mL/min or

Q_a < 1000 mL/min and \geq 25% decrease in Q_a over 4 months

Criteria for AVF

Q_a < 400 mL/min or

Q_a < 1000 mL/min and \geq 25% decrease in Q_a over 4 months

3. Stenosis Monitoring (duplex ultrasound; quarterly)

Measurement:

Requires experienced technician and appropriate ultrasound equipment. Evaluate entire arterial, graft, and venous limbs of access circuit,

Criteria (AVG or AVF)

Evidence of stenosis by B mode and color Doppler

Peak systolic velocity ratio \geq 2.0 (compared to upstream vessel)

DAP, dynamic arterial pressure; DVP, dynamic venous pressure; GIT, glucose infusion technique^{239,240}; UDT, ultrasound dilution technique²³⁹; URR, urea reduction ratio.

based on hematocrit, flow rate, and needle size to correct for the pressure drop in the needle.¹⁶⁰ A company (Vasc-Alert, W. Lafayette, Ind.) has been established that uses on-line machine data to calculate equivalent IAP and notifies the clinic when the threshold for investigation has been exceeded.

Access blood flow is typically measured using an indicator-dilution technique.¹⁶¹ In most cases this is done with the arterial and venous blood lines reversed in the “recirculation” configuration. Multiple techniques are available for Qa, but the gold standard is the ultrasound dilution technique (UDT).^{162,163} In this technique, an ultrasound probe placed on the dialysis tube withdrawing blood from the downstream needle detects the dilution of saline injected upstream into blood flowing through the access. Typical threshold values used for detecting stenosis by UDT are 600 mL/min in an AVG or 400 to 500 mL/min in an AVF, or a drop of 25% in Qa from baseline when Qa is below 1000 mL/min for both an AVG and AVF.^{1,2} The main disadvantages of Qa measurements are the need to reverse the blood lines and the need for an experienced technician to make the measurements. Newer technologies may obviate these problems in the future.

Use of duplex ultrasonography can provide both anatomic and flow data to assess the presence of stenosis.^{153–155} Unfortunately, it requires a skilled technician, is time intensive, and cannot be done effectively during dialysis, so it is not a practical screening tool for most dialysis units.

At this time the choice of which surveillance techniques to use should be based on considerations of cost, availability of equipment, efficiency, and type of accesses currently used in the unit. At a minimum, all accesses should be regularly monitored by clinical criteria as shown in Box 78-2. For AVFs this may be sufficient without resorting to additional techniques.^{133,150} For AVGs, it is recommended that an additional technique, such as IAP, Qa, or duplex ultrasonography surveillance, be used.

K/DOQI recommends that with monitoring and surveillance the incidence of AVG thrombosis should be less than 0.5 episodes per patient-year at risk; the median AVG patency should exceed 2 years.^{1,2} It is important to note that a significant fraction of AVGs (15%) will thrombose with a high flow rate above 600 mL/min and no definitive stenosis.¹⁵⁸ This may be due to volume depletion, hypotension, or access compression. Thrombosis in this situation will not be prevented by active surveillance for stenoses. For an AVF, K/DOQI recommends a thrombosis rate of less than 0.25 episodes per patient-year at risk and median patency of more than 3 years.

A stenosis in which the lumen diameter is $\leq 50\%$ of the reference diameter of the normal upstream or downstream vessel is considered hemodynamically significant and is an indication for intervention.^{164,165} Either angioplasty or surgical revision can be used to treat hemodynamically significant access stenosis in an AVG or forearm AVF.^{166–172} However, angioplasty is generally the first choice. Stenosis in an upper arm AVF is treated with angioplasty. Central venous stenosis is difficult to treat and often requires stenting in addition to repeated angioplasty or occasionally surgical bypass grafting.^{7,173–178} Median patency is typically no more than 6 months after angioplasty of an AVG but greater than 6 months in an AVF, particularly in a forearm AVF.^{132,166,172,179,180} Thrombosis of an AVG or AVF can be

treated by either percutaneous thrombolysis (mechanical or pharmacomechanical) or surgical thrombectomy with satisfactory results.^{181–189} However, survival after access thrombolysis in most reports is decreased compared to angioplasty of a nonthrombosed access.^{138,166,168,190} Salvage of a thrombosed AVF should be performed as soon as possible after recognizing the thrombosis.¹⁸¹ Routine stenting after angioplasty does not improve access survival but may be necessary to prevent elastic recoil, treat complications of venous rupture, and obtain a satisfactory result in central venous lesions.^{191–195}

There is no proven pharmacologic therapy to prevent access thrombosis or stenosis. Randomized, placebo-controlled trials have examined the use of low-dose warfarin as well as the combination of aspirin and clopidogrel; neither has proven successful in prolonging AVG survival.^{196,197} The trial of aspirin plus clopidogrel was closed early due to excessive bleeding.¹⁹⁷ Small trials have suggested a benefit of dipyridamole or fish oil to prevent AVG thrombosis.^{198,199} A large multicenter trial is testing whether Aggrenox extended-release dipyridamole/aspirin will prevent AVG stenosis and thereby prolong AVG survival.²⁰⁰

Infection

Infection occurs in approximately 5% to 15% of AVGs and no more than 1% of AVFs over the duration of patency.^{33,64,127,201,202} Most infections are due to *Staphylococcus aureus* and *S. epidermidis*.^{33,203} Less commonly encountered organisms include Enterococcus, gram-negative bacteria, and occasionally candida or other fungal species.^{33,203} Infection or abscess around the access may present with localized erythema and tenderness over the site, but AVG infection can also present with fever and systemic symptoms without localized evidence of infection.²⁰⁴ An indium-tagged white blood cell scan has been used to detect occult AVG infections.^{13,204–206} Serious complications of access infection include thrombosis, metastatic seeding leading to endocarditis, osteomyelitis, or muramic abscess, as well as sepsis and death. Careful attention to bactericidal cleansing of the skin and infection control practices at the time of needle insertion in the dialysis unit are important quality control measures.^{1,2} The use of preoperative vancomycin before access surgery has been recommended to decrease the frequency of subsequent postoperative graft infections.²⁰⁷

Management of AVG infection typically requires excision of the infected graft material and treatment with antibiotics.^{13,203} AVFs can usually be treated with 6 weeks of appropriate antibiotics without resection unless thrombosis is present. Vancomycin, with addition of gram-negative coverage if the patient is septic, is appropriate. However, indiscriminate use of vancomycin has led to an emerging epidemic of vancomycin-resistant organisms. Hence, long-term use of vancomycin should be avoided, and alternative antibiotics chosen as soon as results of antibiotic sensitivity testing are known. An alternative strategy being studied recently for infected AVGs is to replace the infected graft with a biograft that is more resistant to infection.²² If an endovascular source of infection is present, it should be treated for 6 weeks with appropriate intravenous antibiotics to reduce the risk for late sequelae from metastatic seeding.

Vascular Steal

Vascular steal results from retrograde flow from the distal artery into the access and occurs in approximately 75% of AVFs.²⁰⁸ Symptoms such as vague neurosensory changes, mild swelling, stiffness, or decreased temperature distal to the access may occur after access creation, usually improving or resolving with time. In more severe cases the ischemia may progress to produce painful paresthesias, numbness, ischemic ulcers, trophic changes, or dry gangrene in the extremity. These more severe complications requiring intervention have been reported to occur in 1.6% to 8% of accesses and can occur rapidly after the surgery or arise months or years after access placement.^{201,209} The diagnosis can often be made clinically by noting the decrease in symptoms and return of the radial pulse with compression of the fistula.²¹⁰ In difficult cases, digital plethysmography can be performed, looking for a digital pressure lower than 50 mm Hg or a digital-brachial index of less than 0.47.²¹⁰ In severe cases, the digital pulse waveform contours are monophasic or flat, and occlusion of the fistula leads to augmentation of the pulse wave and normalization of the waveform contour.²¹¹

If symptomatic steal occurs, it is important to look for and correct any arterial stenosis in the artery proximal to the access.¹²⁴ If the symptoms persist, the options include banding the access, ligating the distal artery, ligating the access itself, or performing a distal revascularization with interval ligation procedure. Banding the access or ligating the distal artery is frequently unsuccessful either due to persistent steal, insufficient flow, or thrombosis of the access. Ligating the access solves the problem but leaves the patient without an access. The distal revascularization with interval ligation procedure is often successful at salvaging the distal extremity while maintaining function of the access.²¹² However, it carries the risk of putting the distal extremity at the mercy of an autogenous vein bypass graft.

Heart Failure and Pulmonary Hypertension

Heart failure after arteriovenous shunt placement can develop in the setting of underlying organic heart disease, in which the heart is not able to increase its cardiac output to compensate for the increased flow through the shunt.^{88,89} In addition, many patients with an arteriovenous shunt also demonstrate an increase in pulmonary artery pressure. In the presence of underlying lung disease or primary pulmonary hypertension, this could exacerbate right heart failure.²¹³ An access blood flow to cardiac output ratio above 0.3 has been suggested as a risk factor for heart failure, but there is currently no well-validated tool to predict who will develop symptomatic heart failure after access placement; this remains a clinical judgment.²¹⁴ Development of symptomatic heart failure after access placement can be treated with banding or placing a tapered AVG to reduce flow but usually requires ligation of the access.

Aneurysms and Pseudoaneurysms

Aneurysms and pseudoaneurysms typically result when regional cannulation of one site is used repetitively, leading to weakening of the wall of the vein or graft.¹⁹ Vessel trauma with

extravasation of fluid can also lead to pseudoaneurysm formation. Avoidance of this complication involves employing either the ladder approach to needle placement, in which the entire length of the access is used for cannulation, or the buttonhole technique, in which the same hole is repetitively cannulated with a blunt needle.²¹⁵ If an aneurysm develops, it may be corrected surgically. The presence of a stenosis just downstream of the aneurysm should be investigated and corrected if present.

Chronic Catheter Maintenance

Current tunneled cuffed catheters (TCC, typical size approximately 15F) used for maintenance hemodialysis can deliver blood flows of 400 mL/min or more at arterial and venous pressures approximately -100 mmHg and $+100$ mmHg, respectively. Impaired catheter flow may lead to insufficient dialysis. Catheters should be monitored each dialysis session, looking for evidence of impaired function. Criteria for catheter dysfunction include an inability to achieve 300 mL/min blood pump flow rate (BPRF), a prepump arterial pressure (PPAP) no more than 250 mm Hg or venous pressure higher than 250 mm Hg, a conductance ratio (i.e., BPRF/PPAP) lower than 1.2, progressive decrease in urea reduction ratio below 65% (or $Kt/V < 1.2$), or trouble aspirating and returning blood in the catheter.^{1,2} A trend indicating impaired function should be investigated. Catheter dysfunction occurring within the first 1 to 2 weeks after placement that cannot be resolved by repositioning the patient and flushing the catheter lumens suggests a technical or mechanical problem, such as failure to place the catheter tip in the right atrium, kinked catheter, improperly placed suture, or catheter leak. If persistent or severe this requires evaluation by interventional radiology.

Catheter dysfunction that occurs later is most often due to the presence of thrombus or an external fibrin sheath that impairs catheter flow. This can be treated by intracatheter thrombolysis.²¹⁶ The most convenient agent currently available in the United States for catheters is recombinant tissue plasminogen activator (t-PA; e.g., alteplase, Cathflo Activase). A variety of approaches have been used; currently there is no standardized approach to therapy.²¹⁶ Typically 1 to 2 mg of t-PA (1 mg/mL) is infused into each lumen and allowed to dwell for 30 to 60 minutes before assessing catheter function.²¹⁷ If flow is not restored with the first dose, it can be replaced by a second dose; if necessary this dose may be allowed to dwell longer or until the next dialysis session. Complications have been reported to be low. Restoration of function is expected in 70% to 90% of cases, but recurrence is frequent.²¹⁸ Failure to relieve the obstruction or frequent repeated need for thrombolysis requires evaluation by interventional radiology and probable catheter replacement. If dialysis is needed urgently, it can be attempted with the lines reversed while waiting for catheter revision.²¹⁹ A fibrin sheath may be the source of dysfunction in a substantial number of patients.²²⁰ It can be diagnosed by injecting a small dose of contrast into the catheter, looking for contrast tracking up the sheath.²²¹ If present, balloon dilation of the catheter track can be used to disrupt any external fibrin sheath before reinsertion of the new TCC.²²²

The major complications of CVCs are thrombosis, infection, and central venous stenosis.⁶ Median TCC survival is approximately 1 year, with thrombosis accounting for the

majority of failures.²²³ Monitoring as above and prevention are the keys to dealing with catheter thrombosis. Currently, unfractionated heparin (5,000 U/mL) is the standard catheter lock solution used to prevent thrombosis. Low fixed-dose (1 mg) oral warfarin did not improve TCC survival.²²⁴ Higher doses of warfarin or use of oral antiplatelet agents has not been studied. A study is ongoing to determine whether substituting t-PA instead of heparin once a week for intracatheter lock solution will improve outcomes.²²⁵ Various citrate solutions (4% to 47%) have been studied as an alternative to heparin as a catheter lock^{226,227}; 4% citrate appears to be equivalent to heparin but potentially less expensive. The U.S. Food and Drug Administration has not approved the use of higher concentrations of citrate in the United States.²²⁸

Infections associated with TCCs can involve the exit site, the subcutaneous tunnel, or the bloodstream.²²⁹ Catheter-related bloodstream infection (BSI) is the most feared complication of TCCs, carrying the potential for endocarditis, metastatic infection, and septic shock.²²⁹ The reported risk of catheter-related bacteremia ranges from about 1 to 6.5 episodes/1000 catheter-days and rises with duration of use.¹⁴ K/DOQI recommends a goal of less than 1.5 episodes/1000 catheter-days.^{1,2} Staphylococcal species account for over 60% of all BSIs, but enterococci and gram-negative organisms are also frequent.^{67,229}

Exit site infections can typically be treated with topical and oral antibiotics without the need for catheter replacement.^{229,230} Development of fever, chills, or unexplained hypotension in a patient with a CVC suggests a BSI.^{67,229} Blood cultures should be drawn both from the catheter and a peripheral site if possible. For a probable BSI, treatment is begun with empiric intravenous antibiotics, typically vancomycin until appropriate therapy can be refined by the culture results. Empiric gram-negative coverage (e.g., aminoglycoside or third-generation cephalosporin) may be added, particularly if the patient appears ill or hemodynamically unstable. If the patient is hemodynamically stable and there is no exit site or tunnel infection, the BSI can be treated with either catheter exchange over a guidewire or catheter removal, followed in several days by catheter replacement.^{67,229,231,232} In either case, 3 weeks of appropriate intravenous antibiotics are recommended followed by surveillance blood cultures 1 to 2 weeks after antibiotics are completed. Catheter exchange over a guidewire has been reported to be more cost-effective than either catheter salvage or catheter removal and replacement.²³³ Catheter salvage using systemic antibiotics in conjunction with a concentrated antibiotic/anticoagulant intracatheter lock solution has also been reported to be an acceptable alternative.²³⁴ However, if the fever persists or blood cultures remain positive, the catheter must be replaced. In all cases, follow-up surveillance cultures are critical. Given the difficulty of eradicating *S. aureus* from indwelling catheters and the devastating consequences that can occur, we prefer to treat most BSIs with this organism by catheter removal and replacement after 48 hours when the patient is afebrile and follow-up cultures are negative. Patients who are septic or have a tunnel infection require immediate catheter removal and subsequent replacement. Use of a team approach with an access infection control manager may improve patient outcomes.²³⁵

Attention to good infection control practices when working with CVCs is critical to preventing infections.¹² This includes hand washing and wearing gloves before working with the catheter, using a sterile drape, carefully disinfecting the

caps and hub of the catheter, and using a face mask for both patient and dialysis technician during catheter connection and disconnection. Regular attention to cleaning the exit site and changing the catheter dressing is important to reduce the incidence of exit site infections. Numerous studies have shown that combined antibiotic plus anticoagulant lock solutions can decrease the rate of infection compared to heparin.^{234,236,237} In addition, application of mupirocin ointment or “medihoney” to the exit site may also decrease catheter infections.²³⁸ However, these strategies are not recommended until the long-term effect of these approaches on antibiotic resistance is known.

SUMMARY 889

Hemodialysis currently sustains life for more than a million patients throughout the world, with a projected growth of 7% per year.¹ At this growth rate, the projected worldwide expenditure for managing dialysis patients will be more than a trillion dollars a year in the next decade.¹ This staggering human endeavor mandates an in-depth understanding of all aspects of hemodialysis and a commitment to reducing morbidity and mortality first and foremost by providing adequate dialysis. Although we now have a better understanding of what constitutes adequate dialysis, our knowledge is still incomplete because we do not yet fully understand its target, the uremic syndrome. This chapter reviews what is known about hemodialysis adequacy and its measurement, starting with a historical perspective, followed by discussions of methods of measurement, including new expressions of adequacy and

quantifying more frequent dialysis, as well as troubleshooting, and ending with some practical clinical scenarios.

HISTORY OF HEMODIALYSIS ADEQUACY MEASUREMENTS

Measurement of hemodialysis adequacy has been steeped in empiricism since the early pioneering days of Kolff, who was the first to apply hemodialysis successfully to patients,² and Scribner, who first applied hemodialysis to treatment of chronic kidney disease using a peripheral vascular access.³ Despite extensive research, the exact identity of the uremic toxin(s) remained elusive. Instead, nonspecific surrogates, such as improvements in the uremic syndrome, severity of

anemia, patient activity and performance levels, and nutritional parameters such as appetite and dietary intake, were used to determine the adequacy of dialysis.

The persistently high mortality after patients start dialysis and recognition of the uremic syndrome as a late finding provided the impetus to develop a better way of measuring and optimizing the dialysis dose. Because urea is the most abundant organic substance to accumulate in patients with kidney failure and is readily measured,⁴ it became a natural target for measurement of hemodialysis adequacy. Removal of urea as a measure of dialysis adequacy was further fueled by the growing recognition that blood urea levels correlated with morbidity and mortality, but because interpretation of levels is confounded by urea generation, urea clearance became the favorite measure of adequacy.⁴

A prospective interventional study of dialysis adequacy in the late 1970s, the U.S. National Cooperative Dialysis Study (NCDS), provided clear-cut evidence for a level of urea clearance that was inadequate.⁵ Hemodialysis patients randomized to the group with a low urea concentration (achieved time-averaged urea concentration, 51–54 mg/dL) had fewer medical complications and fewer hospitalizations than those randomized to the group with a high urea concentration (achieved urea concentration, 88–90 mg/dL).⁵ A subsequent mechanistic analysis of the NCDS highlighted the paradox and difficulty of using serum urea concentration as a marker of dialysis adequacy⁶: When urea levels were reduced by dialysis, patient outcome was improved, but when levels were reduced by poor dietary protein intake, outcomes worsened. Because both nutrition and the amount of dialysis contributed to blood urea levels, the focus switched from monitoring absolute urea levels to measuring the relative change in urea concentration during hemodialysis treatments.^{5,6} This relative change in urea concentration is the result of both the dialyzer clearance rate (K) and the treatment time (t), expressed mathematically as Kt/V, the *fractional clearance of urea*, or the urea space cleared per dialysis session. The integrated clearance per dialysis (Kt) is normalized to V, the *volume of urea distribution*, which is a measure of patient size. Currently, both the raw urea reduction ratio (URR) and the more precise expression, Kt/V, are widely accepted and used in dialysis clinics to monitor the adequacy of hemodialysis.

Data from the NCDS was used to set a minimum level of dialysis at a Kt/V of 1.0 per dialysis (three treatments per week), below which poorer outcomes were observed.⁶ Uncontrolled studies since then have suggested that more dialysis, in the form of more prolonged treatments provided three times per week, was better for the patient.^{7–13} Analysis of urea kinetics suggested, however, that providing longer-duration dialysis beyond 3 to 4 hours three times per week provided no additional benefit, because urea concentrations fell logarithmically with time approaching a plateau.^{14,15} Extending the treatment time was considered an inconvenience to the patient, worsening the quality of life without providing significant medical benefit.

The National Institutes of Health (NIH)-sponsored Hemodialysis (HEMO) Study confirmed this theoretical construct.¹⁶ This multicenter, prospective clinical trial randomized 1846 patients to receive standard-dose versus high-dose hemodialysis three times per week, at a time when the accepted minimum Kt/V was 1.2 per treatment.¹⁷ The standard-dose group achieved a single pool Kt/V of 1.32 (equivalent to an equilibrated Kt/V of 1.16 and URR of 66%), whereas the

high-dose group achieved a single pool Kt/V of 1.71 (equilibrated Kt/V of 1.53 and URR of 75%).¹⁶ The subjects were further randomized to receive dialysis using a high-flux membrane (β_2 -microglobulin clearance >20 mL/min) versus a low-flux membrane (clearance <10 mL/min). More dialysis delivered three times per week or the use of a high-flux membrane did not reduce mortality, reduce cardiovascular or infection-related hospitalizations, or maintain higher serum albumin levels. Although subgroup analysis showed a lower mortality and fewer first hospitalizations for cardiac causes in patients treated with high-flux membranes¹⁶ and lower overall mortality in women receiving high-dose dialysis,¹⁸ these findings were of borderline significance and must be confirmed by other studies. As with any randomized study, the power of the study diminishes and the probability of error increases exponentially with subgroup analysis.

Current Target for Hemodialysis Adequacy

Based on current available data and the results of the HEMO Study, all hemodialysis patients should receive a minimum single pool Kt/V of 1.2 per dialysis three times weekly. A higher urea clearance should be considered in women if symptoms or signs suggest inadequate dialysis, but this is not routinely recommended. Providing more frequent dialysis in the form of daily short-duration hemodialysis or daily nocturnal hemodialysis may reduce mortality and morbidity further, based on solute kinetics that assume that the more toxic uremic solutes are more sequestered than urea and not as available to the dialyzer because of their resistance to diffusion across cell membranes or protein binding.^{14,15,19–22}

SOLUTE ACCUMULATION AND UREMIC TOXICITY

Reversing uremia and the uremic syndrome is the purpose of hemodialysis. To better understand the current methods of determining hemodialysis adequacy and dosing of hemodialysis, one must first understand the uremic syndrome. A full discussion of uremia and the candidates for uremic toxins is beyond the scope of this chapter but is presented in Section IV, Chapter 48, Pathophysiology of Uremia, in Brenner and Rector's *The Kidney*, 7th edition. The salient points are reviewed here.

Uremia: The Target of Hemodialysis

All patients with uremia accumulate fluid and solutes, collectively known as *uremic toxins*, which act in concert to create the uremic syndrome.^{4,23–28} Removal of these toxins and fluid is the goal of hemodialysis. Monitoring patients and determining the adequacy of their dialysis is made more difficult because the exact nature or identity of the uremic toxins is not known. Like urine solutes, most of the solutes known to accumulate in uremic patients are low in molecular weight and water soluble, rendering them easily removed with dialysis. The most abundant solute of this type is urea.⁴ However, some solutes are larger, some are lipid soluble or significantly protein bound, and some are relatively sequestered because of a higher resistance to diffusion across cell membranes than urea.^{4,20,23,28,29}

Although urea is a poor marker of native kidney function and demonstrates little toxicity when added to the dialysate to prevent its removal,^{30,31} it has become a surrogate marker for uremic toxins and dialysis adequacy because it is easily measured, the most abundant molecule to accumulate in patients with kidney failure, a marker for protein catabolism and hence nutritional status, and its level correlates with survival on dialysis.^{5,17,32–34} However, the dual effect of urea generation and removal by dialysis makes interpretation of any measured level difficult unless the relative contributions from kidney failure and protein catabolism are separately identified. Mathematical models of urea kinetics using serum urea concentrations measured before and after dialysis treatments allow such a separation and a better quantification of hemodialysis.

Although the HEMO Study confirmed the validity of using urea kinetics to determine dialysis adequacy, it also highlighted the inherent inefficiency of thrice-weekly dialysis. The logarithmic reduction of urea levels during a short-duration hemodialysis,^{14,15} magnified further for the uremic toxins that are not as easily removed as urea,^{4,19–23,28,29} markedly reduces the efficiency of intermittent dialysis. Although thrice-weekly dialysis sustains life, it leaves patients with the *residual syndrome*, consisting of a below-average quality of life and significant morbidity, including increased risk of infection, renal osteodystrophy, and cardiovascular disease. The effectiveness of increasing the frequency of dialysis to eliminate the residual syndrome remains to be proven,^{35,36} although accumulating data suggest that daily dialysis improves removal of sequestered and protein-bound solutes,^{19,21,22} improves blood pressure control, improves anemia and cytokine profiles, and enhances the quality of life.^{35,37–39}

Dialysis versus Filtration

Only pertinent points on the physics of dialysis are discussed here; a more detailed analysis of the physical laws that govern dialysis is available in formal texts dealing with kinetic modeling.^{40–42}

Dialysis removes solutes by molecular diffusion across a semipermeable membrane. The rate of diffusion varies inversely with the membrane thickness and directly with the solute concentration gradient, the membrane surface area, and the *coefficient of diffusion*, a constant that describes the permeability of a particular membrane material to a particular solute. Solute with higher molecular weight move more slowly and collide with the membrane less frequently, resulting in a lower coefficient of diffusion. Protein-bound or lipid-soluble substances are even less likely to diffuse across the dialyzer membrane.

An alternative to hemodialysis is hemofiltration, which removes solutes by convection across similar semipermeable membranes. Unlike diffusive clearance, convective clearance is governed mainly by the hydrostatic pressure gradient across the membrane. As long as the solute is small enough to easily traverse the pores in the membrane, larger molecules will be removed at the same rate as smaller molecules. When diffusion and convection occur simultaneously across the same membrane, they can interfere with each other even if solute movement is in the same direction.

When to Start Dialysis

Delaying the initiation of dialysis until frank uremic symptoms are present is clearly deleterious.⁴³ Based on theoretical grounds, the National Kidney Foundation clinical practice guidelines (K/DOQI)^{44,45} suggested starting hemodialysis when the patient's glomerular filtration rate falls below 10 mL/min/1.73 m². Studies that examine the timing of dialysis initiation have yielded conflicting results, some showing a benefit and others equivalence.^{46–53} A randomized, controlled trial, the IDEAL (Initiating Dialysis Early And Late) Study, is underway to better answer this question.⁵⁴ For now, patients with an estimated glomerular filtration rate near or below 10 mL/min/1.73 m² should be considered for initiation of dialysis, weighing the risks and benefits of vascular access type, quality of life, nutritional status, and comorbidities. If the patient is symptomatic from uremia or volume overload or has significant comorbid conditions,³³ he or she may require initiation of dialysis at a glomerular filtration rate above 10 mL/min/1.73 m².

METHODS FOR MEASURING THE DOSE OF HEMODIALYSIS

Why and How Clearance Substitutes for Toxin Levels

A mechanistic analysis of the NCDS highlighted the difficulty of using urea concentration as a marker of dialysis adequacy⁶ and shifted the focus from monitoring absolute urea levels to the relative change in urea concentration during dialysis (i.e., clearance).^{5,6} By measuring solute clearance instead of an absolute solute level, the focus shifts to dialyzer function, so the measured marker substance need not be toxic.⁵⁵ Because urea is a small molecule that diffuses readily across the dialysis membrane, accumulates in abundance in patients with kidney failure, and is easily measured, it is an excellent solute for monitoring clearance despite its low toxicity. The K/DOQI guidelines recommend using formal urea kinetic modeling to calculate Kt/V to monitor urea clearance and dialysis adequacy, although the URR is acceptable if formal urea kinetic modeling is not possible.³³

Clearance versus Dialysance

Dialyzer clearance can be defined as the removal rate of a substance (urea) relative to its blood concentration (C):

$$\text{Clearance} = \text{removal rate}/C \quad (\text{Eq. 79-1})$$

For single-pass dialysis, in which the dialysate is continually replenished with fresh solution, the clearance of urea is a reasonable measure of dialyzer function. However, if the measured solute is also present in the dialysate, then *dialysance* becomes a more robust term to describe dialyzer function. *Dialysance* is the removal rate of a substance relative to the concentration gradient from blood (C) to dialysate (D):

$$\text{Dialysance} = \text{removal rate}/(C - D) \quad (\text{Eq. 79-2})$$

When changes in sodium concentration are used to measure dialyzer "clearance" on-line (see Ionic Dialysance in this

chapter), *dialysance* is the more proper term because sodium is also present in the dialysate.

Dialyzer Mass Transfer Area Coefficient ($K_{O}A$)

The *mass transfer area coefficient* ($K_{O}A$) describes the maximum clearance of a solute across the dialyzer when blood (QB) and dialysate (QD) flow rates are infinite. It is the product of the solute's membrane permeability, or *mass transfer coefficient* (K_{O}), and the membrane area (A). $K_{O}A$ is a property of the solute and the dialyzer, including the membrane's pore size and thickness, but is independent of solute concentrations and flow rates. Like clearance or dialysance, it has units of mL/min; it is also known as the *intrinsic clearance of the dialyzer* for the measured solute. $K_{O}A$ is the most specific constant describing the efficiency of a particular dialyzer for removing a particular solute, with higher values indicating more efficient solute removal. $K_{O}A$ is used clinically to compare dialyzers and to predict the prescribed dialysis dose.

When QB and QD are finite, dialyzer clearance is lower than $K_{O}A$ because both flow rates govern diffusion. As QB increases, the inflow concentration is unchanged, but the dialyzer clearance increases logarithmically and approaches $K_{O}A$ because of a flow-dependent increase in the mean concentration gradient across the membrane, driving more solute into the dialysate. The relationship among dialyzer clearance (K_{d}), $K_{O}A$, QB, and QD can be described mathematically by the following two equations⁴⁰⁻⁴²:

$$K_{O}A = \frac{QB \cdot QD}{QB - QD} \ln \left(\frac{QD(QB - K_{d})}{QB(QD - K_{d})} \right) \quad (\text{Eq. 79-3})$$

Equation 79-3 is a practical equation for calculating $K_{O}A$ from an instantaneous measurement of solute clearance, QB, and QD when flow is countercurrent. This equation is useful clinically to measure *in vivo* $K_{O}A$, which is usually lower than the manufacturer-published *in vitro* $K_{O}A$.

$$K_{d} = QB \frac{\left[e^{K_{O}A \left(\frac{QD - QB}{QD QB} \right)} - 1 \right]}{\left[e^{K_{O}A \left(\frac{QD - QB}{QD QB} \right)} - \frac{QB}{QD} \right]} \quad (\text{Eq. 79-4})$$

Equation 79-4, which is a rearrangement of Equation 79-3, provides a practical method for calculating expected clearance from QB, QD, and $K_{O}A$. This equation is used to calculate a patient's prescribed or predicted Kt/V using the prescribed QB and QD. It also aids in adjusting the patient's dialysis prescription and eliminates the need to measure blood solute concentrations to predict the effect of changes in flow on clearance. It is often used to compare the prescribed with the achieved or predicted Kt/V; the latter is determined primarily from predialysis and postdialysis urea concentrations. A full discussion of the derivation of these formulas is available in formal texts on kinetic modeling.⁴⁰⁻⁴²

Previously, $K_{O}A$ was thought to be a constant that did not vary with either blood or dialysate flow rates. More recent studies suggest that QB does not influence $K_{O}A$,^{58,60} but that at high dialysate flow rates, *in vitro* $K_{O}A$ can increase by as

much as 14%.⁵⁸ Subsequent data demonstrated a smaller effect of high dialysate flow rates on *in vitro*⁶⁰ and *in vivo*⁵⁶ $K_{O}A$ values ($\approx 5\%$ higher); they also demonstrated that low dialysate flow rates, such as those used in daily dialysis, resulted in lower $K_{O}A$ values.⁶¹ That $K_{O}A$ varies with dialysate flow rates has implications for prescribing dialysis, because predicted clearance calculated from Equation 79-4 may overestimate or underestimate actual clearance, depending on the value for $K_{O}A$ used. This variation in $K_{O}A$ renders even more important the use of formal urea kinetics to measure delivered Kt/V using blood urea concentrations that do not depend on $K_{O}A$.

Formal Urea Modeling to Measure Clearance

Dialysis *in vitro* is a simple procedure, but it becomes much more complicated when applied *in vivo*. Many factors influence the delivery of dialysis; these include the access device, the patient's compliance with the dialysis prescription and dietary restrictions, and solute disequilibrium. Because the precise uremic toxins are not known, measures of dialysis adequacy have been tested using surrogate endpoints, such as mortality, morbidity, serum albumin concentration, and health-related quality of life.^{5-13,16,24,28,32,34,62-73} To determine that the observed effect is due to dialysis, detailed studies of large populations with careful attention paid to the many variables that affect outcome are required, preferably by randomizing subjects to different doses of dialysis. To date, only two such randomized studies are available.^{5,6,16} Because of the diversity of parameters required for the measurements, such as patient size, ultrafiltration rate, and solute generation rate, complex mathematical models with multiple variables are required even when a simple solute such as urea is used to monitor clearance. These factors add complexity to the relatively simple laws of diffusion and flow, so that the results of solute clearance calculations in patients are often approximations.

Why Kt/V_{urea}?

The simplest measure of clearance is the *instantaneous cross-dialyzer clearance* (K_{d}), which can be measured by sampling blood on both sides of the dialyzer while simultaneously recording QB using the following equation:

$$K_{d} = QB(C_{in} - C_{out})/C_{in} \quad (\text{Eq. 79-5})$$

C_{in} is the inflow solute concentration, and C_{out} is the outflow concentration. Care must be taken to account for ultrafiltration during the measurement and for blood water content because clearances may differ for substances that do not distribute in red cells or are significantly protein bound.^{40-42,55} Lastly, loss of surface area from clotting or changes in QB or QD during dialysis may reduce the dialyzer clearance later in the treatment, rendering instantaneous dialyzer clearance less useful.

The *effective clearance*, or integrated dialyzer clearance, accounts for these differences and changes by linking the clearance measurement to the predialysis and postdialysis blood urea nitrogen (BUN) concentration. This clearance, also known as the *delivered clearance*, is the average urea clearance required to reduce the BUN from the measured predialysis

value to the postdialysis value. The formal mathematical solution for effective clearance using predialysis and postdialysis BUN values requires a computer-dependent iterative process known as *urea modeling*. Urea modeling can take into account all of the contributing and confounding variables discussed here. Both single- and two-compartment mathematical models have been applied. The single-compartment model requires a predialysis and immediate postdialysis BUN, and the two-compartment model requires intradialysis or postdialysis BUN measurements as well. The most widely accepted expression of the hemodialysis dose, both prescribed and delivered, is Kt/V_{urea} , validated by the NCDS and the HEMO Study^{5,6,16} and recommended by the K/DOQI.^{17,33}

The Delivered Dose: Mathematical Model of Single Pool Urea Kinetics

The molecular properties of urea that allow it to distribute in aqueous environments and the presence of membrane transporters allow it to diffuse rapidly among the various body water compartments so that a single space of distribution (total body water) can be assumed for most approximations of urea clearance. If urea generation and volume changes during hemodialysis are ignored, fractional urea removal (dC/C) is constant.

$$(dC/C)/dt = -k = -K/V \quad (\text{Eq. 79-6})$$

where k is the fractional removal rate, K the average clearance, and V the volume of urea distribution. Because the fractional removal rate is constant, the absolute removal rate is proportional to the concentration.

Integration and log transformation of Equation 79-6 yields a powerful expression for the normalized clearance (Kt/V):

$$Kt/V = \ln(C_0/C) \quad (\text{Eq. 79-7})$$

Equation 79-7 shows that the effective delivered clearance, integrated over an entire dialysis session and factored for patient size (V), can be determined simply by measuring a predialysis BUN (C_0) and a postdialysis BUN (C), eliminating the need to measure the dialyzer clearance, K_0A , the native kidney clearance during dialysis, the patient's urea volume, or even the duration of each dialysis. However, the simplified Equation 79-7 ignores the change in volume that occurs during dialysis from ultrafiltration (dV) and the contribution of ultrafiltration to clearance (together up to 30% more clearance), as well as the small amount of urea generation that occurs during dialysis (G).

A consideration of urea mass balance requires that the opposing contributions of ultrafiltration and urea generation be added to Equation 79-6. After its synthesis in the liver, urea enters the blood, is quickly distributed in total body water, and is eliminated by the patient's native kidneys (K_r) and by the dialyzer (K_d). Hence, the rate of change of urea content in the pool [$d(CV_{\text{urea}})/dt$] is the difference between the generation rate (G) and the elimination rate [$(K_d + K_r)C$]:

$$d(CV_{\text{urea}})/dt = G - (K_d + K_r)C = G - KC \quad (\text{Eq. 79-8})$$

where C is the concentration of urea and K is the total clearance or the sum of K_r and K_d . Equation 79-8 is the mathematical foundation of the single pool urea model; integration

yields a more complicated equation than Equation 79-7, with four variables that cannot be resolved directly but can be determined using computer iteration, or *modeling*, considering BUN changes during and between dialyses:

$$C = C_0 \left[\frac{V - B \cdot t}{V} \right]^{\left(\frac{K_r + K_d + B}{B} \right)} + \frac{G}{K_r + K_d + B} \left[1 - \left[\frac{V - B \cdot t}{V} \right]^{\left(\frac{K_r + K_d + B}{B} \right)} \right] \quad (\text{Eq. 79-9})$$

where V is total body water after dialysis (mL) and B is the rate of change in V (mL/min), which is usually negative during dialysis and positive between dialyses. The model allows calculation of the delivered or effective dose of hemodialysis as a single-pool (sp) Kt/V_{urea} from the measured predialysis BUN (C_0), postdialysis BUN (C), and the change in weight during dialysis (B). It gives a more accurate measure of delivered Kt/V , and it also provides a method for calculating G and V .

Simplified Methods

Because the complexity of urea modeling requires a computer program to model $spKt/V_{\text{urea}}$ and modeling is not implemented in all dialysis facilities, simplified methods for estimating urea clearance have been developed and are available to clinicians.

Urea Reduction Ratio

The most commonly available and easy to use method is the URR,⁷⁴ recommended as the alternative if calculation of Kt/V_{urea} is not available.³³ It is simply the fraction of urea removed during dialysis [$(C_0 - C)/C_0$] expressed as a percentage:

$$\text{URR} = \left[1 - (C/C_0) \right] \times 100 \quad (\text{Eq. 79-10})$$

where C_0 is the predialysis BUN and C the postdialysis BUN. Several retrospective clinical studies have validated use of URR as an indicator of mortality in hemodialysis patients.^{10,75,76} However, URR does not take into account convective clearance provided by ultrafiltration during dialysis, because ultrafiltration does not alter the BUN level. URR also does not allow calculation of V , residual kidney function, urea generation rate, and normalized protein catabolic rate (PCR_n) and is therefore less useful in rooting out the causes of errors in the delivered dose of dialysis (see the section Pitfalls and Troubleshooting in this chapter). Also, it cannot be applied to continuous dialysis or account for continuous native kidney function.

Simplified Equations for $spKt/V_{\text{urea}}$

Alternatives to URR that take into account ultrafiltration and convective clearance, yet do not require computer iteration, are available as simplified explicit equations that approximate $spKt/V_{\text{urea}}$.^{77,78} The most widely used equation, proposed by Daugirdas in 1993, is also known as the second-generation logarithm formula.^{79,80} This equation was formulated to approximate results from the single pool urea model, including urea generation

and volume changes during dialysis, and provides reasonably accurate estimates of Kt/V in the range of 0.7 to 2.1.⁷⁹

$$Kt/V = -\ln\left[\left(\frac{C}{C_0}\right) - 0.008 \cdot t\right] + \left[4 - 3.5 \cdot \left(\frac{C}{C_0}\right)\right] \cdot \Delta BW/BW \quad (\text{Eq. 79-11})$$

where C_0 is predialysis BUN, C is postdialysis BUN, t is treatment time in hours, and BW is body weight.

Equation 79-11 has been compared with other empiric equations and is one of the most accurate.^{78,81,82} Like URR, it does not provide a value for G and PCR_n , and it does not permit a rigorous and quantitative analysis of the dialysis prescription to detect sources of errors. However, once $spKt/V_{urea}$ is determined, PCR_n can be estimated using similar empirical equations based on the predialysis BUN.^{79,80,83}

Solute Sequestration and Disequilibrium

When solutes are sequestered in a remote body compartment during hemodialysis, the efficiency of dialysis is reduced. The lower BUN levels during dialysis and the BUN rebound after dialysis, compared with levels predicted by the single-compartment model (Figs. 79-1 and 79-2), provide evidence for solute disequilibrium, even for a very diffusible solute like urea. Hemodialysis-induced solute disequilibrium has two forms: (1) diffusion-dependent

Figure 79-1 Changes in blood urea nitrogen (BUN) concentrations during and after dialysis. BUN levels measured during and immediately after dialysis best fit a two-compartment variable-volume mathematical model (*solid line*). The single-compartment variable-volume model (*dashed line*) overestimates BUN levels during dialysis and does not predict the rebound. The upper horizontal line is the simple arithmetic mean of the predialysis and postdialysis BUN (40 mg/dL). The middle horizontal line depicts the log mean BUN during the treatment (36 mg/dL), as predicted by the single-compartment model. The lower horizontal line is the true mean BUN (34 mg/dL), obtained from multiple measurements throughout dialysis.

Figure 79-2 Postdialysis blood urea levels. Because of the rapid changes that occur in the postdialysis blood urea nitrogen (BUN) level, timing of blood sampling is critical to ensure consistent and accurate measurements of the urea kinetics value and normalized protein catabolic rate. Sampling blood at Point A may yield a falsely low BUN due to a dilution artifact from access recirculation. Obtaining a blood sample at Point B from the arterial or inflow port 10 to 20 seconds after slowing the blood pump at the end of dialysis eliminates this artifact. Drawing the blood sample 2 minutes postdialysis at Point C eliminates the effects of cardiopulmonary recirculation on urea disequilibrium. Urea equilibration is complete 1 hour after dialysis (Point D). (From Depner TA: Assessing adequacy of hemodialysis: Urea modeling. *Kidney Int* 1994;45:1522-1535. Used with permission of Kidney International.)

disequilibrium caused by resistance to diffusion across cell membranes, and (2) flow-dependent disequilibrium due to varying blood flow rates among vascular beds.

Two-Compartment Kinetics: Diffusion Model

Urea is unique because it diffuses rapidly across cell membranes, especially the red cell membrane, where its diffusion is facilitated by urea transporters.^{84,85} Therefore, the single-compartment model assumption that urea distributes rapidly through all body fluid compartments, including plasma, interstitial fluid, and intracellular water, is reasonable in the interval between dialyses when urea accumulates slowly and urea concentrations change slowly. However, during hemodialysis, when blood concentrations change quickly, urea gradients appear (see Figs. 79-1 and 79-2). To better explain these discrepancies, more complicated mathematical models assuming more than one body fluid compartment were developed.⁴⁰⁻⁴²

The two-compartment model assumes that total body water is divided into two pools and that solutes must diffuse from one pool into another through a barrier to reach the dialyzer. Typically, for urea, the two pools are thought to be intracellular and extracellular water, and the cell membrane is the semipermeable barrier. The resistance to diffusion is inversely proportional to the intercompartment mass transfer coefficient, K_C . This solute-specific constant is analogous to K_{O_A} and, like K_{O_A} , has units of mL/min. The higher the resistance to diffusion, the lower the K_C , and the slower the solute equilibrates between the fluid compartments. Because solutes are removed rapidly during

hemodialysis, resistance to diffusion between compartments sets up intercompartment solute gradients that subsequently cause a rebound in solute concentration after completion of dialysis.

Solute disequilibrium is more pronounced for solutes other than urea, presumably due to lower rates of diffusion among body compartments, as reflected in their lower K_C values. Most solutes require a multicompartment model to explain their behavior during dialysis.

Recirculation: Flow Model

The two-compartment model described above accounts for solute disequilibrium on the basis of a finite resistance to diffusion among body compartments. The model assumes that the concentration is uniform throughout the blood compartment. More recent data show that blood concentrations are not uniform and that flow-dependent mechanisms contribute to solute disequilibrium.^{86–92} Mathematical models developed to describe pure flow-dependent disequilibrium assume that diffusion among compartments is instantaneous and that solute gradients are caused solely by differing blood flow rates to various vascular beds.⁹⁰ Regardless, both types of solute disequilibrium lead to lower intradialysis solute concentrations than predicted by the single-pool model, followed by a postdialysis rebound in solute concentration, thereby reducing the efficiency of dialysis (see Fig. 79-1). The largest contributors to flow-dependent disequilibrium are vascular access recirculation^{87,93–95} and cardiopulmonary recirculation.⁸⁹

When dialyzer blood flow is higher than vascular access blood flow (as occurs in venous outflow or central venous stenosis), the dialysis needles are too close together, or the arterial and venous needle placements are reversed, blood that has just been dialyzed can return immediately to the dialyzer, creating access recirculation. Because the dialyzer is functioning properly, dialyzer clearance is not reduced, but the recirculated venous blood dilutes the concentration of solute in the dialyzer inflow (arterial blood), lowering the solute concentration gradient across the dialyzer membrane, which decreases total solute removal. Although access recirculation is uncommon ($\approx 5\%$ of dialyses), when it is present, the timing of blood sampling for the postdialysis BUN is critical for accurate measurement of the delivered Kt/V . Sampling arterial (inflow) blood immediately at the end of dialysis without slowing the blood pump (Point A in Fig. 79-2) yields an artificially low BUN and inflates Kt/V . Instead, arterial (inflow) blood should be sampled 10 to 20 seconds after slowing the blood pump at the end of dialysis to eliminate the dilution effect of access recirculation (Point B in Fig. 79-2).

In dialysis patients with peripheral arteriovenous shunts and fistulas, cardiopulmonary recirculation is always present.⁸⁹ The circulatory system can be represented as blood flowing from the heart, essentially through various parallel vascular circuits before returning back to the heart. The shunt or fistula has a lower resistance to flow and diverts blood directly from the arterial to the venous circulation, bypassing all capillary beds and returning more quickly to the heart. Because the blood in this circuit has a lower solute concentration, it dilutes the solute concentration of blood returning from other vascular circuits to other parts of the body. Dialyzer clearance is preserved, but the concentration gradient across the dialyzer

membrane is reduced, thus reducing total solute removal and dialysis efficiency. Cardiopulmonary recirculation contributes to the early phases of rebound in urea concentration (and other solutes) seen after completion of dialysis when the various vascular circuits equilibrate (see Fig. 79-2). Patients with central venous catheters as their dialysis access do not have cardiopulmonary recirculation because blood is obtained from and returned to the central blood pool in these patients. This has implications for simplified methods for calculating eKt/V (see Rate Equations in this chapter).

Cardiopulmonary recirculation is a special instance of flow-dependent solute disequilibrium. Differential blood flow rates through other vascular circuits also contribute to solute disequilibrium,⁸⁶ such as slower blood flow through dermal vascular beds when the patient is cold or increased gastrointestinal blood flow in the patient who ate before undergoing dialysis. This type of flow-dependent solute disequilibrium invalidated the previous practice of peripheral venous blood sampling for calculating vascular access recirculation.^{88,91,92}

Rate Equations

Two-compartment urea kinetic models have been developed to explain the more complex behavior of urea as well as most other solutes, such as creatinine, phosphate, and β_2 -microglobulin, during dialysis. Such models allow calculation of whole body or patient clearance that is always lower than the delivered dialyzer clearance calculated from single-pool models. This effective or equilibrated clearance can also be calculated using the single-compartment model but obtaining the postdialysis BUN after re-equilibration among the fluid compartments (Point D in Fig. 79-2). For urea, measuring the equilibrated postdialysis concentration requires delayed blood sampling, at least 30 minutes after the treatment, which is not practical clinically. Fortunately, simple mathematical equations have been derived that predict the equilibrated, or eKt/V_{urea} , from $spKt/V_{\text{urea}}$ and either the intensity (K/V) or the duration of dialysis (t).^{76,96–100}

For arteriovenous fistulas:

$$\begin{aligned} eKt/V &= spKt/V - 0.6 (K/V) + 0.03 & (\text{Eq. 79-12}) \\ &= spKt/V (1 - 0.6/t) + 0.03 \end{aligned}$$

For venous catheters:

$$\begin{aligned} eKt/V &= spKt/V - 0.47 (K/V) + 0.02 & (\text{Eq. 79-13}) \\ &= spKt/V (1 - 0.47/t) + 0.02 \end{aligned}$$

where K/V is $spKt/V$ divided by t in hours. The equilibrated eKt/V is lower when the vascular access device is an arteriovenous fistula because of the added presence of cardiopulmonary recirculation. Equation 79-12 has been validated by other investigators and was the basis for prescribing doses of hemodialysis in the HEMO Study.^{101,102} The targeted dose of dialysis for the control arm of the HEMO Study¹⁶ was an eKt/V of 1.05, but the achieved eKt/V was 1.16 ± 0.08 .

Impact of Treatment Time

Equations 79-12 and 79-13 predict that for the same $spKt/V$, eKt/V varies with treatment time. In other words, even though dialyzer clearance, expressed in mL/min, remains constant, patient or whole body clearance improves with longer dialysis

treatment times, likely due to reducing the effects of solute disequilibrium on the efficiency of dialysis. This effect of time on patient clearance is even more pronounced for solutes that are less diffusible than urea (lower K_C).

The NCDS, which was the first controlled study of dialysis dose versus outcome, reported a borderline significant effect of treatment time on outcome.^{5,6} This effect was attributed to larger molecules that are removed more slowly by diffusion. Kinetic studies assessing rebound after short and conventional hemodialysis treatments found that urea concentrations rebounded more after short treatments,¹⁰³ as would be expected. However, the postdialysis rebound of β_2 -microglobulin was similar for both short and conventional dialysis, suggesting that sequestration may play a more important role than the molecular weight of the solute.

An extreme example of solute disequilibrium is exhibited by phosphate. Phosphate removal varies directly with the serum phosphate concentration and dialyzer clearance, and is greatest during the first hour of dialysis.^{37,104,105} After the first hour, phosphate removal falls to half of its initial rate, and the serum level does not decrease further, suggesting that initial phosphate removal is from the blood compartment, and subsequent removal is from sequestered compartments with low K_C values.^{37,105,106} From the previous discussion, increasing dialysis treatment time should enhance phosphate removal. Clinical studies have shown that although postdialysis phosphate rebound is greatest when phosphate removal is greatest during dialysis, increasing the duration of each dialysis session eventually reduces predialysis serum phosphate concentrations.^{37,104,107} Increasing the dialysis frequency may also increase phosphate removal and lower blood levels. Short daily treatments may improve removal,¹⁰⁷ but long-duration nocturnal hemodialysis has the greatest impact,^{37,107} confirming the importance of treatment time for removing sequestered solutes.

Using Other Solutes to Monitor Adequacy

Measuring dialysis adequacy using urea clearance, whether in simple equations or formal urea kinetic modeling, requires careful and precisely timed blood sampling to minimize the effects of solute disequilibrium. Because of these challenges, adequacy is usually measured once a month, which may not be frequent enough to detect vascular access dysfunction or other factors that may reduce the effectiveness of dialysis. Previous advances in on-line monitoring of urea clearance made it possible to monitor urea removal and dialysis adequacy during each dialysis treatment.^{108–114} However, urea monitoring devices are cumbersome and expensive to use and therefore are not used widely in clinical practice.^{106,113} More recently, on-line monitoring of conductivity has become increasingly available in routine dialysis practice as a reliable surrogate marker for urea clearance.

Ionic Dialysance

The electrical conductivity of dialysate is influenced mainly by the concentration of sodium and its anions. To determine ionic dialysance (Dt/V), which is equivalent essentially to sodium dialysance, conductivity is measured at the dialysate inlet and outlet at baseline and after pulsing the dialysate sodium concentration.^{106,113,115,116} Because the out-

let conductivity is determined by the inlet conductivity, the patient's plasma conductivity, and the ionic dialysance, two separate measures of outlet conductivity allow calculations of both plasma conductivity and ionic dialysance.^{116,117} This calculation rests on the assumption that the plasma conductivity remains constant between the two sets of conductivity measurements. Therefore, the time elapsed between the dialysate sodium pulse and the second measure of outlet conductivity is critical. If the time period is too long, plasma conductivity may change due to ongoing solute removal. If the elapsed time is too short, there may be insufficient time for the outlet conductivity to stabilize. Currently, most methods allow an elapsed time of 2 minutes before obtaining the second set of inlet and outlet conductivity measurements.

Several studies have validated the use of ionic or sodium dialysance in place of urea clearance.^{106,113,115,116,118–120} The correlation with both urea clearance and Kt/V derived from formal urea kinetic modeling is excellent, achieving R values greater than 0.9 in most studies. The main sources of discrepancies between ionic dialysance and urea clearance are: (1) not correcting urea clearance for access and cardiopulmonary recirculation, because ionic dialysance is an effective or patient dialysance by virtue of Dt/V being derived from conductivity measured in the dialysate,^{106,113,116,118} and (2) using an anthropometrically derived V to calculate Dt/V instead of a V derived from formal urea kinetic modeling.^{106,118,120} If the latter is used as the denominator, values for Dt/V are virtually identical to eKt/V values derived from either formal urea kinetic modeling using a 30-minute postdialysis BUN or from simplified rate equations (Equations 79-12 and 79-18).^{106,116,120}

MEASURES AND APPLICATION OF UREA GENERATION

As is evident from the NCDS and other studies, poor protein intake leading to a low urea generation rate (G) and low BUN is associated with a poor outcome.^{121,122} Therefore, to assess prognosis and allow intervention, measuring urea generation and its derivative, the patient's protein catabolic rate (PCR), is clinically useful.

Two-BUN Method

As can be seen from Equation 79-9, formal urea kinetic modeling allows calculation of G . Only two BUN values are required if the computer iterative method is used.⁴¹ Once G (mg/min) is available, PCR (g/day) can be calculated from the following equation^{123,124}:

$$\text{PCR} = 9.35 \cdot G + 11 \quad (\text{Eq. 79-14})$$

Equation 79-14 illustrates that, under steady state conditions, most of the nitrogen released from net catabolism of endogenous and dietary protein is converted to urea. Only about 11 grams ($\approx 10\%$) are converted each day to nonurea nitrogenous compounds, such as creatinine, hippurate, and uric acid.^{123,124} Urea generation varies directly with protein intake, whereas generation of the other nitrogenous products varies with patient size but not with protein

intake. During steady states of protein balance, PCR approximates protein intake, so PCR is a useful marker of protein nutrition.

Clinically, PCR is normalized by ideal body size based on total body water or V_{urea} to yield PCR_n (g/kg/day), allowing comparison among patients of varying size:

$$PCR_n = 5420 (G/V) + 0.17 \quad (\text{Eq. 79-15})$$

ADDITION OF RESIDUAL NATIVE KIDNEY CLEARANCE

When significant residual native kidney function is present, it may contribute significantly to clearance and, therefore, reduce the clearance required from dialysis. However, because residual native kidney clearance (K_r) is continuous and exerts most of its effect between dialysis treatments, it cannot be directly added to dialyzer clearance.

The intermittent clearance obtained with thrice-weekly hemodialysis is less efficient than the continuous clearance provided by native kidneys. The reduced efficiency is due to inherent limitations of intermittent dialysis, which are enhanced by the effects of solute disequilibrium. First, although dialyzer clearance remains constant throughout each dialysis session, the amount of solute removed declines with time as blood solute concentrations decrease logarithmically.^{41,125,126} Even if each hemodialysis session were able to remove all of the solute, accumulation between dialysis sessions would result in time-averaged concentration (TAC) and average predialysis concentration that are higher than would be seen in the absence of kidney failure. Solute disequilibrium accentuates this inefficiency by lowering the blood concentration sooner, thereby limiting access of the solute to the dialyzer. For continuous modalities, solute concentrations are stable at a lower level, and the amount of solute removed each hour remains constant. In addition, solute disequilibrium is minimal or absent with continuous modalities.

Because residual kidney clearance is continuous, adding it directly to the intermittent dialyzer clearance would grossly underestimate the contribution of K_r to total clearance. To allow a direct comparison of the relative clearances from the dialyzer and the native kidney and to report a total clearance, two approaches have been proposed. The first, which is used more commonly, involves converting the continuous native clearance to an equivalent intermittent clearance to allow direct addition^{41,42}:

$$Kt/V_T = (K_d \cdot t_d + K_r \cdot t_r) / V_{urea} \quad (\text{Eq. 79-16})$$

where Kt/V_T is total Kt/V , K_d is dialyzer clearance, K_r is residual kidney function, and V_{urea} is the volume of distribution of urea or total body water. T_d is the duration of each dialysis session, and t_r is the mean time interval between dialysis sessions. Because continuous clearance is more efficient than intermittent clearance, t_r must be inflated to account for the effect of K_r . The magnitude of the upward adjustment varies with the frequency of dialysis, such that as dialysis becomes more frequent, the adjustment is smaller^{41,42} (Table 79-1).

The second, less commonly used, method involves reducing the intermittent dialyzer clearance to a continuous equivalent clearance and then simply adding the residual clearance

Table 79-1 Adjustment to Residual Kidney Function (Values for T_r) to Allow Direct Addition of K_r to K_d Using Equation 79-16

Treatments/ wk (N)	No Adjustment	Adjust to Mean BUN	Adjust to Predialysis BUN

BUN, blood urea nitrogen

without adjustment. Methods for calculating a continuous equivalent clearance are discussed here.

SOLUTE DISTRIBUTION VOLUME

To ensure that patients of varying sizes receive the same dose of dialysis, clearances are adjusted for body size. This adjustment is analogous to the practice of adjusting creatinine clearance to body surface area. For mathematical convenience, dialysis clearance is typically normalized to total body water, which is equal to the volume of distribution of urea (V), an intrinsic element in the term Kt/V . Various methods can be used to calculate V , including indicator dilution,⁴¹ bioimpedance,¹²⁷ anthropometric methods,¹²⁸⁻¹³⁰ and formal urea kinetic modeling.⁴¹ The most common methods used in clinical practice are anthropometry and formal urea kinetic modeling.

Anthropometric V

Anthropometric formulas using the patient's height in centimeters, weight in kilograms, gender, and age in years are the easiest methods to estimate V . Although other formulas are available,^{127,128} the most commonly used is the Watson formula¹³⁰:

$$\begin{aligned} \text{Males: } V \text{ (liters)} &= 2.447 - 0.09516 \cdot \text{age} + \\ &0.1074 \cdot \text{height} + 0.3362 \cdot \text{weight} \end{aligned} \quad (\text{Eq. 79-17})$$

$$\begin{aligned} \text{Females: } V \text{ (liters)} &= -2.097 + 0.1069 \cdot \text{height} + \\ &0.2466 \cdot \text{weight} \end{aligned} \quad (\text{Eq. 79-18})$$

These equations were designed for a wide range of anatomy, but the coefficient of variation is large¹³⁰ because variables other than height and weight can influence V .¹²⁸

Modeled V

Urea kinetic modeling yields a more accurate measure of V in individuals because the model makes no anthropometric assumptions and because V is obtained from an average of

repeated modeling sessions in the same patient. This method is analogous to the use of indicator dilution methods to measure V , with urea as the indicator. In the HEMO Study, modeled V was 13% to 19% lower than anthropometrically derived V ,¹³¹ and lower in whites than in blacks. The difference between modeled and anthropometric V was least for the Watson formula. The etiology for this discrepancy is debated; it may be due to measurement errors in anthropometry, a contracted total body water space in dialysis patients, or differences between the urea distribution volume and total body water.

FREQUENCY OF DIALYSIS

The HEMO Study finding that a higher delivered dose of dialysis did not improve survival¹⁶ has stimulated renewed interest in daily hemodialysis. Observational data suggest that daily hemodialysis improves blood pressure control and may reduce the need for erythropoietin, improve nutrition, regress cardiac hypertrophy, improve phosphate control, reduce inflammation, and improve both quality of life and survival.^{35–39,132–139} Currently, daily dialysis is provided either as short daily sessions lasting 1.5 to 3 hours or as nocturnal sessions lasting at least 6 hours while the patient is asleep. Because treatments occur daily, the effects of solute disequilibrium and solute sequestration are minimized, effectively increasing dialysis efficiency while improving its tolerance. In particular, nocturnal dialysis given 6 to 7 nights weekly is expected to control levels of sequestered, protein-bound, and larger molecular weight solutes more effectively.

Available data to date on daily dialysis are observational and frequently retrospective.³⁶ Two randomized, multicenter studies are currently underway to evaluate the safety and efficacy of more frequent hemodialysis.¹⁴⁰ The Frequent Hemodialysis Network (FHN) Trial Group is conducting two linked studies comparing both short in-center daily hemodialysis and home daily nocturnal hemodialysis with conventional thrice-weekly hemodialysis. Primary outcomes are left ventricular mass index, quality of life, and mortality; secondary endpoints consist of cognitive function, depression index, serum albumin, serum phosphate, blood pressure control, anemia, and hospitalization rates. Complications and the economics of daily dialysis are also monitored. Results of the FHN Trial are not yet available, but mathematical models of solute kinetics suggest that approximately 50% of the benefit derived from daily dialysis can be achieved by increasing the frequency from three to four treatments per week.¹⁵

RECENT MODIFICATIONS OF UREA MODELING

As discussed, intermittent hemodialysis has inherent inefficiencies because of the effects of solute disequilibrium, solute sequestration, logarithmic decline in solute concentration during dialysis, and the obvious lack of clearance between dialysis sessions. These inefficiencies are attenuated by more frequent or more prolonged treatments, but the improvement is not reflected in currently used measurements of spKt/V and even equilibrated eKt/V .^{15,141,142} Several modifications to formal urea kinetic modeling have been proposed to allow

improved assessment of dialysis adequacy for more frequent dialysis: equivalent continuous clearance, standard Kt/V , and normalized Kt/V .

Equivalent Continuous Clearance (EKR)

One method, as mentioned in the Addition of Residual Native Kidney Clearance section in this chapter, converts the intermittent hemodialysis component to an equivalent continuous clearance¹⁴³:

$$\text{EKR} = G/\text{TAC} \quad (\text{Eq. 79-19})$$

where EKR is the continuous equivalent of intermittent clearance, has units of mL/min, and includes both the dialyzer and residual kidney clearance. G is the urea generation rate, and TAC the mean concentration (time averaged concentration) of urea; both are obtained from formal urea kinetic modeling.

EKR is the equivalent continuous urea clearance required to maintain the BUN at a level equal to the measured mean level, assuming a steady state of urea nitrogen balance. An example of the clinical application of EKR is its use to explain the discrepancy between the targeted dialysis dose in hemodialysis versus peritoneal dialysis. The minimum spKt/V per hemodialysis treatment is 1.2, giving a weekly Kt/V of 3.6, which results in a hemodialysis mortality rate comparable to that for peritoneal dialysis at a weekly Kt/V of 2.0. Using Equation 79-19, the quantity of dialysis needed to keep a patient's time-averaged BUN constant decreases from 3.6/week to an EKrt/V of approximately 3/week.¹⁴¹ Converting an intermittent hemodialysis urea clearance to a continuous equivalent brings weekly urea clearance closer to the targeted weekly peritoneal clearance, but there remains a significant difference. This logic suggests that simply maintaining an equivalent mean BUN is not sufficient to explain the discrepancy between hemodialysis and peritoneal dialysis targets.

Standard Kt/V

Substituting average predialysis BUN (average peak BUN) for TAC in Equation 79-19 yields standard clearance (stdKt/V)^{15,55,141,144}:

$$\text{stdK} = G/(\text{average predialysis BUN}) \quad (\text{Eq. 79-20})$$

G and average peak BUN are derived from formal urea kinetic modeling. An alternative mathematical calculation for stdKt/V from eKt/V is also available and has been validated against the computer-based modeling.¹⁴⁵

Because the predialysis BUN is always higher than the mean BUN, standard clearance is always lower than EKR. Although stdKt/V more closely approximates the peritoneal dialysis weekly Kt/V target, it is unlikely that peak urea levels mediate uremic toxicity because urea itself is not very toxic.^{30,125} Rather, the more potent uremic toxins probably are more sequestered than urea, so levels correlate better with the peak urea levels.

Normalized Kt/V

A third new expression for continuous equivalent clearance is the normalized fractional clearance (nKt/V).^{55,141} Unlike the previous Kt/V expressions, in which the urea removal rate

(equal to the generation rate when in steady state) is divided by a urea concentration, the normalized clearance (nK) is redefined as the urea removal rate divided by the mean concentration of a sequestered solute:

$$nKt/V = G/(\text{mean concentration of sequestered solute})$$

(Eq. 79-21)

This theoretical solute behaves like urea in being easily dialyzed, but is more sequestered than urea in other solute compartments, leading to more solute disequilibrium during dialysis and larger rebound after dialysis. Preliminary estimates suggest that a solute with K_C of approximately 100 mL/min and dialyzer clearance similar to urea would provide an excellent model.¹⁴⁶

Scaling by Surface Area Instead of V

Use of V to adjust urea clearance for body size and to allow direct comparison of urea clearance among patients and populations is debated for several reasons.^{33,147-149} First, V itself is associated independently and inversely with mortality and may confound analyses of dialysis dose versus mortality. Second, factoring urea clearance for V may lead to underdialysis of women and small patients, especially if the assumption that smaller patients need proportionally less dialysis is incorrect. Third, true uremic toxins may not behave like urea and therefore may not distribute only in total body water or V.

Instead, some authors have proposed using Kt alone as a measure of dialysis adequacy.¹⁵⁰ Others suggest factoring clearance (Kt) by body surface area as an adjustment for body size. Factoring for body surface area augments the adjusted dialysis dose for smaller patients (i.e., relatively higher clearance) and reduces the adjusted dialysis dose for larger patients (i.e., relatively lower clearances). This adjustment is straightforward for on-line monitoring of adequacy, which yields Kt. However, if adequacy is obtained using predialysis and postdialysis BUN levels and urea kinetic modeling, the expression for adequacy already includes V. Multiplying Kt/V obtained from kinetic modeling by $3.27 \times V/V^{0.667}$ effectively converts the denominator from total body water to body surface area.³³ Applying this correction to the modeled Kt/V yields the same dialysis dose when V is 35 L, augments the dose if V is less than 35 L, and reduces the dose if V is higher, similar to the effect described above for factoring Kt by body surface area.

REQUIREMENTS FOR DIALYSIS AMONG PATIENT SUBPOPULATIONS

As discussed, the NCDS showed that both high and low blood urea concentrations were associated with increased mortality, due to insufficient dialysis in the former and to poor nutrition in the latter.^{6,121} This ambiguity in interpreting the blood urea concentration led to the adoption of urea clearance as the determinant of dose. A mechanistic analysis of the NCDS data demonstrated improved outcomes when spKt/V was 1.0 or greater per dialysis performed three times weekly.¹²¹ Subsequently, data from observational studies suggested that increasing Kt/V to 1.2 or greater yielded additional benefit.⁷⁻¹³

Recommendations from the Renal Physicians Association, the National Kidney Foundation, and the National Institutes of Health adopted a Kt/V of 1.2 per dialysis as the minimum dose. Findings from the HEMO Study confirmed the above minimum, showing that increasing the single pool Kt/V from 1.3 to 1.7 did not further reduce morbidity or mortality in patients dialyzed three times weekly.¹⁶

Factors other than dialysis dose also influence mortality. Several studies have demonstrated that a larger body size, whether assessed by body weight, body mass index, or total body water (as determined by the Watson formula), was associated with a lower mortality.^{18,150-155} Black race also confers a survival advantage for patients on hemodialysis.¹⁵² Whether increasing the dialysis dose has a further impact on the effects of body size and race on mortality is controversial.^{150,152,154,155} A secondary analysis of the HEMO Study confirmed that a larger body size is associated with a lower mortality, but a higher dialysis dose had no further effect.¹⁸ However, even after adjusting for the effect of body size (smaller in women), women benefited from a higher dose of dialysis, with a 19% lower mortality risk.¹⁸ Men did not appear to benefit from a higher dialysis dose. Analysis of two large databases (Dialysis Outcomes and Practice Patterns Study and Centers for Medicare and Medicaid Services) also showed that women may benefit from a higher dose of dialysis, whereas men did not.¹⁵⁶ Because of the potential errors seen with secondary analysis and with retrospective studies, current recommendations are to provide women with the same dose of dialysis as men, unless symptoms suggestive of uremia are present.

PITFALLS AND TROUBLESHOOTING

Discrepancies in the Delivered versus Prescribed Dialysis Dose

Formal urea kinetic modeling provides a measurement of the delivered dose of dialysis, allowing a comparison with the prescribed dose. A discrepancy between the two may result from large difference between total body water calculated from anthropometric formulas (V_{Calc}) such as the Watson formula (see Equations 79-17 and 79-18) and the modeled V derived from formal urea kinetics (V_{UKM}). Assuming that V_{Calc} is accurate, when V_{UKM} is larger than V_{Calc} , the delivered Kt/V is lower than that prescribed (Box 79-1). The converse is true when V_{UKM} is smaller than V_{Calc} . Various common causes of differences between V_{UKM} and V_{Calc} are listed in Box 79-1.

Alternatively, if the urea kinetic modeling program only reports Kt/V, both prescribed and delivered, a significant difference between the two should prompt an evaluation to detect errors in the delivery or monitoring of dialysis (Boxes 79-2 and 79-3; see also Box 79-1). When delivered Kt/V is greater than prescribed Kt/V or V_{Calc} is greater than V_{UKM} , the cause is usually an error in sampling the postdialysis urea level (see Box 79-1), and not from an erroneous dialysis prescription.

Blood sampling errors can also lead to an artificially low delivered Kt/V when the prescribed Kt/V is appropriate (see Boxes 79-1 to 79-3). In addition, other problems can lead to a real reduction in delivered Kt/V despite an adequate prescribed Kt/V (see Boxes 79-1 to 79-3). These problems include a poorly functioning vascular access, inadequate

Box 79-1 Causes of a Discrepant Volume of Urea Distribution Obtained from Formal Urea Kinetic Modeling (V_{UKM}) Versus that Obtained from Anthropometry (V_{calc})

$$V_{UKM} > V_{calc}^*$$

Delivered Kt/V < Prescribed Kt/V

Low blood flow in vascular access
 Inadequate dialyzer performance
 Low dialysate flow during dialysis
 Prescription entered incorrectly
 Early termination of dialysis
 Predialysis urea level drawn too late

$$V_{calc} > V_{UKM}$$

Delivered Kt/V > Prescribed Kt/V

Postdialysis urea level drawn from venous line
 Postdialysis urea level drawn with recirculation present
 Postdialysis urea level drawn after very efficient dialysis in small patient → urea disequilibrium
 Postdialysis urea level diluted with normal saline

*assuming that V_{calc} is accurate

Box 79-2 Common Causes for a Lower Delivered Dose of Hemodialysis than the Prescribed Dose*

Compromised Urea Clearance

Access recirculation

Poor dialyzer function

- Overestimation of dialyzer performance
- Inadequate dialyzer reprocessing
- Dialyzer clotting during hemodialysis
- Dialyzer leaks

Actual QB < prescribed QB

- Poor vascular access function
- Blood pump malfunction

Actual QD < prescribed QD

- Dialysate flow miscalibration

Reduced Treatment Time

Delay in starting dialysis

Failure to account for interruptions

Premature discontinuation of dialysis

- Staff convenience or error
- Patient request

Laboratory or Blood Sampling Errors

Predialysis blood sample diluted with saline

Predialysis blood sample drawn after dialysis initiated

Postdialysis blood sample drawn before dialysis ended

Postdialysis blood sample drawn >5 minutes after dialysis ended

Laboratory measurement error

*An expanded analysis is presented in Box 79-3.

dialyzer performance, lower than prescribed dialysate flow, and shortened dialysis treatment time, all of which compromise urea clearance directly (see Box 79-2). Clinical events, such as hypotension, muscle cramping, chest pain, problems with needle placement, and hemodialyzer blood leaks, also contribute to reduced urea clearance, either by shortening the dialysis treatment time or by lowered QB below that prescribed (see Box 79-3).

Most troubleshooting focuses on causes of a reduced delivered Kt/V, because interventions to improve the dialysis treatment itself are necessary to correct the underlying problem and because the delivered Kt/V is actually low in most cases, not artificially low due to blood sampling errors. A discussion

of some specific clinical problems that can affect delivered Kt/V follows.

Measurement Errors

Because of the nonlinear removal of urea at the beginning of hemodialysis and the rapid rebound in BUN at the end of dialysis, timing of blood sampling is critical for accurate determination of the delivered dialysis dose. Drawing the predialysis blood sample for urea measurement after dialysis has begun or contaminating the predialysis blood sample with saline solution or with the catheter lock solution will falsely lower the predialysis urea level and result in a falsely lower delivered Kt/V (see Boxes 79-1 to 79-3). Similarly, poor technique in blood sampling at the end of dialysis can result in erroneously high or low urea levels and a spuriously inaccurate delivered Kt/V (see Boxes 79-1 to 79-3). Falsely low postdialysis urea levels will result if blood is sampled from the venous instead of arterial line, without flushing the blood tubing and needle to eliminate recirculated blood, or while saline solution or blood is infused. These errors all lead to an artificially high delivered Kt/V. Sampling blood too late after discontinuation of dialysis will result in a falsely low delivered spKt/V because of the effects of urea rebound (Point C and beyond in Fig. 79-2). These causes of a spuriously low delivered spKt/V must be distinguished from causes of a true reduction in delivered Kt/V.

Guidelines from The Kidney Disease Outcomes Quality Initiative (K/DOQI) on hemodialysis adequacy provide evidence-based recommendations for sampling of blood both predialysis (Box 79-4) and postdialysis (Box 79-5).³³ Accurate laboratory processing of the blood sample to measure BUN is also important to yield a true measure of the delivered dialysis dose.

Procedure for Sampling Blood Postdialysis

At the completion of hemodialysis, if access recirculation is present, the arterial blood entering the dialyzer may be contaminated with just-dialyzed blood from the venous return. The urea concentration is lower in this recirculated blood, diluting the urea concentration of the arterial blood and leading to an artificially high delivered Kt/V. Hence, postdialysis blood samples will yield an appropriate BUN value only if the effect of access recirculation is eliminated. Two methods exist to reduce the effect of access recirculation: the slow-blood-flow method^{33,157} and the stop-dialysate-flow method^{33,158,159} (see Box 79-5).

Box 79-3 Error Analysis Algorithm to Detect One of Several Potential Common Problems in Hemodialysis Delivery That Is Responsible for a Lower Delivered Dose of Hemodialysis Than the Prescribed Dose

Actual Dialyzer Clearance < Assumed Dialyzer Clearance

Elements of the hemodialysis procedure affecting solute clearance include dialyzer permeability (K_{DA}), effective dialyzer surface area, blood flow rate (QB), and dialysate flow rate (QD).

1. Assess fistula for recirculation
 - Review arterial and venous needle placement, proximity, and orientation
 - Verify direction of blood flow through the vascular access device
2. Review record of hemodialysis treatment on the date of measured dialysis adequacy
 - Hemodialyzer reuse log to evaluate total cell volume of dialyzer
 - Maintenance log for dialysis machine for last calibration date and results
 - Hemodialysis treatment log to determine whether prescribed treatment parameters for the following were followed: blood flow rate (QB), dialysate flow rate (QD), and type of hemodialyzer
 - Hemodialysis treatment log to assess for the presence of clinical events that may have altered QB: hypotension, muscle cramp, chest pain, and problems with needle placement
3. Assess for episodes of dialyzer clotting
 - Review anticoagulation regimen for hemodialysis
4. To determine whether hemodialyzer clearance is overestimated, review results of formal urea kinetic modeling of other patients using the same dialyzer

Effective Hemodialysis Treatment Time < Prescribed Treatment Time

Hemodialysis treatment time is the total time at the prescribed blood and dialysate flow rates with the prescribed dialyzer. If the hemodialysis treatment is interrupted, the total dialysis time must be extended by an equivalent amount to ensure the same solute clearance.

1. Review the hemodialysis treatment log to determine the total effective treatment time

2. Review the treatment log for the following:
 - Patient arrival time in the clinic
 - Late hemodialysis start time without compensatory extension at the end
 - Patient request for early termination of treatment
 - Clinical events that may have interrupted or caused premature termination of treatment: hypotension, muscle cramps, chest pain, dialyzer clotting, hemodialyzer blood leak, problems with needle placement that required recannulation of the vascular access, pressures in the extracorporeal circuit close to alarm limits

Errors in Sampling or Processing Blood Specimen

Blood samples that provide predialysis and postdialysis urea levels to allow calculation of delivered dialysis dose with formal urea kinetic modeling must be obtained consistently to avoid: (a) dilution with saline or heparin, (b) contamination by recirculated blood, or (c) confounding by urea disequilibrium

1. Causes of falsely low predialysis BUN concentration
 - Dialysis needle was filled with saline
 - Heparin or locking agent was incompletely removed from the hemodialysis catheter
 - Blood sample was drawn after initiation of hemodialysis
 - Laboratory error in assaying blood sample
2. Causes of falsely high postdialysis BUN concentration
 - Blood sample was drawn too late after the discontinuation of hemodialysis
 - Laboratory error in assaying blood sample
3. Causes of falsely low postdialysis BUN concentration
 - Blood sample was drawn from the venous line
 - Blood sample was drawn without flushing the blood tubing and needle to eliminate recirculated blood
 - Blood sample was contaminated with infused saline
 - Laboratory error in assaying blood sample

Box 79-4 Blood Sampling Techniques for Determination of Predialysis BUN

Arteriovenous Fistula or Graft

Obtain the blood sample from the arterial needle immediately after insertion and before flushing the needle with heparin or connecting to blood tubing

Ensure no saline or heparin is in the arterial needle

Do not draw blood specimen if dialysis has begun

Venous Catheter

Using sterile technique, withdraw any heparin or saline, along with blood, from the arterial port to a total volume of 5 mL; discard

Using a new syringe, draw the blood sample for BUN measurement

Start hemodialysis per clinic protocol

The slow-blood-flow method is by far the most popular and has been in use longer^{33,157} (see Box 79-5). Reducing the blood flow rate to 100 mL/min eliminates or greatly reduces access recirculation. Waiting for 15 seconds at the lower QB before obtaining a blood sample allows nonrecirculated blood from the vascular access to replace any potentially recirculated blood. Because 100 mL/min is about 1.6 mL/sec, waiting for 15 seconds at this blood flow rate will allow 24 mL of nonrecirculated blood to displace an equivalent amount of potentially recirculated blood. If the blood tubing volume from the arterial needle tip to the arterial sampling port approaches 24 mL, the waiting period must be longer than 15 seconds. This volume in most blood tubing/needle sets is closer to 8 mL. An alternative site for blood sampling is the arterial needle hub, which eliminates the use of additional needles but requires a sterile disconnect (see Box 79-5). Although the slow-blood-flow method eliminates the error from access recirculation, which resolves immediately

Box 79-5 Blood Sampling Techniques for Determination of Postdialysis BUN**Slow-Blood-Flow Method**

Drawing the sample from the blood line sampling port

1. At completion of hemodialysis, turn off QD, or decrease to its minimum setting.
2. Turn off ultrafiltration or decrease it to the lowest setting.
3. Decrease QB to 100 mL/min for 15 seconds (longer if bloodline volume from needle tip to sampling port > 15 mL).
4. Obtain the sample, either with QB at 100 mL/min or off.
5. After sampling, stop the blood pump if not already done, and complete dialysis takeoff.

Stop-Dialysate-Flow Method

1. At completion of hemodialysis, turn off QD.
2. Turn off ultrafiltration or reduce it to the lowest setting.
3. Wait 3 minutes; do *not* reduce QB.
4. Obtain the blood sample from the arterial sampling port, the arterial needle hub, or the arterial port of the dialysis catheter. Stopping QB during blood sampling is optional.
5. After sampling, complete dialysis takeoff.

after stopping dialysis (Point A to B in Fig. 79-2), it does not account for the effect of cardiopulmonary recirculation (Point B to C in Fig. 79-2), which takes about 2 to 3 minutes to resolve.

The stop-dialysate-flow method offers an alternative to the above^{158,159} (see Box 79-5). To apply this method, the dialysate flow is stopped for 3 to 5 minutes before the postdialysis arterial blood sample is drawn. By stopping dialysate flow and thus eliminating urea removal, the urea concentration in the dialyzer outlet and venous blood tubing approaches that in the dialyzer inlet and arterial blood tubing.

Errors from Access Recirculation

Not only does access recirculation interfere with accurate measurement of the postdialysis BUN, but it also reduces the efficiency of hemodialysis by diluting the arterial solute concentrations, effectively decreasing delivery of solutes to the dialyzer. Causes of access recirculation are myriad. If the venous needle is placed incorrectly and abuts the venous wall, turbulence results and slows the egress of blood from the access, promoting recirculation. Placing the arterial and venous needles too closely together promotes recirculation, especially at high QB. Vascular access malfunctions, such as venous outflow stenosis, arterial insufficiency either from atherosclerotic disease in the supplying artery or inflow anastomotic stenosis, or a fibrin sheath around the dialysis catheter, may also cause access recirculation. Vascular access dysfunction can be detected through a combination of physical examination, measuring vascular access blood flow and recirculation, direct imaging of the access, and venous pressure monitoring.¹⁶⁰

Dialyzer Clotting

Clotting of the hemodialyzer during a dialysis session reduces the surface area available for solute removal and compromises the efficiency of dialysis. If reuse is practiced, some of the thrombosed hollow fibers may not respond to cleaning and may continue to adversely affect dialyzer clearance. Adequate anticoagulation is therefore important to maintain dialyzer clearance throughout treatment.

Blood Pump Malfunction

Because dialyzer clearance is a function of dialyzer blood flow (QB) (see Equations 79-4 and 79-5), errors in QB due to blood pump malfunction can reduce the delivered dialysis dose or patient clearance. The blood pump in most dialysis machines is a peristaltic roller pump with two or three rollers that move blood through the tubing by sequentially compressing the tubing pump segment against a curved rigid track. The elastic tubing then recoils and refills with blood after one roller arm has passed and before the next one arrives.

QB displayed on the dialysis machine flowmeter is calculated only from the speed of rotation of the roller pump, but true QB is the product of the rotation speed and the volume of blood forced from the tubing during each cycle. If the pre-pump pressure is too low or the blood tubing is too pliable, the pump segment may not re-expand fully between the roller excursions, leading to a lower QB than indicated by the flowmeter. The lower QB reduces the actual dialyzer clearance. This error is more likely to occur at the higher QB used for high-efficiency and high-flux dialysis, or if the vascular access cannot support the prescribed blood flow.¹⁶¹

PRACTICAL EXAMPLES**Four Dialysis Treatments per Week**

Many patients receive dialysis four times weekly to help manage refractory anemia, to improve solute clearance in larger patients, to control volume in those with excessive weight gain, and to improve blood pressure control. The challenge is how to measure the delivered dialysis accurately. Ideally, formal kinetic modeling to calculate standard Kt/V (stdKt/V) (see Equation 79-20) or normalized Kt/V (see Equation 79-21) expressed as a weekly dialysis dose would allow comparisons among different dialysis schedules. Alternatively, stdKt/V may be approximated using the following equation¹⁴⁵:

$$\text{stdKt/V} = \left\{ 100803 \left[(1 - e^{-\text{eKt/V}}) / t \right] \right\} \div \left\{ \left[(1 - e^{-\text{eKt/V}}) / \text{spKt/V} \right] + (10080 / \text{Nt}) - 1 \right\}$$

(Eq. 79-22)

where N is the number of treatments per week. Single pool Kt/V (spKt/V) must be available and converted to equilibrated Kt/V (eKt/V) using Equations 79-12 and 79-13. Derivation of Equation 79-22 is based on a symmetric weekly schedule, no residual kidney function, and a fixed urea volume, but the result is approximately accurate in most patients. Also, the

minimal goal has not been firmly established for these newer expressions of clearance.

A simple but practical way to determine the solute clearance needed for four treatments per week is to take the minimum total weekly spKt/V of 3.6 for three treatments per week and divide by 4 to yield a minimum spKt/V of 0.9 for each dialysis session.³³ This simple calculation does not take into account the gain in efficiency with more frequent dialysis and therefore overestimates the dialysis dose needed, but protects the patient from underdialysis.

Phosphate Removal

Because phosphate is a secluded solute with significant resistance to diffusion across cell membranes, standard thrice-weekly hemodialysis has little effect on controlling its level despite its ready diffusion from plasma into the dialysate.^{29,105} Even short daily hemodialysis fails to improve control of hyperphosphatemia in most studies.^{36,37,107} For patients with persistent symptomatic hyperphosphatemia uncontrolled by dietary restriction and phosphate binders, daily long-duration hemodialysis may provide the solution.^{36,37}

Shortening versus Extending Treatment Time

Near-universal use of high-efficiency dialyzers has reduced the treatment time in many dialysis clinics, especially those in the United States. However, Equations 79-12 and 79-13 show that effective dialyzer clearance (eKt/V) is time dependent and that shortening the treatment reduces its efficiency. Shortening the treatment accentuates the effects of intermittence and exacerbates solute rebound.^{41,98,162,163} Additional problems with shortening the treatment include reduced removal of larger molecules, which is more time dependent,^{164,165} and an obligatory increase in the filtration rate above the maximum 0.35 mL/min/kg (1.5 L/hr in a 70-kg patient) that is tolerated.^{164,166,167} Also, any time lost during dialysis due to technical problems, late arrival, or access recirculation is magnified with shorter treatments.

Patients with large interdialysis weight gains will benefit from a longer treatment time because more time is available for fluid removal. However, beyond 4 hours or so of treatment, removal of small solutes is greatly reduced. Larger size patients would benefit more from increasing the frequency than the duration of thrice-weekly dialysis.

SUMMARY

It would be a mistake to consider preservation of life the only goal of hemodialysis. The quality of the life preserved must be linked to the adequacy of dialysis in ways that are not yet fully understood, but without question, removal of small solutes, analogous to removal of the same solutes by the native kidney, must be a major target of treatment. This chapter focuses on methods for ensuring adequate control of small solute concentrations in the patient using a variety of monitoring and measuring techniques. The successful dialysis caregiver must be aware of these methods and how they can be applied, including their pitfalls and recent modifications that will hopefully continue to improve patient outcomes.

Considering that more than 50 million hemodialysis treatments are performed every year in a single country such as the United States,¹ hemodialysis should be generally regarded as a very safe procedure. This safety is particularly remarkable considering that a large volume of blood is circulated extracorporeally over hours of treatment, with substantial changes in fluid volumes as well as plasma osmolality and chemistry. On one hand, technical advances have been made that make the procedure safer. On the other hand, the older age and higher comorbidities of U.S. dialysis patients predispose to complications. Some of the complications, such as symptomatic hypotension, are expected on a physiologic basis, whereas others, such as erroneous dialysate composition, are technically mishaps. The severity of these reactions ranges from mild and transient to catastrophic and fatal. This chapter covers these spectra, but limits discussion to complications that result from the treatment, rather than those inherent to the patient's underlying uremia and comorbidities.

DIALYSIS REACTIONS

During hemodialysis, large volumes of blood are exposed to components of the extracorporeal circuit, including the dialyzer, tubing, and other foreign substances related to the manufacturing and sterilization processes. This interaction between the patient's blood and the extracorporeal system can lead to various adverse reactions, which manifest as a continuum ranging from subtle to severe and fatal.^{2,3} The signs and symptoms are made up of combinations of angioedema, dyspnea, coughing, chest tightness, sneezing, rhinorrhea, lacrimation, skin flushing,

pruritus, paresthesia, burning sensation, nausea, vomiting, abdominal cramps, and diarrhea. These reactions are often referred to as *dialysis reactions* or *dialyzer reactions*. The former terminology is preferred because some of these reactions are not caused by the dialyzer per se.

The etiologies of these reactions are diverse and are often difficult to establish in individual cases. In general, they can be classified into two broad categories: anaphylaxis or anaphylactoid reactions and direct toxic effects. Anaphylaxis is caused by degranulation of mast cells or basophils induced by IgE and usually requires prior sensitization by the allergen. *Anaphylactoid reactions* are anaphylaxis-like reactions in response to the direct effectors or mediators, such as complement activation products or histamine, and do not require the release of IgE. *Direct toxic effects* are those induced by other substances, such as ethylene oxide (EtO) or formaldehyde. This classification only provides a general framework to facilitate the understanding and research of these reactions. Neither this nor other classification systems, however, provide definitive clues to the etiology or the management of the individual patient, because there is probably substantial overlap in clinical manifestations between different categories. Some of the etiologies are discussed in the following.

Leachable Substances

Perhaps the best studied leachable substance from the hemodialysis circuit is EtO.⁴⁻⁶ EtO gas is used to sterilize some dialyzers. The potting compound that anchors the hollow fibers in place has been shown to be a reservoir for EtO, essentially

providing sustained release of EtO into the lumen during the functional life of the dialyzer.^{6,7} The exposure of chronic dialysis patients to EtO and their immune response to the compound can be demonstrated by the presence of specific IgE antibodies against EtO that has been conjugated to serum albumin in vivo. In some studies, two thirds of patients with apparent reactions to dialyzers have circulating IgE antibodies against EtO.⁴ This test is not specific, because 10% of patients with no prior history of dialysis reactions also have circulating levels of anti-EtO IgE.^{6,8} Since EtO is a residue in dialyzers and may be important in the pathogenesis of some dialysis reactions, it is not surprising that these reactions are more common when a new, instead of a reprocessed, dialyzer is used. This phenomenon leads to the term *first-use syndrome*.^{2,3,9} Accordingly, rinsing the blood compartment of the dialyzer with saline solution can decrease the incidence of these events. Rinsing the dialysate compartment with dialysate is also effective, because the circulating dialysate can also remove the EtO in the blood compartment by diffusion. If EtO allergy is suspected, changing to a dialyzer sterilized by gamma radiation or steam is appropriate.

Dialysis reactions can also be due to residual disinfectants in the dialyzer, such as formaldehyde, glutaraldehyde, and peracetic acid/hydrogen peroxide. Life-threatening reactions have been observed in dialysis patients in whom serum antibody against formaldehyde was detected.¹⁰ Instead of first-use syndrome, these reactions are appropriately called *reuse syndrome*^{11,12} because they occur during dialyzer reuse. If the diagnosis is correct, proper reprocessing of the dialyzers and rinsing of the dialyzer before use are also expected to decrease these reactions.

Other leachable substances that have been suspected to cause dialysis reactions include isopropyl myristate, which is used in the spinning process of hollow-fiber fabrication,⁴ isocyanates found in the potting compound,^{13,14} and nonendotoxin *Limulus* amoebocyte lysate-reactive material.^{15,16} The latter is believed to be cellulose in origin and to react to the *Limulus* amoebocyte lysate assay.

Another leachable substance found in the dialysis circuit is the plasticizer, di(2-ethylhexyl)phthalate (DEHP), although this compound has not been incriminated in acute dialysis reactions.¹⁷⁻¹⁹ The flexibility of polyvinylchloride tubing is achieved by the addition of DEHP into the polymer matrix.²⁰ Although there is no clear evidence to confirm its toxicity, DEHP can bind to plasma lipids and lipoproteins, and significant tissue levels of DEHP have been recovered at autopsy of dialysis patients. Furthermore, hepatitis-like syndrome and necrotizing dermatitis have been reported in association with polyvinylchloride exposure in dialysis patients. The practice of reusing blood tubing may provide a potential clinical advantage by reducing the exposure to plasticizers. Leachability studies of another plasticizer, trimellitate,^{21,22} from blood tubing show a lower rate of release compared with DEHP.²⁰

Membrane Bioincompatibility

Another causative factor of dialysis reactions is dialysis membrane bioincompatibility; in particular, interactions between the dialysis membrane and plasma proteins. Two cascades of plasma protein activation have been most intensely studied in this regard. Activation of the complement system via the

alternative pathway is practically universal for all dialysis membranes, albeit to various degrees.^{23,24} Presumably, by virtue of the free hydroxyl moieties on the surface, unsubstituted cellulosic membranes activate complement rigorously. Complement fragments C3a and C5a generated²³⁻²⁵ from C3 and C5, respectively, are known as *anaphylatoxins*, because of their potential to induce anaphylactoid reactions. The functional activities of these complement fragments are, however, markedly diminished by the action of a serum carboxypeptidase.²⁶ Thus, despite the high plasma levels of C3a and C5a commonly found during hemodialysis, especially with unsubstituted cellulosic membranes, dialysis reactions are uncommon. The frequency at which complement activation is responsible for dialysis reactions is unknown, but it is likely to be rare. Compared to unsubstituted cellulosic membranes, substituted cellulosic membranes^{27,28} (in which some of the hydroxyl moieties are substituted by other moieties) and synthetic membranes^{11,23} tend to activate complement less and would therefore be preferable if complement activation is to be minimized.

The second plasma protein cascade that is of particular relevance to hemodialysis is the intrinsic (or contact) pathway of coagulation. Severe anaphylactoid reactions have been reported in patients dialyzed with the AN69 membrane who were also taking angiotensin-converting enzyme (ACE) inhibitors.²⁹⁻³¹ The likely pathogenetic mechanisms are as follows. Binding of Hageman factor (factor XII) to a negatively charged surface leads to its activation and subsequent conversion of kininogen to bradykinin.^{29,30} The AN69 membrane is composed of a copolymer of acrylonitrile and methallyl sulfonate. The latter moiety is negatively charged and is therefore an activator of the intrinsic coagulation pathway. Because angiotensin converting enzyme is also a kininase, the catabolism of bradykinin is inhibited in the presence of an ACE inhibitor. The combination of dialysis with the AN69 membrane and use of an ACE inhibitor therefore results in the accumulation of bradykinin in the plasma and consequently anaphylactoid reactions and hypotension.²⁹ The obvious preventive strategy for this cause of dialysis reaction is the avoidance of this type of dialysis membrane or ACE inhibitors.

Several anaphylactoid reactions have also been reported in patients dialyzed using polysulfone membranes reprocessed with bleach and also treated with ACE inhibitors.^{12,32} These reactions ceased once the use of bleach was discontinued. Furthermore, a cluster of anaphylactoid reactions was observed in patients treated with ACE inhibitors and dialyzed with various membranes reprocessed using hydrogen peroxide/peracetic acid. The reactions abated once reprocessing was discontinued, despite continued use of ACE inhibitors.

Other Factors

The use of acetate dialysate has been implicated in dialysis reactions. Potential mechanisms of these reactions include the direct effect of accumulated acetate and the transient loss of bicarbonate in the plasma prior to conversion to bicarbonate,³³ and the stimulation of interleukin-1 production by monocytes.³⁴ These reactions tend to be mild and are not acutely life-threatening. Acetate dialysate is seldom, if at all, used in the United States currently. Bacterial products, such as endotoxin fragments,

present in the dialysate that traverse across the dialysis membranes are also known to induce cytokine release by monocytes and consequently pyrogenic reactions.³⁵ These pyrogenic reactions tend to be mild. They may occur more frequently with high-flux membranes,³⁶ especially those reprocessed using bleach, because reprocessing is associated with increased porosity of the membrane,^{37,38} thus facilitating the transfer of bacterial products.

Drugs administered during hemodialysis can also cause adverse reactions that are sometimes difficult to distinguish from other causes of dialysis reactions. Intravenous iron dextran is not infrequently associated with adverse reactions, although severe anaphylactoid reactions are rare, occurring in 0.6% to 1% of patients.^{39,40} The mechanisms responsible for dextran-induced anaphylactoid reactions are unclear; the dose-dependent release of histamine from basophils may be responsible.^{41,42} More frequently, iron dextran administration is associated with various degrees of hypotension, headache, myalgia, arthralgia, and fever.^{39,43} Intravenous iron gluconate appears to be associated with fewer adverse reactions.^{40,43} Although it is uncommonly used now in dialysis units, deferoxamine therapy for the chelation of aluminum or iron can produce hypotension during dialysis and, rarely, allergic reactions, gastrointestinal disturbances, loss of vision, auditory toxicity, bone pain, or exacerbation of aluminum encephalopathy.^{44–46}

Treatment of Dialysis Reactions

Prevention of dialysis reactions depends on identification of the causative factor. Immediate reactions that occur within the first few minutes of the procedure are likely to be due to preformed agents, such as EtO or formaldehyde. Laboratory tests (e.g., assays for plasma EtO antibodies or bradykinins) are not routinely performed in clinical cases. Further, the predictive value of these assays for clinical diagnosis of these reactions has not been established. Most often, the etiology of the reaction is never firmly established and the reaction ceases after the dialyzer is switched empirically to another type (e.g., from an EtO-sterilized dialyzer to a gamma-radiated dialyzer or from an AN69 membrane to a polysulfone membrane). The dialysis reaction may also be caused by the blood tubing^{17,18,20,22,47,48} or even medications, such as heparin,⁴⁹ that are administered during the hemodialysis procedure. Switching blood tubing and heparin (e.g., from porcine to bovine heparin) should also be considered. Not uncommonly, dialysis reactions cease with extensive rinsing of dialyzers before use or even if the dialysis procedure and the supplies are unchanged.

The immediate treatment of dialysis reactions depends on the severity of the clinical manifestation. If the reaction is severe, and in particular if it occurs early during the treatment, the extracorporeal circulation should be immediately stopped. Under these circumstances, the blood in the circuit should be discarded rather than being returned to the patient, because it likely contains the causative agent. Otherwise, treatment is largely supportive and targets the specific signs and symptoms. Oxygen supplementation, bronchodilators, sympathomimetic agents, and vasoactive medications are used as indicated. Antihistamines and corticosteroids may be helpful. In mild cases, dialysis can be continued with or without other interventions.

CARDIOVASCULAR COMPLICATIONS

Intradialytic Hypotension

The definition of intradialytic hypotension (IDH) has been inconsistent in different reported series.^{50–52} Consequently, the reported incidence (<5%–40%) has also varied widely. The incidence of IDH, however, will likely continue to increase despite technological advances,⁵³ as more patients with advanced age, diabetes mellitus, and underlying cardiovascular diseases will need dialysis therapy in the future. To maintain the consistency of definition and to assess the response to different therapeutic interventions, the K/DOQI guidelines proposed that IDH be defined as a decrease in systolic blood pressure (BP) of at least 20 mm Hg or a decrease in mean arterial pressure by 10 mm Hg in combination with the symptom complex and a need for active therapy.⁵⁴

When evaluating the etiology of hypotension, it is important to consider more ominous events, such as acute coronary syndrome, arrhythmias, pulmonary embolism (blood clots or air embolism), pericardial effusion or constrictive pericarditis, dialysis reactions, and overestimation of dry weight leading to hypotension. At times other nonspecific symptoms, such as sudden onset sensation of dizziness or fainting, nausea, and vomiting with or without diaphoresis, may be indirect predictors of impending hypotension.⁵⁵ The symptom complex due to IDH can vary and include generalized lethargy, nausea and vomiting, muscle cramps, restlessness, dizziness, anxiety, diaphoresis, chest pain, acute confusion, presyncope, or syncope.⁵⁵ These symptoms may be severe enough to compel termination of the dialysis therapy. Consequently, frequent episodes of IDH can lead to inadequate delivery of the dialysis dose and volume overload.^{56,57} Patients at risk of developing IDH are those who have large interdialytic fluid gain due to fluid or salt intake or poorly controlled hyperglycemia that causes osmotic thirst. Other patients at risk for IDH are those with myocardial, valvular, and pericardial diseases.

Healthy people can tolerate a decrease in blood volume of up to 20% before the development of hypotension. In contrast, dialysis patients can develop hypotension with smaller changes in the blood volume (2%–29%).^{58,59} The combination of extracorporeal fluid removal and fluid shifts to the intracellular compartment predisposes to acute intravascular hypovolemia, particularly when the rate of fluid loss from the plasma compartment exceeds the plasma refilling rate.^{60–62}

The variability in blood volume changes could be explained by the presence of several pathophysiologic conditions, such as (1) the lack of an increase in cardiac output due to the presence of myocardial disease, thus preventing an increase in myocardial contractility in response to changes in intravascular volume^{59,60,63,64}; (2) lack of increase in heart rate and peripheral vascular resistance in response to a decrease in blood volume due to the presence of autonomic dysfunction^{55,65,66}; (3) paradoxical and sudden withdrawal of sympathetic response, resulting in bradycardia (Bezold-Jarisch reflex) in response to severe ventricular underfilling (defined as bradycardic hypotension)^{67,68}; (4) failure of capacitance vessels to constrict in the face of hypovolemia, with impairment in venous return.⁶⁹ Impaired reactivity of resistance and capacitance vessels could be secondary to autonomic dysfunction, cytokine release due to exposure to extracorporeal circulation,⁷⁰ an increase in core body temperature due to energy

transfer from the dialysate, an increased production of nitric oxide,⁷¹ or decreased vasopressin release in the presence of a low-output state.⁷² Other patient-related factors are delayed filling of the central blood volume in patients with arteriovenous fistula or graft.⁵² Dialysis-related factors that may increase the risk of developing IDH include the use of acetate dialysate⁷³ or low-calcium dialysate.⁷⁴ Occasionally, IDH may develop because the target dry weight has been underestimated⁷⁵ or the dialysis machine has been erroneously programmed to remove more than the expected volume.

The management of patients with IDH includes urgent resuscitation to relieve patient discomfort, maintain hemodynamic stability, and monitor for the development of adverse cardiovascular events. Routine measures for the treatment of IDH include placing the patient in Trendelenburg's position to augment venous refilling and administering saline boluses to increase the systolic BP to 100 to 110 mm Hg as appropriate. The amount of saline solution required varies greatly. Some patients are grossly fluid overloaded systemically and should be given as little fluid as possible to temporarily relieve the symptoms related to the acute plasma volume depletion. On the other hand, some patients are systemically volume depleted even before starting dialysis because of a preexisting condition such as diarrhea; fluid resuscitation under these circumstances may require more aggressive intradialytic saline hydration. Hypertonic saline solution (in 5–10 mL bolus of 7.5% concentration) and, less commonly, hypertonic glucose (25–50 mL bolus of 50% concentration) in nondiabetic patients and mannitol (bolus of 12.5–25.0 g) can also be used. All of these agents are readily dialyzable. If mannitol is administered toward the end of the hemodialysis session, however, it may be retained in the plasma and can accumulate in the visceral organs. The long-term consequences of mannitol accumulation are not known. After an episode of severe symptomatic hypotension, the patient should be monitored for the development of cardiovascular events and evaluated for orthostatic hypotension before discharge from the dialysis unit. Strategies to prevent the occurrence of future episodes should be considered if the IDH is recurrent.

Intradialytic hypotension can be prevented by modifying the dialysis prescription based on the individual center experiences and technical skills of the dialysis staff. Hemodialysis therapy using isothermic (same as body temperature) dialysate is invariably associated with an increase in core body temperature despite heat loss by convection in the extracorporeal circuit.^{76,77} The increase in core body temperature decreases the reactivity of resistance and capacitance vessels, and venous return may not increase in response to changes in blood volume during ultrafiltration.⁶¹ To avoid these phenomena, dialysate temperature can be adjusted and maintained at 1° to 2°C below the body temperature. This technique is known as *cool-dialysate dialysis*. Dialysis with cool dialysate improves the reactivity of peripheral resistance and capacitance vessels and increases myocardial contractility.^{61,78–80} The most common adverse effects are cold sensation and shivering. A lack of response to cool-dialysate hemodialysis could be due to the failure of fluid shifts from the third compartment in the presence of severe vasoconstriction of the capacitance vessels.⁶¹ Urea clearance usually remains unchanged during cool-dialysate hemodialysis.⁸¹ The temperature of the dialysate can be controlled by continuous biofeedback systems,^{82,83} but this technology is not widely available.

Another common strategy to prevent IDH is to manipulate dialysate sodium concentrations. High dialysate sodium concentrations increase plasma osmolality, thus enhancing extracellular and plasma refilling rates. Most studies, but not all, found that the use of conventional dialysate sodium (138–144 mmol/L) compared to low sodium (<135 mmol/L) concentration is associated with lower incidence of IDH.^{84–88} High sodium (>144 mmol/L) dialysate can further prevent the development of IDH, but may also lead to interdialytic weight gain and hypertension.^{89–91} *Sodium profiling* is the technique of varying dialysate sodium concentration during the dialysis session, which is often accomplished automatically by programming the dialysis machine. Dialysate sodium concentration can be increased or decreased linearly or in a stepwise fashion. Less frequently, alternating high and low concentrations of sodium throughout the dialysis session can be employed. The objective of tapering dialysate sodium concentration during dialysis (*sodium ramping*)^{86,88} is to avoid high plasma sodium concentrations at the end of the dialysis session. The counterargument to this strategy is that plasma and interstitial fluid volumes and pressure are high at the beginning of the dialysis session, and therefore high dialysate sodium levels are unnecessary. Toward the end of the dialysis session, interstitial fluid pressure has decreased and plasma refilling rate decreases accordingly. At that time, high dialysate sodium levels are more useful in increasing the serum sodium concentration and osmotic pressure that draw fluids from the intracellular compartment. Increasing dialysate sodium levels during the dialysis session is known as reverse sodium modeling.⁹¹ Fine-tuning of sodium concentration during hemodialysis can be guided by the on-line measurement of conductivity of the plasma and ultrafiltrate and on-line measurement of the ionic mass transfer to prevent the salt retention due to sodium ramping.^{92–94} Similar to sodium modeling, ultrafiltration profiling can be used to prevent IDH: it allows adjusting ultrafiltration from a high rate at the start to a lower rate at the end of the dialysis session.

Changes in ionized calcium can play an important role in myocardial contractility during hemodialysis therapy, because myocardial contractility decreases in the presence of low dialysate calcium (1.25 mmol/L) compared to normal dialysate calcium (1.75 mmol/L).^{50,74,95,96} Very high-calcium dialysate can lead to positive calcium balance, an increase in arterial calcification, and adverse effects on myocardial relaxation.^{96,97} One randomized crossover study demonstrated that the combination of dialysate calcium of 1.50 mmol/L and bicarbonate of 32 mmol/L was associated with less significant drop in systolic BP than the combination of calcium and bicarbonate concentrations of 1.25 mmol/L and 26 mmol/L, respectively.⁹⁸ Another randomized crossover study compared three different regimens of dialysate calcium levels: constant 1.25 mmol/L versus constant 1.50 mmol/L versus a profiled regimen of 1.25 mmol/L during the first 2 hours and 1.75 mmol/L during the remaining 2 hours.⁹⁹ Both the dialysate calcium of 1.50 mmol/L as well as profiled calcium regimens were more effective in reducing the incidence of IDH than the 1.25 mmol/L regimen.⁹⁹ Because the impact of dialysate calcium concentration on vascular calcification remains unknown, the K/DOQI working group for Clinical Practice Guidelines for Bone Metabolism and Disease in Chronic Kidney Disease recommends a routine prescription of dialysate calcium of 1.25 mmol/L; higher

concentrations of dialysate calcium should be considered for maintaining intradialytic hemodynamic stability.^{100,101}

Reducing intradialytic weight gain is the most important strategy for the prevention of IDH in most patients. Careful estimation of the optimal dry weight is useful and can be facilitated by analytic tools, such as inferior vena cava sonogram,¹⁰² bioelectrical impedance,¹⁰³ and continuous monitoring of blood volume variations.¹⁰⁴ Serum biomarkers, such as brain natriuretic peptide^{105,106} or adrenomedullin,¹⁰⁷ may also be helpful in assessing dry weight.

Short-acting antihypertensive agents should ideally be avoided immediately before the hemodialysis procedure. The avoidance of food intake immediately before and during the dialysis procedure is helpful, because it prevents the diversion of blood flow to the splanchnic circulation.⁸⁷ The benefits of vasoactive agents for either treatment or prevention of IDH have been inconsistent. Midodrine is an α_1 -adrenergic receptor agonist that constricts the splanchnic circulatory bed, as well as systemic precapillary resistance and capacitance vessels, with an increase in circulatory blood volume. Oral midodrine given at a dose of 2.5 to 10 mg 30 minutes before the dialysis session has been reported to prevent IDH.^{108–110} The most frequent adverse effects of midodrine therapy include piloerection, scalp itching or tingling, weakness, paresthesias, flushing, headache, sleep disturbances and, rarely, bradycardia. It is effectively cleared by hemodialysis and its half-life is less than 2 hours in dialysis patients.¹¹⁰ Sertraline is a selective serotonin reuptake inhibitor; its oral administration in a small number of patients has demonstrated small benefits in the prevention of IDH. Adverse effects of sertraline include dizziness, insomnia, fatigue, somnolence, and headache.^{111–113} Recently the use of intravenous vasopressin has been shown to facilitate fluid removal while maintaining hemodynamic stability.^{114,115}

Other therapies that have shown inconsistent results for the prevention of IDH include the use of convective therapies such as on-line hemofiltration, hemodiafiltration and acetate-free biofiltration.^{61,94,116–118} Although convective therapy compared to standard hemodialysis treatment preserves the reactivity of resistance and capacitance vessels, it is postulated that benefits of convective therapies are mostly due to the cooling effect and therefore vasoconstriction from the infusion of substitution fluids.^{119–121} Chronic supplementation with L-carnitine at 20 mg/kg during dialysis therapy has been demonstrated to improve vascular reactivity and prevents IDH in patients with recurrent IDH.^{122,123}

Intradialytic Hypertension

Different degrees of increase in blood pressure, even with fluid removal, can develop either during dialysis or immediately after the dialysis session is completed. Repeated episodes of intradialytic hypertension can be an important risk factor for cardiovascular morbidity and mortality. Intradialytic hypertension appears to be less common, and the pathophysiology more elusive, than IDH. Intradialytic hypertension can be precipitated by the use of hypernatremic dialysate during sodium modeling.⁹⁰ Other risk factors include the use of erythropoiesis-stimulating agents and hemoglobin levels above 13 g/dL. Increased plasma levels of renin and endothelin-1 and decreased nitric oxide/endothelin-1 ratio⁸⁸ result in an

increase in peripheral vascular resistance, as is often present in long-term dialysis patients, and may be contributory to intradialytic hypertension. The administration of hypertensive medications immediately before dialysis may be useful to minimize intradialytic hypertension in patients who are prone to this phenomenon.

Sudden Death and Cardiac Arrest

Cardiac arrest and cardiac arrhythmias account for more than 50% of all cardiac deaths in chronic hemodialysis patients.¹²⁴ Sudden cardiac arrest in dialysis patients is multifactorial and is likely related, at least in part, to fluctuations in fluid and electrolytes during hemodialysis therapy. Survival after cardiac arrest in dialysis patients remains dismal, with 30-day survival of 32% and 1-year survival of less than 15%.¹²⁵ K/DOQI guidelines recommend that all dialysis facilities should support on-site availability of an automated external defibrillator.⁵⁴ In addition, the K/DOQI recommends performing an echocardiogram in all dialysis patients after achieving the optimal volume control within 30 to 90 days after dialysis initiation and periodically thereafter to detect abnormalities that may predispose to sudden death and other cardiac events.

Dialysis-Associated Steal Syndrome

Diversion of blood flow through the arteriovenous fistula or graft decreases blood flow to the artery that is distal to the arteriovenous or arteriovenous anastomosis.¹²⁶ The hemodynamics of these shunts that predispose to peripheral ischemia are complex and involve interactions among the high blood flow into a low-resistance vein, reversal of flow away from the higher-resistance distal arterial bed, and competing with distal collateral blood vessels.¹²⁷ More than two thirds of these shunts have different degrees of retrograde flow, but only 6% to 10% develop peripheral ischemia (*dialysis-associated steal syndrome*).¹²⁸ The symptom complex from the steal syndrome can vary from time to time and can include numbness, weakness, pain, cramps, and cold sensations of the part distal to the fistula or graft. These symptoms may increase in intensity by routine use of the hand, which increases the demand of blood supply, or during dialysis treatment, which may draw more blood from the distal site into the extracorporeal circuit. Physical findings may include cold sensations of the hand, decreased pulse and decreased capillary refilling rate (>3 seconds), acrocyanosis, trophic lesions of nails, hair loss, muscle atrophy, and progression to ischemic ulcers and gangrene.^{129–131} Some of these symptoms can also be produced by mononeuritis, carpal tunnel syndrome, ischemic monomelic neuropathy,¹³² peripheral neuropathy due to diabetes mellitus, uremia, collagen vascular diseases, and acral calciphylaxis.¹³³ Doppler ultrasonography, digital blood pressure phlethysmography, and digital-brachial indices (<0.60) can be used as adjunctive tests,¹²⁷ although angiography remains the gold standard for the definitive diagnosis of steal syndrome.

The most common conservative treatment is symptomatic relief (e.g., using a mitten to keep the hand warm during hemodialysis). In 1% to 10% of patients with clinical steal symptoms, invasive interventions are required. These interventions include angioplasty of the stenosis that may be present in the

inflow artery or ligation of the fistula. Different methods have also been used to decrease the fistula outflow, such as stitching¹³⁴ or placement of a cuff¹³⁵ around the outflow vessel. These maneuvers, however, often lead to thrombosis of the graft. The most advanced technique for treating dialysis-associated steal syndrome is the distal revascularization-interval ligation procedure, which has a high rate (90%) of relieving symptoms while maintaining graft patency at 1 year in more than 85% of patients.^{132,136–138}

Air Embolism

Air embolism is rare nowadays because of technical advances and the keen awareness of most dialysis personnel. Nonetheless, the potential rapid and catastrophic nature of this complication demands particular attention. The prepump tubing segment, arterial needle, and saline infusion tubing are particularly significant points of air entry, because of the high negative pressure that draws the air. The high blood pump speeds used currently also enhance the chance of entry of large volumes of air. Intravenous infusion setups that are attached to, but are not inherent parts of, the dialysis circuit can also be potential points of entry. Yet another point of entry that escapes the safety features of the dialysis circuit is the venous connection of the central venous catheter. The key preventive measure lies in the dialysis machines, which are almost always equipped with a venous air-bubble trap and a foam detector that triggers an alarm and automatically shuts off the blood pump and clamps the venous blood tubing if air is detected.

Clinical manifestations of air embolism depend on the volume of air, the site of entry, and the patient's position.¹³⁹ Microbubbles of air introduced at a slow rate dissolve slowly in the blood and may not be associated with clinical sequelae. In the sitting position, air entry through an arm vascular access bypasses the heart, causes venous emboli in the cerebral circulation, and induces central nervous symptoms rapidly. In contrast, a large bubble introduced from the central venous line when the patient is supine will be trapped in the right ventricle and will interfere with cardiac output. Dissemination of microemboli into the pulmonary vasculature under these circumstances induces acute pulmonary symptoms.

The diagnosis of air embolism is based on clinical signs and symptoms and is often triggered by a keen sense of suspicion. The appearance of foam in the tubings and the typical churning sound on cardiac auscultation when the bubble is in the chest facilitate the diagnosis. If the patient lies in the reverse Trendelenburg position, the air emboli actually migrate to the venous circulation, causing ischemia of the lower extremity.¹⁴⁰

Swift actions are absolutely essential once the diagnosis of air embolism is suspected. The venous blood tubing should be immediately clamped and the blood pump stopped to prevent further air entry.¹⁴¹ For right heart air emboli, the patient should be placed in a recumbent position on the left side with the chest and head tilted downward. Cardiopulmonary support is then instituted. Aspiration of the air from the ventricle by a percutaneously inserted needle or right atrial dialysis catheter can be attempted. The patient is then transported, in the recumbent position, to an acute care facility for hyperbaric oxygen and other supportive therapies.¹⁴²

NEUROLOGICAL COMPLICATIONS

Dialysis Disequilibrium Syndrome

Although dialysis disequilibrium syndrome (DDS) is no longer a frequent complication of hemodialysis, it is still a potential problem if proper precautions are not taken. DDS can result in central nervous system damage with long-term sequelae. Cerebral edema can be observed on brain imaging studies if DDS is severe.^{143,144} An attractive hypothesis for its pathogenesis is that of osmotic disequilibrium between the plasma and cerebrospinal fluid that results from the rapid removal of urea from the former compartment during dialysis, thus causing a shift of water into the brain.¹⁴³ Paradoxical acidosis in the cerebrospinal fluid has also been observed.^{145,146} Recent studies have shown decreased expression of the urea transporter UT-B1 and increased expression of aquaporins (AQP4 and AQP9) in the brain of uremic rats.¹⁴⁷ These abnormalities would exacerbate the retention of urea in the brain despite the rapid removal of urea in the plasma and the promotion of water entry into the brain cells. The risk factors for DDS include severe azotemia and preexisting neurological disorders, such as recent stroke, head trauma, subdural hematoma, and malignant hypertension.^{148–150}

DDS usually occurs toward the end of dialysis and may be delayed up to 24 hours.^{151,152} The manifestations are restlessness, headache, nausea, vomiting, blurred vision, muscle twitching, tremor, disorientation, and hypertension.¹⁵³ This syndrome is usually self-limited, but full recovery may take several days. Severe symptoms, such as obtundation, seizures, coma, and death, occur occasionally.¹⁵⁴ DDS is usually a clinical diagnosis, although the presence of cerebral edema on brain imaging studies provides supportive evidence. Electroencephalographic findings are nonspecific.

Because DDS occurs during rapid hemodialysis, preventive measures are directed toward slower removal of urea, especially during the first session of hemodialysis for acute kidney injury or end-stage renal disease. This can be accomplished by short and more frequent dialysis for the first few days, initially using small-surface-area dialyzers and slow blood rates.¹⁴³ Maintaining plasma osmolality using high-sodium dialysate and infusing sodium bicarbonate or mannitol while plasma urea is being removed would minimize the osmotic disequilibrium between the plasma and the brain. Early initiation of dialysis therapy in both the acute and chronic settings of renal failure, before plasma urea concentrations become very high, can prevent the development of DDS.

Muscle Cramps

Muscle cramps are the most common acute neuromuscular complications; they are observed commonly in the elderly and in hemodialysis-dependent patients,¹⁵⁵ and can occur in 5% to 20% of hemodialysis patients. Cramps usually occur late during dialysis and frequently involve the legs, although muscles in other parts of the body are not spared. Although cramps are transient and are unlikely to result in long-term sequelae per se, they account for premature discontinuation of the dialysis session in some instances. Electromyography performed during hemodialysis has shown tonic electrical activity in the muscles, which steadily increases throughout the session in those who develop cramps, in contrast to a

steady decline in electrical activity in those who do not.¹⁵⁶ A subset of patients has elevated predialysis levels of serum creatine kinase during periods of cramps.¹⁵⁷

The pathogenesis of intradialytic cramps is unknown. Rapid plasma volume contraction is the strongest predisposing factor; changes in osmolality and serum electrolytes, such as potassium and magnesium, induced by hemodialysis, as well as underlying carnitine deficiency, have also been incriminated.¹⁵⁸

The most important measure to prevent intradialytic muscle cramps is to minimize intradialytic fluid removal, which unfortunately is difficult for some patients. Increasing the duration of the dialysis session or the frequency of dialysis may be necessary. Increasing the dry weight is often useful, if it does not result in significant fluid overload. Low-dose (5 mg) enalapril twice weekly has been shown to be effective in limiting thirst, presumably by inhibiting angiotensin II production. Oral oxazepam (5–10 mg), given 2 hours before, or quinine sulfate (325 mg) given at the initiation of dialysis has been shown to reduce the incidence of muscle cramps.¹⁵⁹ Quinine sulfate is, however, currently considered by the Food and Drug Administration to be both unsafe and ineffective for this purpose. Dialysate sodium modeling, using an exponential, linear, or step-decrease algorithm, was similarly effective in decreasing intradialytic muscle cramping.¹⁶⁰ Finally, stretching exercise of the affected muscle groups or carnitine supplementation has been shown to decrease the frequency of muscle cramps.¹⁶¹

The acute management of muscle cramps is directed at restoring plasma volume. Intravenous fluid administration is effective but would defeat the overall goal of dialytic fluid removal. Plasma volume can also be restored by increasing the plasma osmolality, resulting in the recruitment of fluid from the extravascular space.¹⁵⁴ Intravenous infusion of hypertonic (23.5%) saline (15–20 mL), 25% mannitol (50–100 mL), or 50% dextrose (25–50 mL) has been shown to be equally effective in relieving muscle cramps.¹⁶² Both hypertonic saline and mannitol cause transient warmth or flushing during the infusion. In addition, retention of these agents may result in a persistent increase in serum osmolality and hence postdialytic thirst and interdialytic fluid gain. Hypertonic dextrose is preferred, especially in nondiabetic patients, because it is readily catabolized and is inexpensive, but it causes transient hyperglycemia. A sublingual capsule of 10 mg nifedipine has been reported to provide relief of cramps without causing significant hypotension and may be related to the minimization of hypo-osmolality-induced changes in cellular ionized calcium levels.¹⁶³

Headache

Headache during dialysis is common.¹⁶³ The pain can be intense, accompanied by nausea or vomiting. It is not typically accompanied by visual disturbances as in migraines. The etiology of intradialytic headache is unknown. It may be a mild manifestation of the dialysis disequilibrium syndrome¹⁵³ or may be related to the use of acetate^{118,164} or glucose-free dialysate.¹⁶⁵ It can also be due to other common etiologies, such as hypertension and caffeine withdrawal, or, in rare circumstances, intracranial bleeding exacerbated by heparinization for the dialysis procedure. Preventive measures include a reduction in urea clearance, as described in the section on DDS,

or a change to dialysate containing bicarbonate and glucose. Treatment of the headache is largely symptomatic with analgesics if no other serious causes are identified.

Restless Legs Syndrome

Restless legs syndrome (RLS) is a common symptom in dialysis patients. The symptoms are deep paresthesias, creeping and crawling sensations or even pain in the calves and legs that occur exclusively when the legs are inactive, such as during hemodialysis.¹⁶⁶ Although the tendency to move can be temporarily suppressed, it is ultimately irresistible; movement of the legs yields prompt relief. Perhaps paradoxically, RLS is encountered in severely uremic patients and is relieved within a few weeks of initiating or intensifying dialysis therapy.¹⁶⁶

The results of clinical and electromyographic examinations in RLS are generally unremarkable. This disorder is differentiated from peripheral neuropathy, in which the paresthesia is constant and unrelieved by activity. When RLS symptoms develop in an otherwise stable hemodialysis patient, anxiety, progressive lower extremity vascular insufficiency, and inadequate dialysis need to be considered. Benzodiazepines taken before bedtime may mitigate some of the RLS symptoms, but their use may be complicated by drowsiness.¹⁶⁶ Opiates are remarkably effective but are associated with well known adverse effects. Carbamazepine and levodopa have also been advocated, but tolerance to these agents may develop rapidly.¹⁶⁷ A reasonable approach is to alternate these agents with different mechanisms of action on a weekly or biweekly basis. Gabapentin has been used with success in dialysis patients.¹⁶⁷ In the nondialysis population, the dopamine receptor agonists, such as pramipexole and ropinirole, have been shown to markedly ameliorate RLS symptoms.¹⁶⁸ Data on dialysis patients are limited. Nonpharmacologic approaches, such as transcutaneous electrical nerve stimulation, are yet another form of treatment.¹⁶⁶

HEMATOLOGIC COMPLICATIONS

Blood Loss

Acute blood loss during hemodialysis can be a catastrophic event. The most serious cause is disengagement of the venous needle from the arteriovenous access without initiating remedial action. At a blood pump speed of 400 mL/min drawing blood from the arterial needle, fatal exsanguination within several minutes has been reported. Disconnection of the arterial needle instead leads to entry of air into the dialysis circuit (see the discussion of air embolism in the section Cardiovascular Complications in this chapter). The obvious preventive strategy is proper securement of needles and tubing. A very low venous pressure, resulting from the disconnected circuit and hence low resistance, should trigger an alarm in the dialysis machine, but the sensitivity of this monitoring system depends on the degree of circuit disconnection and the preset venous pressure parameter. In some instances, devices that sense fluids (i.e., enuresis detection devices) can be wrapped around the sites that are more prone to disconnection. These devices are not usually employed in dialysis centers but are sometimes used in home dialysis settings, especially for patients undergoing nocturnal hemodialysis.

Perforation of the vessels and other anatomic structures by femoral or central catheters leads to internal bleeding (e.g., into the pleural sac or retroperitoneum). Inadvertent puncture of the femoral, iliac, or carotid artery can be more troublesome. The clinical sequelae are those related to intravascular volume depletion (e.g., shock) or the presence of the blood in an unintended space (e.g., dyspnea or pain from bleeding into the pleural sac).¹⁶⁹ Perforation of the vessels by the catheter may not always be apparent during the catheter insertion procedure, but may only manifest during the hemodialysis session when the systemic blood is circulated at high pump speeds. Rupture of the dialysis membrane in the dialyzer is a rare occurrence and should be evident by the presence of blood or pink fluid in the dialysate compartment. Creation of local hematoma or false aneurysm of the vascular access can also occur as a result of puncture of the vessel wall. The management of acute blood loss in these settings depends on the circumstances and severity. It may include the immediate discontinuation of hemodialysis, cardiopulmonary support, and detection and management of the extravasated blood as necessary. Attention should also be directed to the assessment and potential reversal of anticoagulation to stop the bleeding.⁶⁴

Chronic blood loss in the dialyzer occurs with the trapping of residual blood in the hollow fiber lumens. Higher heparin doses decrease dialyzer blood loss on one hand, but may enhance bleeding in patients with underlying pathology in the gastrointestinal tract. The amount of blood lost in the dialyzer also depends on patient characteristics (e.g., coagulability) and the rigor of saline rinsing during blood return to the patient. The estimate has been one to several milliliters for each dialysis session. Of course, with the clotting of the whole dialysis circuit, up to 200 mL of blood can be lost. Another source of external blood loss associated with dialysis is the puncture sites remaining after the needles have been removed from the native fistula or graft. In addition to systemic bleeding diathesis as a result of intrinsic clotting defects or heparinization, high hydrostatic pressure in the vascular access as a result of outflow tract stenosis is another cause of prolonged postdialysis bleeding from these sites. This blood loss is difficult to quantify and is often ignored in the estimation of the amount of supplemental iron required on an ongoing basis.

Intradialytic Hemolysis

The survival of red blood cells in the circulation is decreased from the normal of 120 days to 60 days in hemodialysis patients,^{170–172} which aggravates the anemia in this population. Certain events during hemodialysis predispose to hemolysis. In the early years of hemodialysis, the roller pump for the dialysis tubing caused traumatic red cell fragmentation,¹⁷³ but newer technical designs have effectively eliminated this problem. Other rare mechanical causes of hemolysis include arterial tubing collapse as a result of poor arterial blood inflow generating very high negative pressure, kinking of dialyzer blood tubing, and defective tubing with constricted lumens.

Over a period of 1 year, one dialysis unit reported that 10 patients developed intravascular hemolysis accompanied by severe abdominal pain and back pain. Six of these patients also developed acute pancreatitis; one patient died. After extensive evaluation, a kink was detected in a batch of arterial blood tubings. Further episodes of hemolysis were prevented

by changing to a new batch of arterial blood tubing and removing the redundant length of tubing that predisposed to kinking.⁴⁸ In another episode, a total of 30 patients from seven dialysis centers in three different states over a period of 15 days experienced intradialytic hemolysis. Five of these patients died. Careful examination of the used dialyzer tubings demonstrated severe narrowing of the aperture at the outlet of the bubble trap through which blood was pumped.^{174,175}

Another etiology for the development of hemolysis in dialysis patients can be due to the addition of chloramine to city water supplies to decrease bacterial contamination.¹⁷⁶ Besides public announcements, many municipal offices specifically warn healthcare facilities about such plans. Deionization of the water or neutralization of the chloramine with the addition of ascorbic acid to the dialysate prevents hemolysis from chloramine.^{176–178} Nitrate/nitrite intoxication can occur during home hemodialysis in patients who use water from ground wells that is contaminated with urine from domestic animals, causing methemoglobinemia and hemolysis.¹⁷³ Clues to methemoglobinemia are nausea, vomiting, hypotension, cyanosis, and the inability of oxygen supplementation to eliminate the black color in the blood in the extracorporeal circuit. Copper from building water pipes also causes oxidative injury to erythrocytes, leading to methemoglobinemia and hemolysis.¹⁷³ Copper intoxication is associated with skin flushing, abdominal pain, and diarrhea. Analysis of the water supply confirms the nature of the contamination, such as copper and chloramine.

Residual formaldehyde and hydrogen peroxide from dialyzer reprocessing for reuse has been associated with hemolysis.^{173,179} Formaldehyde induces hemolysis via two mechanisms. It is a potent reducing agent that inhibits erythrocyte glycolysis. It may also act as a hapten that induces the formation of anti-N-like cold agglutinins.¹⁷³ Other rare causes of hemolysis related to hemodialysis include overheating of dialysate to 42°C, hypotonic dialysate that results from erroneous preparation and defective monitoring of the dialysate conductivity, and hypophosphatemia as a result of dialytic clearance of phosphorus.¹⁷³

The diagnosis of acute severe hemolysis is self-evident when grossly translucent hemolyzed blood is observed in the tubing. More subtle hemolysis can be confirmed by elevated reticulocyte count, serum free hemoglobin, lactate dehydrogenase level, decreased serum haptoglobin, positive Coomb's test, and the presence of schistocytes and Heinz bodies in the peripheral blood smear. Acute hemolysis is a medical emergency, partly because the associated hyperkalemia can be rapidly fatal. Among other diagnostic tests and investigations for the cause of the hemolysis, serum potassium should be immediately determined and an electrocardiogram obtained for hyperkalemic changes, depending on the degree of suspected hemolysis. A safe extracorporeal circuit should be set up for immediate hemodialysis of the patient to correct the hyperkalemia, if the clinical condition (e.g., hemodynamic stability) permits.

Activation of Complement System and Leukocytes

A number of disorders in various types of leukocytes, including neutrophils, lymphocytes and monocytes, and platelets, have been described in hemodialysis patients. The functional

defects in these cells are partially attributed to uremia per se, but the extracorporeal circulation during hemodialysis may also be contributory. A general theme of the mechanisms by which extracorporeal circulation impairs cellular functions is the intradialytic activation of the humoral factors and the direct activation of the cells in the blood, as a result of exposure to the dialysis membrane and dialysate constituents. As a consequence of this intradialytic activation, pro-inflammatory and procoagulatory mediators are generated and released, including anaphylatoxins,¹¹ kinins,¹⁸⁰ reactive oxygen species,¹⁸¹ proteases,^{182,183} and cytokines,¹⁸⁴ leading to tissue injury. In addition, leukocytes¹⁸⁵ and platelets¹⁸⁶ become deactivated and respond suboptimally to stimuli postdialysis. The intradialytic activation of these cellular and noncellular elements has been used as an index of dialysis membrane biocompatibility assessments. Dialysis membranes that are more prone to activate blood constituents are called *bioincompatible membranes*. However, there is no consensus on the criteria by which dialysis membranes are classified as biocompatible or bioincompatible.

Interactions between plasma proteins and dialysis membrane surfaces are known to activate the complement,²⁵ intrinsic coagulation, and fibrinolytic pathways.¹⁸⁷ The magnitude of complement system activation, usually via the alternative pathway, is often substantial. Therefore, plasma levels of complement activation products, C3a and C5a, and their respective derivatives, C3a_{desArg} and C5a_{desArg}, are commonly used as markers of bioincompatibility. The potential acute effects of anaphylatoxins C3a and C5a in mediating dialysis syndromes have been discussed. The desArginine derivatives of anaphylatoxins lack anaphylactic properties, but still have leukocyte-directed properties capable of activating neutrophils and monocytes.^{26,188,189} The extent to which these complement fragments are in fact responsible for intradialytic leukocyte activation and postdialysis cell deactivation is unclear.

Unsubstituted cellulosic membranes, which tend to be associated with the highest intradialytic levels of C3a_{desArg},¹⁹⁰ are often classified as bioincompatible. In contrast, substituted cellulosic membranes and synthetic membranes tend to be associated with lower plasma C3a_{desArg} levels^{23,190} and are generally considered biocompatible. This schema is unfortunately too simplistic, because it ignores the other factors that determine plasma level of complement activation products (e.g., removal by transport into dialysate and adsorption onto the dialysis membrane) and other cellular and noncellular blood constituents that may be affected.

In addition to C5a, peripheral blood monocytes can be activated by other components of the extracorporeal circuit. Bacterial products, such as endotoxins, are well known to be potent stimulants of monocytes. The degree to which bacterial product contaminants in the dialysate can exert their effects on cells in the blood compartment has been extensively studied.^{35,36,191,192} Evidence suggests that, whereas the intact endotoxin molecules are too large to traverse the pores of the dialysis membrane, smaller fragments with molecular weights lower than 5 kDa that are also functionally active would not be restricted by high-flux membranes.^{36,191} Thus, some investigators have advocated the use of ultrapure dialysate to minimize the potential transfer of bacterial fragments into the blood compartment.¹⁹² The acetate used in dialysate also activates monocytes,³⁵

although this type of buffer is not commonly used in the United States nowadays. Regardless of the mechanisms of cell activation, the release of pro-inflammatory cytokines from the monocytes can potentially induce multisystemic complications.

Repeated intradialytic activation of leukocytes and their subsequent deactivation may have subacute or long-term sequelae on dialysis patients. Thus, several reports have suggested that mortality in patients receiving dialysis for either acute kidney injury¹⁹³ or end-stage renal disease¹⁹⁴ is influenced by the selection of dialysis membranes, although the results are not uniform. It must be noted that not only were the patient populations, dialysis prescriptions, and study designs different among the various studies, but the types of membranes compared were also highly heterogeneous, making it difficult to conclude if any differences in the observed outcomes were due to differences in certain biocompatibility characteristics or differences in transport or adsorptive properties of the dialysis membranes. Nonetheless, the results of these studies in general suggest that substituted cellulosic membranes and synthetic membranes are associated with better patient survival,^{194,195} compared to unsubstituted membranes.

Platelet Abnormalities

By removing urea and other nitrogenous compounds, such as guanidine succinic acid, hemodialysis improves platelet function. On the other hand, the hemodialysis procedure can also acutely predispose the patient to bleeding by several mechanisms. The most obvious one is systemic heparinization. The techniques of regional anticoagulation were devised to avoid systemic anticoagulation. In the regional heparin technique,¹⁹⁶ heparin is infused into the dialyzer arterial tubing, and the heparinization in the extracorporeal circuit is reversed by the infusion of protamine in the dialyzer venous tubing. In the regional citrate technique, citrate is infused into the arterial tubing, and the anticoagulation is reversed by the infusion of calcium in the venous tubing.^{197–200} Neither regional technique is widely used in the United States because they are quite cumbersome. Excessive protamine can paradoxically function as an anticoagulant. Citrate infusion involves large fluid volumes and can cause metabolic alkalosis,¹⁹⁹ whereas inaccurate calcium titration induces hypercalcemia or hypocalcemia.^{199,200} Decreasing or eliminating the systemic heparin dosages, with periodic flushing of the bubble trap using saline solution,^{13,14} is often sufficient to avoid significant systemic anticoagulation and clotting of the extracorporeal circuit.

Heparin-induced thrombocytopenia is often suspected in dialysis patients, although the prevalence is probably lower than the estimated figure of 4%.²⁰¹ Transient thrombocytopenia may result from the interaction between blood and the dialysis membrane, with the nadir of the platelet count being lower than 100,000/ μ L observed at approximately 1 hour after starting hemodialysis.¹⁸⁶ Impaired aggregation of platelets has also been observed in blood samples obtained after dialysis compared to predialysis samples, despite the removal of plasma uremic toxins during the treatment.¹⁸⁶ This impairment in aggregation is presumably due to intradialytic activation of the platelets by the dialysis membrane and consequent cell deactivation.

PULMONARY COMPLICATIONS

Hypoxemia

Hypoxemia was common during hemodialysis before the 1990s. The arterial oxygen tension usually drops by 5 to 30 mm Hg during dialysis, reaching a nadir between 30 and 60 minutes in some cases and persisting to the end of dialysis in others.^{202–204} In either case, the hypoxemia resolves within 60 to 120 minutes after discontinuation of dialysis. The etiology of hemodialysis-induced hypoxemia is probably twofold. First, during dialysis using unsubstituted cellulose membranes, complement activation and the associated peripheral leukopenia occur intensely during the initial 15 minutes. Experiments in animals and limited data in patients showed that the peripheral leukopenia was due to the accumulation of leukocytes in the pulmonary arterioles, in essence resulting in diffuse leukocyte thromboembolism. This leukocyte-based pulmonary embolism causes a ventilation/perfusion mismatch and complement-induced extravasation of vascular fluids; both of these events result in impairment in gas diffusion.²⁰³ This mechanism is responsible for the early and transient type of hypoxemia that can develop during the early stages of hemodialysis therapy regardless of the use of different types of hemodialysis membranes.

The more significant cause of dialysis-induced hypoxemia is the loss of carbon dioxide into the dialysate when acetate-containing dialysate is employed.²⁰² This leads to central hypoventilation and hypoxemia. This type of hypoxemia tends to be more persistent during the hemodialysis session, especially in patients with slow metabolism of acetate, and can be prevented by the use of bicarbonate-containing dialysate.^{205,206}

In the modern era of hemodialysis, unsubstituted cellulose membranes and acetate dialysate are not commonly employed. The most important cause of dialysis-associated hypoxemia nowadays is probably related to hypoventilation as a result of intentional or unintentional sedation or perhaps mild disequilibrium syndrome. Transient dialysis-associated hypoxemia is usually of no clinical significance unless underlying cardiopulmonary diseases are present. Oxygen supplementation should be provided as necessary.

METABOLIC DISTURBANCES

Potassium

The most important danger of potassium removal during hemodialysis is the genesis of cardiac arrhythmia. Potassium removal during hemodialysis does not conform to single-pool kinetics.^{207,208} The rate of removal of potassium from the extracellular space exceeds its rate of removal from the intracellular space. The transfer of potassium from the intracellular to extracellular compartment occurs at a relatively slow rate and is modulated by many factors, including pH, insulin, catecholamines, and membrane-bound Na^+/K^+ -ATPase. Serum potassium levels rebound rapidly within 5 hours of completing dialysis and may be 30% higher than immediate postdialysis values.^{207,208} Therefore, potassium supplementation based solely on the immediate postdialysis values should be largely avoided.

The use of potassium modeling (changing dialysate potassium concentration during treatment) and longer hemodialysis sessions have been advocated to avoid severe rebound.²⁰⁸ The use of potassium-free dialysate is usually unnecessary and can induce arrhythmias.²⁰⁹ Even in the presence of severe hyperkalemia, for example, with a serum potassium of 8 mEq/L, dialysate potassium of 2 to 3 mEq/L would provide a steep gradient for potassium diffusion.²¹⁰ The pace of hyperkalemia correction is also influenced by the simultaneous correction of metabolic acidosis during hemodialysis, which shifts potassium into cells. Thus, the correction of hyperkalemia may occur faster than the scenario in which acidosis is absent. Although a dialysate potassium concentration of 2 mEq/L is quite safe for most chronic dialysis patients, it should be tailored to the specific patient's need. A dialysate potassium concentration of 3 mEq/L may be necessary for patients with underlying cardiac arrhythmias or those receiving digitalis therapy.

Sodium

Both hyponatremia and hypernatremia can occur during hemodialysis, depending on the sodium concentration in the dialysate employed. Dysnatremias resulting from technical errors in the dialysate are discussed under "Intradialytic Hypotension." Although sodium concentrations usually do not equilibrate between the serum and dialysate compartments during a regular 4-hour hemodialysis session, prescribed dialysate sodium levels that are higher than 145 mEq/L will tend to increase serum sodium concentration and induce thirst during the interdialytic period. Low dialysate sodium concentrations promote hypotension by enhancing the shifting of serum water into the extravascular space to achieve osmolar equilibrium.²¹¹ In the presence of severe predialysis hypernatremia or hyponatremia, extra precautions should be exercised in the prescription of dialysate sodium concentrations to avoid rapid correction of the dysnatremic state and central nervous system symptoms.

Calcium, Phosphorus, and Magnesium

Similarly, hypercalcemia and hypocalcemia can also occur during hemodialysis, with or without technical errors. High dialysate calcium concentration (e.g., 3 mEq/L) allows the transfer of calcium to plasma and may promote vascular calcification. In contrast, low dialysate calcium (e.g., 2 mEq/L) often enhances calcium loss from the plasma, thereby impairing myocardial contractility and inducing hyperparathyroidism, unless supplemental calcium or vitamin D is provided. Very low dialysate calcium is sometimes used to remove body calcium for the treatment of hypercalcemia, tumoral calcinosis, calciphylaxis, or vascular calcification.²¹² For these purposes, dialysate calcium of 1 to 1.5 mEq/L can be used judiciously,²¹³ preferably with cardiac monitoring. The use of calcium-free dialysate is generally discouraged, except under extreme circumstances or experimental conditions, because of the high potential for cardiac arrhythmias.²¹⁴ Correction of acidosis during dialysis can also decrease the plasma ionized calcium; this should be taken into consideration for patients with significant predialysis acidemia.

All commercial dialysates are free of phosphorus. Hypophosphatemia is not usually a concern in dialysis patients. In

patients with poor dietary intake, total parenteral nutrition supplementation without phosphorus, excessive phosphate-binder administration, or intensive hemodialysis such as nocturnal dialysis²¹⁵ can induce hypophosphatemia. If severe, hypophosphatemia can cause muscular weakness and respiratory arrest. Although dialysate enriched with phosphorus has been used,²¹⁶ oral or intravenous phosphorus supplementation is simpler and usually sufficient.

Because commercial dialysates do not contain magnesium, hypomagnesemia can also develop with hemodialysis. Oral or intravenous magnesium supplementation can be used as indicated.

Dyslipidemia

Although a variety of lipid and lipoprotein abnormalities are observed in chronic dialysis patients,²¹⁷ they are primarily the results of uremia rather than the hemodialysis procedure. Hypertriglyceridemia is a hallmark of chronic kidney disease and is a manifestation of the accumulation of triglyceride-containing lipoprotein remnant particles. A decrease in plasma lipase activity, with consequent impairment in lipoprotein catabolism, appears to be an important mechanism by which these remnant particles accumulate in the plasma. The repeated administration of heparin for hemodialysis has been postulated to be a cause of lipase depletion.^{218,219} To what extent dialysis-associated heparinization actually contributes to the hypertriglyceridemia in dialysis patients is unclear.

The intradialytic activation of neutrophils by unsubstituted cellulosic membranes results in the release of reactive oxygen species and oxidation of proteins.²²⁰ Vitamin E coating of cellulosic membranes has been developed to provide anti-oxidative properties.²²¹ In spite of this potential sequence of events, the association of intradialytic release of reactive oxygen species with atherosclerosis remains speculative.

Protein Catabolism

Hypoalbuminemia is a strong predictor of mortality in chronic dialysis patients. The etiology of this disorder is multifactorial, with chronic inflammation and poor dietary intake likely to be the two major causes. The hemodialysis procedure may be contributory by several mechanisms. First, the loss of plasma amino acids into the dialysate has been well documented.²²² The magnitude of this loss is substantial, regardless of the use of low-flux or high-flux dialyzers,²²³ because of the low molecular weights of these molecules. An average of 1.5 to 3 g²²³ are often lost per session of dialysis; that is equivalent to approximately 4% to 8% of the weekly dietary intake of amino acids in proteins. The loss of glucose into the dialysate would exacerbate the catabolic state, but commercial dialysates nowadays usually contain 200 mg/dL of glucose, thus minimizing or eliminating the glucose loss. Second, plasma albumin can also be lost directly into the dialysate.^{38,223} Albumin has a molecular weight of 60 kDa and does not usually traverse even high-flux dialysis membranes. Large amounts of plasma protein loss—as high as 20 g in a single hemodialysis session—have been reported during treatment using high-flux polysulfone dialyzers reprocessed with bleach.³⁸ Presumably, the pore size increases as a result of the action of the bleach on the copolymer of the dialysis membrane. Subsequent changes in the fabrication of these membranes have apparently markedly

diminished the permeability of the polysulfone membranes to albumin, even when bleach is included in the reprocessing.²²⁴ Finally, protein catabolism has been reported during sham hemodialysis using unsubstituted cellulosic membranes, apparently mediated by the generation of prostaglandin E₂ after interactions between blood and the dialysis membrane.²²⁵ Although the transmembrane loss of amino acids and albumin and the protein catabolism induced by membrane bioincompatibility contribute to the hypoalbuminemia, it is unclear if hypoalbuminemia from these mechanisms carries the same prognostic value as hypoalbuminemia associated with uremic inflammation or poor dietary intake.

Vitamins

Similar to most other hydrophilic small molecules, water-soluble vitamins, including folate, ascorbate, and vitamin B₆, are readily diffusible through low-flux and high-flux dialysis membranes. Daily supplementation of these vitamins is therefore recommended. In contrast, the fat-soluble vitamins—vitamins A, D, E, and K—are not dialyzable. Commercially available multivitamins specifically designed for dialysis patients usually contain 1 mg of folate, 1.5 mg of thiamine (vitamin B₁), 1.2 mg of riboflavin (vitamin B₂), 10 mg of pantothenic acid (vitamin B₅), 10 mg of pyridoxine (vitamin B₆), 6 µg of cyanocobalamin (vitamin B₁₂), and 300 µg of biotin. Vitamin B₁₂ is of particular interest in hemodialysis because this molecule (13.5 kDa) had been commonly used as a middle-molecule marker.²²⁶ Although low-flux dialyzers are also permeable to vitamin B₁₂, clearance of this molecule is higher with high-flux dialyzers. Vitamin doses higher than those that are necessary to replace dialytic losses are sometimes used for pharmacologic purposes. For example, high doses of folate and pyridoxine have been used to lower serum homocysteine levels, but did not improve survival and did not reduce vascular events in these patients.^{227,228}

DIALYSATE CONTAMINATION

Dialysate contamination occurs when either the dialysate concentrates or the water supply is contaminated. Dialysate concentrates are stored in each dialysis facility. The “acid” dialysate concentrates (without bicarbonate) and the bicarbonate concentrates are usually mixed to produce the final dialysate. Bicarbonate concentrates are particularly prone to bacterial growth. The chronic dialysis patient is exposed to 2000 to 3000 L of water in the dialysate during each month of therapy. The water in the dialysate is usually tap water from municipal sources, which has undergone purification using reverse osmosis or carbon filter treatment before it reaches the dialysis machine. Although the majority of dialysis units use reverse osmosis, which has reduced the clinical occurrence of water contamination, serious accidents due to chemical contamination of dialysis water can still occur.²²⁹ In addition, microbial contaminants can be detected in the water system, including bacteria and their cell wall degradation products, such as endotoxins and peptidoglycans. Fungi, viruses, and protozoa may also be present in the dialysis water treatment system. Microbial contamination of the dialysate can lead to intradialytic pyrogenic reactions and hypotension. Exposure to bacterial contaminants over a prolonged period potentially leads to the chronic inflammatory state,

which initiates or aggravates dialysis-related amyloidosis, atherosclerosis, and malnutrition.²³⁰

The Association for the Advancement of Medical Instrumentation's (AAMI) Renal Disease and Detoxification Committee in 2006 revised its standards for water treatment; the new standards include alternative and supplementary methods of removing toxic chloramines from water, because water supply quality and municipal water treatment practices vary substantially. The revised standards should be applied to the water used for the preparation of concentrates from dialysis powder, the preparation of bicarbonate solution, and the reprocessing of dialyzers for multiple uses. It covers all devices, piping, and fittings between the point at which potable water is delivered to the water treatment system and the point-of-use of the treated water. Disinfection must involve all the pipes in the distribution system of either water or dialysate solution and connectors to the dialysis machine to prevent the development of *biofilm*, a layer of polymeric organic matrix in which bacteria and fungi can grow. Once developed, biofilms are resistant to disinfecting techniques.^{231,232}

Both AAMI as well as the European Pharmacopoeia have established standards for chemical and microbial quality. The AAMI recommends that tryptic soy agar at 37°C for 48 hours should be used for the detection of microbial contamination and endotoxin levels. The European Pharmacopoeia, however, does not make any prespecified recommendations as to the type of medium to be used for such testing. The use of other specialized mediums, such as Reasoner's agar and tryptone glucose extract agar, along with extended incubation for 5 to 7 days at 20° to 25°C, are more sensitive techniques to detect contamination.²³³ AAMI recommends that microbial contamination should not exceed the upper limit of 22 cfu (colony forming units) per mL and endotoxin levels should not exceed 2 IU/mL. Bacterial growth of more than 50 cfu/mL and endotoxin concentration of more than 1 IU/mL should be followed by a corrective action plan that includes a new cycle of disinfection and retesting. The European Pharmacopoeia recommends that bacterial growth at any time should not exceed 100 cfu/mL and endotoxin level should remain less than 0.25 IU/mL.^{234,235} These standards for water treatment should be applied to chronic dialysis facilities, acute hospital dialysis units, and homes for patients undergoing home hemodialysis therapy. During the past decade, several studies have demonstrated that more than 35% of water samples from different dialysis centers did not fulfill the expected standards specified by AAMI.^{229,236} The medical directors of dialysis units should participate in the quality assurance process for water treatment.¹⁹²

Ultrapure dialysate is defined as a dialysate in which the microbial contamination is less than 0.1 cfu/mL and endotoxin level is less than 0.03 IU/mL.²³⁷ A relatively convenient method of achieving this level of water purity is by techniques of on-line purification of the dialysate.^{238,239} Only France has put forth a national directive regarding the use of on-line dialysate production and the achievement of ultrapure dialysate in dialysis units. The use of ultrapure dialysates has been reported to decrease peripheral blood cytokine production during dialysis therapy,^{240,241} improve the chronic inflammatory state and nutritional status,^{242–244} prevent the development of amyloidosis,^{245,246} decrease serum pentosidine levels (a marker of systemic oxidation),^{246,247} decrease the dose requirement of erythropoietin,^{248,249} and preserve the residual kidney function.²⁵⁰

These reports notwithstanding, the effects of ultrapure water in the prevention of long-term dialysis complications remain controversial.^{251–254}

HEPATITIS IN HEMODIALYSIS UNITS

Hepatitis C

Chronic dialysis patients are at risk for nosocomial infections due to regular exposure to extracorporeal circulation.^{255,256} The environment of dialysis facilities also directly increases the risk for person-to-person transmission of infectious agents and indirectly through the transmission to equipment and supplies.²⁵⁷ When the Centers for Disease Control and Prevention investigated three different outbreaks of hepatitis C virus (HCV) infection in chronic hemodialysis centers, seroconversions were found to be associated with (1) lack of disinfection of the dialysis machines between patient use, (2) sharing of multiple-dose medication vials, (3) use of common medication carts to prepare and distribute medications at patients' station, (4) blood spills that were not cleaned up immediately, and (5) potential contamination by blood of the pressure-sensing port of the machine, which is not easily accessible to routine disinfection. Multiple blood groups have been found in pressure transducers of the dialysis machine, which are most difficult to disinfect, suggesting cross-contamination by multiple patients.^{257,258} Blood transfusions and frequent surgical procedures for various indications, such as the placement and revision of dialysis vascular access, pose additional risks.

The prevalence of HCV infection among patients receiving dialysis varies between countries²⁵⁹ and between different centers within a given country, ranging from 3% to more than 70%.^{260,261} The risk of HCV transmission to patients on maintenance dialysis has not been eliminated despite a significant reduction in blood transfusion as a result of the availability of erythropoiesis-stimulating agents and the introduction of a blood-donor screening program for the detection of anti-HCV antibodies. Among the risk factors associated with HCV seroconversion are the history of blood transfusion and number of years on dialysis. The prevalence increased from an average of 12% in patients with less than 5 years on dialysis to 37% in those receiving dialysis for more than 5 years.

To prevent transmission of HCV and other blood-borne viruses from both recognized and unrecognized sources of infection, the hemodialysis staff requires training and education, with strict adherence to infection control precautions. Patients who are anti-HCV positive or HCV RNA-positive do not need to be isolated from other patients or dialyzed separately on dedicated machines. Such patients can even participate in dialyzer reuse programs, because reprocessing of such dialyzers does not appear to increase the risk for infection to either dialysis staff members or other dialysis patients.

Hepatitis G

Similar to HCV infection, hepatitis G virus (HGV) or GBV-type C (GBV-C) is a blood-borne virus, a member of the family Flaviviridae. HGV is distributed globally; nearly 1.7% of volunteer blood donors are positive for HGV. An epidemiologic study demonstrated that among new cases of non-A, non-B hepatitis in the United States, 80% were

due to HCV infection and the other 20% were due to HGV infection.²⁶² Also, among patients with HCV infection, more than 20% can have HGV-RNA present in the blood.²⁶³

The prevalence of HGV infection in hemodialysis patients has been reported to be variable among countries and in different regions within a country. HGV has been reported in 20% of hemodialysis patients in the United States and Europe,^{264–267} less than 4% in the Japanese dialysis population,²⁶⁸ 58% of those in France,^{269,270} but in more than 55% of those in Indonesia.²⁷¹ It is known that HGV follows the patterns of blood-borne transmission and that HGV viremia can persist for years. Whether HGV will cause liver damage or remains an innocent bystander in the long term is, however, unclear.^{263,272}

PREGNANCY AND HEMODIALYSIS

Women of childbearing age seldom become pregnant while on chronic dialysis due to disturbances in the hypothalamic-pituitary-ovarian axis and other associated psychological factors.^{273–275} The incidence of pregnancy, defined by a gestational age of 3 months or more, was only 0.3 per 100 patient-years over a period of 20 years even in women of reproductive age; the successful live birth rate is less than 60%.²⁷⁶ The risk of intrauterine growth retardation, polyhydramnios, and premature rupture of membranes is increased. Most living babies are born prematurely. The likelihood of a successful pregnancy is higher in patients with kidney transplants compared to patients on dialysis therapy. These differences are most likely due to the lesser degree of uremia in the transplant patient, although complications of the hemodialysis procedure cannot be ruled out.

During pregnancy, it is recommended that the predialysis blood urea nitrogen be maintained at less than 50 mg/dL, which may require increasing the dose of dialysis therapy.^{276,277} It is particularly important to frequently and carefully estimate and adjust the dry weight to minimize maternal hypotension and fetoplacental circulatory compromise. The dry weight adjustments should take into consideration that there is a 30% increase in plasma volume during pregnancy and almost a linear physiologic weight gain of approximately 1 pound per week after the first 12 weeks of gestation. In addition, pregnant women on dialysis will need to maintain 1.8 g/kg/day of protein intake.^{278–280} The dialysate bicarbonate concentration may need to be adjusted because pregnancy is associated with respiratory alkalosis.^{279,281} The dialysate calcium concentration and vitamin D supplement should be reassessed to account for the placental production of 1,25-dihydroxyvitamin D₃.^{279,281} The dose of folate supplement should be increased to 2 mg/day to account for the increased requirement during the pregnancy to prevent neural tube defects.^{280,282} In addition, the dose of erythropoiesis-stimulating agent needs to be increased to maintain hemoglobin levels at 10 to 11 g/dL as the demand for erythropoiesis increases with gestational age. Iron stores should be frequently monitored.^{276,277,283} Although definitive evidence is lacking, there appears to be an increased incidence of congenital anomalies associated with the exposure to formaldehyde and ethylene oxide; thus, these agents should be avoided during the gestational period.

- Typical Modifications of the Dialysis Prescription 921

CONCLUSIONS 921

In 2004, there were 335,963 patients on dialysis in the United States. Of these, 91.4% were on in-center hemodialysis, 0.6% on home hemodialysis, 3.2% on continuous ambulatory peritoneal dialysis (CAPD), and 4.4% on automated peritoneal dialysis (APD).¹ There were 6686 incident peritoneal dialysis (PD) patients that year, 40% of whom had diabetes mellitus as their primary cause of end-stage renal disease, 31% of whom were older than age 65 years, and 59% of whom were male. Where PD is an accepted practice, in 2004 the reported percentages of dialysis patients on PD varied from lows of 3.6% in Japan and 5.1% in Germany to 42.6% in New Zealand and a high of 69.9% in Mexico, suggesting that there may not be medical reasons for the modality distribution between PD and hemodialysis (HD) seen in the United States.¹ It appears there are other, nonmedical reasons for modality distribution that are multifactorial in origin and include but are not limited to access to PD, physician comfort/expertise with the therapy, and government reimbursement policies.^{2,3}

Potential benefits of PD include simplicity of use, lower cost, relatively less restricted diet, easier availability to travel, and potential survival advantage for certain subgroups of patients compared to hemodialysis. The principal components of the therapy are rather simple and have been reviewed elsewhere.⁴ As with hemodialysis, the dialysate and blood compartments in PD are separated by a semipermeable membrane, which serves as a selective barrier for the diffusive clearance of retained solutes and osmotic-driven removal of excess water from the peritoneal capillaries to the peritoneal dialysis fluids.

Unlike hemodialysis, in which the blood is brought to the dialysate so that the blood circuit and dialysis fluids are extracorporeal, in PD, the dialysis fluids are intraperitoneal and therefore sterile, and the blood supply is that of the peritoneal organs and abdominal wall. Peritoneal fluid is instilled into the peritoneal cavity and allowed to “dwell” therein while diffusion and ultrafiltration takes place. The fluid is then drained at specified intervals so new fluid can be instilled and the processes of diffusion and ultrafiltration renewed. Patients can either do all these dialysis fluid “exchanges” manually (i.e., CAPD) or one can use an automated device (i.e., APD) to assist in these exchanges while the patient sleeps.

To understand the nuances between these techniques and how to individualize a patient’s prescription, it is important to have a basic understanding of peritoneal physiology and the physics of peritoneal ultrafiltration. This physiology and types of PD solutions available are briefly reviewed in this chapter. As with any form of dialysis, it is important to have access to the blood system, so PD catheters are also reviewed.

COMPONENTS OF THE PERITONEAL DIALYSIS SYSTEM

Renal replacement therapies require three key components: (1) access to the bloodstream so that blood and dialysate compartments are separated by a semipermeable membrane, (2) dialysis solutions, and (3) the semipermeable membrane.

In the case of PD, this semipermeable membrane is the peritoneal membrane itself and its associated vascular supply. Each of these components has some distinct differences from its counterpart in hemodialysis. First, the optimal chronic PD access must traverse both a sterile (intraperitoneal portion) and a nonsterile (extraperitoneal portion) environment as opposed to the sterile, subcutaneous placement of the optimal accesses in use for chronic hemodialysis (the subcutaneous fistula or synthetic graft). The access is for delivery of the PD solutions in PD, whereas it is used to access the blood supply and establish an extracorporeal circuit in HD. Second, PD solutions must be sterile, easily stored, and easily transported to the patient's home. Third, PD patients are "born" with their dialyzer membrane. However, just as with HD, PD patients have different membrane types (in terms of diffusion of small solutes). The physician must learn how to tailor the therapy for each patient's peritoneal membrane type by adjusting dwell time and dialysis solutions.

CATHETERS

Catheter Design

The sole purpose of the PD catheter is to provide quick and easy access for the dialysis fluids to the intraperitoneal space in a way that minimizes risk for bacterial or fungal contamination and resultant infection.

Acute Use Catheters

Acute use PD catheters were a historical approach to access the peritoneum. Introduced by Westin and Roberts⁵ in 1965, they were straight, relatively rigid conduits about 3 mm in diameter and 25 to 30 mm in length that could be placed at the bedside. This catheter design was associated with a high risk for peritonitis, malfunction, and bowel perforation. Therefore, their use has largely been abandoned; if PD is contemplated for acute renal failure, even in an intensive care unit setting, the safer, more current chronic use catheter is recommended.

Chronic Use Catheters

Standard chronic indwelling peritoneal catheters are constructed of soft materials, such as silicone rubber or polyurethane. The most frequently used material is silicone rubber, a polymer of methylsilicate. It is relatively biocompatible and inert, has no leachable plasticizers, and is not traumatic to surrounding tissues. Polyurethane catheters have better wall strength and, therefore, can be manufactured with a smaller catheter wall thickness, larger internal lumen, and increased flow rates with the same external diameter catheter.⁶ However, cracking of the polyurethane catheter has been reported, especially after prolonged exit site care with polyethylene glycol, alcohol, or topical mupirocin. This catheter material is therefore not likely to be reliable for long-term use.

Design Modifications

Historical chronic use PD catheters were a straight tube with multiple side holes at the intraperitoneal end for dispersion of PD fluid. Straight PD catheters were associated with a high rate of pain on inflow, external cuff extrusion, and catheter migration (often resulting in failure to drain). These complications

Figure 81-1 Standard peritoneal dialysis catheters.

led to design modifications to both the subcutaneous and intraperitoneal portions of the catheter. The intraperitoneal portion of chronic use catheters usually contains many 1-mm side holes for passage of fluids, but it may also have modifications to facilitate fluid movement, alleviate symptoms associated with inflow or drainage, decrease catheter migration, and prevent trapping by omentum. These modifications include a curled tip, two perpendicular discs (Oreopoulos-Zellerman), and a column disc (Lifecath). Extraperitoneal modifications include various means of external fixation and preformed angles in the subcutaneous portion designed to prevent catheter infections, migrations, and dialysate leaks. Some of these are shown schematically in Figure 81-1.

Design modifications to the subcutaneous portion of the catheter include alterations in location and number of subcutaneous Dacron cuffs and the use of disc-bubble cuffs. Other alterations of the subcutaneous portion of the catheter include a pail-handle design (Cruz catheter), a 90-degree turn (Lifecath), and a fixed bend, or swan neck in the catheter.⁷ Catheters with two cuffs allow the fixation of both the deep preperitoneal and subcutaneous portions of the catheter. If the superficial subcutaneous cuff is infected, one can shave it off and the deep cuff still serves as an anchor. Swan neck catheters have two cuffs, but they also have a permanent bend in the subcutaneous portion of the catheter. This results in an arcuate tunnel that is convex upward so that both the internal (peritoneal) and external (skin) exits point downward. This is designed to decrease the likelihood of cuff extrusion and exit site infections. A description of the insertion technique has been reported elsewhere.⁸ These catheters are reported to have a longer 3-year survival probability, lower peritonitis rates, and fewer problems with cuff extrusion or catheter migration in small cohort studies; these studies, however, do not mention patient selection criteria, and that caveat must be remembered. A further modification of this catheter type has the exit site in the presternal area.⁸ This modification is based on the theory that presternal exit sites would be subject to less trauma and therefore less infection. Another advantage to the presternal exit location is that it allows patients to "immerse" in water (i.e., to use hot tubs and baths without immersing the exit site). Conventional wisdom suggests that obese patients should all have this type of catheter because it allows for better exit site location and care.

Catheter Implantation Techniques

PD catheter implantation and postoperative care have a significant influence on long-term catheter outcome. Sterile conditions are essential, and an experienced catheter insertion team is needed. A panel of experts has agreed on five general standards for catheter placement: (1) the deep cuff should be in the anterior abdominal musculature; (2) the subcutaneous cuff should be near the skin surface and not less than 2 cm from the exit site to allow for drainage and provide a firm anchorage that prevents pistonlike movements of the catheter⁹; (3) the catheter exit should be positioned laterally; (4) the exit site should be directed downward or laterally; and (5) the intra-abdominal portion of the catheter should be placed between the visceral and parietal peritoneum and should not be placed in the middle of loops of bowel.¹⁰

The techniques for catheter insertion include the following. Surgical insertion of catheters (placement by dissection) is the most commonly used placement procedure in clinical practice today. After surgical dissection through the rectus muscle, the catheter is placed in the pelvis under direct visualization.¹¹ Peritoneoscopic insertion, which allows direct visualization of the course of the catheter, has results similar to those seen with surgical insertion in experienced hands.^{12,13} Blind placement does not allow direct visualization of the catheter or peritoneum. This procedure should not be used in markedly obese patients and in those who have had previous abdominal surgery because of the higher risk of complications, such as bowel perforation, in patients with unsuspected adhesions. In the Moncrief-Popovich technique, at the time of implantation, the entire extraperitoneal portion of the catheter is placed subcutaneously, theoretically allowing the cuff to heal in a sterile environment and preventing any bacterial colonization. At a subsequent date (typically 4–6 weeks after implantation), the external portion of the catheter is exteriorized, and dialysis can be initiated immediately.¹⁴

Historical review of these techniques suggests that in appropriate patients, outcome does not depend on the technique used for implantation as much as on the person who inserts the catheter. The most important requirement may be to have a trained, knowledgeable, and dedicated catheter insertion team.¹⁰ A recent modification of these techniques, coined the advanced laparoscopic insertion technique, which includes rectus sheath tunneling (to prevent catheter tip migration), prophylactic omentopexy in appropriate patients (to prevent omental entrapment), selective resection of epiploic appendages (to prevent catheter obstruction), and adhesiolysis to eliminate compartmentalization,¹⁵ has been reported to even further reduce complication rates. With this technique, reported risk of pericatheter dialysate leaks was 2% compared to published reports of 1% to 27%.¹⁶

Catheter Break-in

It is normal to flush the peritoneal cavity with between 500 and 1500 mL of dialysis fluid until clear immediately after placement. Heparin (500–1000 U/L) can be added in cases where fibrin is present. Optimally, PD should not be initiated until 10 to 14 days after catheter placement to allow wound healing and cuff maturation and to minimize the risk of leaks or infection. However, the PD catheter *can be used immediately*

after placement if clinically indicated. In these cases, low-volume (if possible starting with as little as 500 mL/exchange, aiming for < 1500 mL/exchange), supine PD should be prescribed. Often the patient has some residual renal function, so “full doses” of PD are not needed. Furthermore, the risk of leak and peritonitis during these urgent PD starts should be less than the risk of bacteremia from a tunneled HD catheter in experienced hands. Experience from using the Moncrief-Popovich insertion technique suggests that the catheter does not need to be flushed during the postoperative period. Nevertheless, some authors recommend periodic flushing; if done, a once-weekly approach seems reasonable. After catheter implantation, the exit site should be covered by sterile gauze and a nonocclusive dressing. The dressing should not be changed for several days unless there is evidence of excessive bleeding. To ensure optimal tissue healing during this period, the catheter should be immobilized to prevent trauma to the exit site.¹⁷ Sutures at the exit site should be avoided. During this time, patients should avoid submerging the exit site in water. Once the catheter exit site has “matured,” daily exit site care is initiated. This includes cleansing agents and prophylactic antibiotics.

Catheter Survival

Transfer from PD to HD is often precipitated by catheter-related problems; in a recent review of cohorts that started dialysis in 2000, 2001, 2002, and 2003, catheter-related problems were responsible for 17% of transfers.¹⁸ Transfer is usually due to an issue related to catheter infection, but occasionally due to catheter migration or dialysate leaks. Early CAPD registry data (based on patients who were undergoing dialysis between January 1981 and August 1987) showed that the cumulative probability of a CAPD patient’s experiencing at least one catheter replacement was 32% at 2 years and 42% at 3 years.¹⁹ These data were collected before widespread use of swan neck type catheters, which have improved catheter survival, and laparoscopic insertion techniques. Catheter survival has been shown to correlate with the patient’s weight, and weight at initiation of dialysis was predictive of catheter loss due to infectious complications.²⁰ Outcomes of 213 curled catheters placed either surgically or percutaneously (63%) were analyzed over a 4-year period.²¹ Actuarial catheter survival was 61% at 3 years and did not differ with the implantation technique used. Kaplan-Meier survival of 138 surgically placed straight double-cuff catheters at one center was 87%, 69%, and 65%, at 1, 2, and 3 years, respectively.²² Others²³ report a 90% 3-year survival with swan neck catheters versus 80% with the straight PD catheter. Using the advanced laparoscopic placement approach, the initial catheter success rate was 99%.¹⁶ Once placed, catheters usually function well although occasionally there is failure to fill or drain due to malposition, kinking, or omental wrapping. This can be treated surgically or with laparoscopic intervention.^{24,25}

Indications for Catheter Removal

Indications for catheter removal include malfunction, relapsing or recurrent peritonitis, peritonitis that fails to resolve, chronic exit site or tunnel infection, fungal peritonitis, *Pseudomonas*-related peritonitis that is slow to respond to

therapy, perforated viscus, multiorganism-related peritonitis, recovery of kidney function, and permanent transfer to hemodialysis.²⁶

DIALYSIS SOLUTIONS

The history of PD fluid development and currently available PD solutions has been reviewed elsewhere.⁴ Typical peritoneal dialysis fluid solute concentrations are found in Table 81-1. These solutions have historically used lactate as the buffer (although bicarbonate-based solutions are now approved), are sterile, are easily shipped, and come in various volumes (such as 1.5-, 2-, 2.5-, and 3-L volumes for manual or automated exchanges and 5- and 6-L bags for automated exchanges). The typical osmotic agent is glucose-based (although others are available), and the ultrafiltration profile is varied by choice of osmotic agent instilled and the percent glucose concentration for glucose-containing solutions. Peritoneal dialysis solutions have an unphysiologic pH, a high osmolality, use lactate for the buffer, and contain aldehydes or glucose degradation products (GDPs) that form during the sterilization process or during storage. These GDPs can be absorbed and may cause local and systemic inflammation. Recent development and modification of these fluids has made them more *biocompatible* (lower GDP content, more physiological pH), with a more sustained ultrafiltration profile (polyglucose-icodextrin-containing solutions).

Electrolytes

Sodium

Sodium (Na^+) has been added to the dialysate in concentrations ranging from 120 to 140 mEq/L. The lower the dialysate sodium, the greater the potential for diffusion-related sodium removal.

Early during a dwell with glucose-containing fluids and crystalloid-induced ultrafiltration, some water is transported from the blood to the dialysate compartments via aquaporin channels, which allow for movement of water only and do not

allow for the passage of any solutes, such as Na^+ . This portion of the ultrafiltrate volume is sodium free or, in other words, *free water*. The physiologic phenomenon is called *sodium sieving*. As a result, early during a dextrose dwell, dialysate sodium decreases. This decrease is most pronounced in patients who are slow transporters and when hypertonic dialysis fluids are used. The clinical consequence is that, after multiple rapid exchanges with hypertonic glucose, systemic hypernatremia can occur.²⁷ During long dwells, after transcellular water movement ceases, sodium is transported from the blood to the dialysate and dialysate sodium concentrations are eventually equilibrated.

Potassium

Potassium (K^+) is not typically added to PD dialysis fluids. During a dwell, dialysate K^+ approaches equilibrium with that of plasma. Therefore, if one were to do four 2-L exchanges of dialysate a day with an ultrafiltrate volume of an additional 2 L using dialysis fluid with no added K^+ , the patient would tend to lose approximately 35 to 40 mEq/day in the dialysate while maintaining a serum K^+ concentration of approximately 4 mEq/L.²⁸ Net ultrafiltration increases K^+ removal. However, as with Na^+ , ultrafiltrate concentrations are less than that in serum because of potassium sieving across transcellular aquaporins. With rapid cycling, K^+ losses are augmented, but maximal rates are approximately 8 mEq/hr.²⁹ If needed, K^+ removal can be slowed by adding K^+ to the dialysate. As a result of this daily removal of K^+ , most PD patients do not need a potassium-restricted diet.

Calcium

It is now recognized that the calcium (Ca^{2+}) concentration of PD fluids needs to be tailored to different clinical situations.^{30,31} During the late 1970s and early 1980s, the standard of care was to use calcium- or aluminum-containing binders along with dietary phosphate restriction to control serum phosphate levels. It was also common practice to treat the tendency for hypocalcemia by using a relatively high dialysate Ca^{2+} concentration (3.5 mEq/L) that would facilitate mass transfer of Ca^{2+} from the dialysis fluids to the blood. When calcium salts are used as the phosphate binder in patients also using dialysis fluids containing Ca^{2+} concentrations of 3.5 mEq/L, hypercalcemia (in 35%–56% of patients) and metastatic calcification have been frequent complications.^{32–36} Because of these complications, dialysis fluids were developed with a lower, more nearly physiologic Ca^{2+} concentration (2.5 mEq/L).^{37,38} Clinical trials have shown that use of dialysis fluids with a lower Ca^{2+} concentration (2.5 mEq/L) is associated with a net Ca^{2+} flux from the blood to the dialysate under most physiological conditions.^{39,40} However, there is a risk of net Ca^{2+} loss in some patients, resulting in negative Ca^{2+} balance and an increase in parathyroid hormone levels.^{40,41} Estimated Ca^{2+} loss with 2.5 mEq/L Ca^{2+} solutions is approximately 100 mg/dL of ultrafiltrate or 45 g/year of Ca^{2+} ($\approx 3\%$ – 4% of total bone mineral content per year). As has been noted for Na^+ and K^+ , the greater the ultrafiltration volume, the greater the potential dialysate calcium loss. Although individualization is needed, it seems reasonable to use low-calcium fluids as the standard peritoneal dialysis solution for most patients. This allows the use of higher doses of Ca^{2+} -containing oral phosphate binders with

Table 81-1 Typical Peritoneal Dialysis Fluids

Components	Dextrose Fluid	Icodextrin Fluid
Dextrose (g/dL)	1.5, 2.5, 4.25	—
Icodextrin (g/dL)	—	7.5
Sodium (mEq/L)	132.0	132.0
Chloride (mEq/L)	96.0	96.0
Calcium (mEq/L)	3.5/2.5	3.5
Magnesium (mEq/L)	0.5	0.5
Lactate (mEq/L)	40.0	40.0
Osmolality (mOsm/kg)	346–485	282
pH	5.2	5.2

a lower risk of hypercalcemia or a progressive positive Ca^{2+} balance.

Buffers

Most PD fluids have a racemic mixture of both D- and L-lactate as the buffer. The normal physiologic form of lactic acid is the L-form,⁴² and the normal blood level of this isomer is about 300 times that of the D-form.⁴³ Nolph and coworkers⁴⁴ have shown that despite the high concentration of both isomers in standard dialysis preparations (35–40 mmol/L), even with rapid cycling such as with tidal peritoneal dialysis (TPD), D-lactate levels are only minimally elevated. One significant drawback of lactate-based solutions is that the fluids have an unphysiologically low pH. This may impair cellular functions of resident peritoneal cells and cause pain on inflow in some patients. This pain can be mitigated by using TPD therapies, using bicarbonate-based solutions when available, or adding NaHCO_3 to the dialysate.

A bicarbonate-based buffer system would be preferable for dialysis fluids, but if stored in a single chamber precipitation of Ca^{2+} and Mg^{2+} carbonates would occur. Furthermore, a low pH is favored when heat-sterilizing glucose-containing fluids to prevent formation of aldehydes (i.e., GDPs) during sterilization and storage.⁴⁵ Use of a two-chamber bag, in which the two solutions are combined at the time of use, has been shown to be a safe and easy way to minimize GDP exposure and pain on inflow.^{46,47} Long-term studies using a lactate/bicarbonate mixture (15 mmol/25 mmol/L) have been well tolerated; when compared with standard solutions, there was no difference in serum HCO_3^- levels at baseline and at the end of the study.⁴⁸

Osmotic Agents

Glucose

Standard dialysis solutions have historically used glucose or its hydrated form, dextrose, as a crystalloid osmotic agent. These fluids have been shown to be safe, effective, readily metabolized, and inexpensive. However, glucose is not an “ideal” osmotic agent because of the following properties or effects: rapid absorption; potential for metabolic derangements, such as hyperglycemia, hyperinsulinemia,⁴⁹ hyperlipidemia,⁵⁰ and obesity⁵¹; necessity for an acidic dialysate pH to prevent formation of GDPs; and the potential nonenzymatic glycosylation of peritoneal tissue, especially during periods of mesothelial cell loss.⁵² Because of these theoretical and potential downsides to glucose-containing fluids, other osmotic agents (i.e., polyglucose and amino acids) are also used in clinical practice. Glucose is a relatively small molecule; as such, it is readily absorbed from the peritoneal cavity by diffusion. Once the osmotic gradient is dissipated, transcapillary ultrafiltration ceases and lymphatic absorption of fluid predominates. The rate of absorption of glucose varies based on transport type, and in many patients who use a low glucose concentration (1.36% glucose = 1.5% dextrose) solution, the osmotic gradient for ultrafiltration is dissipated by 4 to 6 hours of dwell time. To augment the ultrafiltration volume or duration of the ultrafiltration profile, higher instilled concentrations of glucose can be used or alternative

osmotic agents, such as the macromolecule icodextrin, which is slowly absorbed from the peritoneal cavity, can be used for the long dwell.

Amino Acids

There is an obligatory daily loss of protein (4–15 g/day) and amino acids (3–4 g/day) into the peritoneal effluent.⁵³ Amino acid-containing fluids could therefore potentially replace those lost amino acids⁵⁴ and provide a caloric source that would be protein-based without the concomitant phosphorus load associated with oral protein sources.⁵⁵ Possible complications include the development of metabolic acidosis and increased levels of serum urea nitrogen, at times necessitating an increased dialysis dose. Most,^{56,57} but not all,⁵⁸ studies have shown a benefit in nutritional parameters with amino acid-containing solutions over the short term. A long-term observational study using 1.1% amino acid solutions in malnourished Korean patients showed a significant improvement in lean body mass (72% of patients) and hand grip strength but no change in serum albumin.⁵⁹ Despite data that show that daily absorption of amino acids exceeds daily protein losses and that short-term balance studies suggest a benefit,⁵⁴ the long-term usefulness of intraperitoneal amino acids has been controversial. Ultrafiltration rates for 1.1% amino acids are similar to those using 1.5% dextrose solutions. An emerging approach to prescribing PD is to use a *glucose-sparing* PD prescription (i.e., one that minimizes glucose exposure by substituting amino acids, minimizing hypertonic glucose solutions, and using icodextrin for ultrafiltration during the long dwells).⁶⁰

Icodextrin

Traditionally, ultrafiltration in PD is due to *crystalloid* osmotic differences between solutions, but *colloid* osmosis is also possible. In this situation, the direction of the osmotic force is determined by the differences in the number of macromolecules in one solution versus the other, even if both are of similar osmolality. In this case the solvent (water) will move to the solution with the larger number of macromolecules.⁶¹

Polymers of glucose (polyglucose or icodextrin) can be used to induce colloid-induced ultrafiltration and are currently in clinical use, because there is potentially more sodium and middle molecule removal than seen with some glucose dwells with similar ultrafiltration volumes.⁶² Another difference is that ultrafiltration with glucose is rapid and occurs early in the dwell (due to large crystalloid osmotic gradient), decreasing over time as glucose is absorbed, whereas with polyglucose, ultrafiltration is slow but sustained throughout long dwells (up to 16 hours) (see Table 81-1). Furthermore, because removal from the peritoneal cavity is by lymphatic absorption and not by diffusion, the rate of absorption is not influenced by peritoneal transport type, as is the absorption rate of glucose by diffusion. There is a growing indication for polyglucose for the long dwell (nighttime, CAPD; daytime, CCPD) to avoid excessive glucose accumulation and to achieve sustained ultrafiltration without hypertonic glucose. The safety of icodextrin use has been established. Complications include skin rash, which is about twice as likely as with glucose-containing fluids. Although an exfoliative reaction is occasionally seen, there has never been a reported case of Stevens-Johnson syndrome. Sterile peritonitis has been described, and usually resolves with

discontinuation of the product.^{63,64} The sterile peritonitis was due to an unrecognized peptidoglycan found in some batches of polyglucose that were used in Europe. This has now been identified and the production process revised. There have been no recent documented cases of this complication. Another complication is interference with certain fingerstick glucose estimations (tests that use the dehydrogenase pyrroloquinoline quinone reaction but not those that use glucose oxidation or hexokinase testing) by maltose and/or other icodextrin metabolites.⁶⁵ Icodextrin and its metabolites may directly interfere with serum amylase determinations, slightly lowering values, suggesting that to make the diagnosis of pancreatitis, one may need to rely more on computed tomography or magnetic resonance imaging or serum lipase levels than serum amylase levels alone.⁶⁶

BIOCOMPATIBILITY

The peritoneal cavity is exposed to new dialysis fluids multiple times a day. These fluids are potentially bioincompatible. They can exert biological and chemical effects locally on the peritoneal membrane, mesothelial cells, and resident leukocytes, macrophages, and fibroblasts and systemically to the absorption of GDPs and glucose itself. Despite these alterations, patients have done well on PD, at times for as long as 20 years. Nevertheless, the concept of biocompatibility is the subject of extensive research. Peritoneal biopsies in patients on long-term PD tend to show ultrastructural changes (e.g., glycosylation of capillary proteins, angiogenesis, and fibrosis), possibly related to the dialysis solutions themselves.⁵² Over time these morphologic alterations seem to be associated with clinically relevant changes in peritoneal transport and ultrafiltration abilities.⁶⁷ Occasionally these changes are associated with the development of a debilitating, sclerosing process within the peritoneum. There is concern that this may be due in part to accumulation of advanced glycation end products within the peritoneal membrane structures, precipitation of a local inflammatory state, and alteration of resident cell function.^{60,68} Preliminary studies suggest that low-GDP solutions may result in better preserved markers of mesothelial cell function at 1 year of use⁶⁹ and, in an observational cohort study, a superior technique and patient survival.⁷⁰

These studies have minor flaws; further long-term data are needed to show that use of these biocompatible solutions will in fact impact positively on patient survival.

CLINICAL USES OF CHRONIC PERITONEAL DIALYSIS

Clinical Observations of Peritoneal Membrane Function

During a typical peritoneal dialysis dwell, the peritoneal effluent drain volume and the concentration of solutes in that drain volume will vary from patient to patient. These differences depend on the individual patients' peritoneal membrane transport characteristics, the infused volume/exchange, the concentration and type of osmotic agent used, rates of lymphatic absorption of fluid, and the dwell time/exchange.⁷¹ Knowledge of individual peritoneal membrane transport characteristics can help efficiently optimize solute and fluid removal.⁷²

Multiple tests measure peritoneal membrane transport characteristics; these tests are designed to *define or classify* an individual patients' rate of solute diffusion and potential fluid removal. They do not quantify the actual amount of solute or volume of fluid removed. To perform the test, a patient must bring in a 24-hour collection of dialysate effluent and residual renal volume, which is analyzed for solute clearance. Once an individual patient's peritoneal membrane transport characteristics are defined, such data can be used to *guide* prescription management and *predict* what the delivered solute removal will be with a certain prescription. Multiple tests have been developed to evaluate various aspects of peritoneal membrane function (Table 81-2). No prospective randomized trials have been designed to determine which test is best for prescription management. Each test has its strengths and weaknesses; all are useful. These have been recently reviewed.⁶⁷

In the United States, peritoneal membrane transport/function is typically assessed by the peritoneal equilibration test (PET).⁷¹ This test, based on observations of peritoneal transport,^{34,73} is a standardized method used to categorize patients into one of four transport categories using the dialysate-

Table 81-2 Standardized Tests for Evaluating Peritoneal Membrane Transport/Function

Aspect of Peritoneal Function	METHOD OF PERITONEAL FUNCTION TESTING		
	PET	SPA	PDC
Small solute transport	D/P creatinine	MTAC creatinine	Area permeability
Ultrafiltration capacity	Drain volume	Drain volume	Estimated ultrafiltration coefficient
Ultrafiltration via water channels	—	D/P sodium	Model for sodium channel
Fluid absorption	—	Dextran 70	Derived
Permeability to macromolecules	—	Restriction coefficients	Large-pore flow

D/P, dialysate-to-plasma ratio; MTAC, mass transfer area coefficient; PDC, personal dialysis capacity; PET, peritoneal equilibration test; SPA, standard permeability analysis.

to-plasma ratio of creatinine (D/P Cr) at 4 hours: high (D/P Cr ratio > 0.81), high average (D/P Cr ratio $0.81-0.65$), low-average (D/P Cr ratio $0.65-0.50$), or low (D/P Cr ratio < 0.50). After an overnight dwell the PET is performed, instilling 2 L of 2.5% dextrose dialysis fluid, allowing the dialysate to dwell for 4 hours. Dialysate urea, creatinine, glucose, and Na^+ concentrations are measured at time 0 and after 2 and 4 hours of dwell time. Serum values are determined after 2 hours. In addition, 4-hour drain volume is also obtained. For each of these dwell times, D/P ratios for both urea and creatinine are obtained. The ratios of glucose at time of drain to the initial dialysis fluid glucose (D/D_0) are also obtained. On the basis of published data, the membrane type can be identified and prescriptions optimized. Several large retrospective studies have shown that most patients are either high-average or low-average transporters.^{34,74}

A modification of the original PET using 1.36% glucose/1.5% dextrose and dextran 70, called the standard peritoneal permeability analysis was developed to better evaluate mass transfer area coefficients of small and middle molecular weight solutes and to better determine residual volume and ultrafiltration kinetics.⁷⁵ The 1.36% glucose/1.5% dextrose solutions were chosen so that there would be less of an osmotic gradient for ultrafiltration and therefore one would be better able to determine the true diffusive (i.e., mass transfer area coefficients) characteristics of the membrane under a situation in which there would be less ultrafiltration and its associated convective removal of solutes. This was subsequently modified; 3.86% glucose/4.25% dextrose solutions were substituted to maximize crystalloid osmotic ultrafiltration and optimize one's ability to evaluate pathologic variations in ultrafiltration capacity.⁷⁶ This modification allows one to evaluate aquaporin-mediated water transport and the sodium versus water removal characteristics of peritoneal transport. The International Society for Peritoneal Dialysis has recommended that a modified PET (3.86% glucose/4.25% dextrose) dwell be used to optimally evaluate patients with ultrafiltration failure.¹⁸ Most centers use the standardized PET as the baseline test to characterize peritoneal membrane transport. The 1.36% glucose/1.5% dextrose PET and 3.86% glucose/4.25% dextrose PET were compared and no clinical differences between D/P ratios for small solutes such as creatinine were found.^{77,78} These data suggest that in common clinical practice, one could compare D/P ratios for small solute transport between tests. If ultrafiltration failure is suspected the 3.86% glucose/4.25% dextrose PET would be most useful even if a 2.27% glucose/2.5% PET was done at baseline.

The initial instillation of dialysate into the peritoneal cavity and the initiation of peritoneal dialysis is associated with mild changes in local cytokine production, peritoneal vascularity, and blood flow.⁷⁹ Therefore, it is recommended that the "baseline" peritoneal membrane transport study be obtained after the first 4 to 8 weeks of dialysis.⁸⁰ During training one could "estimate" peritoneal membrane transport rate by measuring the drain volume from a 4-hour dwell of 2.5% dextrose and comparing expected D/P Cr ratios to the patient's observed drain volume.

In general, peritoneal transport is stable over time.⁸¹ However, small cohort studies suggest that in some patients peritoneal transport changes.⁶⁷ Impaired ultrafiltration is the most common clinically noted abnormality. The prevalence of this change depends on dialysis vintage. One review using a clinical definition for ultrafiltration failure (i.e., need for hypertonic exchanges) suggested that it was present in 3% of patients at

1 year and in 31% after 6 years.⁸² In another cross-sectional study of patients on PD a median of 19 months (range, 0.3–178 mo) and using a laboratory definition of ultrafiltration failure (< 400 mL after a 4-hour dwell with 4.25% dextrose) impaired ultrafiltration was noted in 23% of patients.⁷⁶ The reasons for these changes are unclear. It is thought that continued exposure to nonphysiologic glucose-containing peritoneal dialysis solutions increases the vascularity and thus the "effective" surface area available for transport. Indirect evidence in support of this hypothesis is the observation that increased use of hypertonic glucose solutions preceded the change (increase) in peritoneal transport.⁸³ In the subgroup in whom there was no clinical need for increased use of hypertonic glucose exchanges, peritoneal transport tended not to change.⁸⁴ As a result of the observed stability of peritoneal transport over time in most patients, one does not need to routinely document peritoneal membrane transport characteristics over time with routine laboratory measurement (peritoneal membrane transport testing). However, one should obtain a baseline test to characterize peritoneal transport and then repeat the transport test whenever clinically indicated (such as in patients with unexplained volume overload, decreasing solute removal, or drain volumes).

Choice of Dialysis Modality

Most patients with end-stage renal disease have no contraindication to PD or HD. The patient should be encouraged to learn about dialysis modality choices after a discussion with the physician regarding any potential indications or contraindications to either PD or HD. Potential indications for peritoneal dialysis include patients who have problematic vascular access or who prefer home dialysis but cannot perform home hemodialysis due to a lack of a partner or suitable home environment. Absolute contraindications to peritoneal dialysis include extensive abdominal adhesions that limit dialysate flow or peritoneal surface area; bladder extrophy, gastroschisis or omphalocele and active inflammatory bowel disease because of possible increased infection risk; and physical or mental incapacity to perform peritoneal dialysis. Relative contraindications to peritoneal dialysis include a documented loss of peritoneal function noted during prior use of PD (this may have resolved after a period of peritoneal resting) and patients with recurrent diverticulitis, those with a history of ischemic bowel disease or inflammatory bowel disease, active abdominal wall or skin infections, and those with ostomies (urinary or bowel) because of increased infection risk. Despite the infection risk, PD can be used in patients with ostomies or feeding tubes when clinically indicated, as long as these have been in place for at least 2 months to allow healing at that site to minimize risk of leak.

Obese patients can do well on PD; however, some may not be able to achieve minimal Kt/V goals once anuric, especially low transporters unwilling to do a midday exchange. However, at the start of renal replacement therapy, obese patients often have significant residual kidney function and do not need a "full dose" of PD to achieve the minimal delivered total Kt/V goal. In addition, catheter placement is more challenging in the morbidly obese. Presternal catheters have been advocated to minimize risk of exit-site infections and make daily catheter care easier.

Peritoneal Dialysis Modalities

All PD therapies are based on the same physiologic principles: allow PD fluid to dwell intraperitoneally so that diffusion of solutes from blood to dialysis fluids, ultrafiltration (and convective solute removal), and absorption of wanted solutes from dialysis fluids can occur. These fluids are then drained and replaced at specified intervals to achieve therapeutic goals. Conventional wisdom suggested that patients classified as rapid transporters on PET testing would do best with shorter dwell therapies (i.e., APD, using a cycler); in contrast low transporters would do best with longer dwell therapies (i.e., dwells that are equally spaced out during the day; CAPD). It is now recognized that almost any patient can use either PD therapy at their start of renal replacement therapy; most can still do either once anuric, as long as they are willing to do a midday exchange. For convenience, most patients use a form of APD, and the percentage of patients starting on APD has been increasing yearly.¹

Continuous Ambulatory Peritoneal Dialysis

Since the original description of CAPD in the 1970s,⁸⁵ there have been few changes in the basic therapy. Most patients do four manual exchanges per day—three daytime exchanges of about 5 hours each and one overnight exchange of about 8 or 9 hours. With this type of prescription, one is usually able to achieve adequate daily small-solute clearances due to the continuous nature of the therapy. By adjusting the dwell volumes appropriately or by adding a fourth daytime dwell (see Typical Modifications of the Dialysis Prescription in this chapter), most CAPD patients can achieve an adequate dose of dialysis.

Automated Peritoneal Dialysis or Cyclor Peritoneal Dialysis

The technology for APD, prompted by our better understanding of peritoneal physiology, technology development, and attempts to make the therapy more user friendly for the patient, has evolved. The cyclers themselves are smaller and allow the patient to choose more options regarding fill volume, residual volume, and frequency of exchanges. Additionally, they have been altered so that we do not have to rely on gravity for fills and drain. Newer cyclers can interface with the dialysis unit via the internet so that prescriptions can be changed and information about patient usage and troubleshooting can be done at a distance. A typical patient is connected to the cycler for 8 to 10 hours overnight (dwell time usually depends on amount of time the patient would typically sleep).⁸⁶

If dialysis is only done during the nighttime and the patients have a dry peritoneum during the day (*dry day*), this form of APD is called *nightly intermittent peritoneal dialysis* (NIPD). Most patients will also carry dialysate in the peritoneum for part or all of the day; these patients are considered to have a *wet day*; alternatively, they are described as performing *continuous cycling peritoneal dialysis* (CCPD). Patients on CCPD will typically program the cycler machine to perform a last bag fill; that is, the machine will deliver a dialysate exchange at the end of the nighttime cycler dialysis. The patient will disconnect from the cycler with a full abdomen and carry this fluid for part or all of the day. In some cases, the patient will perform one or more manual exchanges during the day in addition to the last bag fill exchange. These additional exchanges are usually performed so that the patient can receive an adequate dose of dialysis (see adequacy of dialysis, below).

Tidal Peritoneal Dialysis

With TPD, after the initial fill, only a portion of the dialysate is drained from the peritoneal cavity, leaving a residual volume, which is then supplemented by the repeated instillation of small tidal volumes of dialysis fluids with the use of an automated cycler.⁸⁷ The procedure is usually performed nightly. Variables to be chosen include reserve volume, tidal outflow volume, tidal replacement volume, flow rates, and frequency of the exchanges. Theoretically, maintaining an intraperitoneal reservoir by not attempting to completely drain the peritoneal cavity after each dwell results in more continuous contact of the dialysate with the peritoneal membrane. In addition, the more rapid cycling may increase mixing and prevent formation of stagnant fluid films within the abdomen. In most,^{88,89} but not all studies,⁹⁰ however, the use of TPD did not result in an increase in urea or creatinine clearances compared to cycler peritoneal dialysis. The differences in results among these studies are likely due to differences in the cycler PD and TPD prescriptions chosen for analysis. Little evidence suggests that TPD can provide clearances superior to those provided by cycler dialysis. It appears that TPD can decrease abdominal discomfort during inflow and outflow due to the continual presence of some dialysate in the peritoneal cavity during the cycling procedure.⁹¹ A major disadvantage of TPD is the cost of the large volume of fluids needed. A recent review of published studies on TPD⁹² suggested that there does not appear to be the consistent enhanced clearance over APD with TPD originally suggested by animal studies. However, historical studies may not have “optimized” residual volume and drain time. These parameters and their effect on clearance are being re-examined. Despite the questionable effect on clearance, published data and clinical experience have consistently shown that TPD can improve patient comfort, reducing pain on inflow or drainage, and in some cases may minimize inflow and drainage-related device alarms.

WRITING THE DIALYSIS PRESCRIPTION

Initial Prescription

The peritoneal dialysis prescription can be developed either empirically or through the use of a computer modeling program. To optimize the prescription one should know the patient's weight, residual renal function (i.e., glomerular filtration rate), and peritoneal membrane transport characteristics. At the start of PD, peritoneal transport is not known, so the initial prescription assumes the patient is an average transporter. The prescription can then be adjusted if indicated after a PET (or other test) is performed to determine peritoneal transport and a 24-hour collection of urine and dialysate volumes is obtained to calculate solute clearance/removal (typically Kt/V).⁹³ To minimize the risk of leak, it is best to let the PD catheter “mature” for 10 to 14 days before starting PD.⁹⁴ However, data shows it is safe to start PD the day the catheter is placed if clinically needed. In these cases it is best to use low instilled volumes and keep the patient supine as much as possible to avoid increases in intra-abdominal pressure that could cause leakage at the catheter site. Each center needs to decide if they will use “incremental” dialysis prescriptions (i.e., target total Kt/V—dialysis and residual renal—and only prescribe enough PD so that the combined Kt/V is above the minimal goal, adjusting the PD component as renal function declines.⁹⁵ Alternatively, the center's policy may

be to ignore the renal component and prescribe a “full dose” of PD no matter how much residual renal function the patient has. Both approaches work equally well as long as one carefully monitors residual renal function (every 2 months) and adjusts the peritoneal component accordingly.

Two to four weeks after initiation of peritoneal dialysis, 24-hour collections of urine and dialysate should be performed, along with serum chemistries and a complete blood count, to determine solute clearances.⁹³ The initial PET should be performed approximately 1 month after the initiation of dialysis. This waiting period is recommended because PET results can change during the first month of dialysis.⁷⁹ The PET is performed to establish baseline transport characteristics, rule out unexpected problems, and identify patients who are either high or low transporters. These patients will need careful attention to their prescription and drain volumes to optimize solute clearance and blood pressure control once they become anuric. If clearances are below target, the prescription should be modified and adequacy testing repeated.

Typical Modifications of the Dialysis Prescription

It is important to remember that solute clearance/exchange equals the drain volume times concentration of solute in that drain volume, and that the daily solute clearance is the sum of the solute clearance for each of the exchanges done that day. Therefore, for patient convenience, a prescription can be written in which the solute removal for one of the dwells may not be the most efficient possible as long as that is “made up” during another dwell. For instance, although diffusion of small solutes would ultimately stop (D/P ratio = 1) some time during the 15-hour daytime dwell of CCPD, one can still obtain minimal Kt/V goals on APD. Similar adjustments can be made to achieve daily ultrafiltration goals.

To increase solute removal in CAPD patients, it is most efficient to increase the instilled volume/exchange. The most common approach is to increase the dwell volume in 500-mL increments, because commercially available fluids come in 500-mL increments. However, one could increase the instilled volume by only 250 mL/exchange if wanted, discarding the remaining dialysis fluids. Alternatively one could increase the number of exchanges/day. However, this is not as user friendly for the patient and typically does not increase solute clearance as much as an increase in instilled volume/exchange does.

For APD patients, the same principles apply as in CAPD; however, one typically has shorter (nighttime) and longer (daytime) dwells to consider. One would typically start by increasing the dwell volume/exchange at night. Other modifications include increasing the time spent overnight on the cycler, increasing the number of exchanges on the cycler, or increasing the number of daytime dwells. Sometimes combinations of the above measures are used in an individual patient. In a review of cycler prescription use in large cohorts of patients on cycler PD during the years 1997, 2000, and 2003,⁸⁶ the average instilled volume increased from about 2272 mL to about 2397 mL while number of exchanges on average remained similar (4.5 vs 4.4/day) and percentage of patients with five or more cycles per night decreased from 45% in 1997 to 38% in 2003. These trends are consistent with optimization of therapy based on known peritoneal physiology.

CONCLUSIONS

The goal of renal replacement therapy is not only to keep the patient alive, but at the same time to maintain the patient's previous lifestyle and wellness. Peritoneal dialysis is well suited to do this. The therapy and the solutions used in it have evolved along with the understanding of peritoneal physiology and the development of new technologies. Patients continue to do well on PD with improvement in relative risk of death over past years and outcomes similar to or better than those expected with hemodialysis for most patients.

Loss of peritoneal function is a major factor leading to treatment failure in peritoneal dialysis (PD). Although the precise biologic mechanisms responsible for these changes have not been defined, it is widely assumed that alterations in peritoneal function are related to structural changes in the peritoneal membrane. Accumulating, albeit indirect, evidence shows that continuous exposure to components of bioincompatible dialysis solution as well as repeated episodes of bacterial peritonitis play a major role in the long-term changes seen in peritoneal function (i.e., ultrafiltration loss and increased solute clearance). To date, however, the relationship between structure and function has not been fully defined. Although a number of studies have identified various mesothelial, vascular, and interstitial changes in peritoneal morphology during PD, the responsible factors have not been identified. Identified changes include loss or degeneration of mesothelial cells, thickening of the submesothelial compact collagenous zone (variously described as fibrosis or sclerosis), changes in the structure and number of blood vessels, and reduplication of vascular basement membrane.

Recent studies have quantified the changes within the submesothelial collagenous zone and demonstrated a progressive increase in thickness with time on PD (Fig. 82-1). Changes within the peritoneal vascular bed have also been identified. These include progressive changes to the structure of small vessels, ranging from subtle thickening of the subendothelial matrix to complete obliteration of vessels (Fig. 82-2). Thus, evidence is accumulating that changes occur in both the interstitial and vascular compartments of the dialysed peritoneal membrane.¹ The little evidence that is available from matched biopsies also suggests that these changes occur primarily in the parietal membrane, with a lesser degree of involvement of the corresponding visceral membrane.

Although it is likely that these structural changes are related to time on dialysis, episodes of peritonitis, and perhaps

to dialysis solution components, the exact relationships are poorly understood, as is the possible contribution of uremia.

Encapsulating peritoneal sclerosis is a rare but serious complication of peritoneal dialysis. It is characterized by a severe fibrotic reaction, frequently inflammatory, that primarily involves the visceral membrane. Encapsulation of the small bowel results in progressive obstruction. Prolonged treatment with PD is the most important risk factor, with an incidence of 5% to 20% after 10 years of continuous therapy.² Other risk factors include severe bacterial peritonitis and switching modality (e.g., to hemodialysis or transplant). Cases differ in their severity, some requiring no more than nutritional support; in severe cases surgical intervention, including adhesiolysis and peritonectomy, has proved successful in experienced hands.²

INFECTIOUS COMPLICATIONS

Peritonitis

Although the introduction of disconnect systems has reduced the incidence of peritonitis, it remains one of the most important complications of long-term PD. A single episode is rarely life-threatening, but repeated or prolonged infection remains a major cause of treatment failure and results in a forced switch to hemodialysis.

The diagnosis should be suspected in any patient who develops a cloudy bag or abdominal pain. Fever may also be present but is not a universal feature of peritonitis. Patients should be advised to contact their dialysis unit immediately if they have a cloudy bag or persistent abdominal pain. Samples of the dialysate should be analyzed for cell count and undergo microbiologic examination. The diagnosis is confirmed by finding more than 100 white blood cells/ μL , of which at least

Figure 82-1 Changes in the thickness of the peritoneal membrane with origin of biopsy and time on peritoneal dialysis. The submesothelial compact zone was measured in micrometers in samples taken from normal individuals, uremic predialysis patients, hemodialysis patients, and patients undergoing peritoneal dialysis, grouped according to duration of dialysis. Data are presented as box plots representing interquartile ranges.

50% are polymorphonuclear leukocytes. A Gram stain should also be performed to help identify the type of causative organism, although this will only reveal the pathogen in a minority of cases. For most patients, treatment will have to be empirical, pending full results of culture and sensitivity tests. Various culture techniques have been proposed, but white cell lysis is often helpful in increasing the yield of a positive growth.

There is no standard treatment for peritonitis in a PD patient. A number of regimens have been found reasonably effective, none of which give a 100% cure rate without relapse. In the few randomized studies that have been conducted, no antibiotic combination or dosing regimen was found to be superior; just one study found that intraperitoneal rather than intravenous administration resulted in a higher cure rate. The emergence of vancomycin-resistant enterococci, methicillin-resistant *Staphylococcus aureus* (MRSA), and other resistant organisms means that local treatment regimens must be developed in consultation with the microbiology services and infection control team.

The Advisory Committee on Peritonitis Management of the International Society of Peritoneal Dialysis (available at ispd.com) has published detailed guidelines and algorithms for the management of this condition.^{3,4} The recommended initial empirical therapy is a center-specific regimen, based on known local sensitivities of organisms that frequently cause peritonitis, and must include coverage for both gram-positive and gram-negative organisms. For example, this might be a first-generation cephalosporin, such as cefazolin or cephalothin, combined with an aminoglycoside (paying attention to residual renal function). Both types of antibiotic are administered as a loading dose in the first bag and then as a maintenance dose in subsequent bags. Suggested doses of cephalosporin are 500 mg/L for loading and 125 mg/L for maintenance. Once the culture result is available the regimen should be modified

accordingly. If an enterococcus is identified (gram-positive), the cephalosporin should be stopped and ampicillin added at a dose of 125 mg/L. *S. aureus* treatment includes adding oral rifampin 600 mg daily. If the organism is not MRSA, an alternative is to use a specific gram-positive antibiotic such as floxacillin or rifampin. If other gram-positive organisms are identified, the cephalosporin should be continued. Although in vitro tests may suggest resistance of coagulase-negative staphylococci to cephalosporins, the in vivo concentration of the drug is usually sufficient to overcome this potential problem. If, however, clinical improvement is slow or fails to occur, vancomycin may be given at a dose of 30 mg/kg intraperitoneally every 7 days. If the organism is MRSA, vancomycin should be given using the same regimen. For uncomplicated gram-positive infections, an oral cephalosporin can be substituted for the intraperitoneal cephalosporin during the second week of therapy (summarized in Fig. 82-3).

If the culture is negative, combined therapy of cephalosporin and aminoglycoside should be continued for 2 weeks, assuming there is a clinical response (summarized in Fig. 82-4).

If a gram-negative microorganism is identified, subsequent management depends on the sensitivity (summarized in Fig. 82-5). If the bacteria are sensitive to the cephalosporin, it should be continued. On the other hand, isolation of *Pseudomonas* requires withdrawal of the cephalosporin and the addition of an alternative antibiotic with demonstrable activity against the organism, such as a quinolone.

Isolation of multiple organisms, including anaerobes, strongly suggests major bowel pathology, including perforation or a diverticular abscess. Metronidazole should be added

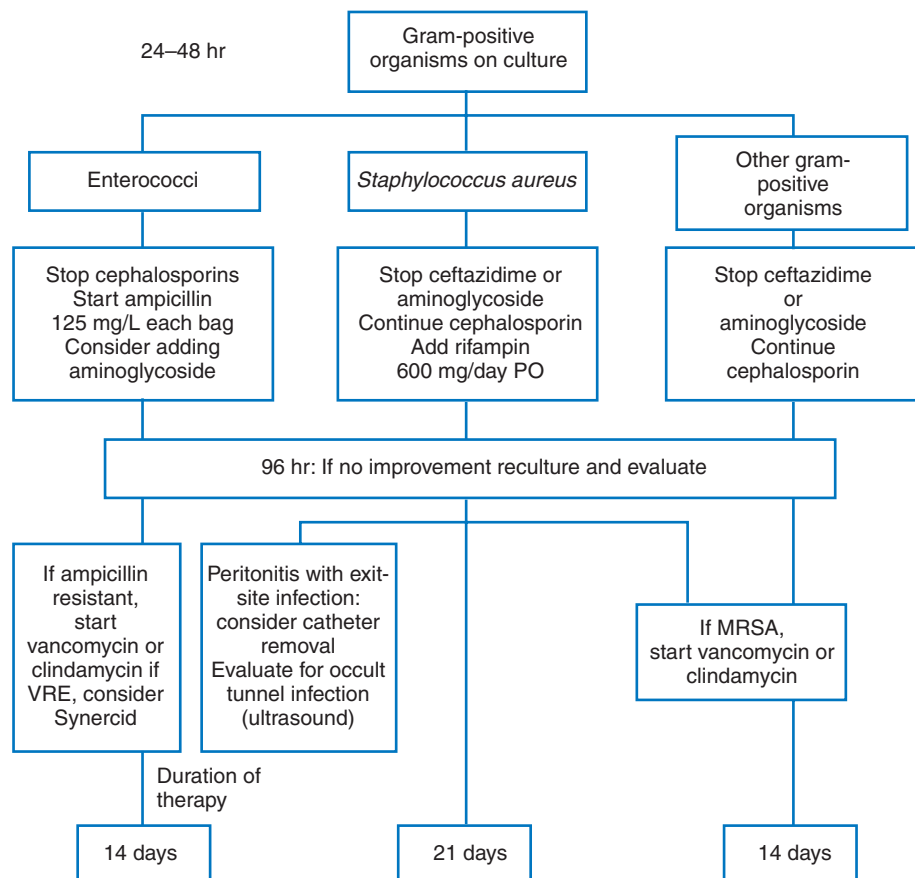

to the regimen intravenously initially (the intravenous dose is 500 mg tid). Bowel pathology should also be considered if a gram-negative peritonitis is associated with severe systemic signs or if the infection proves difficult to bring under control. In these situations, urgent surgical review is required pending a laparotomy.

The identification of yeasts on the Gram stain or isolation of yeasts or fungi on culture is a matter for serious concern. Most clinicians would recommend removing the peritoneal catheter immediately because this type of infection can be difficult to eradicate in the presence of a foreign body. Recent experience suggests that a combination of an imidazole such as fluconazole with flucytosine may be of benefit. The recommendation for adults is daily fluconazole at an oral or intraperitoneal dose of 200 mg, and flucytosine at a loading dose of 2 g orally with a maintenance dose of 1 g/day. Amphotericin B is no longer recommended. Unfortunately, oral flucytosine is not universally available.

The optimum duration of treatment has not been clearly defined by controlled trials. At present it is recommended that for gram-positive organisms therapy should last 14 days, except in the case of *S. aureus*, when 21 days is suggested. For culture-negative episodes 14 days should suffice. The same is true in the case of single-organism gram-negative peritonitis, but 21 days is recommended for *Pseudomonas*, *Stenotrophomonas*, or multiple organisms. Fungal or yeast infections require 4 to 6 weeks of therapy (or 7 to 10 days of therapy after catheter removal).

A patient who is not systemically ill can be treated successfully on an outpatient basis. It is extremely important, however,

Figure 82-3 Management of gram-positive peritonitis. (Reproduced with permission from The Advisory Committee on Peritonitis Management of The International Society of Peritoneal Dialysis: Dialysis-Related Peritonitis Treatment Recommendations: 2000 Update.)

that there is follow-up either in the clinic or by telephone. In the majority of cases, clinical resolution, as judged by clearing of the bags, starts within 48 hours. If there is no improvement within 96 hours despite the correct antibiotic as judged by sensitivity tests, then the fluid must be retested for cell count, Gram stain, and culture. In the case of a persistent *S. aureus* infection, an underlying tunnel infection should be excluded (see Managing Exit-Site and Tunnel Infection in this chapter). In all other situations in which there is failure to improve, serious consideration should be given to removing the catheter. The possibility of intra-abdominal or gynecologic disease, or the presence of unusual organisms such as mycobacterium, should also be considered.

For patients on automated peritoneal dialysis, regimens similar to those outlined above are used, but the dialysis should be modified so that it lasts a full 24 hours, with 3- to 4-hour dwells. Once there is clinical resolution, the usual automated PD regimen can be recommenced, but with a day-time bag containing the antibiotics, until completion of the treatment.

Relapsing peritonitis is defined as separate infective episodes caused by the same organism within 4 weeks of finishing the previous course of antibiotics. In gram-positive infections a 4-week course of a cephalosporin together with oral rifampin should be tried. The recurrence of *S. aureus* infection should trigger a search for a pericatheter infection or tunnel. Relapsing MRSA-related peritonitis will require a prolonged course (4 weeks) of vancomycin or clindamycin. If enterococci or gram-negative organisms are the cause, the possibility of intra-abdominal disease or a diverticular abscess should be

considered. Again a repeat course of antibiotics chosen by sensitivity testing should last 4 weeks. As before, in the case of a relapse, removal of the catheter should be considered if there is no improvement within 4 days.

The best regimen for catheter replacement after removal for peritonitis has not been defined. There are theoretical benefits for the withdrawal of PD as replacement renal therapy for a brief period and avoiding the presence of an intra-peritoneal foreign body, and altering host defenses by instilling dialysate. Some centers, however, practice removal and replacement of the catheter at the same time under antibiotic cover. Such an approach has met with anecdotal success. Each patient should be judged individually to decide what is in his or her best interests.

Prevention

Because of the high rate of peritonitis experienced during the early years of continuous ambulatory peritoneal dialysis (CAPD), considerable efforts have been made to prevent this serious complication. Approaches that have been shown to reduce infection rates in randomized studies include increased intensity of training,⁵ use of flush-before-fill systems,⁶ antibiotic prophylaxis to cover catheter insertion,⁴ and prevention of exit-site infections.^{7,8} There is no evidence that the type of PD catheter used or the approach to insertion (i.e., surgical, medical, or laparoscopic) has any effect on subsequent peritonitis or exit-site infection rates. More important are the experience of the surgical operator and the development of robust preoperative and postoperative care protocols. These should include careful siting of the exit site so that it is visible to the patient and does not lie either on the beltline, where rubbing will occur, or beneath skinfolds. Postoperatively an occlusive dressing should be applied and not removed until healing has occurred. Patients should be trained in exit-site inspection and care; any fresh granulomatous tissue should be removed and kept dry by the careful application of silver nitrate.

Significant advances have been made in the design of delivery systems in an attempt to reduce bacterial entry into the peritoneal cavity and thus reduce peritoneal infection. Buoncristiani and colleagues were the first to show that a Y-set system significantly reduced the rate of infection. This has been confirmed in several randomized, controlled trials.⁶ An integrated twin-bag system, one bag for unused fluid and the other for drainage, is connected to a Y-shaped tube, which has a short stem to link it to the catheter. The principle of the system is that the drainage tube is flushed free of contaminating bacteria before fresh fluid is run in. In addition, the number of times that the continuity of the tubing is broken is reduced. These Y-set systems act by greatly reducing the effects of touch contamination, thus reducing the rate of coagulase-negative staphylococcal infection. This system is now the standard for CAPD. The Y set does not, however, affect the incidence of *S. aureus* peritonitis.

In contrast to coagulase-negative staphylococci, carriage of *S. aureus* appears to be confined to 25% to 30% of PD patients who are more likely to acquire exit-site infections and peritonitis. Several studies, using either historical controls or in comparison with oral rifampin, have found that the regular use of mupirocin applied to the nares (e.g., for the first 5 days of each month) or directly to the exit site (on a long-term daily basis) have reduced the frequency of exit-site infections, and in some cases peritonitis, due to *S. aureus*. Recently a

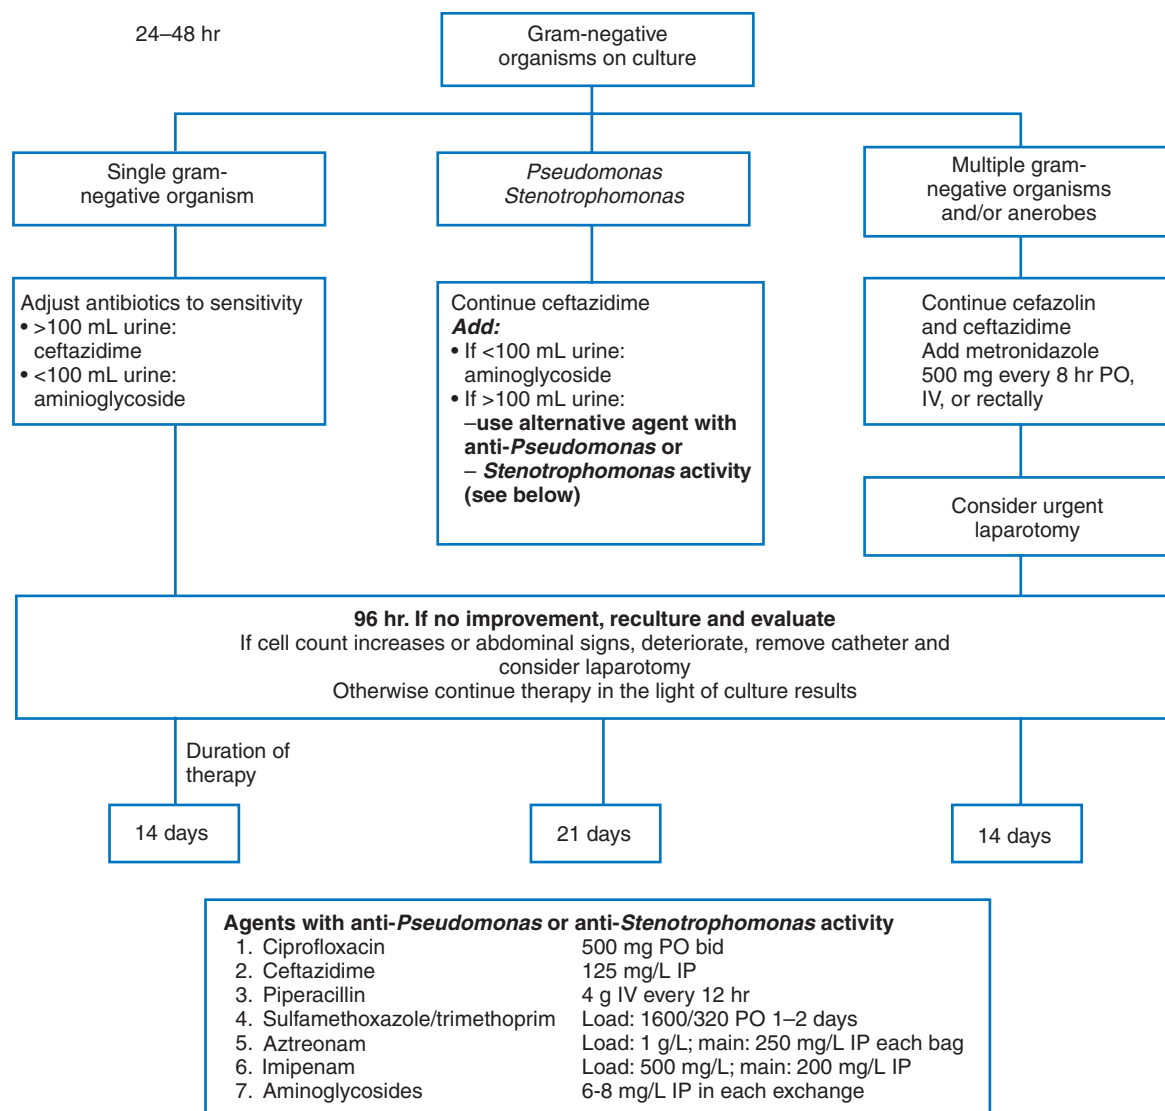

Figure 82-5 Management of gram-negative peritonitis. (Reproduced with permission from The Advisory Committee on Peritonitis Management of The International Society of Peritoneal Dialysis: Dialysis-Related Peritonitis Treatment Recommendations: 2000 Update.)

direct comparison between mupirocin and gentamicin cream applied to the exit site was undertaken; the latter was as effective or even more effective when compared to mupirocin in preventing *S. aureus* infections. It also reduced the frequency of *Pseudomonas* exit-site infection and peritonitis. Concerns remain over the risk of encouraging resistance to gentamicin when used indiscriminately; it is important that any such policy be developed with the local involvement of microbiologists and infection control teams. With the exception of prevention of *Pseudomonas* exit-site infection, there is no proven method of decreasing the incidence of gram-negative infections. Clearly one should avoid PD, if possible, in any patient with a stoma or fistula. Part of the difficulty is that gram-negative organisms often cause problems in the elderly, probably as a result of diverticular disease. Other than keeping the bowels regular by judicious use of fiber, no other measures seem to reduce this type of infection.

Eosinophilic Peritonitis

Eosinophilic peritonitis is diagnosed when the patient presents with a cloudy bag of effluent, which is found to contain eosinophils rather than neutrophils on microscopy. The fluid is culture-negative. It is an uncommon event but tends to occur within the first few weeks of starting PD. The cause is unknown but is assumed to be some form of reaction to the cannula or to the dialysate. It is usually self-limiting, and no treatment is required. Eosinophilic peritonitis has been reported as an allergic response to polyglucose solutions (icodextrin).

Managing Exit-Site and Tunnel Infection

Exit-site infection is an important complication of long-term PD because it influences catheter longevity and increases the risk of peritonitis. The 2005 ISPD guidelines include a simple

scoring system that allows standardization of the assessment of inflammatory changes at the exit site. The site is assessed for evidence of swelling, crusting, redness, pain, and exudates; if any of these is present, 1 or 2 points are given according to severity. In the case of the first three, this is determined by extent: less than 0.5 cm from the exit site (1 point) or more than 0.5 cm from the exit site (2 points). An exudate scores 1 point if serous or 2 points if purulent; pain is scored by severity. A total score of 4 or greater indicates infection, unless there is purulent discharge, in which case infection is definite (Table 82-1). Under these circumstances an antibiotic that will cover both *S. aureus* and *Pseudomonas* (e.g., quinolone) should be commenced until sensitivities from culture are available.

Unfortunately, there are no satisfactory trials comparing different therapeutic regimens; thus, the following recommendations are based on anecdotal experiences from a variety of centers in different countries. Consensus guidelines have been published.^{3,4} The main treatment options are systemic antibiotics and local therapy. If any discharge or significant associated cellulitis is present, it is essential to start with a systemic antibiotic. Because *S. aureus* is the common organism, an agent effective against this species should be prescribed. Unless there is prior evidence that the patient carries MRSA, dicloxacillin 500 mg two times a day or floxacillin at a dose of 500 mg four times a day is appropriate. Alternatively, a cephalosporin can be used if the patient is allergic to penicillin. In most patients, the drug can be given orally, but if the individual is systemically ill, the antibiotics should be administered intravenously until clinical improvement occurs. Hospitalization is not necessary for most patients unless there is evidence of extension of the infection along the tunnel toward the inner cuff, especially if abscess formation shown by ultrasound is present, necessitating catheter removal. If the infection is resistant to methicillin, an alternative to dicloxacillin or floxacillin should be used. In a few cases, the organism may be sensitive to a cephalosporin. In the majority of resistant cases, however, vancomycin should be given as a 1-g intravenous dose (or intraperitoneally if the dwell time is at least 6 hr). The dose is repeated once a week for up to 4 weeks. Should the culture grow a gram-negative organism, ciprofloxacin in an oral dose of 500 mg twice daily will be effective in most cases. Other antibiotics should be substituted according to the in vitro sensitivity results.

Table 82-1 Classification of Exit-Site Infection

	0 Points	1 Point	2 Points
Swelling	No	Exit only; <0.5 cm	>0.5 and/or tunnel
Crust	No	<0.5 cm	>0.5 cm
Redness	No	<0.5 cm	>0.5 cm
Pain	No	Slight	Severe
Drainage	No	Serous	Purulent

Infection should be assumed with exit-site score of 4 or greater. Purulent drainage, even if alone, is sufficient to indicate infection.

A score <4 may or may not represent infection.

Reproduced with permission from Piraino B, Bailie GR, Bernardini J, et al: Peritoneal dialysis-related infections recommendations: 2005 update. *Perit Dial Int* 2005;25:107–131.

Treatment should continue for a minimum of 2 weeks. In gram-positive infections, if there is no improvement within 7 days, rifampin 600 mg/day should be added. If complete healing does not take place after 4 weeks of therapy, further measures should be considered. A number of centers have recommended exteriorizing and shaving the outer cuff. If this cuff is visible or even close to the exit site, it is likely to be involved in the infection. Under local anesthetic, the cuff is exposed by an incision along the line of the catheter. The cuff is freed by blunt dissection and then carefully shaved off the catheter. Temporary resolution of infection often occurs after this procedure; it may prolong catheter life. If the infection persists or relapses, catheter removal must be considered because there is a high risk that the exit-site infection will lead to peritonitis. It is important that the new exit site be located through a different part of the anterior abdominal wall. If the infection is controlled, and there is no evidence of sepsis along the tunnel, it is possible to insert a new catheter under antibiotic cover at the same time as the old one is removed.

NONINFECTIOUS COMPLICATIONS

Inadequate Ultrafiltration

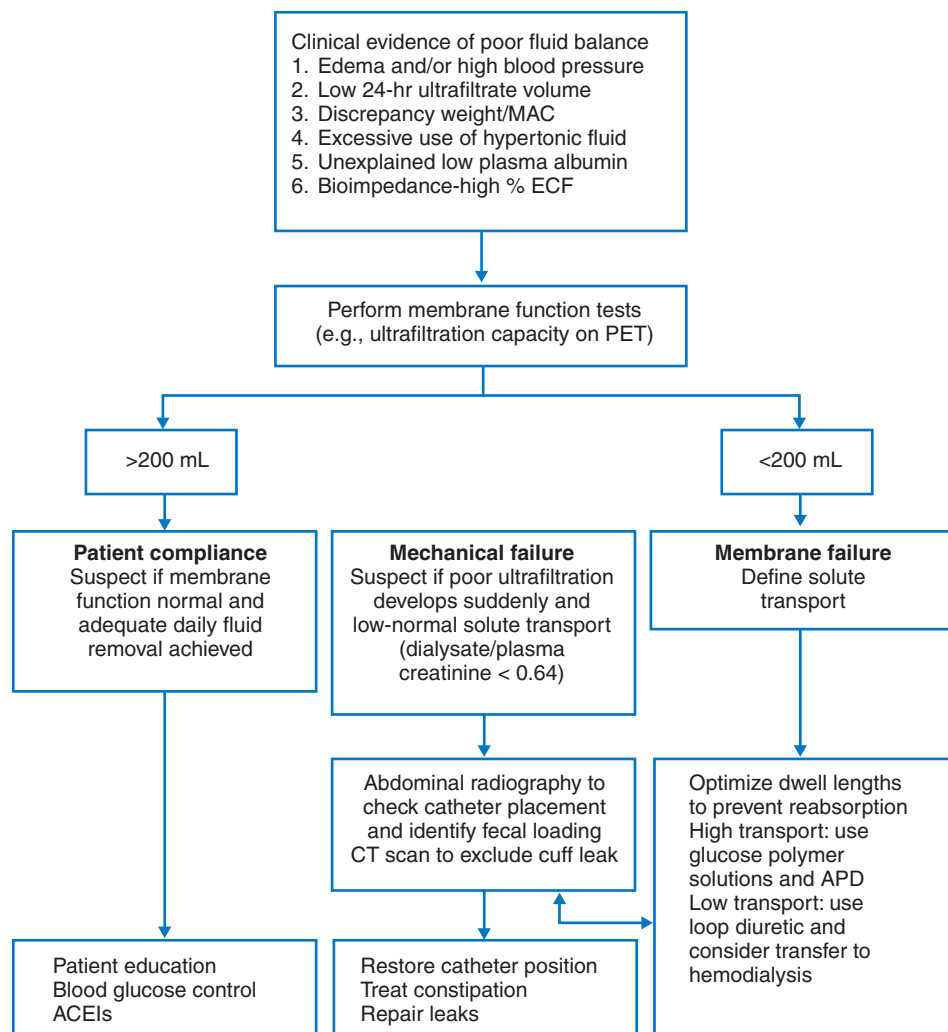

Insufficient ultrafiltration leading to fluid overload is one of the most common problems associated with long-term PD. The incidence of this problem increases with time on treatment, in part from changes in membrane function, but also from the loss of residual urine volume that contributes to satisfactory fluid balance. One study would suggest that up to 30.9% of patients have this problem by 6 years of treatment.⁹

In defining ultrafiltration failure it is possible to take either a patient- or a membrane-centered approach. The former is a relative definition: it is the inability to achieve sufficient peritoneal fluid removal to maintain adequate fluid balance; it is influenced by many factors, including fluid intake, residual urine volume, and the acceptability of using hypertonic (4.25% dextrose) exchanges. The latter is based on the absolute measurement of the ultrafiltration capacity of the peritoneal membrane, using standardized methods, and is influenced by the intrinsic properties of the membrane, such as characteristics of solute transport and fluid reabsorption rates. The clinician needs to integrate these two approaches to identify and manage fluid balance in the PD patient.

Insufficient ultrafiltration should be suspected if there is clinical evidence of fluid overload (Fig. 82-6). This problem is more difficult to identify in PD patients than in hemodialysis patients, partially because it can develop insidiously, but also because driving the weight down to an appropriate dry weight using sequential ultrafiltration during dialysis sessions is not possible. Edema, hypertension, unexplained low plasma albumin, low daily ultrafiltration volumes in anuric patients (<750 mL), excessive dependence on hypertonic exchanges (≥ 2 /day), or increases in weight disproportionate to changes in the midarm circumference all suggest that there is a problem. These findings should lead the clinician to evaluate peritoneal membrane function.

Membrane function should be assessed using a standardized 4-hour dwell as in the peritoneal equilibration test (PET)^{10,11} or the simplified standardized permeability analysis (SPA).^{12,13} The only important difference between these methods is the

Figure 82-6 Algorithm for assessing and managing fluid balance and ultrafiltration failure.

concentration of dextrose used (2.5% for PET, 4.25% for SPA). Both tests measure two aspects of membrane function, the ultrafiltration capacity and the rate of transfer of creatinine (low-molecular-weight solute transport). The *ultrafiltration capacity* is the net volume of fluid removed during the dwell and is determined by several aspects of membrane function. A value of less than 200 mL (which includes the typical overfill of approximately 150 mL for a 2-L exchange that bypasses the patient in the flush-before-fill procedure) using the PET or less than 400 mL when using the SPA have been taken as indicators of ultrafiltration failure.

If membrane function is normal (Fig. 82-7) and the total achieved ultrafiltration is reasonable (>1000 mL/day minus urine volume), it is likely that fluid balance problems can be addressed through patient education and good glycemic control in diabetics. If the ultrafiltration capacity of the membrane is poor but solute transport normal, it is important to exclude a reversible mechanical cause. This is especially the case if the loss of ultrafiltration appears to have developed rapidly. The reason may be obvious—catheter malposition, constipation (abdominal radiograph), or the development of a scrotal and subcutaneous leak—but deep cuff leaks are more difficult to

identify and require a contrast computed tomography scan. Once mechanical causes are excluded, patients with persistent poor ultrafiltration can be conveniently divided into two groups on the basis of PET or SPA results. In those with high or high average rates of solute transport (4-hr dialysate-to-plasma creatinine ratio [D/P Cr] > 0.64), the cause is early loss of the osmotic gradient during the dwell, leading to a reduced and earlier peak in achieved ultrafiltration combined with a more rapid absorption of fluid in the latter part of the dwell; these problems can both be solved by using shorter exchanges with the aid of automated PD and a glucose polymer (icodextrin) in the long exchange. Increasing evidence demonstrates that the increased mortality and technique failure previously found in high-transport patients¹⁴ can be ameliorated by this approach.¹⁵ More difficult to manage is poor ultrafiltration in the context of a D/P Cr ratio less than 0.64 or a much reduced ultrafiltration capacity of the membrane. This is rare in new PD patients but can develop after prolonged periods on dialysis where it is associated with a reduction in the osmotic conductance (efficiency) of the membrane.¹⁶ This type of ultrafiltration problem usually leads to technique failure and transfer to hemodialysis.

Figure 82-7 The relationship between solute transport (x axis) and ultrafiltration capacity observed in the peritoneal equilibration test. The *bold* regression line reflects the inverse relationship between these measures (see text). This and the areas defined as normal or representing mechanical and ultrafiltration failure were established from 1800 consecutive measurements. (Redrawn from Davies SJ, Brown B, Bryan J, Russell GI: Clinical evaluation of the peritoneal equilibration test: A population-based study. *Nephrol Dial Transplant* 1993;8(1):64–70.)

Catheter Malfunction

Inflow Failure

A 2-L bag of dialysate should take 15 minutes or less to run into the peritoneal cavity. If inflow is significantly slowed or nonexistent, mechanical causes should first be eliminated. The tubing and catheter should be checked for kinks, all clamps or rollers must be open for the inflow position, and all frangible seals fully broken. In the absence of such problems, the catheter should be flushed vigorously with 20 mL of heparinized saline. If the catheter now becomes patent, it is wise to add heparin at 500 U/L for the next few cycles, because the cause of blockage is usually a fibrin plug. If the catheter remains blocked, a radiograph of the abdomen must be obtained. If the catheter is in a reasonable position in the pelvis, an attempt to restore patency should be made with the use of urokinase; 2 mL containing 25,000 units of urokinase should be infused into the lumen of the catheter and left in situ for 2 to 4 hours. The catheter is then flushed; if inflow is restored, heparin should be added to the dialysate for the next few cycles. Should this procedure not be successful but fibrin is still thought to be the cause, an endoscopy brush may sometimes prove successful in unblocking the catheter.

If the radiographs show the catheter to be malpositioned, an attempt should be made to reposition the catheter tip into the pelvis. This can be done using a sterile semirigid rod, shaped into a curve and slid down the lumen of the catheter under radiographic screening control. The rod is then rotated. Sometimes the catheter will then move easily and slide back into the pelvis. The technique is not practical when the catheter has a swan neck configuration. Alternatively, the catheter

can be repositioned at laparotomy or peritoneoscopy. It will often be found to be wrapped in omentum. Under these circumstances, current practice is to “hitch” the omentum out of the way in the upper abdomen. This avoids an omentectomy (preserving the omentum for future use if necessary) but prevents the omentum from blocking the catheter for a second time. An algorithm for managing inflow failure is shown in Figure 82-8.

Outflow Failure

The reasons for outflow failure are similar to those causing inflow failure. Constipation is another well-recognized cause of outflow problems. Loading of the bowel with fecal material is often obvious on a plain film of the abdomen. If constipation is a likely cause of the problem, it should be treated by oral laxatives or an enema. Sometimes a strong laxative such as sodium picosulfate (Picolax) is necessary to ensure sufficient evacuation for drainage of the dialysate. Subsequently, bowel action should be kept regular by increasing the fiber in the diet and, if necessary, by adding a mild laxative such as lactulose or senna.

Fibrin in Dialysate

In the presence of peritonitis, it is common for fibrin to be present in the dialysate. If there is any restriction of dialysate flow, heparin should be added to the bags to a concentration of 500 units/L. A few patients have fibrin formation in the absence of peritonitis. The bag may appear cloudy immediately on drainage, but the fibrin will aggregate on standing. The first time this happens, a sample must be sent to the microbiology laboratory to exclude infection. If this proves negative, the patient can be reassured. If catheter plugging

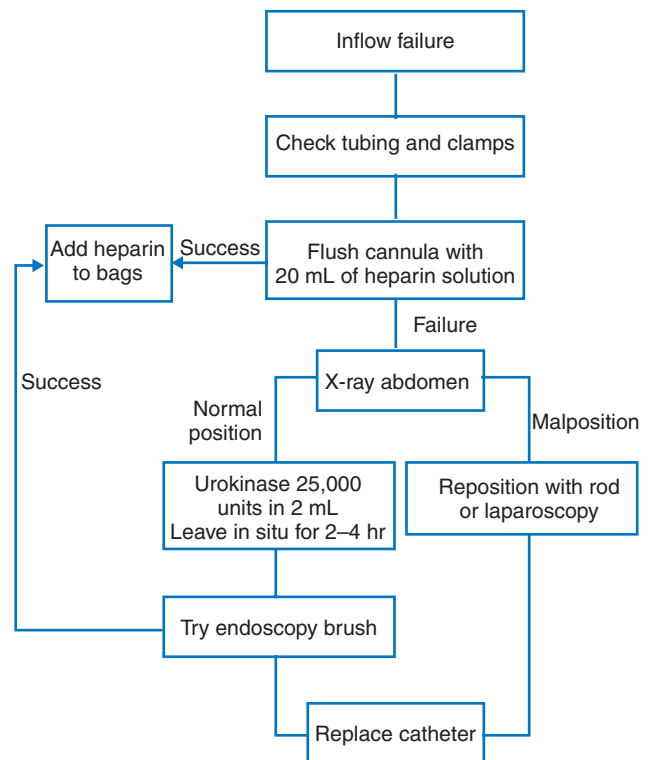

Figure 82-8 Algorithm for managing failure of dialysate inflow.

occurs, regular use of heparin is recommended. This can often be confined to the overnight bag for CAPD or the daytime dwell (if used) for those receiving automated PD.

Fluid Leaks

External

On occasions, fluid may leak from the exit site or even from the incision site where the catheter was inserted into the peritoneal cavity. This problem usually occurs early, particularly if dialysis is started soon after catheter insertion. Whenever possible, elective insertion of the catheter should be performed at least 2 weeks before dialysis is required. In addition, the use of the paramedian approach for the peritoneal entry site is thought to minimize the chances of this complication. If a leak occurs, PD should be withheld for as long as possible. If dialysis is necessary, hemodialysis should be used temporarily for 2 weeks. Alternatively, after at least 48 hours of a “dry” abdomen, PD can be recommenced with the aid of a cycler using a low volume (500 mL for adults) and no dwell. Volumes are then progressively increased over 10 days. Should the leak recur despite either of these regimens, surgical repair of the peritoneal entry site will be required. It may be better to completely remove the first catheter and replace it with a new one at a different site. Once again, if at all possible, the abdomen should be left dry for 2 to 4 weeks to allow full healing with sealing, particularly around the inner cuff.

Internal

Edema of the anterior abdominal wall can occur as part of generalized fluid retention. In this situation there is almost invariably a significant amount of peripheral edema. Treatment involves restricting fluid intake and using more hypertonic bags to improve fluid removal.

Isolated edema of the abdominal wall suggests an internal leak from the peritoneal cavity. This is particularly likely to occur from the catheter insertion site or a previous incision. It also sometimes occurs in association with an overt hernia. The site of the leak can be visualized by computed tomography after the intraperitoneal instillation of contrast media. It may be necessary for the patient to stand or perform other maneuvers to increase intra-abdominal pressure before the leak can be seen. An alternative diagnostic test is to perform scintigraphy after injecting a compound labelled with technetium-99m, such as DTPA. If a major leak is visualized, surgical repair will be required. Often, however, the patient can be managed conservatively by bed rest and using low-volume cycles with little or no dwell. Cessation of PD for 2 weeks with temporary hemodialysis may also allow the leak to seal permanently.

Genital Edema

This symptom can be caused by the same processes as abdominal wall edema; the management is identical. In addition, genital edema can also be caused by a patent processus vaginalis with or without an associated inguinal hernia. As with abdominal wall edema, the leak should be visualized by using computed tomography or scintigraphy. Any hernia requires surgical repair, but once again a small leak may seal off spontaneously if PD is suspended or with continued use of bed rest, low volumes, and a scrotal support for affected men.

Vaginal leakage of dialysate has been described, though relatively rarely. It is not clear whether this phenomenon

occurs through the fallopian tubes or by tracking of fluid through fascial planes to the vaginal vault. There is often an associated peritonitis. Diagnosis is confirmed by the presence of fluid in the vagina with a glucose content much higher than the patient's blood glucose level. If the fallopian tubes are the cause, tubal ligation should cure the problem. Otherwise, leaving the abdomen dry for 2 weeks may allow for spontaneous healing. A recurrence may mean that transfer to hemodialysis would be in the patient's best interest.

Hydrothorax

A pleural effusion can occur because of generalized fluid overload or local lung disease, but occasionally it is due to a leak of dialysate through the diaphragm. This more commonly occurs on the right side. A leak is most simply confirmed by aspirating some of the effusion and finding that it has a glucose concentration that is higher than of the patient's blood glucose. Conservative measures should be tried initially. These include stopping PD, aspirating the effusion to dryness, and leaving the abdomen dry for 2 weeks (using hemodialysis if necessary). This regimen is effective in a number of patients. If the condition recurs, pleurodesis should be tried. Various agents have been advocated including tetracycline, talc, autologous blood, and fibrin glue, but there are no comparative studies to indicate the best regimen.

Hernias

Given the inevitable increase in intra-abdominal pressure due to the presence of a large volume of fluid in the abdomen, any weakness in the abdominal wall may give way, creating a hernia. Hernias are relatively common in PD patients. The major risks are incarceration and strangulation of bowel. The most common sites are inguinal, incisional, pericatheter, and periumbilical. Any patient commencing long-term PD with a hernia should have it repaired. This can be done at the same time as catheter insertion. Pericatheter hernias are less likely if the catheter is inserted in a paramedian position and PD is not started for at least 10 days after the procedure. If a hernia subsequently develops during PD treatment, it should be electively repaired. Postoperatively, the patient should be treated by low-volume (500 mL) cycles with no dwell using a cycler. The volume is progressively increased and CAPD can recommence after 10 days. Alternatively, the patient can be treated by temporary hemodialysis. Should hernias become a recurrent problem, a switch to nightly PD should seriously be considered because intra-abdominal pressure is lower in the supine position. The only other option is a transfer to hemodialysis.

Uterine Prolapse

One special form of hernia is uterine prolapse. Once again the increased abdominal pressure, particularly during CAPD, will exacerbate this problem. Though uncommon, it can be difficult to treat. Ring pessaries are sometimes helpful for controlling uterine descent. If these are not successful, a repair should be considered. In the absence of published information, it is suggested that postoperatively the patient should receive low-volume cycles or switch temporarily to hemodialysis (i.e., managed in the same way as ordinary hernias).

Pain

Inflow Pain

Soon after the commencement of PD, patients may experience pain during inflow of the fluid. This is particularly likely to occur if dialysis commences immediately or within a few days of catheter insertion. It is presumably related to blunt trauma of the peritoneum. This problem usually disappears with time but may require the temporary use of simple analgesics. Slowing the rate of inflow will often reduce the symptoms. Curled-tip catheters are thought to reduce the likelihood of this type of pain. The introduction of air can also produce discomfort. Care with the bag-exchange technique should eliminate this hazard. Pain invariably occurs during peritonitis. The treatment is the same as for any case of peritonitis together with sufficient analgesia if clinically necessary. A small number of individuals have persistent inflow pain. At least some of these can be treated successfully by increasing the pH of the fluid from the usual acidic level of 5.3 to neutral by using neutral pH bicarbonate-based solutions.¹⁷

Backache

In a minority of patients, particularly those undergoing CAPD or having a daytime dwell in association with automated PD, backache may occur. The presence of a large volume of fluid in the abdomen distorts the normal body balance and posture, exacerbating any tendency to lordosis of the spine. Patients with preexisting back problems are most likely to have an exacerbation of their backache although by no means will they all be affected. It is important to investigate the symptom so as to exclude treatable or serious disease. This includes plain views of the spine and, if necessary, magnetic resonance imaging. Renal osteodystrophy, if present, must be treated appropriately. If, however, the problem appears to be due to degenerative disease of the spine (spondylolisthesis or osteoporosis), adjusting the PD regimen can be beneficial. Reducing the volume of dialysate may help but may adversely affect adequacy. Avoidance of fluid in the abdomen while the patient is upright will often allow considerable improvement. This means transferring those on CAPD to nightly PD and avoiding a daytime dwell. If this is ineffective, a switch to hemodialysis should be tried. In addition to the above, exercises for the back are sometimes useful.

Generalized Pain

If peritonitis occurs, some patients will develop generalized abdominal pain, particularly if treatment is delayed. This symptom usually disappears within a few days of controlling the infection. A fixed or strangulated hernia may also cause persistent abdominal pain. Local pain can occur in association with exit-site or tunnel infections. Specific treatment of the cause will eliminate the symptom.

Outflow Pain

Some patients have discomfort or even pain when the dialysate runs out. This emptying sensation is abolished when the next cycle runs in. This commonly occurs during peritonitis but may be experienced in the absence of infection during the first few weeks of treatment. In the latter situation, the symptom usually disappears with time.

Bleeding

After Catheter Insertion

Immediately after the catheter is placed in the peritoneal cavity, a small amount of bleeding can occur from the operation wounds. If excessive, this will usually respond to firm pressure. Rarely, it may be necessary to reopen the wound and secure the bleeding point.

Exit-Site Bleeding

The exit site can be a source of blood loss at any time while a peritoneal catheter is in place. A common cause is the removal of a crust before actual separation has occurred. The bleeding almost invariably stops with local pressure, but a raw area remains, which is liable to get infected. Regular cleaning of the exit site with povidone-iodine will reduce the chances of this complication. Patients should be instructed not to pull off the crust but await its natural separation. Severe infection of the exit site may, on occasion, be accompanied by secondary hemorrhage. This again will usually respond to firm pressure with gauze dressings. The subsequent management is the same as for any exit-site infection.

Blood-Stained Dialysate

This uncommon event, although rarely serious, can cause considerable alarm to the patient. In some individuals, a clear history of trauma to the abdomen or of unexpected strain is seen. Some women relate the episode to their menstrual cycle at the time of ovulation or menstruation. The treatment is to flush the abdomen with a few cycles of dialysate containing heparin (500 units/L) to minimize the chances of clotting in the catheter. It has been suggested that ice-cold dialysis fluid will stop the bleeding more quickly. There is no controlled trial of this, and the procedure is uncomfortable. The problem usually resolves spontaneously and is often visible in only one outflow. It is unusual for the blood-stained dialysate to be associated with infection, although it is wise to have the fluid cultured. Routine use of antibiotics is not necessary. In the rare event of significant hemorrhage occurring, an urgent laparotomy is required.

Chyloperitoneum

An occasional patient may present with a milky effluent. The initial reaction is to suspect peritonitis, but closer inspection reveals that the fluid is not completely opaque; microscopy does not show excess white cells. This appearance is thought to be due to the presence of chylomicrons in the dialysate. There is no obvious cause in some patients, but malignant neoplasm in the retroperitoneum, including lymphoma, can present this way. Reasonable steps should be taken to exclude such a diagnosis. In the absence of malignant disease there is no specific treatment.

Metabolic Complications

The use of glucose-based hyperosmolar solutions for PD results in a significant increase in the glucose load experienced by the patient. A number of reports have measured the daily glucose absorption, which is estimated as between 100 and 200 g/day.

The resulting metabolic effect is a persistent tendency for patients on CAPD to develop hyperglycemia and hyperinsulinemia. In a number of individuals, frank diabetes may

develop. This unused glucose load is also thought to contribute to an increased risk of atherogenesis.

Changes in lipid metabolism peculiar to CAPD are more difficult to define. Triglycerides and cholesterol levels increase during the first year on CAPD. This is due to an increase in very-low-density and low-density lipoproteins. The greater the degree of hyperlipidemia at the start of therapy, the worse will be the changes with time on CAPD. In addition, lipoprotein (a) levels may increase with time on CAPD (although these results are not universally confirmed). On the whole, however, proatherogenic lipid levels are more common in patients on CAPD than those on hemodialysis.

A number of studies have demonstrated the effectiveness of cholesterol-lowering agents in patients on CAPD. Both lovastatin and simvastatin (hydroxymethylglutaryl-coenzyme A reductase inhibitors) have been shown effective in reducing total cholesterol and low-density lipoprotein cholesterol while increasing high-density lipoprotein cholesterol.¹⁸ The long-term effects of such intervention on cardiovascular morbidity and mortality, however, have yet to be established.

The term *adequacy of dialysis* has traditionally been used to refer to small solute clearance in both hemodialysis (HD) and peritoneal dialysis (PD). There is, however, an increasing sense, based on recent studies, that the importance of clearances may have been overstated in the past and that an assessment of adequacy should take into account other elements of the dialysis prescription, in particular, control of volume status. In this chapter, emphasis is given to small solute clearance, but attention is also paid to the equally important areas of volume status and nutrition.

The issue of comparative outcomes on PD, relative to HD, is also a key measure of the adequacy of PD as a renal replacement therapy. A controversial topic, it is reviewed here.

SMALL SOLUTE CLEARANCE

In the late 1980s, the first attempts were made to extrapolate to PD the principles of quantification and prescription of dialytic dose established for HD in the aftermath of the National Cooperative Dialysis Study.¹ In the 1990s, numerous studies attempted to show that measurements of fractional urea clearance (Kt/V) and creatinine clearance corrected for body surface area (CrCl) correlated with, or were predictive of, patient well-being and survival; the first clearance guidelines were introduced. In this decade the results of the first major randomized, controlled trials in this area have appeared and have led to a re-evaluation of the importance of clearances and to a revision of clearance guidelines.

Principles of Quantification

Small solute clearance in PD is made up of both a peritoneal and a residual renal component. The latter is particularly important in that it accounts for a greater proportion of overall clearance achieved than is the case in HD and appears to persist longer in PD patients.

The peritoneal component is calculated by collecting dialysate effluent for 24 hours and measuring its urea and

creatinine content. These are then divided by the serum urea and creatinine levels, respectively, to give peritoneal urea clearance (Kt_{urea}) and creatinine clearance. Dialysate creatinine levels may need to be corrected for the high dialysate glucose content because this interferes with the assay used in some laboratories. The renal component is calculated in the same way, with a 24-hour urine collection. However, in the case of creatinine clearance, an average of residual renal urea and creatinine clearance is typically used, because unmodified creatinine clearance substantially overestimates the true glomerular filtration rate. These clearances are then normalized to total body water (V) to give Kt/V, or to 1.73 m² body surface area to give CrCl. The value for V is estimated using anthropometric formulas, such as those of Watson, based on age, sex, height, and weight.² These estimates, compared with a standard of measurement such as deuterium oxide dilution, are, on average, reasonably accurate in nonobese patients but tend to give an overestimate of V in those who are overweight.³ Nevertheless, because most of the clinical literature is based on a V calculated with these equations and because they are relatively simple, they remain the method of choice. Body surface area is estimated by the Du Bois formula.⁴ Kt/V and CrCl values are typically expressed as weekly, rather than daily, clearances (Boxes 83-1 and 83-2).

Attempts to estimate Kt/V and CrCl using abbreviated methods based on the peritoneal equilibration test (PET) are not sufficiently accurate for clinical practice. Computer programs that calculate clearances are widely available. These can also be used to “model” patient prescriptions and predict the clearances a given prescription will achieve, but they are not accurate enough to replace the 24-hour collection in clinical practice. Collections are more cumbersome in patients on automated peritoneal dialysis (APD), as compared to continuous ambulatory peritoneal dialysis (CAPD), because of the greater volumes involved, and many units train patients to record or measure cyclor effluent volumes and then to take a representative aliquot of dialysate for measurement of urea and creatinine.

Box 83-1 Formulas Required to Calculate Kt/V

$$\begin{aligned} \text{Kt/V} &= 7 \times (\text{daily peritoneal Kt/V} + \text{daily renal Kt/V}) \\ \text{Daily peritoneal Kt} &= \frac{24\text{-hr dialysate urea content}}{\text{serum urea}} \\ \text{Daily peritoneal Kt} &= \frac{24\text{-hr urine urea content}}{\text{serum urea}} \\ \text{V (by Watson)} &= 2.447 - 0.09516 A + 0.1704 H \\ &\quad + 0.3362 W \text{ (in males) or} \\ &= -2.097 - 0.1069 H + 0.02466 W \text{ (in females)} \end{aligned}$$

A, age (years); H, height (cm); W, weight (kg).

Box 83-2 Formulas Required to Calculate Creatinine Clearance (CrCl)

$$\begin{aligned} \text{CrCl (L/wk)} &= \frac{\text{Weekly creatinine clearance (L/wk)} \times \text{body surface area (m}^2\text{)}}{1.73 \text{ (m}^2\text{)}} \\ \text{Weekly creatinine clearance (L/wk)} &= 7 \times (\text{daily peritoneal creatinine clearance} + \text{daily renal clearance}) \\ \text{Daily peritoneal creatinine clearance} &= \frac{24\text{-hr dialysate creatinine content}^*}{\text{serum creatinine}} \\ \text{Daily renal creatinine clearance} &= \frac{24\text{-hr urine creatinine content}}{\text{serum creatinine} \times 2} + \frac{24\text{-hr urine urea content}}{\text{serum urea} \times 2} \\ \text{Body surface area (by Du Bois):} &\log A \text{ (cm}^2\text{)} = 0.425 \log W \\ &\quad + 0.725 \log H + 1.8564 \end{aligned}$$

*Corrected for dialysate glucose by a formula specific to each laboratory.

A, body surface area (m²); H, height (cm); W, weight (kg).

Typically, residual renal function declines gradually towards zero over the first 2 to 3 years on PD; total clearance will also decrease if the dialysis prescription is not modified (Fig. 83-1).⁵ The achievement of clearance targets requires such modifications to be made. In general, dialysate and urine collections should be performed shortly after commencing PD, every 4 months subsequently so as to allow timely detection of declines in residual function, and after any alteration in prescription or otherwise unexplained clinical event. Data suggest that daily collections are not very reproducible, particularly due to major variations in the urinary component.⁶ A 48-hour urine collection might therefore be preferable in some patients. An unexpected result should be confirmed with a repeat collection.

The urea and protein content of the same 24-hour collections done to calculate clearance can be used to measure normalized protein equivalent of nitrogen appearance (nPNA), which, in a stable patient, is an estimate of dietary protein intake. Numerous formulas are used for calculating nPNA, but evidence suggests that those of Bergstrom are best (Box 83-3).^{7,8} Also these collections allow measurement of total

Figure 83-1 Change in creatinine clearance (CrCl) with time and continuous ambulatory peritoneal dialysis (CAPD). Lighter areas and darker areas indicate the proportions of CrCl accounted for by peritoneal and renal clearance, respectively. Figures in the boxes refer to the number of patients at each 6-month interval. (From Blake PG, Balaskas EV, Izatt S, Oreopoulos DG: Is total creatinine clearance a good predictor of clinical outcomes in CAPD? *Perit Dial Int* 1992;12:353–358.)

creatinine excretion, which can in turn be used to estimate lean body mass (Box 83-4).⁹ Similarly, total protein or albumin losses can be helpful in the evaluation of low serum albumin values.

Total Kt/V values achieved with typical PD prescriptions are half to two thirds of those achieved with HD. This might suggest major underdialysis, but it must be remembered that the efficiency, in terms of solute removal, of clearance delivered

Box 83-3 Bergstrom Formulas for Estimating Protein Equivalent of Nitrogen Appearance (PNA) in Patients on Peritoneal Dialysis

$$\begin{aligned} \text{PNA (g/day)} &= 20.1 + 7.50 (\text{daily dialysate} + \text{urine urea nitrogen content [g/day]}) \\ &\text{or} \\ &= 15.1 + 6.95 (\text{daily dialysate} + \text{urine urea nitrogen content [g/day]}) \\ &\quad + \text{daily dialysate} + \text{urine protein content (g/day)} \end{aligned}$$

The same formulas with urea concentrations expressed in SI units are as follows:

$$\begin{aligned} \text{PNA (g/day)} &= 20.1 + 0.209 (\text{daily dialysate} + \text{urine urea content [mmol/day]}) \\ &\text{or} \\ &= 15.1 + 0.195 (\text{daily dialysate} + \text{urine urea content [mmol/day]}) \\ &\quad + \text{daily dialysate} + \text{urine protein content (g/day)} \end{aligned}$$

In all cases, normalized PNA (nPNA) = PNA/desirable body weight.

Modified from Bergstrom J, Heimburger O, Lindholm B: Calculation of the protein equivalent of total nitrogen appearance from urea appearance. Which formulas should be used? *Perit Dial Int* 1998;18:467–473.

Box 83-4 Formulas for Calculating Lean Body Mass by the Method of Keshaviah et al*

Lean body mass (kg)	= 7.38 + 0.029 [creatinine production (mg/day)]
Creatinine production (mg)	= creatinine excretion + creatinine degradation
Creatinine excretion (mg/day)	= 24-hr dialysate creatinine [†] content (mg) + 24-hr urine creatinine content (mg)
Creatinine degradation	= 0.38 [serum creatinine (mg/day) (mg/dL)] × [body weight (kg)]

*Keshaviah PR, Nolph KD, Moore HL, et al: Lean body mass estimation by creatinine kinetics. *J Am Soc Nephrol* 1994;4:1475–1485.

[†]Corrected for dialysate glucose by a formula specific to each laboratory.

intermittently is much less than that of the same amount of clearance delivered continuously.¹⁰ Also, continuous modalities, in comparison to intermittent modalities, avoid substantial disequilibrium. Furthermore, it has also been suggested that continuous modalities are advantageous because peak levels of uremic toxins are theoretically at a lower level for a given quantity of clearance than is the case with intermittent modalities. It has been proposed that peak rather than mean levels of small solutes are proportional to uremic toxicity.¹¹

Clinical Studies on Adequacy of Peritoneal Dialysis

Initial studies correlating small solute clearance and patient outcomes gave varied results and in retrospect have multiple methodologic flaws. The Canada/USA (CANUSA) Study avoided some of these problems in that it was multicenter and prospective, and in that it followed almost 600 incident CAPD patients for up to 3 years, giving it reasonable statistical power.¹² It was, however, a cohort study with no mandated interventions. CANUSA demonstrated a predictive power for both Kt/V and CrCl, such that a 5 L/wk lower CrCl was associated with a 7% greater relative risk of dying, and a 0.1 unit/wk lower Kt/V was associated with a 5% greater relative risk of dying. Patients in CANUSA mainly received standard 4 × 2L per day CAPD with few alterations, so that changes in clearance were mainly due to declines in residual function. CANUSA, on closer analysis, showed a correlation between residual renal clearance and subsequent mortality, but could not show a correlation between peritoneal clearance alone and mortality.¹³ However, the design of the study did not really allow this issue to be addressed.

Subsequent to CANUSA, a variety of other prospective and retrospective studies showed similar correlations between small solute clearance and clinical outcomes, but all were similarly confounded by residual renal function.^{14–16} None could show an independent effect of peritoneal clearance on outcomes, even when there was significant variation in PD dose.¹⁶ Notwithstanding this, clinical practice guidelines from various bodies proposed target Kt/V and CrCl values in the middle and late 1990s.^{17,18} Most notably, the United States National Kidney Foundation's Kidney/Dialysis Outcomes Quality Initiative (K/DOQI) set a weekly Kt/V target of 2.0 for CAPD. For CrCl, the target was set at 60 L/wk, although

this was subsequently modified down to 50 L/wk for low and low-average transporters.^{17–19} Slightly higher targets were set for APD, with and without day dwells, on the grounds that these are somewhat more intermittent modalities than is CAPD. These new clearance targets had a major impact on PD prescription and led to increased use of higher dwell volumes in CAPD and of multiple day dwells in APD.²⁰ The result was a notable increase in delivered clearances.

Randomized, Controlled Trials

The first major randomized, controlled trials addressing the effectiveness of raising peritoneal clearance have appeared since 2000.^{21–23}

The best and most definitive was the ADEquacy of Peritoneal Dialysis in MEXico Study (ADEMEX), which involved 960 incident and prevalent CAPD patients recruited from 25 centers in Mexico.²² Participating patients were randomized to one of two groups. The control group was maintained on a standard 4 × 2L CAPD prescription, and the intervention group had their prescription augmented to achieve a peritoneal creatinine clearance of 60 L/wk. A small number of patients who could achieve a peritoneal creatinine clearance of 60 L/wk on the standard prescription were excluded from the study. The increases in clearance in the intervention group were made using a larger dwell volume or a fifth exchange, delivered with a night exchange device. Follow-up was for an average of 2 years; the primary endpoint was survival. A large variety of secondary endpoints was also examined. Unlike previous studies, ADEMEX had substantial statistical power to detect endpoint differences. The control group achieved, on average, a weekly peritoneal CrCl of 46 L and a weekly peritoneal Kt/V of 1.62; the intervention group had values of 57 L and 2.13, respectively. Corresponding values for total Kt/V were 1.80 and 2.27 and for CrCl were 54 and 63 L/wk, respectively (Table 83-1). There were no significant differences in either primary or secondary outcomes between the two groups. In particular, the relative risk of mortality for a patient included in the intervention group was 1.00 relative to a patient in the control group (Fig. 83-2). This result was surprising to many and, given the high quality of the study, brought into question the appropriateness of the K/DOQI 2000 clearance recommendations.

Concerns have been raised about the ADEMEX findings.²⁴ These include concerns as to whether the results can be extrapolated to non-Mexican patients, to populations with higher rates of cardiovascular disease, or to patients on APD as distinct from CAPD. In support of the ADEMEX findings, however, are the results of the randomized, controlled trial from Lo and colleagues.²³ This study involved 322 incident

Table 83-1 Peritoneal and Total Clearances Delivered in the ADEMEX Study

	Control	Intervention
Peritoneal Kt/V (per week)	1.62	2.13
Total Kt/V (per week)	1.80	2.27
Peritoneal CrCl (L/week)	46.1	56.9
Total CrCl (L/week)	54.1	62.9

Figure 83-2 Life-table intent-to-treat analysis of patient survival showing no difference in survival between the interventions. (Reproduced from Paniagua R, Amato D, Vonesh E, et al: Effect of increased peritoneal clearances on mortality rates in peritoneal dialysis: ADEMEX, a prospective randomized controlled trial. *J Am Soc Nephrol* 2002;13:1307–1320.)

CAPD patients recruited from six centers in Hong Kong between 1996 and 1999. These patients were randomized to three different Kt/V targets, 1.5 to 1.7, 1.7 to 2.0, and above 2.0/wk. The three groups achieved the targeted Kt/V levels, and no difference was found in 2-year survival rates. There was, however, a significantly greater study dropout rate for patients in the group with a Kt/V below 1.7/wk; the authors concluded that Kt/V should be maintained above this level. This study was somewhat underpowered to detect mortality differences, but, in the light of the ADEMEX study, its findings are not so surprising.

These studies show that residual renal function is highly predictive of survival but cannot be replaced on a one-to-one basis by peritoneal clearance, which within the usual therapeutic range is not predictive of survival (see Table 83-1). The concept of adding renal and peritoneal clearance together as if they are the same is not justifiable. Given that increasing peritoneal clearance is not a neutral intervention and may have lifestyle implications for the patient in terms of mechanical symptoms, time commitment, and cost, it is important to avoid an unnecessarily aggressive approach to PD prescription. However, these studies do not prove that there is no link between peritoneal clearance and outcome. Clearly there is

some relationship in that zero dialysis guarantees an adverse outcome. There is no evidence that doses below those recorded by the ADEMEX control group, for example, are safe. Furthermore, the Lo study would suggest that total Kt/V values below 1.7 are problematic.

Accordingly, recent revised guidelines produced by K/DOQI have reset the Kt/V target at 1.7/wk.²⁵ For simplicity and in the absence of evidence to the contrary, the same target is now being used for both CAPD and APD patients, regardless of transport type. Furthermore, K/DOQI suggests that there is no additional benefit from measuring CrCl, although European guidelines still retain this index. This has simplified the prescription of PD and has made the targets easier to achieve.²⁵

The reason for the lack of an effect of higher clearance on key outcomes has been debated, especially in the light of analogous findings in HD.²⁶ One possibility is that substantially higher clearances would be required to improve outcomes, but this is speculative. A plausible alternative is that, once sufficient clearance to control frank uremia has been delivered, outcomes depend much more on critical comorbid conditions such as diabetes and cardiac disease.

PERITONEAL TRANSPORT STATUS

Patients differ in the rapidity with which urea, creatinine, and other solutes equilibrate with dialysis solution across their peritoneal membrane. This is classically measured by the PET, in which dialysate and plasma levels of urea and creatinine are measured during a 4-hour, 2L, 2.5% dextrose dwell, done under standard conditions.²⁷ Equilibration curves are constructed, and patients are defined as low, low-average, high-average, or high transporters (Fig. 83-3). It is generally believed that PET status is a measure of the effective or vascular surface area of the peritoneal membrane, but interestingly it does not correlate with body size.

Patients who are high transporters equilibrate quickly and so, in that sense, dialyze well but they ultrafilter poorly because the osmotic gradient for glucose dissipates rapidly. They might be expected to do better with short dwell times, as in APD, but they need to avoid prolonged day dwells with glucose-based PD solutions. They also have higher dialysate protein losses and are more prone to marked hypoalbuminemia. Conversely,

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

Figure 83-3 Peritoneal equilibration test (PET) results. Ranges of values for dialysate-to-plasma ratios for urea and creatinine (corrected) in standard PET. (From Twardowski ZJ, Nolph KD, Khanna R, et al: Peritoneal equilibration test. *Perit Dial Bull* 1987;7:138–147.)

low transporters ultrafilter well, lose less protein in their dialysate, and have higher serum albumin levels, but equilibrate slowly. Thus, large-volume dwells with longer treatment times are best for achieving good clearance. In practice, the choice between CAPD and APD is much more influenced by lifestyle and economic considerations; with the recent reduction in clearance targets, patients of any transporter type can be adequately dialyzed with either modality, although fluid removal can be problematic in high transporters treated with long-duration dwells. Numerous studies suggest that low, rather than high, transporters have substantially superior long-term outcomes on CAPD.²⁸ This supports the idea that volume status may be more important than clearance. It has led to the suggestion that high transporters might preferentially be directed to APD and to the use of alternative osmotic agents to dextrose, especially when residual renal function is lost.¹⁸ However, there is also evidence to support the alternative suggestion that high transport status may be a marker of older, sicker, more “inflamed” patients; this may be the main driver of the worse outcomes.

INCREASING PERITONEAL DIALYSIS DOSE

Despite the controversy about target clearances in PD, it is important to understand how delivered clearance can be increased in PD patients. In CAPD, the best strategy to raise dialytic dose is to increase dwell volumes to 2.5 L. This is usually well tolerated and minimally disruptive of lifestyle. Larger patients may require and tolerate 3-L volumes. The alternative approach of increasing the frequency of daytime manual exchanges to more than four will tend to lead to inadequate spacing of the exchanges so that equilibration is less complete; this approach also is likely to increase the risk of patient non-compliance.

Automated PD has become increasingly popular in recent years and is the dominant PD modality in the United States. It should not be viewed as a panacea for inadequate PD. If carelessly prescribed, it can lead to clearances that are actually less than those on standard CAPD. Daytime dwells are required to achieve clearance targets in APD patients unless residual renal function is very good, the patient is very small, or the patient is a high transporter. In heavier patients and in low transporters, especially when residual renal function is poor, two day dwells may be required. The cost of this approach can be reduced by using the cycler solutions and tubing to do the daytime exchange. If two daytime exchanges are being done, the number of cycled exchanges at night can be limited to four or even three to minimize cost.

With regard to the actual cycler prescription, 2.5L, and even higher, dwell volumes are usually well tolerated, given that APD is delivered in the supine position. The standard time spent each night on the cycler is 8 to 9 hours. Increasing the frequency of cycler exchanges to more than six or seven over 9 hours gives modest increases in clearance but is generally not cost effective^{29,30} because too much of the cycling time is spent on draining and filling, and too little on actual dialysis. Tidal techniques, which maintain a constant residual volume throughout the cycling time, were devised to help with this problem, but they are not effective in increasing clearance and are only useful when the final phase of drainage is slow or painful.

With both CAPD and APD, hypertonic solutions can be used to increase clearance by maximizing ultrafiltration, but this strategy increases the risk of dehydration as well as that of obesity, hyperglycemia, hyperlipidemia and, perhaps, long-term peritoneal membrane damage. With all strategies, patient lifestyle and willingness to comply should be kept in mind. As stated, dialysis dose should be remeasured soon after each prescription alteration.

VOLUME STATUS IN PERITONEAL DIALYSIS

The favorable prognosis associated with low transporter status on PET gives support to the view that volume status is an important determinant of outcome in PD patients.²⁸ No high-quality data are available that prove that good volume management improves outcome. However, cardiovascular disease is the biggest cause of morbidity and mortality in dialysis patients generally, and hypertension, a crucial risk factor, is common in this population and influenced by volume status. Notwithstanding this, overaggressive volume removal may decrease residual renal function, so a balanced approach is required.

Management of volume status has been the subject of International Society of Peritoneal Dialysis clinical practice guidelines.³¹ Key factors that need to be taken into account in managing volume status in PD patients, in addition to PET findings, include salt and water intake, residual renal function, and adherence to the PD prescription. Useful strategies to control volume status include dietary salt and water restriction, when required; the use of high-dose loop diuretics in patients who still have urine output; and education of patients in the significance of fluid overload and hypertension.³² Randomized trials show that angiotensin receptor blockers and angiotensin-converting enzyme inhibitors help preserve residual renal function and so improve volume control in PD.^{32–34}

A number of aspects of the prescription, however, can be modified. These are the dwell time, the tonicity of solution used, and the choice of osmotic agent. Prolonged dwell times are associated with greater peritoneal fluid absorption, which is particularly an issue with the nocturnal dwell in CAPD and with the day dwell in APD. Ultrafiltration can be enhanced, in both short and long dwells, by increasing the tonicity of the glucose solution used. However, this strategy is limited by the adverse effects of increased glucose absorption, including hyperglycemia, hyperlipidemia, obesity, and peritoneal membrane damage. A more attractive approach to avoid fluid absorption from long-duration dwells has become possible with the availability of the osmotic agent icodextrin.³⁵ This large molecular-weight glucose polymer induces ultrafiltration by colloid osmosis. Because the icodextrin molecule is too large to be absorbed across the peritoneal membrane, the osmotic gradient does not dissipate and there is sustained ultrafiltration throughout the duration of a long dwell. Icodextrin is now frequently used as the long day dwell in APD and as the nocturnal dwell in CAPD. A modest amount of lymphatic absorption of icodextrin occurs, with subsequent metabolism to maltose, but no associated toxicity has been identified after more than 15 years' experience. The disadvantages of icodextrin are its somewhat higher cost and a small rate of exfoliative skin rashes. Evidence from randomized, controlled trials now

indicates that icodextrin not only enhances ultrafiltration, but also leads to better control of volume status, as measured by echocardiography, bioimpedance, and other measures of extracellular fluid volume.^{36,37} Besides improving ultrafiltration, icodextrin can lead to less weight gain and less hyperglycemia and hypertriglyceridemia due to the reduced exposure to glucose. In general, high and high average transporters should be directed toward APD or icodextrin if problems are arising with volume status.¹⁸ In some countries, icodextrin is now routinely used in the majority of patients.

The growth in APD was initially thought to be a positive development for control of volume status because the shorter dwell times on the cyclor would be expected to lead to enhanced ultrafiltration. However, investigators have pointed out that the phenomenon of sodium sieving becomes significant with the typical short dwells of APD, leading to less sodium removal than standard CAPD.^{38,39} Sieving of sodium occurs because about half the ultrafiltrate goes through peritoneal aquaporin channels, which transport water only. The longer dwell times in CAPD allow diffusive sodium removal to compensate for sieving, but this is not the case with the short cycles of APD. In practice, studies have not consistently shown worse control of volume or blood pressure in APD, but a randomized trial is required to address this issue. The use of icodextrin in the day dwell can be used to attenuate volume problems in APD.³⁹

A problem with volume management in dialysis patients is the lack of a reliable and practical method to measure volume status. Blood pressure and clinical examination may be misleading and bioimpedance has methodologic limitations, as do blood levels of natriuretic peptides.⁴⁰ Essentially, volume status is still best optimized by trial and error.

PATIENT COMPLIANCE

Patient compliance with PD exchanges is an important issue for both clearance and volume status. Methodology to detect noncompliance is limited. Ratios between actual and predicted creatinine excretion have not been found to be helpful. Questionnaires are likely to understate the prevalence of noncompliance, and checks on home inventory are probably the nearest to a standard. Using the latter methodology, one U.S. group found a 40% rate of significant noncompliance.⁴¹ A large multicenter questionnaire-based study suggested that the problem was most likely in patients who were young, employed, black, and receiving more than 4 CAPD exchanges daily.⁴² There is a need to be aware of this problem.

MALNUTRITION IN PERITONEAL DIALYSIS

Malnutrition is prevalent in dialysis patients generally; one international study found, using subjective nutritional assessment, that 8% of 224 CAPD patients had severe malnutrition and a further 33% had mild to moderate malnutrition.⁴³

A number of nutritional indices have been shown to predict adverse outcomes. Lower serum albumin is associated with greater mortality, hospitalization rates, and technique failure.¹² In the CANUSA study, the relative risk of dying decreased 6% for each 1 g/L rise in the serum albumin. In PD

patients, however, serum albumin may not primarily be a nutritional marker. A number of studies have shown that high peritoneal transport status and the presence of inflammation, as indicated by a raised serum C-reactive protein level, are the major predictors of a low serum albumin.⁴⁴

Lean body mass, estimated by creatinine excretion, in accordance with the method of Keshaviah,¹¹ and total body nitrogen, by neutron activation analysis,⁴⁵ have also been shown to predict survival, as has the relatively simple clinical tool of Subjective Global Assessment.¹² The predictive data for the nPNA are less consistent. Some of this discrepancy may be related to variation in methods of measurement and normalization. Evidence suggests that the Bergstrom formula, which was specifically derived from PD patients, is most accurate in that it takes full account of the high nonurea, nonprotein nitrogen losses in these patients.^{7,46} Normalization to desirable rather than actual weight is preferable. No clear target for nPNA has been validated. On theoretical grounds, 1.2 g/kg/day has been proposed but is rarely achieved and neutral nitrogen balance may be possible at significantly lower values.^{7,17} Caloric intake has been relatively poorly studied and, although it has been shown to be as important as protein intake for nitrogen balance, no clear studies correlating it with outcome have been published. The general recommendation is that patients receive 35 kilocalories/kg/day, although this should be reduced for obese patients.¹⁷ In many patients, 20% or more of calories will come from dialysate glucose absorption. Other nutritional indices such as serum prealbumin, insulin-like growth factor-1 levels, anthropometrics, and bioelectric impedance, are not widely used.

Malnutrition in dialysis patients is typically multifactorial. Food intake is often low due to uremia per se, dietary restrictions, socioeconomic issues, possible dialysate-induced compression of viscera and, often most significantly, comorbidity, including gastrointestinal disease, cardiovascular disease, and depression. Patients also have obligatory dialysate nitrogen and protein losses and may be catabolic from inadequate intake as well as from intercurrent illnesses, inflammation, and acidosis. The role of endocrine dysfunction, and in particular of the growth hormone insulin-like growth factor 1 axis in impairing the balance between anabolism and catabolism in uremia, has also been recognized.

Management of Malnutrition

Interventions to treat malnutrition are not well validated. They include increases in dialysis dose, oral protein and carbohydrate supplementation, correction of acidosis, intraperitoneal amino acids, and administration of anabolic hormones, such as androgens, and recombinant growth hormone and insulin-like growth factor-1.

A small number of studies, mostly uncontrolled, have looked at the effect of prospective increases in peritoneal clearance on nutrition.⁴⁷ In general, these studies have shown conflicting results with regard to protein intake, with some showing an increase and others no change. The methodology is often confounded by mathematical coupling between indices of dialysis dose and those of nutrition. In studies that have looked at serum albumin, there has been no clear beneficial effect. The ADEMEX study also failed to show a nutritional advantage for the high clearance group.²²

Numerous studies have examined intraperitoneal amino acids. Initially these were confounded by associated increases in uremia and acidosis, but more recently the amino acid composition of the preparations has been favorably modified and strategies for administering them have improved; they are now given as one exchange in the daytime, in association with oral caloric intake. Recent controlled trials have shown an increase in nitrogen balance and better maintenance of serum albumin over 3 years follow-up.⁴⁸ There were additional advantages for women, with better maintenance of lean body mass and body mass index, but the study was too small to detect any survival advantage for treated patients.

Correction of acidosis or even induction of mild alkalosis with oral sodium bicarbonate has been shown to improve nutritional status in PD patients. In one randomized trial of 60 patients followed for 1 year, the bicarbonate-treated patients had superior PNA and Subjective Global Assessment scores and less hospitalization than placebo-treated controls.⁴⁹

One small randomized, controlled trial has shown a benefit for anabolic steroids in increasing lean body mass and functional performance in malnourished HD and PD patients, but concerns about adverse effects have limited their use.⁵⁰ Studies on recombinant growth hormone and insulin-like growth factor-1 have been small and short term but have shown impressive anabolic effects.⁵¹ Effects on serum albumin have been less impressive. Cost and toxicity concerns limit the use of these recombinant agents to research studies at present.

The relative ineffectiveness of most of these nutritional interventions in PD patients raises questions about the nature of malnutrition in dialysis patients generally. Although many patients have malnutrition and its presence predicts adverse outcomes, it is not clear that the malnutrition is the proximate cause of those outcomes or that its correction, when possible, will lead to an improvement in those outcomes. It is at least as plausible that the malnutrition is a consequence of the comorbidity or inflammation, which is the true proximate cause of the patients' morbidity and mortality. If the latter is the case, attempts to treat the malnutrition without dealing with underlying causes may be ineffective both in terms of nutritional status and in terms of ultimate clinical outcomes. Recent data linking malnutrition, inflammation, and cardiovascular disease may be pertinent in this regard.⁵²

COMPARATIVE OUTCOME STUDIES

Interest in adequacy of dialysis has also focused attention on comparative outcomes between HD and PD. Most data come from national or renal registries; none is from randomized, controlled trials. Patient mortality is the usual endpoint used in these studies. A controversial U.S. Registry study published in 1995 suggested an excess mortality on PD, but the methodology was unusual in that the majority of the first year on dialysis was omitted from the analysis.⁵³ This leads to a systematic bias against PD because outcomes on the modality are relatively better in the early years on dialysis.

Subsequent and more contemporary studies from the U.S., Canadian, Danish, Dutch, and Lombardy registries all show a similar picture.^{54–58} The relative mortality rates of the two modalities change with length of time on dialysis (Fig. 83-4). PD has a survival advantage over HD during the first 1 to 3 years of dialysis. This advantage is most marked in younger

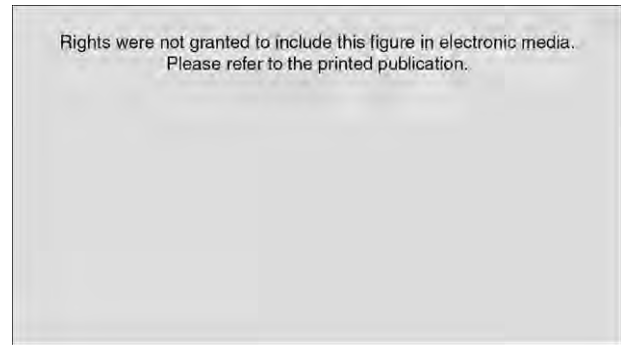

Figure 83-4 Mortality rate ratios (RRs) for peritoneal dialysis relative to hemodialysis (HD) by follow-up interval, adjusted for age, primary renal diagnosis, and comorbid conditions, estimated using Poisson regression. (From Schaubel DE, Blake PG, Fenton SS: Trends in CAPD technique failure: Canada 1981–1997. *Perit Dial Int* 2001;21:365–371.)

patients and in nondiabetic patients (Fig. 83-5). In the United States, however, no significant early advantage for PD is seen in older diabetic patients, and, indeed, in older female diabetic patients, HD has a significant advantage.⁵⁴ After 2 years of dialysis, data are less detailed, but PD appears to lose its advantage and HD is associated with equal or better survival. The reason for the early survival benefit of PD has been debated. One possibility is that it relates to better retention of residual renal function. An alternative is that it simply represents a baseline case mix advantage for PD that cannot be detected in registry studies. This benefit is, however, found in countries with both high and low PD use.^{54,55,57}

A particular concern has been raised in the United States by more recent registry studies showing worse outcomes on PD in patients with cardiac disease.^{59,60} These findings have not been confirmed in other countries but are a concern; they have heightened interest in glucose-sparing approaches because it is sometimes suggested that systemic glucose absorption may be a particular problem in patients with cardiac disease.

In the absence of randomized trials, a number of prospective but nonrandomized cohort studies have compared HD and PD.

Figure 83-5 Relative mortality risk for peritoneal dialysis compared to hemodialysis in incident U.S. dialysis patients, 1994–1998. (From Collins AJ, How W, Xia H, et al: Mortality risks of peritoneal dialysis and hemodialysis. *Am J Kidney Dis* 1999;34:1065–1074.)

A Canadian study of 822 incident patients followed for 2 years found a survival advantage for PD, but this went away after adjustment for the greater comorbidity in HD patients.⁶¹ The Dutch NECOSAD investigators also found some early advantage for PD. There was no overall survival difference in 1222 incident patients over the first 2 years, but there was an advantage for PD in diabetic patients younger than age 60 years. After 2 years, however, a significant benefit for HD was seen in patients age 60 years or older.⁶² The CHOICE study, done in the United States, also showed no early difference in survival but reported a worse outcome on PD after the first year and after adjustment for laboratory tests.⁶³ The methodology used in CHOICE has been questioned, but the high rates of cardiac disease, diabetes, and obesity in the U.S. dialysis population may create particular issues for glucose-based PD.⁶⁴ Overall, therefore, prospective studies show a similar pattern of results to the registry-based ones. Technique failure is undoubtedly more common in PD than HD. The most frequent causes are peritonitis, social reasons, and “inadequate dialysis.” There is some evidence that technique failure rates in PD are falling, principally due to better prevention and management of peritonitis.⁶⁵

A reasonable conclusion from all this is that modality selection should not be significantly influenced by these

comparative studies. Findings are not sufficiently robust to justify making modality decisions based on age, diabetes, or cardiac disease. PD is at least as effective as HD in the early years for patients who choose it. Given its cost advantage in most developed countries, this suggests that PD is a more cost-effective initial therapy. Subsequently, many patients will need to move to HD due to technique failure, and often loss of residual renal function may be associated with this. A dialysis delivery system based on early use of PD but easy availability of HD after 2 to 3 years might be maximally cost effective. This concept has been described as *integrated dialysis care*.⁶⁶

SPECIFIC MANAGEMENT RECOMMENDATIONS

The recent revision of the K/DOQI guidelines on adequacy of dialysis has helped to resolve some of the confusion induced by the results of the ADEMEX study.

A reasonable strategy is to evaluate patients clinically every 1 to 2 months looking for evidence of underdialysis and to monitor both renal and peritoneal Kt/V shortly after the patient initiates PD and routinely at 4- to 6-month intervals with

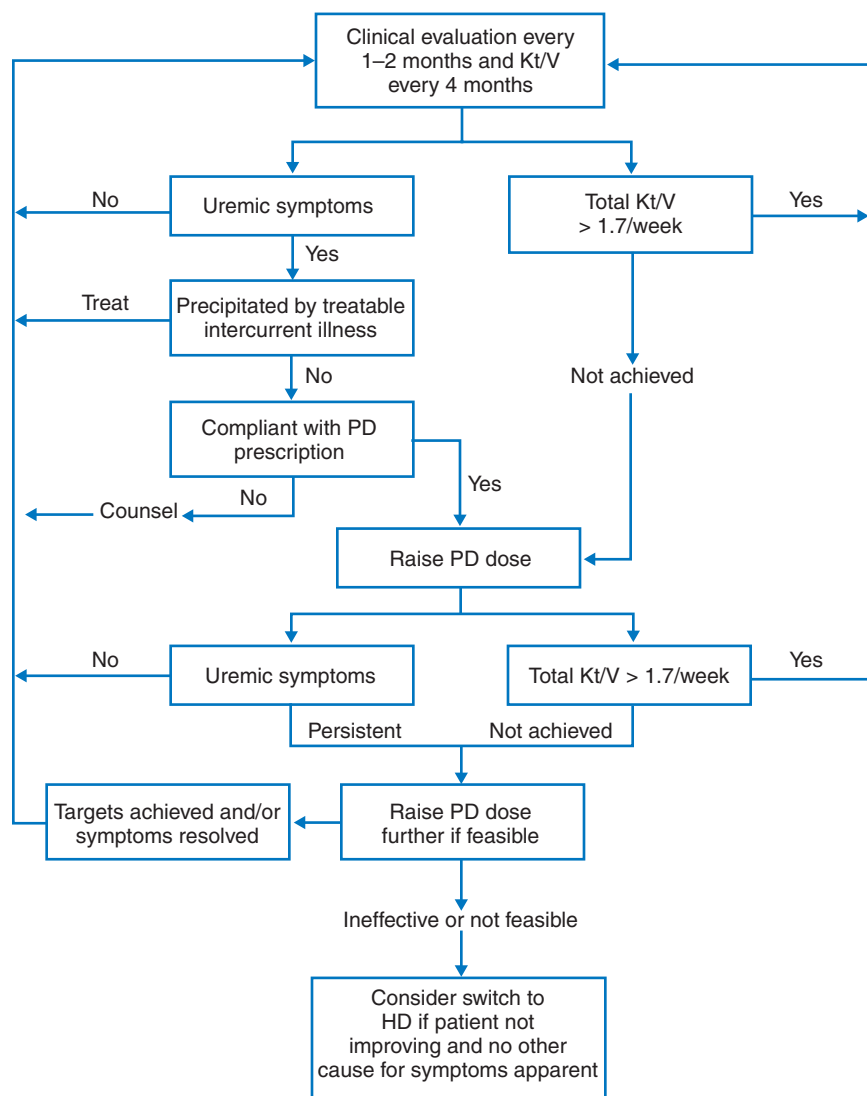

Figure 83-6 Algorithm for the management of clearances in peritoneal dialysis.

a view to keeping the combined value over 1.7/wk (Fig. 83-6). Clearances should also be remeasured soon after any alteration in the prescription and in response to any unexplained clinical changes. Issues such as compliance and the influence of intercurrent illnesses should be kept in mind.

A good approach is to use $4 \times 2\text{L}$ daily in CAPD patients and to increase dwell volumes to 2.5 L if the Kt/V target is not reached. Patients with substantial residual renal function may manage for a while with three exchanges daily. With APD, day dry cycling may provide sufficient clearance in those with substantial renal function, but most patients will soon require a day dwell. If icodextrin is easily available, this can be used to minimize glucose absorption and to avoid the need for a day-time drain. Otherwise, glucose-based solution can be used, but consideration should be given to draining it after 4 to 6 hours to minimize absorption and maximize fluid removal. Cycling can be done with 8 to 10 L delivered as 4 or $5 \times 2\text{L}$ dwells over 9 hours. Upward adjustments in clearance are best achieved by addition of a day dwell in day dry patients or of a second day dwell if one is already being used. Increasing the volume of cycled fluid is an alternative though less cost-effective option.

Careful attention should be paid to volume status, with the aim of keeping the patient edema free and the blood pressure at or below 130/80 mm Hg while also being aware of the need to avoid volume depletion, with consequent loss of residual renal function, and to limit hypertonic glucose exposure. Long-duration dextrose dwells should be avoided, especially if volume status is a problem. In such settings, the use of APD and icodextrin for long dwells should be considered. PET status should be monitored to identify patients who are at risk for volume overload and who might require these interventions. Loop diuretics and renoprotective agents should be considered.

A multidisciplinary approach to malnutrition is recommended. It should be screened for with a combination of tools, including clinical evaluation; assessment of dietary protein and calorie intake by a renal dietitian; Subjective Global Assessment; measurements of serum urea, creatinine, potassium, and albumin; serial 24-hour creatinine excretion as an index of lean body mass; and nPNA. The limitations of each of these indices should be kept in mind, and no individual one should be emphasized to the exclusion of the others. Warning signs for malnutrition include decreasing body weight, low or declining Subjective Global Assessment status, decreasing lean body mass or blood urea, and nPNA below 0.8 g/kg/day using the Bergstrom formula with normalization to desired or standard weight. Serum albumin below 30 g/L should be investigated, not only with nutrition in mind, but also with regard to PET status and the presence of inflammation, which may frequently not be clinically apparent.

Preventive strategies for malnutrition include a timely start on dialysis, targeting a dietary protein intake above 1 g/kg body weight per day, and a dietary calorie intake above 35 kcal/kg/day, avoidance of acidosis, and an adequate PD prescription.

Therapeutic strategies ideally involve a multidisciplinary approach with dietary counseling, diagnosis and treatment of comorbidity with special attention to upper gastrointestinal disease and depression, correction of poor dentition, awareness of cultural and socioeconomic issues, avoidance of excessive numbers of medications, and correction of acidosis and, where possible, inflammation. If this is unsuccessful, interventions to

consider are oral calorie and protein supplementation and the use of intraperitoneal amino acids. Administration of anabolic steroids may sometimes have a role. A trial of HD may be appropriate if the nutritional status is not improving and if no clear cause for this can be identified.

BACKGROUND

In a span of just 30 years, the process of patient selection for dialysis has been transformed from an intensive one in which each candidate was carefully scrutinized by a multidisciplinary committee for acceptability to one in which almost any patient, or family of a patient, who requests dialysis receives it. Nephrologists, medical ethicists, and health-policy experts have identified many factors to explain this transformation, but most prominent among them are the following: (1) federal legislation that pays for dialysis for all patients with end-stage renal disease (ESRD) who are eligible for Medicare; (2) improvements in medical science and technology that have made it possible to achieve long-term survival for some patients who were previously thought to be too sick to undergo dialysis (for example, the elderly and those with diabetes); (3) a changing ethical and legal environment in which respect for patient autonomy and the right of patient self-determination have become almost decisive in medical decision making to start or stop a life-sustaining treatment such as dialysis; (4) the financial self-interests of nephrologists who stand to increase their incomes by treating larger numbers of dialysis patients; and (5) the absence of any attempt before the issuance of a clinical practice guideline in 2000 by the Renal Physicians Association (RPA) and the American Society of Nephrology (ASN), *Shared Decision-Making in the Appropriate Initiation of and Withdrawal from Dialysis*,¹ to define formally patients who would be inappropriate for dialysis.

The consequences of these factors are twofold: The numbers of patients on long-term dialysis and the cost of the ESRD program to the federal government have exceeded all initial projections several times over and observers of dialysis, including the physicians and nurses actively providing it, have questioned the appropriateness of dialyzing some current patients because of their shortened life expectancy and limited quality of life. Of particular note is the rapid growth in rates of dialysis initiation among octogenarians and nonagenarians with a near doubling of the number of patients with incident ESRD who are older than 80 years of age.² These elderly dialysis patients have a survival rate only one sixth that of age-matched patients without kidney disease in the general population and a high prevalence of comorbid conditions including dementia. The controversy about the appropriateness of dialysis initiation in this older patient population has been particularly strong. This chapter examines the following topics: the reported practices of nephrologists and the preferences of patients regarding dialysis decision making, the recommendations of the RPA and the ASN clinical practice guideline *Shared Decision-Making in the Appropriate Initiation of and Withdrawal from Dialysis*, a process for dialysis decision making in individual cases that is based on ethics and the law, recommendations for caring for a patient who wants to forgo dialysis, and the outcomes of the use of the RPA and ASN clinical practice guideline on nephrologists' end-of-life decision making.

NEPHROLOGISTS' CHANGING PRACTICES REGARDING WITHHOLDING AND WITHDRAWING DIALYSIS

In the 1990s, research studies of nephrologists' dialysis decision-making practices provided insight into which decisions nephrologists would typically make in a variety of circumstances and why they made the decisions that they did. These studies documented that deciding to withhold and withdraw dialysis from patients occurs frequently for the vast majority of nephrologists. Most withhold 1 to 5 patients and withdraw 1 to 10 patients from dialysis each year. These studies showed that most nephrology respondents would honor a competent patient's request to stop dialysis but that there was more variability in starting a permanently unconscious patient on dialysis or stopping dialysis in a permanently demented patient.³ In one study of nephrologists in New England, 9 out of 10 nephrologists would stop dialysis at the request of a competent patient, but only 6 out of 10 would agree to stop dialysis for an irreversibly incompetent patient at the family's request if the patient's wishes were unknown. In this study, only 1 out of 100 nephrologists would stop dialysis for an irreversibly incompetent patient for whom the nephrologist thought that dialysis should be stopped if the family requested that dialysis be continued and the patient's wishes were unknown. The authors concluded that consensus exists among nephrologists regarding the right of competent patients to determine the course of their care, including stopping dialysis. They also concluded that nephrologists disagree about the management of incompetent patients with unclear previous wishes and that they have difficulty making decisions for such patients.⁴

In a study of medical directors of dialysis units, 9 out of 10 indicated that they would agree to stop dialysis at the request of a competent patient, but only one third would stop dialysis of a permanently and severely demented patient without advance directives. One sixth of the medical directors would start dialysis for a permanently unconscious patient if requested, but the remainder would not. In this study, some respondents indicated that although they thought dialysis was inappropriate for the demented and permanently unconscious patients, they would not withdraw or withhold it unless they could "convince" the families to agree. Other respondents specifically noted that they would be afraid to stop dialysis for the patient with severe dementia if there were the potential for litigation from family members who wanted dialysis continued. In interpreting the results of their study, the authors suggested that some nephrologists may misunderstand the ethical and legal aspects of making decisions for such patients and may feel obligated to provide dialysis to all patients for whom it is requested.⁵

Similarly, in a study of dialysis decision making by nephrologists in Canada, the United Kingdom, and the United States, more than 9 out of 10 nephrologists from all three countries would respect a competent patient's refusal to start dialysis. However, American nephrologists would offer dialysis significantly more often to demented patients, severely disabled diabetic patients, and patients in a persistent vegetative state than would Canadian or British nephrologists. The American nephrologists significantly more often gave "respect for the patient or family request" as the first reason to offer dialysis and ranked "fear of lawsuit" higher as a reason to offer dialysis than their counterparts in the other countries. The British and Canadian nephrologists significantly more often cited "adequate quality of

life" as a reason to offer dialysis than the Americans did. Despite these variations, there was never more than a 30% difference in the practice of offering dialysis among the three groups. The greatest agreement on offering dialysis was for the young competent patient with muscular dystrophy (>90% in each group). Less than 10% of each group thought that dialysis should be offered to patients in a persistent vegetative state.⁶

Five years after the introduction of the RPA and ASN clinical practice guideline, a follow-up study of nephrology members of the RPA was conducted to determine whether there had been a change in their attitudes and reported practices with regard to dialysis and end-of-life decision making.³ In 2005 compared with 1990, there was less variation in nephrologists' responses; nephrologists were significantly more likely to withdraw dialysis from a permanently and severely demented patient (53% vs. 39%) and to withhold dialysis from a permanently unconscious patient (90% vs. 83%). In both time periods, more than 90% of nephrologists would stop dialysis of a competent patient who requests it. Compared with 1990, in 2005 nephrologists reported that the dialysis unit in which they treated most of their patients was significantly more likely to have written policies on cardiopulmonary resuscitation (86% vs. 31%) and withdrawal of dialysis (30% vs. 15%). These dialysis units were also significantly more likely to honor a patient's request for a do-not-resuscitate order in the dialysis unit (83% vs. 66%). The change in clinical decision making by nephrologists in the 15 years between the studies is consistent with the recommendations for dialysis decision making of the RPA and ASN clinical practice guideline. The authors concluded that the development and dissemination of the guideline have been associated with an improvement in nephrologists' end-of-life decision making.³

PATIENTS' PREFERENCES FOR DIALYSIS DECISION MAKING

In making decisions about which patients should be selected for dialysis, input from patients is important because they are, as a group, the best to judge under which circumstances dialysis would be viewed as beneficial and when it would be burdensome. Regrettably, there are few studies of patients' preferences regarding dialysis, and only one examined the interaction between health state and treatment modalities. In this study, 25% or less of the patients would want to continue dialysis in three health states: severe stroke, severe dementia, and permanent coma.⁷ These findings agree with another study in which 74% of dialysis patients said they would want to stop dialysis if they became permanently and severely demented.⁸

PRACTICE GUIDELINES FOR SELECTION OF DIALYSIS PATIENTS

The idea of practice guidelines for patient selection for dialysis was not new in 2000. In 1978, just 6 years after the passage of the federal legislation creating the Medicare ESRD program, the late Belding Scribner (one of the early nephrologists who pioneered dialysis) was concerned about "how not to dialyze" certain patients with poor prognoses. He recognized even then the need for a "deselection committee."⁹ The Institute of Medicine

Committee for the Study of the Medicare End-Stage Renal Disease Program (IOM Committee), which issued its report in 1991, acknowledged that the existence of the public entitlement for treatment of ESRD did not oblige physicians to treat all patients who have kidney failure with dialysis or transplantation.¹⁰ The IOM Committee noted that for some ESRD patients the burdens of dialysis might substantially outweigh the benefits. Specifically, the IOM Committee questioned the appropriateness of providing dialysis to two groups of patients: those with a limited life expectancy despite the use of dialysis and those with severe neurological disease. The first group included patients with kidney failure and other life-threatening illnesses, such as atherosclerotic cardiovascular disease, cancer, chronic pulmonary disease, and acquired immunodeficiency syndrome. The second group included patients whose neurological disease rendered them unable to relate to others, such as those in a persistent vegetative state, those with severe dementia, and those with cerebrovascular disease. The IOM Committee recommended that guidelines be drafted to assist nephrologists in making these decisions so that dialysis could be used appropriately. In 2000, the RPA and the ASN heeded this call for a clinical practice guideline when it published *Shared Decision-Making in the Appropriate Initiation of and Withdrawal from Dialysis*.¹ To draft this guideline, the RPA and ASN organized a working group that included representatives from multiple disciplines and organizations within the dialysis community, kidney patients, internal and family medicine physicians, and experts in bioethics and health policy. The working group developed a priori analytic frameworks regarding decisions to withhold or withdraw dialysis in patients with acute renal failure and ESRD. Systematic literature reviews were conducted to address prespecified questions derived from the frameworks. In most instances, the relevant evidence that was identified was contextual in nature and only provided indirect support for the recommendations. In formulating their nine recommendations, the working group used research evidence, case and statutory law, and ethical principles. They recommended shared decision making as the basis for making decisions about starting and stopping dialysis. Shared decision making is a process by which physicians and patients agree on a specific course of action based on a common understanding of the treatment goals and the risks and benefits of the chosen course compared with the alternative courses. These recommendations appear in Box 84-1. Their recommendations for who should be dialyzed, although more systematically developed and justified, are consistent with those previously recommended.¹¹ This agreement suggests that there is now a real consensus in the nephrology community on this topic (Box 84-2).

DECIDING TO WITHHOLD OR WITHDRAW DIALYSIS IN INDIVIDUAL CASES

The Process of Informed Consent as the Paradigm for Decision Making

The ethical and legal literature agree that medical decisions for individual patients (such as withholding or withdrawing dialysis) should be made according to the process of informed consent, in which there is active, shared decision making.¹² This agreement formed the basis for the first two recommendations

in the RPA/ASN guideline. Thus, if a physician determines that a patient has decision-making capacity, the patient is informed of his or her medical condition, in this case, ESRD, and all the benefits, risks, and consequences associated with each of the available treatment options, including the option not to undergo dialysis. After determining the patient's values and preferences, the physician recommends what might be best for the patient based on those preferences. Through further conversations, in which there is mutual participation and respect, the patient reaches a decision about dialysis—whether to consent to it or to refuse it. For some patients, the balance of the benefits and the burdens of dialysis may not be clear, and the nephrologist may not know whether to recommend dialysis. In such situations, there is an ethical recommendation for a limited trial of dialysis of approximately 30 days. During this time, the patient's responses to dialysis can be assessed, and afterward, both the patient and physician are in a better position to decide about continuation.

Deciding for the Incompetent Patient

If the patient lacks decision-making capacity, physicians make decisions with the patient's legal agent as designated in the patient's advance directive (e.g., durable power of attorney for health care or health care proxy). If the patient has not completed a written advance directive specifying an agent, physicians need to make decisions with a surrogate who should be appointed according to the provisions of the state law in which the care is being provided. Surrogates should base their decisions on what the patient would choose if he or she were competent to do so; if the patient's views about treatment are unknown, the surrogate's decision should be based on the patient's best interests.

Resolving Conflict between the Surrogate and the Nephrologist

Occasionally, there are conflicts between the patient's legal agent and the nephrologist in which the agent requests dialysis and the nephrologist does not believe that it is appropriate. Based on the studies reviewed in this chapter, many nephrologists report that they would do as the agent requests, even if they thought it was wrong. In yielding to pressure from the agent, nephrologists potentially weaken the integrity of their specialty and shirk their responsibility to be good stewards of the federally funded ESRD program, a program to which every taxpayer, including every nephrologist, contributes. Recommendation 4 of the RPA/ASN guideline provides a systematic approach for resolving these conflicts, and Figure 84-1 presents sequential steps for resolving the conflict.

Withholding or withdrawing dialysis of an incompetent patient, over the objections of the agent, surrogate, or family, may be both ethical and legal.¹³ Such decisions should be made openly and should focus clearly on the patient's wishes or best interests. At a minimum, such decisions should be reached only after following Recommendation 4 of the RPA/ASN guideline, which recommends extended conversation with the patient's agent about the diagnosis of ESRD, about options for treatment including palliative care without dialysis, the prognosis, and the reasons for not offering or for stopping dialysis; the agreement of other members of the dialysis team including at least one other nephrologist; the concurrence of an ethics committee (if available); a detailed note in the patient's medical record

Box 84-1 Renal Physicians Association and the American Society of Nephrology Recommendations for Initiation and Withdrawal of Dialysis**Recommendation No. 1: Shared Decision Making**

A patient-physician relationship that promotes shared decision making is recommended for all patients with either acute renal failure or end-stage renal disease. Participants in shared decision making should involve at a minimum the patient and the physician. If a patient lacks the decision-making capacity, decisions should involve the legal agent. With the patient's consent, shared decision making may include family members or friends and other members of the renal care team.

Recommendation No. 2: Informed Consent or Refusal

Physicians should fully inform patients about their diagnosis, prognosis, and all treatment options, including (1) available dialysis modalities, (2) not starting dialysis and continuing conservative management that should include end-of-life care, (3) a time-limited trial of dialysis, and (4) stopping dialysis and receiving end-of-life care. Choices among the options should be made by patients or, if patients lack the decision-making capacity, their designated legal agents. Their decisions should be informed and voluntary. The renal care team, in conjunction with the primary care physician, should ensure that the patient or legal agent understands the consequences of the decision.

Recommendation No. 3: Estimating Prognosis

To facilitate informed decisions about starting dialysis for either acute renal failure or end-stage renal disease, discussions should occur with the patient or legal agent about life expectancy and quality of life. Depending on the circumstances (e.g., availability of nephrologists), a primary care physician or nephrologist who is familiar with prognostic data should conduct these discussions. These discussions should be documented and dated. All patients requiring dialysis should have their chances for survival estimated, with the realization that the ability to predict survival in the individual patient is difficult and imprecise. The estimates should be discussed with the patient or legal agent, the patient's family, and the medical team. For patients with end-stage renal disease, these discussions should occur as early as possible in the course of the patient's renal disease and continue as the renal disease progresses. For patients who experience major complications that may substantially reduce survival or quality of life, it is appropriate to discuss and/or reassess treatment goals, including consideration of withdrawing dialysis.

Recommendation No. 4: Conflict Resolution

A systematic approach for conflict resolution is recommended if there is disagreement regarding the benefits of dialysis between the patient or legal agent (and those supporting the patient's position) and (a) member(s) of the renal care team. Conflicts may also occur within the renal care team or between the renal care team and other health care providers.

This approach should review the shared decision-making process for the following potential sources of conflict: (1) miscommunication or misunderstanding about prognosis, (2) intrapersonal or interpersonal issues, or (3) values. If dialysis is indicated emergently, it should be provided while pursuing conflict resolution, provided the patient or legal agent requests it.

Recommendation No. 5: Advance Directives

The renal care team should attempt to obtain written advance directives from all dialysis patients. These advance directives should be honored.

Recommendation No. 6: Withholding or Withdrawing Dialysis

It is appropriate to withhold or withdraw dialysis for patients with either acute renal failure or end-stage renal disease in the following situations:

- Patients with the decision-making capacity who, being fully informed and making voluntary choices, refuse dialysis or request dialysis be discontinued
- Patients who no longer possess the decision-making capacity who have previously indicated refusal of dialysis in an oral or written advance directive
- Patients who no longer possess the decision-making capacity and whose properly appointed legal agents refuse dialysis or request that it be discontinued
- Patients with irreversible, profound neurological impairment such that they lack signs of thought, sensation, purposeful behavior, and awareness of self and environment.

Recommendation No. 7: Special Patient Groups

It is reasonable to consider not initiating or withdrawing dialysis for patients with acute renal failure or end-stage renal disease who have a terminal illness from a nonrenal cause or whose medical condition precludes the technical process of dialysis.

Recommendation No. 8: Time-Limited Trials

For patients requiring dialysis but who have an uncertain prognosis or for whom a consensus cannot be reached about providing dialysis, nephrologists should consider offering a time-limited trial of dialysis.

Recommendation No. 9: Palliative Care

All patients who decide to forgo dialysis or for whom such a decision is made should be treated with continued palliative care. With the patient's consent, persons with expertise in such care, such as hospice health care professionals, should be involved in managing the medical, psychosocial, and spiritual aspects of end-of-life care for these patients. Patients should be offered the option of dying where they prefer including at home with hospice care. Bereavement support should be offered to patients' families.

Box 84-2 The Consensus on Patients for Whom Dialysis Is Inappropriate

- Patients who refuse dialysis or who have previously indicated they did not want it
- Patients who are terminally ill with a nonrenal disease
- Patients who are permanently unconscious
- Patients who are unable to relate to others
- Patients who are unable to cooperate with the dialysis process

documenting all the factors relevant to the decision; and an attempt to transfer the patient's care if the agent wishes it. If the patient is already receiving dialysis and if (after all the above steps) the agent still requests dialysis and no other nephrologist has been found who is willing to accept the patient in transfer for dialysis, then the agent is given some time (usually 72 hours) to consider other options, including contacting a lawyer, before dialysis is stopped. Such a course of action by the nephrologist is justified for patients who are deemed inappropriate for dialysis (see Box 84-2). In using such an approach, for example, a nephrologist might refuse to dialyze a patient who is permanently unconscious, basing his or her decision on Recommendation 6 of the RPA/ASN guideline. In taking such an approach, nephrologists should indicate that they understand the agent's request and should give an explanation along the lines of "I am sorry, but we do not dialyze patients in your loved one's condition. Our profession is guided by ethical principles that require us to be of benefit and do no harm. In your loved one's case, dialysis cannot help her get better, and it may harm her." Nephrologists say this not because they lack respect or compassion for the agent but because their primary commitment is to the patient.¹³

ETHICAL PRINCIPLES IN DECISION MAKING

In their 1993 annual report, the End-Stage Renal Disease Data Advisory Committee to the U.S. Renal Data System articulated ethical justifications and general and specific principles to be used in making decisions about offering or not offering dialysis. This report included the deliberations of an ad hoc committee gathered to examine bioethical issues related to ESRD; the ad hoc committee was composed of nephrologists, ethicists, and health-policy experts. The Data Advisory Committee endorsed the recommendations of this ad hoc committee. The report described two ethical justifications for withholding or withdrawing dialysis: (1) the right of patients to refuse dialysis based on the ethical principle of respect for autonomy and the legal right of self-determination and (2) a judgment that dialysis does not offer a reasonable expectation of medical benefit based on the ethical principles of beneficence and nonmaleficence.¹⁴

LEGAL BASIS FOR DECIDING TO WITHHOLD OR WITHDRAW DIALYSIS

The ethical principle of respect for patient autonomy is applied to the treatment of the dialysis patient through the process of obtaining informed consent or refusal. In turn,

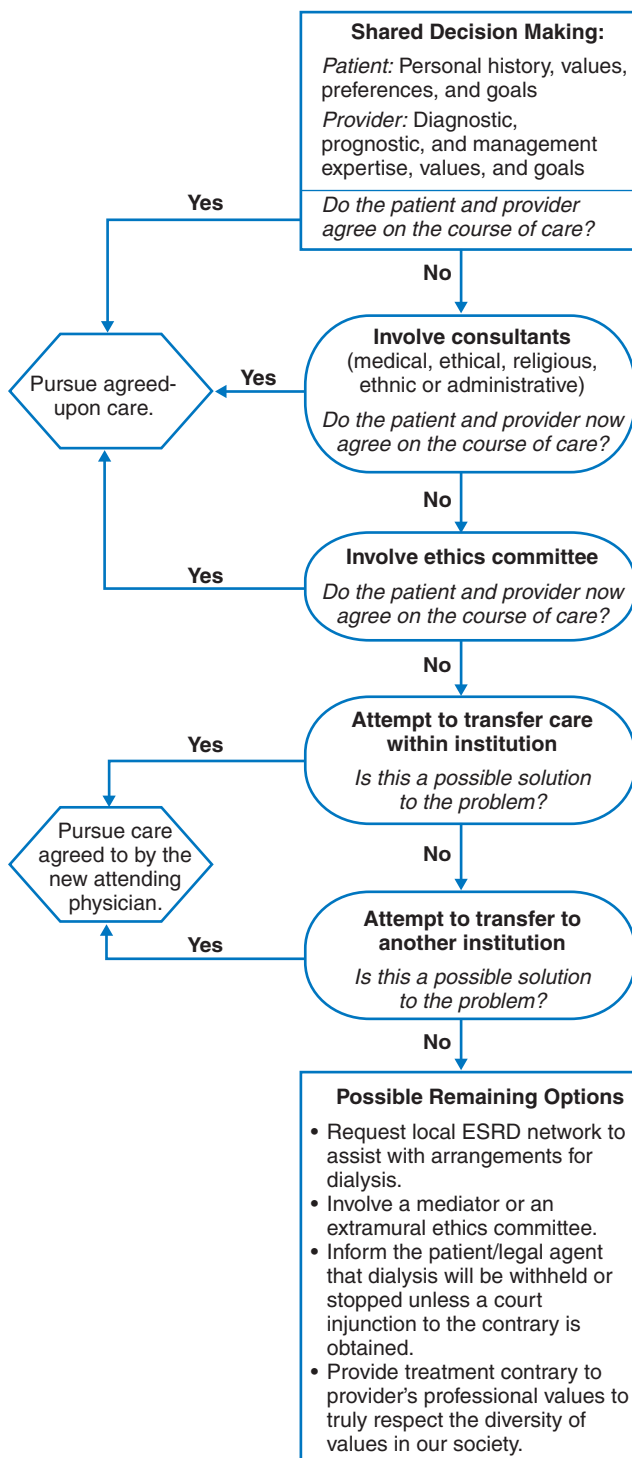

Figure 84-1 Systematic approach to resolving conflict between the patient and the renal care team. (Used with the permission of the Renal Physicians Association.)

the obtaining of consent or refusal is firmly grounded in the law: common law, constitutional law, and federal statute. The right of patients to accept or refuse dialysis is first based on common law dating back to the 1914 case of *Schloendorff v Society of New York Hospital*. In this case, Justice Benjamin Cardozo wrote, "Every human being of adult years and sound mind has a right to determine what shall be done with his body." In the 1990 U.S. Supreme Court case of *Cruzan v*

Director, the legal doctrine of informed consent was determined to be a constitutionally protected right. The Supreme Court justices held that “[t]he doctrine of informed consent arose in recognition of the value society places on a person’s autonomy and as the primary vehicle by which a person can protect the integrity of his body. If one can consent to treatment, one can also refuse it. Thus, as a necessary corollary to informed consent, the right to refuse treatment arose.”¹⁵ The Patient Self-Determination Act (included in the Congressional Omnibus Reconciliation Act of 1990, Public Law 101-508) became effective on December 1, 1991, and protected by federal statute the right of dialysis patients to consent to or to refuse dialysis. It is important for nephrologists to understand the law because if a nephrologist were to dialyze a competent patient against the patient’s will, the nephrologist could be civilly liable for medical battery.

THE ROLE OF ADVANCE CARE PLANNING

Deciding to stop a life-sustaining treatment such as dialysis for an incompetent patient is among the most difficult ethical problems faced by physicians.¹⁶ Because there is a presumption in favor of continued dialysis for patients who cannot and have not expressed their wishes, patients’ rights to forgo dialysis in certain situations are usually difficult to achieve unless patients have explicitly stated their preferences in advance or named a legal agent to speak on their behalf. The usual practice of nephrologists in treating patients who have become incompetent and who have provided neither oral nor written advance directives regarding their preferences for stopping dialysis is to continue dialysis. These considerations underscore the importance of advance care planning with patients with chronic kidney disease. Advance care planning is a process in which a patient’s preferences for a health care proxy and for future medical care under a variety of circumstances are determined (sometimes in the form of a written advance directive), are updated, and then followed in a manner in which the patient intended once the patient loses decision-making capacity. Advance care planning has been recognized as particularly important for dialysis patients for four reasons¹⁶: approximately half of the dialysis population is elderly, and the elderly have the shortest life expectancy on dialysis and are the most likely to withdraw or be withdrawn from dialysis; previous discussion of advance directives has been shown to help dialysis patients and their families to approach death in a reconciled fashion¹⁷; patients who discuss and complete written advance directives are significantly more likely to have their wish to die at home respected; and unless a specific directive to withhold cardiopulmonary resuscitation is obtained—which can be done in the framework of advance care planning—it will be automatically provided, although it rarely leads to extended survival in dialysis patients.¹⁸ For these reasons, nephrologists have been encouraged to discuss the circumstances under which patients would want to discontinue dialysis and forgo cardiopulmonary resuscitation and to urge patients to complete written advance directives.¹⁹

Despite these benefits, the practice of advance care planning, including the completion of advance directives, has not been optimized for dialysis patients. First, most of these patients do not discuss or complete an advance directive, even

though advance directives are particularly important for these chronically ill patients with shortened life expectancy who are dependent on life-sustaining treatment for their daily existence. Dialysis units were not included in the U.S. Patient Self-Determination Act list of health care providers who were required to ask patients about completion of advance directives and also provide them with an opportunity to execute an advance directive. Second, even when patients undergoing dialysis complete written advance directives, only one third have indicated to their family the circumstances under which they may want to stop dialysis.²⁰ This failure to indicate their preferences is disappointing because, as noted previously, patients undergoing dialysis have strong preferences about stopping dialysis and other life-sustaining treatments in certain health states. Recognizing these deficiencies, the ASN, the National Kidney Foundation, the RPA, and the Robert Wood Johnson Foundation’s ESRD Workgroup on End-of-Life Care have all strongly encouraged dialysis units to provide advance care planning to dialysis patients and their families and in the process to include a discussion of health states in which patients would want to stop dialysis and other life-sustaining treatments. Patients undergoing dialysis and their families have been encouraged to view advance care planning as a way to maintain control over present and future health care, relieve burdens on loved ones, strengthen interpersonal relationships, and prepare for death. Research with patients undergoing dialysis and their families shows that patients prefer to center the advance care planning process within the patient-family relationship rather than the patient-physician relationship. Clinicians who treat patients undergoing dialysis should urge them to participate in an advance care planning discussion with their families and should instruct them to tell their families and put in writing under what circumstances they would not want life-sustaining treatment, including dialysis.²¹ As part of the advance care planning process, patients should be asked to address where they prefer to die and whether they would like to receive hospice services.

Nephrologist researchers have studied how best to conduct advance care planning with dialysis patients. The nature of advance care planning has changed from a document-driven, decision-focused event in which the goal is completion of a written advance directive to a relational *process* in which the patient’s goals for treatment are identified and communicated to those in the patient’s support system (Box 84-3).²²

CARING FOR PATIENTS WHO WANT TO FORGO DIALYSIS

Response to a Patient’s Refusal to Start Dialysis

Patients with ESRD may have encephalopathy or depression that renders them incapable of decision making. The first assessment of patients with ESRD who refuse to initiate dialysis is whether they have decision-making capacity. If they have decision-making capacity, then the nephrologist should determine whether the refusal of dialysis is informed and valid. The nephrologist is obligated to determine why the refusal has been made and to ensure that the patient correctly understands the information that has been presented and the consequences of the decision. Patients and families should be informed that

Box 84-3 The Process of Advance Care Planning for Dialysis Patients**Facilitation**

Identification and participation of patient's designated proxy decision maker in the planning
 Patient and proxy understanding of patient's condition, prognosis, and likely illness course
 Elicitation of patient's goals and preferences for treatment in a variety of health states (e.g., permanent coma, advanced dementia, and persistent vegetative state), including those in the likely illness course
 Communication between patient and proxy so that proxy/family know and understand patient's goals for future care and are committed to respecting them

Documentation

Patient's designated decision maker and goals and preferences for treatment in the future when incapacitated are recorded in the medical record and on the state-specific advance directive form. Depending on state law, patient may complete a health care proxy form to designate a proxy decision maker and a living will to provide directives for treatment if the patient becomes terminally ill or in a persistent vegetative state.
 Completion of a physician order form, called Physician Orders for Life-Sustaining Treatment form in Oregon, specifying the patient's treatment decisions so that they can be honored throughout the health care system²³; an increasing number of states are using such a form.

Timing

Initial advance care planning discussion is appropriate when the patient is first diagnosed with progressive chronic kidney disease and may include only designation of proxy decision maker and completion of a living will if the patient chooses to execute one.
 A more complete discussion of the patient's goals and preferences for treatment is appropriate when the nephrologist answers "no" to the question "Would I be surprised if this patient died in the next year?"²⁴ At this time in the patient's disease course, complications that are likely to cause the patient's death can be anticipated and the treatments that the patient would and would not want can be identified and documented.

Systems and Processes

Dialysis units need to have a policy and procedure for conducting advance care planning. In most dialysis units, the social workers are assigned primary responsibility for implementing the advance care planning policy.²⁵

Quality Improvement

Clinical performance measures can be used to evaluate the advance care planning process and guide further process enhancement.

death from uremia is usually a comfortable one in which the patient becomes increasingly somnolent and then dies. Patients also need to be instructed to maintain salt and fluid restrictions so that pulmonary edema does not occur and mar the comfort of the dying process.²⁶

If the refusal is judged to be valid, then the patient should be considered terminally ill because a terminal illness is defined as one in which death is expected within 6 months or less. At this point, the RPA and ASN clinical practice guideline and the RPA and ASN statement on Quality Patient Care at the End of Life²⁷ recommend that the renal care team should refer the patient to a hospice or adopt a hospice-like approach to patient care. Such an approach considers medical, emotional, social, and spiritual needs of the dying patient and the family. If the renal team remains involved in the patient's care after hospice referral—such continuity is desirable—they should, in conjunction with hospice, take the following steps: (1) encourage the patient to participate with them in advance care planning if it has not already been done; (2) issue a do-not-resuscitate order that applies to the outpatient setting; (3) discuss with the patient and family contingencies for the final hours of the patient's life so that the family or caregivers do not panic and call emergency medical services when the patient experiences a cardiopulmonary arrest; and (4) address the needs of the family with regard to grieving while the patient is dying and bereavement after the patient has died.

Response to a Patient's Request to Stop Dialysis

A patient's request to stop dialysis should trigger a systematic response on the part of the dialysis team, including the inquiry in Box 84-4. Such an inquiry might uncover potentially reversible factors responsible for the patient's request, including difficulties with dialysis treatments, concerns about the burdens that the patient is placing on family, undue influence or pressure from outside sources, conflict between the patient and others, and dissatisfaction with the dialysis modality, the time, or the setting. It is usual for most dialysis units to ask a patient who wishes to stop dialysis to be evaluated by a counseling professional, either a psychiatrist, psychologist, or social worker, or someone in pastoral care to be sure that the patient has the decision-making capacity and that reversible factors are identified. Dialysis units also usually try to persuade patients to stay on dialysis for a period of time to see whether patient satisfaction is increased as reversible factors are addressed.

As for ESRD patients who choose not to initiate dialysis, for those who choose to withdraw, nephrologists should assure them and their families that death from uremia is usually a comfortable one as long as patients maintain salt and fluid restrictions so that pulmonary edema does not mar the dying process. Nephrologists are often willing to provide ultrafiltration without

Box 84-4 Questions to Be Answered in Responding to a Patient's Request to Stop Dialysis

1. Does the patient have the decision-making capacity or is the patient's cognitive capacity diminished by depression, encephalopathy, or other disorder?
2. Why does the patient want to stop dialysis?
3. Are the patient's perceptions about the technical or quality-of-life aspects of dialysis accurate?
4. Does the patient really mean what he or she says or is the decision to stop dialysis made to get attention, help, or control?
5. Can any changes be made that might improve life on dialysis for the patient?
6. Would the patient be willing to continue dialysis while the factors responsible for the patient's request are being addressed?
7. Has the patient discussed his or her desire to stop dialysis with significant others such as family, close friends, or spiritual advisors? What do they think about the patient's request?

diffusion dialysis to control symptoms of fluid overload in patients from whom dialysis has been withdrawn. The RPA and ASN recommend that nephrologists refer dialysis patients who stop dialysis to hospice, but research indicates there is room for improvement. Only half as many dialysis patients die with hospice care compared with the general population. Even among dialysis patients who are withdrawn from dialysis and whose death within a month is fairly certain, less than half die with hospice care.²⁸ Death with hospice care for dialysis patients is associated with lower costs and a much greater percentage of patients dying at home.

NEPHROLOGISTS' PREPAREDNESS FOR END-OF-LIFE DECISION MAKING

The ESRD patient population is increasingly composed of older patients with multiple comorbid conditions, high symptom burden, and a shortened life expectancy. Chapter 75 addresses pain and symptom management for ESRD patients. Because of the changing nature of the ESRD population and the fact that older patients are the most likely to withdraw from dialysis, nephrologists commonly engage in end-of-life decision making with dialysis patients and their families. Researchers have studied how prepared nephrologists report they are for decisions such as withholding or stopping dialysis or initiating it on a time-limited basis. In an online survey of RPA members, 39% identified themselves as being very well prepared for dialysis decision making. Those who reported that they were most prepared had been in practice longer and were knowledgeable of and used the RPA/ASN *Shared Decision-Making* practice guideline more often than those who reported that they were less well prepared.²⁹ In the preceding year, the very well prepared nephrologists had stopped dialysis of more patients, referred more patients to hospice, and used a time-limited trial of dialysis more often. The benefits of using the guide-

line recommendations prospectively in patient care have also been demonstrated.³⁰ These findings validate the contribution of the RPA/ASN guideline to nephrology clinical practice and underscore the importance of teaching the guideline recommendations to nephrologists and nephrology fellows.

CONCLUSIONS

Since the inception of dialysis for chronic renal failure in the early 1960s, dialysis decision making has undergone a dramatic transformation. Dialysis selection committees have disappeared, and decisions about whether to start or stop dialysis are made within the confines and privacy of the patient-physician relationship, governed by the process of informed consent.

In the 1990s, the wide range of discretion afforded to patients and nephrologists in making decisions about dialysis had resulted in a large variation in the way in which these decisions were made. Commentators on the ESRD program, including nephrology physicians and nurses, were concerned that some patients receiving dialysis were not appropriate candidates. In 2000, the RPA and ASN published a clinical practice guideline to assist nephrologists in dialysis decision making. Research shows that nephrologists who report that they are most prepared to make dialysis decisions are aware of and use the guideline. Research also shows that nephrologists in 2005 were making dialysis decisions more often in accordance with the guideline recommendations compared with nephrologists in 1990.

Excluding those patients who are identified as inappropriate dialysis candidates by the RPA/ASN guideline, the best approach for patient selection seems to be a liberal policy for accepting patients who might benefit from dialysis, including the use of time-limited trials of dialysis, combined with a readiness to withdraw patients from dialysis when the burdens of treatment outweigh the benefits. Successful implementation of such a policy requires good advance care planning at the start of dialysis and continuing dialogue between the physician, the patient, and the family about the patient's values, wishes, and goals. Patients should be informed that they have the right to stop dialysis. However, the goal of the nephrologist and the dialysis team should be to optimize the care of each patient so that each patient is satisfied with his or her quality of life for as long as possible and chooses to continue dialysis until a catastrophic event or unacceptable disease progression occurs. When it does occur, good advance care planning will prove its worth. Then everyone will know that the patient would no longer wish to receive dialysis, and it may be withdrawn, with the patient, family, and dialysis team all reconciled to the patient's death and knowledgeable about the patient's preferences for terminal care, including the use of hospice, so that those preferences can be honored. Renal palliative care (see Chapter 75) should have been begun at the start of dialysis with pain and symptom management and advance care planning; it will now become especially important to ensure that the patient is comfortable and that the patient and the family receive psychosocial and spiritual support, including bereavement support during and after the patient's death.

QUALITY OF LIFE AFTER LIVING DONATION	966

Kidney transplantation saves lives, especially if performed before a patient with end-stage kidney disease (ESRD) initiates dialysis (Fig. 85-1).¹⁻³ This survival benefit is seen for the young, the old, and those with diabetes and hepatitis.¹⁻⁴ For a full discussion of the outcomes of renal transplantation, see Chapter 87. This chapter focuses on the evaluation of the recipient and donor. These evaluations should be performed within 6 months of the predicted need for recipient dialysis, typically with a glomerular filtration rate (GFR) less than 15 mL/min, especially when a living donor kidney transplant is an option (www.uktransplant.org). If no living donor is available, the average wait for a deceased donor transplant in the United States is 3.3 years for blood group A, more than 5 years for blood group O, and more than 5.6 years for blood group B (www.unos.org). Currently, the time to transplantation is also significantly influenced by geographic location and allosensitization.

RECIPIENT EVALUATION

Guidelines for the evaluation of kidney transplant recipients have been published by the American Society of Transplantation, the European Renal Association-European

Dialysis and Transplant Association, and the British Transplantation Society and Renal Association (www.uktransplant.org).⁵⁻⁷ An overview of the evaluation is shown in Box 85-1.

Blood Type and Histocompatibility

The potential donor and recipient must be ABO blood group compatible to avoid hyperacute rejection; however, Rh factor incompatibility is not a contraindication to transplantation. Likewise, histocompatibility testing is performed to help identify recipient/donor combinations that would result in poor allograft survival. Both donor and recipient HLA-A, HLA-B, and HLA-DR antigens of the major histocompatibility complex are determined. Antigen-specific antidonor profiles are also performed, and unacceptable antigens are determined for the recipient. Histocompatibility testing is discussed in detail in Chapter 87.

Age and Transplantation Success

Older age has been a relative contraindication to transplantation due to concern over decreased survival. From 1988 through 2004 in the United States, 2623 individuals between 71 and 75 years of age underwent transplantation as did 503

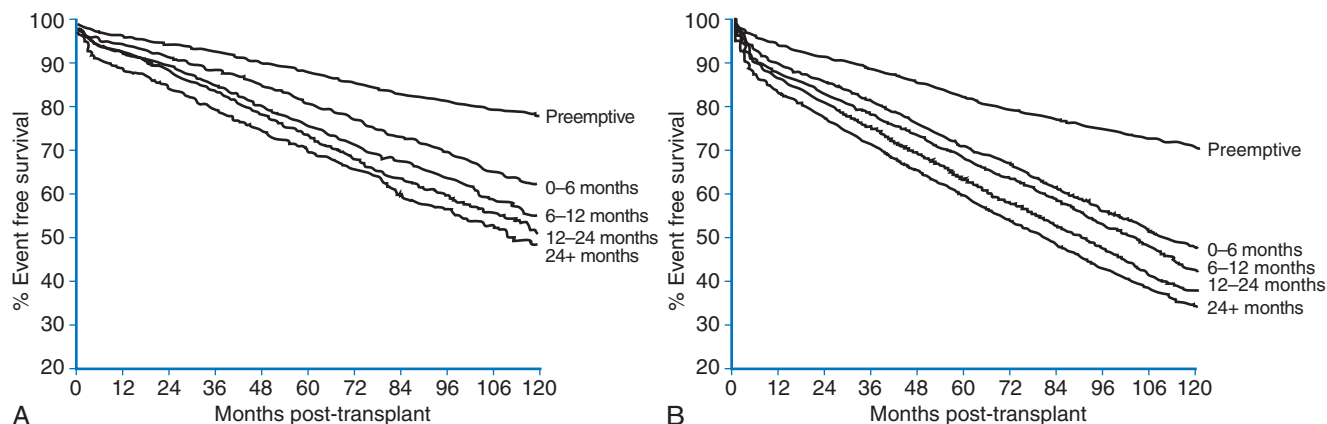

Figure 85-1 Kidney transplant survival by timing of transplantation for living and deceased donor transplants. Patients were evaluated by the timing of transplantation in relation to starting dialysis; preemptive candidates underwent transplantation before starting dialysis. **A**, Graft survival by timing of living donor kidney transplantation. **B**, Graft survival by timing of deceased donor kidney transplantation. (Reprinted from Meier-Kriesche HU, Kaplan B: Waiting time on dialysis as the strongest modifiable risk factor for renal transplant outcomes: A paired donor kidney analysis. *Transplantation* 2002;74: 1377–1381, with permission.)

Box 85-1 Recipient Evaluation

1. Transplant Specific
 - HLA typing
 - PRA (panel reactive antibody) determination
 - ABO typing
2. General areas of focus
 - History
 - Cardiovascular: symptoms, smoking, diabetes, exercise tolerance, previous cardiovascular events, hypertension, phosphorus
 - Pulmonary: symptoms, limits, treatments, exposures
 - Type of renal disease: obtain biopsy report if available
 - Family history: malignancy, cardiac disease, renal disease
 - Urine output
 - Nephrolithiasis
 - Infection: residence, travel, work, activity exposure, treatments, transfusions
 - Malignancy screening, symptoms
 - Surgeries and tolerance
 - Medication tolerance
 - Gastrointestinal: peptic ulcer disease, bowel habits, bleeding, diverticulitis, cholelithiasis, liver disease
 - Neurologic: cerebral ischemia, peripheral neuropathy
 - Examination: height, weight, blood pressure; focus on cardiovascular examination; focus on neurological examination; focus on signs of malignancy; focus on signs of infection
 - Laboratory
 - Complete blood count with platelet count
 - Prothrombin time/partial thromboelastin time
 - More detailed evaluation if there is a history of coagulation disorders
 - Comprehensive panel (electrolytes, transaminase levels, albumin, calcium, phosphorus, alkaline phosphatase, bilirubin)
 - Urinalysis if possible, with culture if indicated
 - 24-Hour urine for volume, protein if possible
3. Cardiovascular
 - Electrocardiogram
 - Chest radiograph
 - As clinically indicated, cardiac stress testing and/or echocardiography
 - As clinically indicated, vascular duplex or angiography
4. Malignancy
 - PAP test for all adult female candidates
 - Mammogram for all women 40 or older, earlier if previous findings or strong family history
 - Digital prostate examination and prostate-specific antigen test for all male candidates 40 or older
 - Colonoscopy for all candidates older than 50 or younger with increased family risk or positive stool guaiac
5. Infection: screen for
 - Cytomegalovirus, Epstein-Barr virus, herpes simplex virus, varicella-zoster virus
 - Human immunodeficiency virus types 1 and 2
 - Human T-lymphotropic viruses 1 and 2
 - Hepatitis B surface antigen
 - Hepatitis B core antibody IgM/IgG
 - Hepatitis B surface antibody
 - Hepatitis C virus
 - Rapid plasma reagin
 - Tuberculosis
 - Toxoplasmosis, depending on exposure risk
 - Geographically determined testing: coccidiomycosis, *Strongyloides*, *Trypanosoma cruzi*, malaria, human herpesvirus 8
 - Consider human herpesvirus 6 and West Nile virus
6. Recurrent disease
 - Review past diagnosis, biopsy results, and clinical course for the risk of diagnoses that frequently recur
7. Psychosocial status: education, support, smoking, recreational drug use, compliance, depression/anxiety

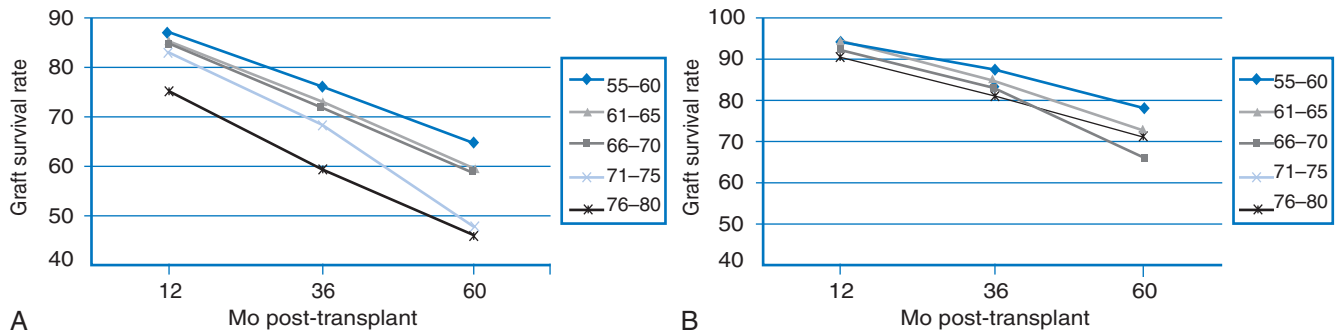

Figure 85-2 Kidney transplant survival by recipient age (over 55 years old) at transplantation for deceased donor and living donor allografts (United Network for Organ Sharing data as of March 2005). **A**, Transplant survival by recipient age for deceased donor transplants. **B**, Transplant survival by recipient age for living donor transplants.

individuals 76 to 80 years old and 48 individuals older than age 80. Although individuals older than 70 must be carefully evaluated, they may successfully undergo transplantation and demonstrate acceptable survival (Fig. 85-2 [www.unos.org; UNOS data as of May 2007]).

Cardiovascular Disease

Cardiovascular disease is a major contributor to the increased premature mortality rate seen in renal transplant recipients. An overview of the work-up algorithm is shown in Box 85-1. There is no general consensus regarding the type or extent of testing.

Ischemic Heart Disease

It is recommended that asymptomatic patients undergo further assessment if they are older than 50 years of age, are diabetic, have smoked cigarettes in the past 5 years, or have a resting electrocardiogram that shows a rhythm disturbance or ST segment abnormalities, although these recommendations are made on underpowered and nonrandomized studies.^{8,9} Further assessment begins with a noninvasive test of occult cardiac ischemia, realizing it is not possible to justify one particular test. Exercise tests probably have the most discriminating power but may not be practical, making pharmacologically driven cardiac stress testing more popular. Combined dipyridamole and exercise thallium imaging or dobutamine stress echocardiography are the most commonly used tests.¹⁰ The discovery of significant reversible ischemia requires coronary imaging with subsequent management directed per current protocols. If left ventricular function is adequate and symptoms are controlled, then transplant listing is recommended. Transplantation during treatment with Plavix (clopidogrel) is still without rigorous examination. Coronary calcification testing has not yet predicted posttransplantation outcomes.¹¹

Cerebrovascular Disease

There is no evidence to support screening asymptomatic potential renal transplant recipients for cerebrovascular disease, although carotid plaque is positively associated with cardiovascular events.^{12,13} Additionally, silent cerebral infarction is not uncommon and not necessarily related to carotid artery disease.^{14,15} Patients with a completed stroke or a transient ischemic attack within the past 6 months should be referred for neurological assessment and transplantation reconsidered af-

ter medical and surgical management has been optimized and the patient is free of recurrent transient ischemic attacks for 6 months. Screening in the presence of an asymptomatic carotid bruit is prudent but may not alter the decision for treatment or transplantation.

Peripheral Vascular Disease

If patients are asymptomatic with good femoral pulses, then only a plain radiograph is recommended to rule out extensive vascular calcification.¹⁶ In contrast, patients with claudication or lack of palpable femoral pulses require vascular imaging and a surgical assessment of whether it is technically possible to implant the graft and whether the transplant would be predicted to lead to steal and critical ischemia in the distal leg.¹⁷

Cancer

Cancer rates are increased in patients with ESRD on dialysis and after transplantation.^{18,19} The impact of immunosuppression on recurrence of a previously treated malignancy has not been clarified. However, transplant cancer registries and common sense dictate that potential recipients with an incurable malignancy should not undergo transplantation and those previously successfully treated for cancer should delay transplantation until the time of maximum recurrence of malignancy has passed. Recurrence rates of cancer post-transplantation have been demonstrated to decrease the longer the waiting time, with 53% recurring within 2 years, 34% between years 2 and 5, and the last 13% recurring after 5 years.^{20,21} In reality, most programs wait 2 years after successful treatment of most cancers before transplant listing. Exceptions without a recommended delay include asymptomatic incidentally discovered renal cell carcinoma confined to the kidney, in situ cancer of the bladder or cervix, and basal cell and squamous cell carcinomas of the skin. In contrast, cancers with a high risk of recurrence, such as colorectal cancer, malignant melanoma, and cancer of the body of the uterus, should have a 5-year delay. It is difficult to know how best to advise patients with treated breast cancer as the majority of relapses occur after 3 years.²²⁻²⁵ The safest approach for most cancers due to the heterogeneity of prognosis depending on staging, tumor markers, and treatment advances is to individualize the approach after consultation with an oncologist.

Consensus is nonexistent in the transplant community regarding the necessity of screening for malignancy as the numbers needed to screen to save one life are large and vary from

338 to more than 5000 for colorectal, breast, and prostate cancers.²⁶ However, to the individual recipient, this may have a huge impact on outcome as well as be a key factor in a possible living donor's decision to donate. Therefore, although some programs will not routinely screen for cervical, prostate, breast, or colon cancer, it is suggested that at least appropriate age, personal history (von Hippel-Lindau disease, analgesic nephropathy), and family history (familial polyposis) screening be performed. Last, renal cell cancer is increased in those with ESRD; some, but not all, recommend that screening start with an ultrasound scan.²⁷

Infection

The pretransplantation evaluation for infection should include testing for the infections listed in Box 85-1.²⁸ Treatable infections must be eradicated before transplantation. Infections of the teeth, sinuses, ears, chest, urinary tract, gastrointestinal tract, and the feet of those with diabetes and patients with peripheral vascular disease must be cleared up before transplantation. Chest radiography should be performed for signs of pulmonary tuberculosis or other pulmonary infection. Controversy exists with regard to patients who are hepatitis B virus surface antigen positive or hepatitis C virus antibody positive because of the risk of immunosuppression leading to enhanced viral replication and promoting progressive liver disease and death from liver failure.²⁹ However, survival is better with transplantation than with dialysis.^{30,31} Patients with active viral infection are recommended to undergo a liver biopsy to stage the disease and to receive antiviral treatment (lamivudine hepatitis B virus or pegylated interferon alfa hepatitis C virus) before transplantation.^{31,32} These patients also require monitoring for the development of hepatocellular carcinoma (alpha-fetoprotein and ultrasonography) and progressive liver disease while waiting.³³ If necessary, combined kidney-liver transplantation is an option.

A potential candidate for organ transplantation who is seropositive for human immunodeficiency virus (HIV) antibody but is asymptomatic should be on highly active antiretroviral therapy and compliant and have an undetectable viral load and CD4⁺ cell counts of at least 200 cells/mm³.^{28,34} In this setting, transplantation success may approach the uninfected population, although rejection remains a significant issue.^{34,35} Guidelines have been produced by the British HIV Association and are available via the British Transplantation Society website at www.bts.org.uk/ and information about HIV and transplantation in the United States is available at www.clinicaltrials.gov/ and www.a-s-t.org/.

Testing for fungal or parasitic infections is partially determined by geographic location and travel history (see Box 85-1).^{5,28} In regions of the world where herpes hominis virus-8 infection is common, it may be helpful to know the serology of individuals before grafting given the strong association of the virus with Kaposi sarcoma. Recipients who have negative Epstein-Barr virus who receive Epstein-Barr virus–positive renal transplants have a sevenfold increased risk of developing posttransplantation lymphoproliferative disorder. The knowledge of recipient serologies may therefore influence postgraft immunosuppressive strategies. In particular, the cytomegalovirus serology at the time of grafting helps guide antiviral prophylactic strategies.²⁸

Tuberculosis may reactivate after transplantation. As such, all patients should undergo chest radiograph to look for inactive disease and have a tuberculin skin (purified protein derivative test) test. Although a positive purified protein derivative test

result correlates with past infection, a negative skin test in the uremic patient may represent a false-negative result.^{36,37} Patients identified as high risk (history of tuberculosis, positive chest radiograph, positive purified protein derivative test result, or living in an endemic area) and who have not previously received isoniazid should start pretransplantation treatment or receive daily isoniazid for 9 months after transplantation.

Obesity

Obese individuals carry an increased risk of posttransplantation wound infections and perioperative complications.³⁸ Obesity is also a risk factor for posttransplantation diabetes and allograft dysfunction.^{39–41} According to the United States Renal Data System database, a live donor transplant affords an advantage for all obese subjects; however, deceased donors provide survival benefit only for recipients with a body mass index (BMI) of less than 40 kg/m².⁴² Obese transplantation candidates should be encouraged to lose weight. Many programs have a BMI threshold for acceptance.

Recurrent Disease

Graft loss attributed to recurrent disease has increased in recent years but is still only thought to be responsible for approximately 5% of allograft loss.^{43,44} The highest risk of recurrence is seen with membranoproliferative glomerulonephritis type 1 and oxalosis but is also important for hemolytic uremic syndrome, focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis type 1 IgA nephropathy, membranous nephropathy, diabetes, and vasculitis.

Gastrointestinal

The rate of colonic perforation after transplantation is approximately 1% and is most commonly associated with diverticular disease.⁴⁵ Although still somewhat controversial, especially in candidates with polycystic kidney disease, screening of asymptomatic patients is not justified as studies have found that patients with significant diverticular disease rarely have symptomatic disease after transplantation.^{45–47} Patients with symptomatic disease should undergo imaging and consideration should be given to resection of extensive disease. Screening of asymptomatic individuals for peptic ulcer disease is not recommended because of the low morbidity rate.^{48,49} Those with active symptoms or a history of peptic ulcer disease should, however, undergo endoscopic evaluation before transplantation.⁵⁰ If an ulcer is present, it should be treated medically for 6 weeks, followed by a repeat endoscopy. If the ulcer has not healed, surgical therapy should be performed before transplantation. Incidentally identified cholelithiasis should be managed expectantly as no advantage has been found to prophylactic cholecystectomy.⁵¹

Genitourinary

Patients with recurrent urinary tract infections should have a voiding cystourethrogram. If persistent high-grade reflux is demonstrated, bilateral nephrectomy and ureterectomy are indicated. Additionally, native nephrectomy is advised for persistent infection due to nephrolithiasis or infected cysts or uncontrolled hypertension; in patients with polycystic kidney disease and recurrent cystic bleeding, shortness of breath, early satiety; or to make space for the allograft.⁵² Consideration of residual renal function is essential. Transplant nephrectomy

before retransplantation is indicated if it is the source of infection, there are chronic inflammatory symptoms, or space is needed for the new transplant. Prostate hypertrophy is not a contraindication to transplantation. Treatment depends on the amount of urinary output; less than normal urine output should delay transurethral resection until after transplantation due to the risk of urethral stenosis. Neurogenic bladder or bladder outlet obstruction resulting in high intravesical pressures as suggested by clinical history and examination necessitates evaluation by urology to determine whether urinary diversion, bladder augmentation, or intermittent self-catheterization is the best option.

Failed Allografts

Whether surgical removal of a failed graft minimizes the degree of HLA sensitization is not clear.^{53,54} In practice, grafts that fail within 6 months are usually removed. The decision to remove a graft that fails later needs to balance surgical morbidity against the resistance to the effect of erythropoietic agents seen with a failed graft left in situ, the advantage of rapid tapering of immunosuppression, and whether residual urine output contributes meaningfully to fluid balance. Slow tapering of immunosuppression to avoid adrenal insufficiency is usually safe if the graft is not removed.

Bone

Bone fracture rates are increased in patients with ESRD.⁵⁵ However, there is important heterogeneity in the association of bone mineral density studies and fractures in this population as well as after transplantation.^{56,57} As such, routine bone density measurements are not indicated, but evaluation of the effectiveness of the treatment of hyperparathyroidism, attention to pain medication use, and exercise with fall avoidance is advised.⁵⁸

Pulmonary

Pulmonary function tests are generally performed in the preparation for surgery if the clinical history or examination suggests chronic lung disease. Obstructive lung disease itself is not a contraindication for transplantation. All patients who smoke cigarettes should be advised to quit because active smokers have a 5.5-fold increased risk of pulmonary complications compared with those who do not smoke. Patients with bronchiectasis require careful assessment as they carry significant risk of serious septic complications post-transplantation.

Psychosocial Evaluation

The psychosocial evaluation is critical for the transplantation candidate as psychosocial variables can affect transplantation outcome.⁵⁹ The main psychosocial concerns include impaired capacity, treatment adherence and noncompliance, the use of illicit drugs, and lack of social support. Successful postoperative transplant care inevitably requires a supportive environment, frequent hospital attendance, and adherence to a complex drug regimen. Some individuals can be identified before listing for which additional support post-procedure can minimize the risk of premature graft failure due to the inability to comply with management. Other individuals may be at such poor psychosocial risk that transplantation is not in their best interest. It is best

in these circumstances to collate views from several of the health professionals involved in the patient's care as well as from the patient and immediate family members.

Re-evaluation of Patients on the Waiting List

Following placement on the waiting list, patients may wait years before receiving a transplant offer. Due to this wait, candidate medical re-evaluation is a logical step, but there are no data to help decide how often this should be or what tests should be performed. Brief guidelines have been proposed but are not backed by rigorous data. Some assessments are part of regular dialysis care such as monitoring hepatitis and HIV status. Cancer screening should proceed per population guidelines. Cardiovascular assessment, however, is the most controversial; only clinically triggered testing has been shown to be of benefit.^{60,61} Even so, it seems prudent to perform cardiac re-evaluation every 2 years on diabetic and every 4 years on nondiabetic wait-listed candidates.^{9,62,63}

EVALUATION OF THE LIVING KIDNEY DONOR

Transplant programs have historically used varied evaluation and selection criteria for living donors such that transplant organizations and government transplant agencies have started to develop guidelines for programs to follow (e.g., UK transplant, the American Society of Transplantation, the American Society of Transplant Surgeons, New York State, and United Network for Organ Sharing [UNOS]).⁶⁴⁻⁶⁸ The elements necessary in the consenting process are available on the UNOS website, those for the psychological evaluation are shown in Box 85-2 and those for the medical evaluation in Box 85-3.^{67,69} Detailed consent is of utmost importance due to the increasing dependence on living donation and because during 2006 in the United States, 21.6% of living donors were unrelated to the recipient (Fig. 85-3) (www.health.state.ny.us/nysdoh/liver_donation/pdf/liver_donor_report_web.pdf).

Optimally, the team evaluating the living kidney donor should include a nephrologist, transplantation surgeon, social worker or psychologist or psychiatrist, dietitian, donor coordinator, and pharmacist. At least one member of the team should be completely independent of the transplantation team taking care of the potential recipient and be able to stop the donation process if discoveries are made that could lead to donor harm.⁷⁰ Preferably, the entire donor team would be independent of the team taking care of the recipient with some not being members of the transplantation program at all.

Risk of Living Donation

Death

The risk of death after living donation is reported to be 0.02% to 0.04% within 90 days of donation.^{71,72} UNOS initiated tracking of donor deaths in October 1999. From October 1999 through December 2006, 14 (of 43,882 donors, 0.03%) living kidney donor deaths were reported to UNOS or identified by examination of the Social Security Death Master File to have occurred within 30 days of donation. During the same time period, by

Box 85-2 Required Components of the Living Donor Psychosocial Evaluation

To accomplish the goals of the psychosocial evaluation, the following components must be included.⁶⁹

- a. *History and current status*: Obtain standard background information regarding such areas as the prospective donor's educational level, living situation, cultural background, religious beliefs and practices, significant relationships, family psychosocial history, employment, lifestyle, community activities, legal offense history, and citizenship.
- b. *Capacity*: Ensure that the prospective donor's cognitive status and capacity to comprehend information are not compromised and do not interfere with judgment; determine risk of exploitation.
- c. *Psychological status*: Establish the presence or absence of current and previous psychiatric disorders, including but not limited to mood, anxiety, substance use, and personality disorders. Review current or previous therapeutic interventions (counseling, medications); physical, psychological or sexual abuse; current stressors (e.g., relationships, home, work); recent losses; chronic pain management. Assess repertoire of coping skills to manage previous life or health-related stressors. A focus on the extent of anxiety and depression is needed.
- d. *Relationship with the transplant candidate*: Review the nature and degree of closeness (if any) to the recipient (e.g., how the relationship developed) and whether the transplant would impose expectations or perceived obligations on the part of either the donor or the recipient.
- e. *Motivation*: Explore the rationale and reasoning for volunteering to donate (i.e., the "voluntariness") including whether donation would be consistent with past behaviors and apparent values, beliefs, moral obligations, or lifestyle and whether it would be free of coercion, inducements, ambivalence, impulsivity, or ulterior motives (e.g., to atone or gain approval, to stabilize self-image, to remedy psychological malady).
- f. *Donor knowledge, understanding, and preparation*: Explore the prospective donor's awareness of any potential short- and long-term risks of surgical complications and health outcomes, both for the donor and the transplant candidate; recovery and recuperation time; availability of alternative treatments for the transplantation candidate; financial ramifications (including possible insurance risk). Determine that the donor understands that data on long-term donor health and psychosocial outcomes continue to be sparse. Assess the prospective donor's understanding, acceptance, and respect for the specific donor protocol (e.g., willingness to accept potential lack of communication from the recipient, willingness to undergo future donor follow-up).
- g. *Social support*: Evaluate significant other, familial, social, and employer support networks available to the prospective donor on an ongoing basis as well as during the donor's recovery from surgery.
- h. *Financial suitability*: Determine whether the prospective donor is financially stable and free of financial hardship, has resources available to cover financial obligations for expected and unexpected donation-related expenses, is able to withstand time away from work or established role including unplanned extended recovery time, has disability and health insurance.
- i. Discussion with the donor support person.

Box 85-3 Medical Evaluation of the Living Kidney Donor

1. Donor typing to determine the risk of acute transplant failure
 - a. ABO blood group typing × 2
 - b. HLA typing
 - c. Crossmatch
2. General history and physical examination
 - a. History specifically includes evaluation of family history of kidney disease, diabetes, hypertension, birth weight if possible, gestational diabetes, birth weight of offspring, clotting disorders or deep venous thrombosis, use of nonsteroidal anti-inflammatory drugs (e.g., ibuprofen, indomethacin), urinary tract infections, nephrolithiasis, chronic infections, cancer and kidney injury; prospective donors should be asked whether they have dental coverage and have had a dental examination recently
 - b. Physical examination including blood pressure (done three times at three different times; if possible, it is preferable to perform a 24-hour blood pressure monitor); height; weight; calculated body mass index; waist circumference; a search for evidence of heart, lung, liver, and blood vessel disease; abnormal lymph nodes; and large spleen
 - c. Medical psychological evaluation and social history should include questioning about alcohol intake, smoking history, substance use and abuse, history of mental illness and treatment used
3. General laboratory tests: complete blood count with platelet count, prothrombin time/partial thromboplastin time, more detailed evaluation if there is a history of coagulation disorders, comprehensive panel (electrolytes, transaminase levels, albumin, calcium, phosphorus, alkaline phosphatase, bilirubin), human chorionic gonadotropin quantitative pregnancy test if younger than 55 years, urine toxicology screen, serum protein electrophoresis in those older than 60 years
4. Cardiovascular: heart and blood vessel tests
 - Chest radiograph
 - Electrocardiogram
 - Echocardiogram and/or exercise stress test if the prospective donor is more than 50 years old or has risk factors (hypertension, smoking, hyperlipidemia, family history, exercise shortness of breath) or physical findings that demonstrate increased risk of heart disease including, but not limited to, the following: borderline blood pressure, abnormal electrocardiogram, abnormal chest radiograph, murmur
 - Pulmonary function tests for smokers

Box 85-3 Medical Evaluation of the Living Kidney Donor—cont'd

5. Renal-focused evaluation

Urinalysis, looking for protein and cells in the urine

Urine culture (if symptoms or abnormal urinalysis)

Protein excretion: 24-hour urine for protein and/or microalbumin excretion or protein-to-creatinine ratio and/or albumin-to-creatinine ratio $\times 2$; if one is abnormal, repeat

If protein detected, evaluation for postural proteinuria by split urine collection over 24 hours (8 hours recumbent and 16 hours active)

Serum creatinine

Glomerular filtration rate (GFR) measurement: clearance testing, 24-hour urine for creatinine clearance measurement or preferably a measured clearance using urine or plasma clearance of iothalamate, iohexol, or other suitable marker. GFR should be expressed per 1.73 m^2 . Calculated GFR measurements using the serum creatinine are not felt to be adequate. GFR should be within 2 SD for age or be calculated to be at $40 \text{ mL/min}/1.73 \text{ m}^2$ at age 80.

Screen for polycystic kidney disease as indicated by family history, ultrasound scan if older than 30 years, linkage genetic testing if younger than age 30

6. Metabolic-focused evaluation

Fasting blood glucose

Uric acid

Thyroid-stimulating hormone

Fasting lipid profile (cholesterol, triglycerides, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol)

Determine the number of elements of the metabolic syndrome that are present; obtain consent for risk if three or more risk factors

If at increased risk for diabetes (family history of diabetes, gestational diabetes, or elevated triglyceride levels, perform an oral glucose tolerance test and include calculations for insulin secretion/insulin resistance index

Hemoglobin A1C

7. Infection

Cytomegalovirus, Epstein-Barr virus, herpes simplex virus, varicella-zoster virus

Human immunodeficiency virus types 1 and 2

Human T-lymphotropic viruses 1 and 2

Hepatitis B surface antigen

Hepatitis B core antibody IgM/IgG

Hepatitis B surface antibody

Hepatitis C virus

Rapid plasma reagin

Tuberculosis

Toxoplasmosis, depending on exposure risk

Geographically determined testing: coccidiomycosis, *Strongyloides*, *Trypanosoma cruzi*, malaria, human herpesvirus 8

Consider human herpesvirus 6 and West Nile virus

8. Anatomic evaluation

Determine which kidney is the safest to remove and which kidney (the one with the best function) is to be left with the donor. Additionally, the presence of abnormal liver, nodes, adrenal glands, and spleen can be determined.

a. The test of choice will depend on the local radiological expertise and surgical preference but may include a computed tomography angiogram, magnetic resonance angiogram, or angiogram. It may also be advised to perform an abdominal ultrasound scan to evaluate liver for fatty infiltration and unexpected abnormalities of the liver, pancreas and spleen if a full abdominal computed tomography or magnetic resonance imaging scan is not performed.

b. Renal scan with differential renal function

9. Cancer screening

Determines that the donor does not need both kidneys to help with tolerance of anticancer treatment and that the donor does not have a tumor that would be transferred to the recipient

Testing to be performed depending on gender, age, or family history

a. PAP for all women

b. Mammogram for all women over 40 or according to family risk

c. Prostate-specific antigen test for all men older than 50; for all African American men older than 40, or if from a high-risk family

d. Colonoscopy for all donors older than 50 or younger according to family history

e. Chest computed tomography for those with a history of smoking

12 months post-donation, 37 of 43,882 (0.08%) donors had died. The most common reasons for death at any time were, in descending order of occurrence, unknown (47.2%), cancer (9.4%), cardiovascular disease (7.5%), motor vehicle accident (7.5%), homicide (5.7%), suicide (3.8%), hemorrhage (2.8%), infection (1.9%), and respiratory failure (1.9%).

Morbidity

During the second half of 2006, 14 of 3154 (0.4%) U.S. living kidney donors underwent reoperation before initial discharge.⁷³ The most common reasons for reoperation were bleeding and bowel obstruction. Readmission after donation was necessary for 47 of 3154 (1.5%) donors.⁷³ The most

common reasons for donor readmission were abdominal problems (nausea, vomiting, abdominal pain, constipation, bowel obstruction) and bleeding. Less frequent reasons included chylous ascites, pancreatitis, pulmonary embolism, subphrenic fluid, and infection (wound, pneumonia, urinary tract). In 2006, 86.9% of donations were performed laparoscopically.⁷³

End-Stage Renal Disease

The risk of ESRD varies according to the time after donation, the family history, and donor ethnicity. The impact of access to health care is not known. To date, on average, between 0.1% and 0.5% of living donors have developed ESRD.^{74–76}

Figure 85-3 United Network for Organ Sharing/Scientific Registry for Transplant Recipients: Living Kidney Donor Relation. Relationship of living donors to their recipients over time by year (United Network for Organ Sharing data as of December 2006).

From January 1996 through February 2007, UNOS reports that 146 previous living donors have been listed as kidney transplant candidates.⁷³ Sixty-three percent donated 16 or more years before the onset of ESRD; 8.3% donated 0 to 5 years before listing, 14% between 6 and 10 years, and 14.9% between 11 and 15 years. Donor ethnicity is reported to be white in 42.5%, black in 42.5%, Hispanic in 8.9%, and Asian in 3.4%. The causes of ESRD have been reported as follows: glomerular diseases ($N = 36$, mostly focal segmental glomerulosclerosis), hypertensive nephrosclerosis ($N = 32$), diabetes ($N = 16$), and renovascular and other vascular diseases ($N = 11$). The data reported above do not include those starting dialysis but not wait-listed for a transplant and those dying of ESRD but not receiving renal replacement therapy.

Long-Term Mortality

Most studies have found that long-term mortality after living donation is due to cardiovascular disease and cancer, identical to the general population. Indeed, of donors donating from 1999 onward in the United States, 10 have died of cancer and 8 of cardiovascular causes.⁷³ Special mention, however, must be made of other causes. Of donors donating from 1999 on in the United States, causes of death were auto accidents in eight, other trauma in four, homicide in six, suicide in four, and drug overdose in one. The last group of causes suggests a renewed focus on the psychosocial evaluation for living donor candidates and that analysis of their support systems is in order.

Evaluation

An outline of the usual donor evaluation is shown in Box 85-3 and includes blood and urine screening tests, chest radiograph, electrocardiogram, an age- and family history-appropriate cardiac stress test and cancer screening, and radiographic assessment of the kidneys and vessels. Accepted contraindications to living donation are listed in Box 85-4.

Box 85-4 Contraindications to Living Kidney Donation

Absolute Exclusion Criteria

1. Age younger than 18 years
2. Hypertension: blood pressure $> 130/90$ in someone younger than 50, evidence of end-organ damage, nonwhite, on three or more antihypertensive medications
3. Diabetes (diagnosis of diabetes)
4. Abnormal glucose tolerance test: 2-hour oral glucose tolerance test > 140
5. History of thrombosis or embolism
6. Psychiatric contraindications
7. Obesity: body mass index > 35
8. Coronary artery disease, reduced cardiac function
9. Symptomatic valvular disease
10. Chronic lung disease
11. Recent malignancy
12. Urologic abnormalities of donor kidney
13. Creatinine clearance < 80 mL/min or projected glomerular filtration rate with removal of one kidney at 80 years of age of < 40 mL/min
14. Peripheral vascular disease
15. Proteinuria > 300 mg/24 hr
16. Human immunodeficiency virus infection
17. Hepatitis C virus infection
18. Hepatitis B virus infection

Relative Contraindications

1. Age 18–21 years, older age relative to the medical condition
2. Obesity (body mass index 30–35)
3. Kidney stones
4. Distant history of cancer
5. History of psychiatric disorder
6. Renovascular disease
7. Thin basement membrane disease

Renal Function and Live Kidney Donation

The threshold of acceptable donor renal function has declined with time. In general, it would appear prudent to require living donors to have a GFR at donation at the average of the age-specific GFR.⁷⁷⁻⁷⁹ Furthermore, the estimated GFR over time should also fit the average curve for age. Thus, as the GFR decreases with age, a donor's projected GFR at age 80 should be greater than or equal to 40 to 50 mL/min/1.73 m² (www.bts.org.uk/).^{77,79}

Hypertension

The optimal evaluation of blood pressure for living donors is with 24-hour blood pressure monitoring. This allows detection of white coat hypertension as well as undetected hypertension.^{80,81} If elevated blood pressure is detected and the prospective donor is still under consideration, then a chest radiograph, electrocardiogram, echocardiogram, and ophthalmologic evaluation should be obtained to look for secondary consequences of hypertension. Preliminary evidence indicates that donation is acceptable for hypertensive individuals if they are white, blood pressure is controlled, GFR is age appropriate, and protein/albumin excretion is normal.⁸² However, more detailed information about these donors and their long-term outcomes is needed before generally accepting hypertensive individuals as donors as donors will on average have a 5-mm Hg increase in blood pressure over 5 to 10 years from donation above that anticipated for normal aging.⁸³

Donor Obesity or Family History of Diabetes

Obesity may affect perioperative complications, future renal function, and the cardiovascular health of the living donor. Obesity is a risk factor for the development of nephrolithiasis, renal cell and other cancer, as well as ESRD.⁸⁴ For ESRD, the relative risk is 3 for a BMI between 30 and 34.9 kg/m² and 4.7 for a BMI of 35 to 39.9 kg/m².⁸⁵ Obese individuals may be more prone to develop renal disease after donation. In one study, obese (BMI > 30) subjects had an increased rate of proteinuria and renal impairment 10 to 20 years after nephrectomy.⁸⁶ Despite these concerns, many programs accept the obese as living donors. Heimbach and colleagues⁸⁷ prospectively evaluated obese donors for 12 months. To date, the obese donors have not had lower GFR (by iothalamate clearance) or higher protein excretion rates compared with the normal BMI donors at follow-up. The Swiss donor registry has likewise not noted a change in albuminuria in obese donors over 5 years from donation, although one donor developed diabetes, hypertension, proteinuria, and renal failure.⁸⁸ Obesity greatly increases the future risk of diabetes, and as a consequence all obese prospective donors or those nonobese subjects with a first-degree relative with diabetes or with a history of gestational diabetes should be evaluated with an oral glucose tolerance test. This recommendation may change, however, as equations from large population studies are developed to more accurately predict the development of type 2 diabetes.⁸⁹⁻⁹¹ Abnormal glucose tolerance is a contraindication to donation.

Nephrolithiasis

Those with a history of bilateral or recurrent stones and those with systemic conditions associated with recurrent stone disease should not donate. An asymptomatic potential donor with a current single stone is suitable if the donor does not have a high risk of recurrence and the stone is less than 1.5 cm in size and is removable during transplantation.^{67,92} The evaluation of an asymptomatic donor with a single previous episode of nephrolithiasis should include serum calcium, creatinine, albumin, parathyroid hormone, and spot urine for cystine; a urinalysis and urine culture; a helical computed tomography scan; chemical analysis of the stone if available; and a 24-hour urine for oxalate and creatinine.⁹³

History of Malignancy and Infectious Disease

A history of the following malignancies excludes live kidney donation: melanoma, testicular cancer, renal cell carcinoma, choriocarcinoma, hematologic malignancy, bronchial cancer, breast cancer, and monoclonal gammopathy.^{67,94,95} A history of malignancy may be acceptable for donation if previous treatment of the malignancy does not decrease renal reserve or place the donor at increased risk of ESRD and does not increase the operative risk of nephrectomy. A history of malignancy may be acceptable if the specific cancer is curable and transmission of the cancer can reasonably be excluded; consultation with an oncologist may be required. Consent to receive a renal transplant must include a discussion with the donor and the recipient that the risk of transmission of malignant disease cannot be completely excluded.

Infection

A living donor should not be accepted if there is a history of active infection that requires nephrotoxic treatments or would put the donor at risk of developing renal disease. These infections include HIV, hepatitis C, hepatitis B, recurrent urinary tract infections, endocarditis, and malaria.^{28,67}

Venous Thromboembolism

Unless the history suggests a medical condition that would necessitate a comprehensive coagulation profile, these tests are not likely to yield useful information.⁹⁶ Previous thromboembolism is a relative contraindication to live donation and will require an evaluation of the likelihood of recurrence. Oral contraceptives and hormone replacement therapy are commonly used and present an increased risk of postoperative venous thrombosis and thus should be withheld for at least 2 months before elective surgery.^{97,98}

Renovascular Disease

Fibromuscular dysplasia is found on average in 2% to 4% of prospective donors.^{99,100} Donors with severe and diffuse disease should not be selected for donation. The age of the prospective donor should also be considered with the outcome in donors older than age 50 seemingly more predictable and benign than in younger donors.¹⁰¹

Atherosclerotic renal vascular disease is a relative contraindication to living donation. If it is present, the donor should be normotensive, have normal renal function, and have only unilateral disease.¹⁰² Careful evaluation for coronary disease and peripheral vascular disease should be undertaken given the significant correlation with renal artery stenosis.

Isolated Hematuria

Isolated hematuria in a prospective donor necessitates consideration of thin basement membrane nephropathy and IgA nephropathy as well as urinary tract infection, malignancy, and nephrolithiasis. This is a relatively common problem; a mass screening study in Japan found a single test point prevalence of 4% of adult men and 10% of adult women.¹⁰³

Some investigators have reported the development of ESRD in individuals with thin basement membrane disease.^{104,105} Currently, one approach to prospective donors with hematuria and thin basement membrane disease would be to limit selection to those older than age 50 who have the least risk and those with predictable family histories of disease and normal functional studies.^{106,107}

IgA nephropathy is a contraindication to live donation. The implications of isolated mesangial IgA without other manifestations of nephropathy require further study, and donation should be decided on in the context of family history, absolute renal function, the presence of interstitial disease, and age.¹⁰⁸ If during live donor evaluation, persistent isolated asymptomatic hematuria is detected, the work-up should include a renal biopsy because, in that setting, the biopsy specimen is often abnormal and aids the decision-making process.¹⁰⁹

Autosomal Dominant Polycystic Kidney Disease

Familial studies have shown the sensitivity of ultrasonography to be 100% in individuals at risk of autosomal dominant polycystic kidney disease who are age 30 or older.¹¹⁰ Wherever possible, linkage analysis in addition to ultrasound testing should be performed in prospective donors at risk who are younger than age 30.^{111,112} Mutation-based molecular diagnostics must still be treated with care in the clinical setting.¹¹² If linkage studies are not possible, computed tomography and/or magnetic resonance imaging may provide better sensitivity than ultrasonography.¹¹³

Cardiopulmonary Disease

Cardiac evaluations need to be performed based on the family history, personal history, physical examination, electrocardiogram, and chest radiograph. If the history, examination, and tests suggest ischemia or valvular disease, then an exercise or pharmacologic stress test and/or echocardiogram should be performed. An individual with myocardial dysfunction or coronary ischemia should not donate. Absolute contraindications to donation are symptomatic valvular disease, severe valvular disease even if asymptomatic, and valvular disease with abnormal cardiac function and/or ischemia.¹¹⁴ The possibility of valvular abnormalities should be particularly considered in family members of those with autosomal dominant polycystic kidney disease. Relative contraindications are the presence of a prosthetic valve and moderate regurgitant valvular

disease with otherwise normal echocardiographic findings. Finally, the donor with valvular disease should be informed of the risk of perioperative endocarditis even with antimicrobial prophylaxis, bleeding in those treated with anticoagulants, and thromboembolism during changes in anticoagulation.

Pulmonary contraindications to donation include chronic lung diseases that significantly increase the risk of anesthesia and hypertension.¹¹⁵ If indicated by history and examination, pulmonary function testing, echocardiography, and/or sleep studies should be performed. In all cases, donors should cease smoking for at least 4 to 8 weeks before surgery to minimize the risk of pneumonia.¹¹⁶ Optimally, donors should stop smoking permanently due to the increased risk of vascular disease, renal arteriosclerosis, and cancer.

QUALITY OF LIFE AFTER LIVING DONATION

Physical and psychological function in living donors is higher than the community norm. Physical issues reported by donors after donation frequently include a decrease from baseline in energy, whereas some note a longer time to full recovery (as long as 4 months) than they had anticipated and incision pain that lasted longer than they expected. Psychological factors usually include an improved relationship with the recipient, an improved self-image, and frequently a positive effect on their life. Even though most donors have a very positive experience, a small number do regret the decision to donate (0%–5%).^{117,118}

		MISCELLANEOUS COMPLICATIONS	974

Renal transplantation is regarded by most physicians as the preferred treatment for chronic renal failure.¹ According to the United Network for Organ Sharing, the 1-year graft survival rate for the 15,657 renal allografts (living and cadaveric donor) placed into adult recipients during 2003 to 2004 in the United States was 90%. The recipient mortality in the first year was less than 5%.² Rejection and the donor shortage are the major obstacles to the routine application of renal transplantation. As the proportion of grafts lost to rejection decreases and the value of each donor graft increases, the importance of technical perfection is magnified. Surgical skills are best exercised in the context of judicious intra- and perioperative decision making based on a thorough understanding of medicine and biology. It is equally important to evaluate and treat complications as quickly and judiciously as possible to prevent graft loss.

RECIPIENT EVALUATION

- The renal graft is usually transplanted heterotopically in the extraperitoneal iliac fossa of the pelvis. In most cases, the native kidneys are left intact. From the narrow yet important perspective of technical issues, the evaluation of the renal transplant candidate raises several questions:
- Is the domain of either iliac fossa or pelvis adequate?
- Will arterial inflow and venous outflow be sufficient?
- What is the condition of the urine-collecting system and bladder?

Most often, a careful medical history and physical examination of the candidate will provide the answers to these questions and no further anatomical studies are necessary. Examination of the abdomen may reveal surgical scars, masses, organomegaly, or abdominal wall defects that dictate the site of transplantation. In the patient with polycystic kidney disease, physical examination may reveal a large native kidney encroaching on the iliac fossa. Palpation of weak or absent femoral pulses

betrays serious vascular disease that may contraindicate renal transplantation or at the very least require further investigation. Previous surgical records should be reviewed to understand any prior vascular reconstruction. If there is any doubt as to the availability of an appropriate vascular site for anastomosis, then additional studies should be obtained (e.g., magnetic resonance angiography, computed tomography angiography, arteriography). If a patient has had multiple previous transplants, then surgical records and imaging studies should be obtained to better understand the anatomy.

Routine cystoscopy or cystography is not indicated. These studies may be of value when there is a history of voiding problems, urinary reflux, recurrent infection, or previous urologic procedures. A cystogram in a patient who has been anuric or oliguric for several years while on dialysis may demonstrate a small-capacity, noncompliant bladder. In the instance of an unsatisfactory urinary reservoir, an ileal loop or bladder augmentation may be needed before transplantation.

Bilateral native nephrectomy is seldom necessary, but indications include symptomatic polycystic kidney disease (e.g., cyst rupture, bleeding), massive vesicoureteral reflux, heavy proteinuria, persistent upper tract infection, severe renovascular hypertension, symptomatic stone disease, and renal cell carcinoma.

DONOR CRITERIA AND PROCUREMENT

Brain death standards for cadaver donors are stringent. There are accepted general donor criteria such as no extracranial malignancy or human immunodeficiency virus infection. However, given the severe donor organ shortage, general criteria are expanding. Currently the United Network for Organ Sharing national waiting list exceeds 103,000 candidates, of whom more than 75,000 are awaiting kidney transplants.³ The increasing disparity between organ supply and demand challenges the transplantation community to maximize the use of organs from all consented donors. This includes the use of

kidneys from older donors, donors with serologies positive for hepatitis C or hepatitis B core antibody, and donors with a history of diabetes and hypertension. United Network for Organ Sharing defined a specific group of these donors, known as extended criteria donors, as all deceased donors older than 60 years of age and deceased donors between the ages of 50 and 59 with any two of the following criteria: history of hypertension, cerebrovascular cause of brain death, or terminal serum creatinine level greater than 1.5 mg/dL.⁴ Concerns about the need to assess these kidneys before transplantation have led to initiatives to use *ex vivo* biopsies and machine-preservation technology. Microscopic analysis is used to determine tubular, interstitial, and vascular changes.

There are other donor kidneys that can be included in this category of extended criteria donors that do not fit the United Network for Organ Sharing definition, but with judicious selection can be transplanted. This includes small pediatric donors (<15 kg) whose renal mass may be considered insufficient—considered extended criteria grafts. The controversy about how to use these grafts centers on whether to transplant them as an *en bloc* transplant or as single grafts. Using 6-cm length and donor weight of more than 14 kg as basic variables for the ability to split the graft seems to improve the results of these donor grafts.⁵ Another large group of donors are non-heart beating organs that are procured as a result of donation after cardiac death. These donors are usually individuals with devastating irreversible neurological injuries who do not meet formal brain death criteria. Despite ethical controversies surrounding this type of organ donation, the contribution of organs from donation after cardiac death has grown rapidly and the organs, when chosen appropriately, function well.⁶

Once a deceased donor kidney is recovered, there are two methods of preservation: simple cold hypothermic storage and pulsatile preservation. Pulsatile perfusion involves an *ex vivo* hypothermic pulsatile perfusion machine that delivers oxygen and nutrients through a specialized preservation solution to the kidney and removes waste products in an attempt to mimic circulation, thereby preserving endothelial and parenchymal integrity and reducing vasospasm. Some initial data suggest that pumping kidneys decreases the rate of delayed graft function, especially in extended criteria donors. In addition, pump parameters (i.e., flow rates and resistance) can be used in determining the appropriate use of a kidney.⁷

The length of cold ischemia time becomes a factor in organ preservation as well. A time interval up to 24 hours is generally considered to be appropriate, although there are widely differing opinions among centers, with a few centers routinely transplanting organs with 30 to 48 hours of cold time. Most literature suggests that ischemia beyond 24 hours is particularly detrimental, although the increased risk of graft failure associated with this prolonged ischemia is on average only approximately 10%, but with much higher rates of delayed graft function.⁸ Kidneys obtained from elderly or extended criteria donors are particularly sensitive to effects of prolonged ischemia. Pulsatile perfusion appears to minimize or ameliorate the delayed graft function observed with longer ischemia time.

The retrieval of cadaver donor kidney grafts is usually one component of a complex multiple organ procurement. A common technique employed is *in situ* perfusion using iced preservation solution and *en bloc* removal of both kidneys based on the aorta and inferior vena cava. Multiple arteries are

found in approximately 20% of donors. During procurement, care is taken to leave multiple arteries intact. In a cadaver donor, renal arteries can be centered on a Carrel patch of donor aorta to facilitate the arterial anastomosis. The hilum of the renal graft is not disturbed to avoid injuring arterial arborizations. Because the arterial blood supply to the kidney is segmental, inadvertent ligation of a polar artery, for example, creates a discrete infarct. If the vessel supplies the upper pole, a small scar of little consequence may result. Conversely, a lower pole vessel is important because it supplies the ureter. A devascularized ureter will necrose and leak or fibrose and obstruct. To ensure good vascularization of the graft ureter, the procurement surgeon leaves a “fan” of investing periureteral tissue.

With a live donor, the surgeon has the advantage of preoperative imaging of the renal vasculature. Arteriography, computed tomography angiography, or magnetic resonance angiography will identify multiple vessels or an early bifurcation of the renal artery. Gadolinium-enhanced magnetic resonance angiography is an attractive choice because it is minimally invasive, has multiplanar capability, and is able to evaluate the renal parenchyma and the vascular anatomy without using iodinated contrast media and does not expose patients to radiation.⁹ If both kidneys have a single artery and vein, the left kidney is preferred because of the longer vein and technical ease of approach. A longer vein facilitates the implantation and the donor nephrectomy, particularly if the surgery is performed laparoscopically. In addition, technical considerations, including the need to retract the liver and the increased number of lumbar veins, make laparoscopic right-side nephrectomy more challenging. At one time, the right side was used as a last resort, but more recently, many groups have endeavored to better define the indications for selecting one kidney over another for donation (e.g., renal vascular abnormalities). Studies show that ischemia time is similar for both sides, and all kidneys had adequate vein length.¹⁰ A guiding principle is that if there is a defect, the live donor is left with the more perfect kidney. In addition, laparoscopic donor nephrectomy is being extended to donors with multiple renal arteries with no difference in warm ischemia time, donor morbidity, or graft outcome.¹¹

TRANSPLANTATION

General endotracheal anesthesia is induced with the patient in the supine position on the operating table.¹² A urinary balloon catheter is inserted. The bladder can be filled with antibiotic solution, which is left indwelling, or the Foley catheter can be attached to a Y-connector and irrigation system so the bladder can be filled. Intraoperative monitoring may include a central venous pressure catheter, pulse oximetry, and/or arterial blood pressure line. A curvilinear incision is made in either the right or left lower abdomen. The extraperitoneal iliac fossa is used because of the presence of the iliac vessels and its proximity to the urinary bladder. The transplant is protected by the iliac bone posterolaterally and the abdominal musculature anteriorly, yet the graft is superficial enough for percutaneous biopsy. The right side is generally preferred because the external iliac vessels are more superficial on this side. In theory, the renal graft can be transplanted anywhere that there is a suitable recipient artery, vein, and urine conduit or reservoir.

Three layers of the abdominal wall, the external oblique, internal oblique, and transversus abdominis, are divided to afford access to the iliac fossa. The inferior epigastric vessels are divided, and a long stump of the inferior epigastric artery is preserved in case its use may be necessary in a separate anastomosis to a lower pole renal artery. The spermatic cord is preserved in men, and in women, the round ligament is divided. The diaphanous peritoneal membrane is rolled medially off the external iliac vessels. Lymphatic channels that overlie the iliac vessels are divided to expose the artery and vein. These channels are ligated to prevent lymphatic leaks, lymphocele formation, and subsequent ureteral obstruction or iliac vein compression. It is common practice to anastomose the transplant artery end to side on the external iliac artery. If multiple arteries are present, they can be reconstructed in several ways. They can be syndactylized, the inferior epigastric artery can be used as mentioned earlier, or they can be sewn in on a common aortic patch. The renal vein is routinely sewn to the side of the external iliac vein. The left donor kidney is generally preferred because of its longer vein; however, a short right renal vein of a deceased donor kidney can be extended using the attached inferior vena cava.¹³ In the case of multiple draining renal veins, the decision of whether to implant both veins separately, leave them on a common caval patch, or ligate the smaller of the veins must be made. Because venous drainage is not segmental, unlike arterial inflow, it is usually safe to ligate smaller veins.¹⁴ The clamps are then removed and reperfusion begins. The time that transpires between removing the graft from ice and reperfusion with oxygenated blood is known as the warm ischemia time. This period ranges from 20 to 45 minutes. Warm ischemia time longer than 45 minutes is associated with increased incidence of delayed graft function, and longer than 60 minutes may promote primary nonfunction.

Urinary drainage from the renal graft is established by surgically connecting the graft ureter to the bladder. The ureteroneocystostomy is usually accomplished via the extravesical approach, whereby the spatulated end of the transplant ureter is sewn to the bladder, mucosa to mucosa, after incision through the detrusor muscle. The detrusor muscle is then reunited to buttress the anastomosis and create an antireflux valve (an extravesical Lich-Gregoir ureteroneocystostomy.) A double pigtail ureteral stent is sometimes placed to prevent ureteric complications. The stent is then endoscopically removed several weeks later. There are complications associated with stents as well, namely, an increase in the incidence of urinary tract infections, calcification, and stent migration. As a result, studies now support a practice of selective stenting based on the surgeon's judgment (e.g., for anastomoses that are technically difficult, a contracted bladder, or friable mucosa).¹⁵ In addition, stent removal requires a second procedure that not only increases cost, but can also be a source of morbidity. Other techniques of ureteral drainage include tunneling of the graft ureter via cystotomy (Leadbetter-Politano), modifications of the Lich technique using a tunnel but with an extravesical approach, and sewing of the native ureter to the transplant renal pelvis (ureteropyelostomy). After meticulous hemostasis is achieved, the wound is closed in two layers. A drain can be placed if necessary. Depending on the patient's body habitus, the operation lasts for 2 to 4 hours. Postoperatively, the Foley catheter remains in place for 2 to 5 days. If the

patient has difficulty voiding spontaneously and bladder urodynamics are markedly abnormal, the bladder may be used as a passive reservoir coupled with intermittent self-catheterization after transplantation.

Some variations on the standard operation deserve special mention. The first is the use of dual-kidney transplantation, where two aged adult kidneys (which were turned down as single transplants) are placed into an adult recipient, as a way to help alleviate the continued organ shortage. The two kidneys are generally implanted as separate transplants on the same side but may be implanted in opposite iliac fossae. Recipients of these transplants have been shown to have acceptable long-term graft survival.¹⁶ It is important to reduce cold storage time when using aged kidneys for dual transplantations to reduce the incidence of delayed graft function.

Patients who have undergone more than one transplantation were once considered to be at higher risk of graft failure than first graft recipients, but retransplantation survival rates have improved substantially as a result of improved pretransplantation screening and posttransplantation management. Recipients of a third or subsequent graft constitute a unique population because of the previous manipulation of two iliac fossae for previous transplants and frequently the removal of earlier grafts. This results in surgical challenges for retransplantation, mainly in vessel and bladder dissection due to scarring from previous surgery.¹⁷

There are several additional considerations for pediatric recipients. In children, the relative size discrepancy between the graft and the recipient may dictate placement of the renal transplant intraperitoneally with anastomosis to the aorta and inferior vena cava.¹⁸ In particular, children weighing less than 15 kg present a challenging subgroup. The size discrepancy can be troublesome during abdominal closure, and these small patients are at high risk of kinking and obstruction of graft vessels or abdominal compartment syndrome. Even with maximum intravascular volume, an adult kidney transplanted into an infant or small child cannot achieve more than two thirds of the blood flow present in the donor. Therefore, it is imperative to maintain optimum intravascular volume in the intraoperative and postoperative periods.¹⁹ Bladder dysfunction can pose a great challenge in the pediatric population as well. If the pretransplantation evaluation reveals a contracted, noncompliant bladder, a urine reservoir can be established with an ileal loop or bladder augmentation with a segment of intestine. A final consideration in pediatric recipients is the high occurrence of graft loss secondary to vascular thrombosis. Increasingly, centers are now testing for thrombophilias and anticoagulation in patients perioperatively with good results.²⁰

SURGICAL COMPLICATIONS

Wound Complications

Wound infection is the most common complication after renal transplantation. Contributory factors include obesity, diabetes, uremia with protein malnutrition, and immunosuppression. Typically, the characteristic findings of fever, local erythema, swelling, and drainage present 4 to 7 days after surgery. However, it is important to remember immunosuppressed patients may not manifest the same signs and symptoms, and one must have a higher level of suspicion for wound and abdominal infections.

For infection confined to the subcutaneous space, treatment consists of opening the skin to allow drainage, followed by local wound care measures such as packing until the wound heals. Antibiotics are usually warranted, and antibiotic selection depends on the culture results. If there is suspicion of a subfascial abscess, an ultrasound study or the removal of fascial sutures will demonstrate deep involvement. Drainage of clear fluid from the wound is common, especially in obese patients. Placement of a collection bag allows the determination of fluid creatinine to distinguish urine (from a urine leak) from serum (lymphatic leak or draining seroma). A seroma, a subcutaneous collection of tissue fluid, can be left alone to resolve with time or can be drained either by repeated needle aspiration or drain placement. The approach depends on the clinical circumstances. Dehiscence of the transplant wound is unusual. However, the inhibition of wound healing from the malnutrition of chronic renal failure, steroids, or sirolimus may contribute to fascial disruption. Dehiscence requires emergent reoperation and reclosure.

Vascular Thrombosis

The prevalence of thrombosis of the transplant artery or vein is 1%. Clinically, acute anuria raises the concern of graft thrombosis. Hyperacute rejection can result in thrombosis, but faulty technique is usually responsible. Technical problems include intimal dissection, especially in recipients with long-standing diabetes or hypertension; kinking of the artery or vein from malpositioning of the graft; torsion of the vessels; and narrowing of the anastomosis. Doppler ultrasonography or radionuclide scanning shows greatly decreased or no flow to the graft. If the index of suspicion for thrombosis is high, for example, an uneventful live donor graft that does not diurese postoperatively, the patient should be taken back to the operating room for immediate exploration. Arteriography is seldom of value and delays surgical exploration. At exploration, arterial thrombosis is suggested by a small, pale kidney; with venous thrombosis, the kidney transplant is blue, swollen, and sometimes bleeding from a fracture. Thrombectomy and graft salvage have been reported, but warm ischemia that lasts more than 45 to 60 minutes results in irreversible injury. When the vascular compromise is incomplete (e.g., venous kinking), the chance of salvage is improved, but a prolonged delay in graft function can be expected. Protracted warm ischemia or primary nonfunction of a graft mandates transplant nephrectomy.

It is imperative to consider risk factors for vascular thrombosis in the recipient evaluation. One must consider and test when appropriate for the presence of an inherited hypercoagulable state such as patients with previous deep vein thrombosis/pulmonary embolism, multiple vascular thromboses, spontaneous abortions, end-stage renal disease due to lupus or hemolytic uremic syndrome. Interventions to decrease the thrombotic risk including heparin, warfarin, and aspirin have been evaluated and appear to decrease the risk of renal allograft thrombosis significantly.²¹

Bleeding

Characteristically, “surgical” bleeding, requiring a return to the operating room, presents in the early postoperative period with tachycardia, hypotension, and, after volume resuscitation, decreasing hematocrit. Bleeding is more likely in renal transplant recipients than in normal patients because of decreased

platelet adhesiveness secondary to uremia. Some surgeons fully heparinize renal transplant recipients, and this practice may contribute to bleeding. A decreasing hematocrit in the early postoperative period should not be ascribed to “medical” causes. Correction of clinically significant bleeding is amenable only to re-exploration. A bleed at the vascular anastomosis or a vessel in the graft hilum is often the culprit. Mild hematuria that resolves without intervention is not uncommon.

Urine Leak

The prevalence of urine leak is approximately 2%. A large urine leak at the ureter-to-bladder anastomosis due to a technical flaw results in a rapid decrease in urine output in the early postoperative period. Ureteral necrosis and leak may be due to procurement errors (e.g., degloving) or ischemia from rejection-induced vasculitis and thrombosis of periureteral blood supply. Labial or scrotal edema may occur. Clear fluid from the wound may be distinguished from the more common finding of a draining seroma by creatinine determination. Patients frequently complain of abdominal, pelvic, or rectal discomfort or pain from the inflammation of extravasated urine. A urine leak can be confirmed by a radionuclide scan showing extravasation of “hot” tracer outside the confines of the collecting system.²² If ultrasonography demonstrates a fluid collection, the collection is tapped and the fluid analyzed for creatinine to make the diagnosis of urinoma. Emergent exploration is the treatment of choice for a urine leak. Treatment of a leak with interventional radiologic techniques such as percutaneous nephrostomy and drain placement is successful only for small leaks at the ureteroneocystostomy. Although these techniques are helpful for diagnosis or as a temporizing measure in patients who are unfit for surgery (e.g., untreated urinary infection), the definitive solution is surgery. Reconstruction of the ureter may involve reimplantation after cutting back to well-vascularized tissue. If the transplant ureter is too short to reach the bladder, the bladder may be extensively mobilized and fixed superiorly to the psoas muscle, a psoas “hitch”; the distal native ureter may be sewn to the transplant pelvis, or a tube can be fashioned from the bladder wall (Boari flap) to bridge the gap. After reconstruction, both a ureteral stent and a drain are placed to allow egress of urine until the urinary mucosa heals watertight. The drain is removed when output ceases, and the stent is cystoscopically removed at approximately 4 to 6 weeks.

Obstruction of the Collecting System

Obstruction occurs in approximately 2% of renal transplants. Blockage of urine flow in the early postoperative period may be the result of technical misadventure in the construction of the ureteroneocystostomy, such as a too-tight antireflux tunnel, or a problem with the graft ureter, such as a twist, entrapment by the spermatic cord, or an extrinsic compression by a hematoma or urinoma. Weeks to months after transplantation, ultrasonographic investigation of an elevated serum creatinine value may reveal a dilated urine collecting system due to ureteral stricture, stone disease (either de novo, retained, or of donor origin), fungus balls, shed tissue from papillary necrosis, or lymphocele. After percutaneous needle biopsy, hemorrhage can fill the pelvis with clot, but the thrombolytic effect of urokinase in urine makes obstruction

of the collecting system unusual. Ischemia and acute rejection of the ureter are the most frequent causes of ureteral stricture in adults; however, ureteritis and subsequent ureteral strictures can also be the result of a viral infection. Cytomegalovirus and human polyoma BK virus have both been implicated in the development of stricture formation.

When a dilated transplant ureter with mild to moderate hydronephrosis is seen, the urodynamic significance of the findings may be uncertain. If renal transplant function is only mildly impaired, a furosemide washout radionuclide study may be helpful. An antegrade pyelogram provides the best image and can be converted to a percutaneous nephrostomy to decompress an obstructed system. If there is a clinically significant obstruction, there will be a postobstructive diuresis and decrease in the serum creatinine. In equivocal cases, a Whitaker test or manometric study of urodynamics can be performed by saline infusion through the percutaneous nephrostomy. If there is obstruction, the pressure in the manometer will increase steadily as saline is infused. If ultrasonography reveals the collecting system to be massively dilated, the patient should be scheduled for definitive decompression. Decompression can be accomplished by percutaneous, endourologic, open surgical approaches, or a combination of modalities. Percutaneous decompression with percutaneous nephrostomy is often the first step in relieving obstruction and further defining anatomy and cause for a more definitive and durable repair. Endourologic management of transplant ureteral stenoses with balloon dilatation or Acucise endoureterotomy are used. After either procedure, indwelling stents are left in place and removed cystoscopically at 6 to 8 weeks. These methods, if successful, can avoid the morbidity of open revision.²³ However, disruption of the ureter and recurrent strictures can occur with both methods. Furthermore, stenting introduces a foreign body that may be a nidus for encrustation, stone formation, or infection. Often the best approach is surgical correction. This is usually carried out either by graft ureteral reimplantation into the bladder or by rerouting of urine from the transplant into the native ureter by ureteroureterostomy or pyeloureterostomy. In constructing either bypass, the native kidney does not have to be removed; rather, the proximal native ureter is ligated and residual function is shut down by the resultant hydrostasis.²⁴

Vesicoureteral Reflux

Voiding cystography in transplant recipient demonstrates a reflux rate of 2% to 6%. Whether urine reflux per se damages a renal transplant is debatable; what is not debatable is the deleterious effect of reflux when infection is present. Antibiotic suppression of urinary tract infection will decrease the incidence of graft pyelonephritis, but if infections recur, a revision of the ureteroneocystostomy or conversion to transplant-to-native ureteroureterostomy is indicated to eliminate reflux. A newer approach is the endoscopic correction of vesicoureteral reflux with subureteral injections of Deflux (dextranomer microspheres in sodium hyaluronic acid solution.) This substance is biodegradable and has no immunogenic properties and no potential to cause malignant transformation. Most of the available data are in nontransplant pediatric patients with reflux, but show a 69% success rate for endoscopic treatment versus a 38% success rate for antibiotic prophylaxis after 1 year of treatment. Although open surgery achieves a success rate of

92% to 98%, it is an invasive procedure and is not free of complications, especially in transplant recipients. An important advantage of endoscopic treatment is its easy repeatability in cases of failure after the first injection.²⁵

Lymphocele

Transected lymphatic channels that course over the iliac vessels may leak lymph and develop into a lymphocele, a cystlike collection of lymph that may impinge on the graft ureter. The standard treatment for lymphocele is surgical fenestration of the peritoneum. A window is created in the lymphocele wall via the laparoscope or open surgery to allow lymph to drain into the peritoneal cavity, where it is absorbed. A lymphocele can also be treated by sclerosis with iodine or caustic antibiotic preparation (e.g., tetracycline) to obliterate the cavity.

Transplant Renal Artery Stenosis

Typically, transplant renal artery stenosis (TRAS) usually occurs months after transplant surgery. The prevalence of this disorder has varied in the literature, ranging from 1% to 23%. This discrepancy has been ascribed to several factors: The definition of hemodynamically significant TRAS has not been standardized, and the ready availability of noninvasive screening modalities, such as color Doppler ultrasonography and magnetic resonance angiography, may lead to increased pursuit of this diagnosis.²⁶ The diagnosis is suggested by hypertension that is intractable to an escalating regimen of antihypertensive drugs. On physical examination, a bruit may be heard over the transplant, but this finding is nonspecific. The cause of TRAS is multifactorial and includes surgical technique during organ removal and transplantation, acute rejection, delayed graft function, and cytomegalovirus infection.²⁷ TRAS often has an insidious onset. Angiography is the gold standard in diagnosis, and if TRAS is present, percutaneous transluminal angioplasty can be carried out concurrently. The treatment of TRAS with both surgical and endovascular techniques has been evaluated in multiple studies. Surgical correction has a 66% to 90% initial success rate with a 12% recurrence rate. The reported success rate with percutaneous transluminal angioplasty is lower, but has improved in more recent studies, with a similar recurrence rate. Percutaneous transluminal angioplasty is favored as the first-line treatment because of the technical demand of an open repair with the risks of allograft loss, ureteral injury, and surgical mortality.²⁶ TRAS is associated with a significant decrease in long-term allograft survival, but it is still unclear as to whether this is due to the stenosis, the repair, or the factors that predisposed to the condition.²⁷ TRAS can be mimicked by stenosis of the proximal iliac artery ipsilateral to the renal transplant or an arteriovenous fistula after a needle biopsy.^{28,29}

MISCELLANEOUS COMPLICATIONS

Leg edema ipsilateral to the graft is common owing to ligation of lymphatics and/or compression of the external iliac vein by the graft. The diagnosis of deep venous thrombosis may be entertained, and a Doppler study or venography may be indicated. Neurapraxia of the femoral nerve is rare and may result

from retractor trauma or ischemia. Patients with preexisting diabetic neuropathy are particularly susceptible. Femoral nerve injury is manifested by the inability of the supine patient to lift the leg off the bed. Restoration of function, assisted by physical therapy, takes several weeks.

Understanding the basis of transplant immunology is required to comprehend the role of the tissue typing laboratory in managing potential transplant recipients, to understand the mechanisms of immunosuppression, and to be able to appropriately detect and diagnose acute or chronic rejection. The chapter begins with a general overview of the immune response, focusing on those aspects that are important to understand the logic behind the clinical use of immunosuppressive drugs. We then outline clinically relevant characteristics of individual immunosuppressive agents currently used, as well as new immunosuppressive medications, focusing on mechanisms of action, interactions, and toxicities of individual medications. We then provide a rationale for the current immunosuppressive protocols and summarize relevant clinical trials.

BASIC TRANSPLANT IMMUNOLOGY

Components of the Immune System

The human immune system can respond to a nearly infinite range of foreign antigens by generating and maintaining immune responses that are rapid, antigen specific, and protective. The cardinal features of the adaptive system are specificity to antigenic diversity, memory, and tolerance of self.^{1,2} The adaptive immune system is composed of cellular (T cells) and humoral (B cells/antibodies) components. T cells are derived from the thymus and play a central role in cellular immunity. They can be divided into subsets of CD4 and CD8 T cells and can recognize antigens presented by the major histocompatibility complex (also called HLA), through T-cell receptors

(TCRs) expressed on their cell surface. B cells express a highly specialized form of antigen receptors, surface immunoglobulins, and are the precursors of plasma cells, which can secrete a soluble form of immunoglobulin, the antibody. In addition to the adaptive system, the mammalian immune system consists of innate components. There are important interactions between the two systems. Innate immunity is composed of a series of nonpolymorphic proteins (e.g., defensins, cytokines, Toll-like receptors, and complement) and cells (e.g., macrophages, dendritic cells, natural killer cells, and neutrophils).

Recognition of Alloantigen

The highly polymorphic HLA loci are the primary targets of the alloimmune response.^{3,4} Class I HLA molecules (HLA A, B, and C) are expressed on essentially all somatic cells and are recognized by CD8 T cells. Class II HLA molecules (HLA DR, DP, and DQ) are recognized by CD4 T cells and are found predominantly on a few specialized cell types, including macrophages, dendritic cells, and B cells, which are called professional antigen-presenting cells (APCs).

Humoral Alloimmunity

Alloantibodies are produced by alloreactive B cells specific for HLA molecules and participate in transplant injury. Alloreactive B cells recognize allogenic HLA molecules through surface-bound IgM receptors but require second costimulatory signals (e.g., CD40/CD154) for full activation and differentiation into antibody-secreting plasma cells.^{1,2} Donor-specific anti-HLA antibodies (DSAs) can be present in a patient before transplantation due to sensitization through a previously failed allograft, blood transfusion, or pregnancy. In rare circumstances, they may have developed a cross-reactive antibody because of underlying autoimmune disease or an environmental agent mimicking the structure of an HLA molecule. The presence of pre-transplant DSAs can predispose kidney transplant recipients to hyperacute rejection of the allograft as well as acute or chronic antibody-mediated rejection. Blood group antigens are other targets for the antidonor humoral immune response. Natural antibodies against these antigens cause complement-mediated hyperacute rejection, generally precluding transplant across ABO differences, but transplantation can be performed in infants, before natural development of the antibodies or after desensitization protocols, which is discussed in the section “Immunosuppression and Sensitization.”⁵

Cellular Alloimmunity

Initial recognition of alloantigen predominantly occurs in secondary lymphoid organs as recipient T cells interact with antigens derived from the donor. The primed T cells then migrate back to the allograft where they re-encounter antigen and mediate their effector functions.⁶ Alloreactive T cells recognize major histocompatibility complex–peptide complexes via two distinct pathways: the direct and the indirect allorecognition pathways.⁷ Direct refers to recipient T cells recognizing donor major histocompatibility complex on donor APCs, and indirect presentation refers to the recognition of the donor alloantigen presented within the groove of recipient major histocompatibility complex on recipient APCs. As donor APCs migrate out of the allograft over time and are replaced by infiltrating recipient APCs, indirect

recognition may be the dominant effector pathway within the allograft.⁸ Successful initiation of an adaptive immune response depends on two major signals being delivered to the T cell: (1) antigen-specific recognition via the TCR and (2) a costimulatory signal. The costimulatory signal results from the interaction of a receptor–ligand pair (one on the T cell and the other on the APC) that, in conjunction with TCR ligation, induces T-cell activation, proliferation, and differentiation. Without costimulation, T cells may undergo apoptosis (deletion) or become unresponsive to future encounters with the antigen (anergy). The best characterized costimulatory pathways involve the T cell membrane-bound molecules CD154 (CD40L) and CD28 and their APC-expressed cognate ligands CD40 and CD80/CD86 (B7.1/B7.2).^{9,10} A high-affinity variant of cytotoxic T lymphocyte (CTL) A4 immunoglobulin (blocks the CD28 and CD80/CD86 interaction), named LEA29Y (belatacept), is in clinical trials (see “New Immunosuppressive Medications”).¹¹ If a T cell receives a signal through both the TCR and the second costimulatory signal(s), then a number of intracellular activation steps ensue. A calcium flux activates the intracellular molecule calmodulin and allows it to bind to a calcium-binding protein called calcineurin (the target of cyclosporine and tacrolimus). This activates a phosphatase followed by a number of downstream reactions that lead to binding of the transcription activating factor nuclear factor of activated T cells to the interleukin (IL)-2 promoter. As a consequence, up-regulation of IL-2 gene expression occurs followed by synthesis and release of this potent T-cell growth factor. Full T-cell activation leads to up-regulation and expression of the high-affinity α chain of the IL-2 receptor (CD25) on the surface of the T cell (the target of anti-CD25 monoclonal antibodies). The synthesized and released IL-2 acts in an autocrine and paracrine manner and binds to the up-regulated IL-2R. Signaling through the IL-2R then initiates another (kinase-dependent) cascade mediated in part through a protein called mTOR (mammalian target of rapamycin, the therapeutic target of the drug sirolimus). This results in translation of new proteins and allows the cell to progress from the G₁ phase to the S phase of the cell cycle, resulting in proliferation. Azathioprine and mycophenolic acid (MPA) are inhibitors of DNA synthesis and thus inhibit T-cell activation at this stage.

T-cell activation induces differentiation, which can have many manifestations, as reflected by the variety of different T-cell subsets, referred to as T-helper cells (Th)1, Th2, Th17, and T regulatory 1. These phenotypes primarily refer to the pattern of cytokines produced by the activated T cells. In general, Th1 cells secrete interferon- γ and tumor necrosis factor α and Th17 cells secrete IL-17, which lead T-cell traffic to sites of inflammation, facilitate ongoing inflammation at those sites, and promote destructive T-cell immunity, whereas T regulatory 1 phenotypes secrete transforming growth factor β and IL-10 and are associated with T-cell regulation and tolerance. Although such categorizations have utility, the pattern of cytokine production does not necessarily correlate with outcome: Th2 immunity can be associated with rejection, and interferon- γ , the prototypical Th1 cytokine, is required for tolerance in mice.¹²

Effector Mechanisms

In this phase of the immune response, activated effector cells, including T cells, B cells, natural killer cells, and macrophages, migrate to the site of original antigen encounter and use a

combination of mechanisms to kill and/or neutralize their targets. In the case of cellular immune responses, the primary mediators are CTLs, macrophages, and selected cytokines produced in the local microenvironment. CTLs, primarily major histocompatibility complex class I–restricted CD8 T cells, kill their targets through direct cell-cell contact by one of two means. The first method uses proteins such as perforin and granzyme B, which are contained in secretory granules of the CTL. These proteins can create pores in the membranes of the target cells and trigger a cascade that results in cell lysis. Once inside the cell, these serine proteinases proceed to cleave the precursors of caspases, activating them to cause the cell to self-destruct by apoptosis (programmed cell death). Fas ligand/Fas provides another means of destroying target cells. Fas ligand is a membrane-bound effector molecule on CD8 T cells and binds to Fas, which is expressed on the graft cells. Activation of Fas, a member of the tumor necrosis factor receptor family, induces apoptosis. In each case, CTLs are antigen specific, meaning that they only kill selected targets after recognition of the antigen and activation through its TCR. Unlike CTLs, macrophages are antigen nonspecific and can kill their target cells by phagocytosis or by soluble factors such as reactive oxygen intermediates, proteases, and tumor necrosis factor. In the case of the humoral immune response, the primary mediators are alloantibodies and complement. Antibody-induced activation of the complement cascade via the classic pathway can induce acute organ damage and intravascular thrombosis. The resultant complement by-products (i.e., C3a and C5a) also act as chemoattractants for additional inflammatory cells. C4d is one split product that is released by the complement activation cascade, and C4d staining of human kidney transplant biopsy specimens has become the primary method for assessing whether antibodies are participating in the antibody-mediated rejection process.

CLINICAL APPLICATION OF TRANSPLANT IMMUNOLOGY

Tissue-Typing Techniques

To define class I and II HLA molecules, the serological microcytotoxicity test has been the standard test for HLA typing since 1964. Currently, DNA-based tests are the method of choice due to their greater accuracy, sensitivity, and specificity. These polymerase chain reaction–based assays use oligonucleotide primers that define a unique HLA locus, allele, or group of alleles.

Detection of Anti-HLA Antibodies

Sera from prospective transplant recipients are routinely screened for the presence of HLA antibodies to determine the extent of HLA alloimmunization. The screening is performed against a panel of 30 to 60 cells, representing most antigens encountered in the general population, using a form of complement-dependent cytotoxicity (CDC) assay. Lymphocytes from a panel of donors are mixed with sera of the recipient, and complement is added to determine whether the recipient has antibodies that bind to donor cells and activate complement and the membrane attack complex leading to cell death. The results are reported as the percentage of panel cells that

are killed by reacting with the HLA antibodies in a patient's serum, thus the term PRA (panel reactive antibody). The CDC method is a nonspecific test, and positive results indicate the existence of antidonor antibodies in the recipient's sera, but depending on the nature of the cells used in the panel, it may be possible to determine the anti-HLA antibody specificity. The solid-phase assays, enzyme-linked immunosorbent assays (ELISA), or flow cytometry bead–based assays (Flow Specific Beads and FlowPRA [Luminex, Canoga Park, CA] which are purified HLA antigens coupled to microparticles) are the most specific and sensitive tests to identify anti-HLA antibodies.¹³

Crossmatch Methods

After Patel and Terasaki¹⁴ reported in 1969 that 80% of the kidneys transplanted into crossmatch-positive patients were lost within 2 days, a CDC assay became obligatory before kidney transplantation. There are two types of CDC crossmatch that depend on the type of donor lymphocytes used (T and B cells). A positive T-cell CDC crossmatch is an absolute contraindication to kidney transplantation. Further modifications have been introduced in the crossmatch technique to increase the sensitivity, such as extending the incubation time to add wash steps to eliminate anticomplementary factors and unbound serum (Amos CDC crossmatch) or to add antihuman globulin (AHG) to detect low-titer anti-HLA antibodies (AHG CDC crossmatch), where antihuman globulin binds to antidonor antibody already bound to lymphocytes.¹⁵ Antihuman globulin CDC assay is now the standard lymphocytotoxicity assay in most tissue-typing centers. IgG-type anti-HLA antibodies are the most detrimental immunoglobulins to the allograft. IgM type antibodies are mostly non-donor-specific antibodies and can be removed by heating or treating the serum with the reducing agent dithiothreitol. However, not all IgM antibodies are benign, and donor-specific IgM anti-HLA antibodies can be detrimental to the allograft.

The flow cytometry crossmatch (FCXM) was introduced in 1983 and detects DSAs independent of complement fixation. Patient sera are incubated with donor lymphocytes and stained with fluorescence-labeled anti-CD3 (T cell) and anti-CD19 (B cell). Flow cytometry may detect very low titers of either complement-fixing DSAs or noncomplement-fixing DSAs as well as non-HLA–related antibodies. It is a sensitive test but lacks specificity. To confirm the specificity of a positive FCXM, specific solid phase assays should be done to determine the specificity of the alloantibody. Another problem with interpreting the results of a positive FCXM on allograft outcome is that the technique does not discriminate between cytotoxic and noncytotoxic antibodies.

The clinical significance of CDC B-cell or flow cytometry T or B cell–positive crossmatches is controversial. A positive CDC or FCXM B-cell may indicate anti–class II, weak anti–class I, or anti-immunoglobulin antibodies, which are abundant on B cells. Most positive B-cell crossmatch results are due to low-affinity and low-titer IgM antibodies, which do not harm the graft, but there are some reports of poor graft outcome in recipients with positive CDC B-cell crossmatches. The main reason for the controversial outcomes in the literature is the lack of studies to confirm DSAs. A recent study using a combination of tests to demonstrate DSAs by CDC, ELISA, and flow cytometry showed that the majority of B cell–positive crossmatches were

not due to DSAs. Although B cell–crossmatch positive patients with anti-HLA II antibodies had lower allograft survival, patients without DSAs have a graft survival similar to that of B-cell crossmatch–negative controls.¹⁶ The Fc receptors on B cells bind IgG nonspecifically and may lead to a false-positive crossmatch result. Using pronase to cleave Fc receptors from B-cell surface might decrease those false-positive results.¹⁷

Most studies have linked T-cell FCXM positivity to increased acute humoral, cellular, or chronic rejection and decreased allograft survival. Gebel and colleagues¹⁵ reviewed the previous studies that investigated the effect of positive FCXM results on allograft survival and reported that although 20% of primary grafts and 60% of regrafts were lost within 3 months if the FCXM was positive, those rates were only 5% and 15%, respectively, with FCXM negative results.

IMMUNOSUPPRESSIVE MEDICATIONS

The mechanisms of actions, dosing, and side effects of immunosuppressive agents used in kidney transplantation are summarized in Figure 87-1 and Table 87-1.

Induction Agents

Induction agents are polyclonal lymphocyte–depleting antibodies (Thymoglobulin), monoclonal lymphocyte–depleting antibodies (alemtuzumab), or monoclonal nondepleting antibodies to IL-2R (basiliximab and daclizumab) that are given during the early peritransplantation period to decrease the risk of delayed graft function (DGF) and acute rejection, which are major factors adversely affecting graft outcome. Induction treatments are given mostly to immunologically high-risk patients (high PRA, crossmatch positive, retransplant, African American, pediatric, combined kidney/pancreas or pancreas transplant recipients), deceased donor recipients, and patients

at higher risk of developing DGF and patients receiving early steroid withdrawal. Some centers use induction treatment in all transplant recipients other than HLA-identical pairs.

Polyclonal Lymphocyte–Depleting Antibodies

Polyclonal antibody preparations are IgG fractions isolated from serum of animals (rabbits or horses) immunized against human lymphocytes. The antigenic preparation used may be human thymocytes (thymoglobulin, lymphocyte immune globulin [Atgam]), or activated human T-cell line (ATG-Fresenius), and the antibodies are directed to a wide variety of T- and B-cell antigens, natural killer cell surface antigens, and adhesion and costimulatory molecules. These antibodies are also used for the treatment of acute rejection.

Mechanism of Action

The exact mechanism of action is not fully understood, but polyclonal lymphocyte–depleting antibodies work by binding to peripheral lymphocytes, blocking their function and targeting them for destruction. Shortly after administration, these preparations lead to lymphocyte depletion via complement-mediated lysis, removal by the reticuloendothelial system, and antibody-dependent cell-mediated cytotoxicity (ADCC).¹⁸ In contrast to other immunosuppressive agents, polyclonal agents do not depend on T-cell activation but can eliminate preactivated noncycling memory lymphocytes, which may be critical in presensitized recipients. The more potent rabbit antithymocyte globulin Thymoglobulin has, for the most part, replaced Atgam.

Dosing and Side Effects

The usual dose of thymoglobulin is 1.5 to 2.0 mg/kg/day and 15 mg/kg/day for Atgam over 4 to 6 hours as an intravenous infusion. Thymoglobulin is recommended to be started during

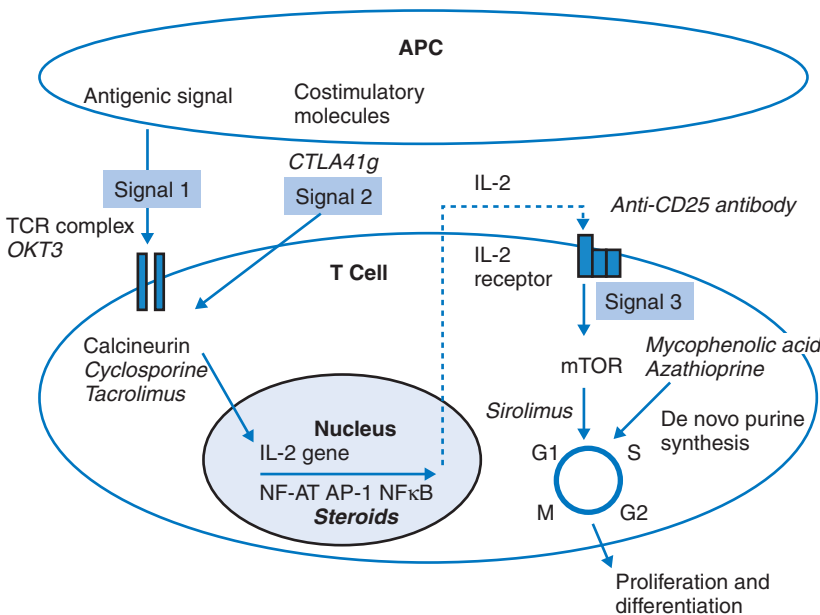

Figure 87-1 Schematic representation of the three signals for T-cell responses and the main mediators in T-cell activation. The major steps involved in T-cell activation are outlined and sites of action of some of the principal immunosuppressive medications are shown in italics. Cyclosporine and tacrolimus prevent the generation of nuclear factor of activated T cells by inhibiting the activity of calcineurin. Sirolimus binds to immunophilin and then combines with mammalian target of rapamycin (mTOR), inhibiting cell-cycle progression. Mycophenolic acid and azathioprine inhibit proliferation by restricting the supply of guanosine available for DNA synthesis. Anti-CD25 antibodies block the interaction between interleukin-2 and CD25. Cytotoxic T-lymphocyte antigen 4 (CTLA4) immunoglobulin blocks the interaction between CD28 on T cells and CD80/CD86 on antigen-presenting cells. OKT3 is directed to the CD3 T-cell receptor (TCR) complex. AP, activator protein; NFκB, nuclear factor κB.

Table 87-1 Immunosuppressive Drugs: Dose Forms, Mechanisms of Action, Adverse Effects, and Dosing Guidelines

Drug	Mechanism of Action	Adverse Effects	Dosing Guidelines
Polyclonal-Depleting Antibodies			
Thymoglobulin: 25-mg/vial Atgam: 50 mg/mL (5 mL)	Causes lymphopenia and impairs T-cell responses. Cell depleting via CDC, removal by the reticuloendothelial system, and ADCC	Fever, chills, arthralgias, serum sickness, anaphylaxis, leukopenia, thrombocytopenia, thrombophlebitis	Given as IV infusion over 4 hr for 3–5 days when used as induction agent, for 5–10 days when used to treat acute allograft rejection. Thymoglobulin 1.5–2.0 mg/kg/day and Atgam 15 mg/kg/day: doses should be titrated according to WBC and platelet counts
Monoclonal-Depleting Antibodies			
Orthoclone (OKT3): 1 mg/mL (5 mL)	Depletes cells by binding to CD3 ⁺ T cells and impairs T-cell responses by modulating the TCR–CD3 complex	Cytokine release syndrome: fever, chills, pulmonary edema, hypotension, myalgias, aseptic meningitis	Given as IV infusion for 5–14 days when used as induction agent; standard dose is 5 mg/day
Alemtuzamab (Campath-H1): 30 mg/mL	Directed against the CD52 antigen, which is expressed on all blood mononuclear cells and induces ADCC, CDC, and apoptosis	Fevers, rigors, hypotension, dyspnea, and nausea related to cytokine release	Given as 1 or 2 doses on the day of transplantation and the first postoperative days. The total dose of 30–40 mg is administered as an IV infusion over 2 hours but can be also given subcutaneously
Rituximab (Rituxan): 10 mg/mL	Binds to CD20 ⁺ B cells and eliminates B cells in a highly selective fashion directly by CDC, ADCC and indirectly by structural changes and apoptosis	Mainly associated with first dose reactions: hypotension, fever, tachycardia, and arthralgias	Dose depends on indication but usually given as 1 dose of 375 mg/m ² in desensitization protocols or for treatment of antibody-mediated rejection. Once weekly for up to 4 doses in PTLD
Monoclonal Nondepleting Antibodies			
Basiliximab (Simulect): 10 mg, 20 mg/vial Daclizumab (Zenapax): 5 mg/mL	Targets CD25 of the IL-2 receptor on activated lymphocytes	Uncommon other than hypersensitivity	Basiliximab is given as two 20-mg IV doses, the first on day 0 and the second on day 4 post-transplantation. Daclizumab is given as 1 mg/kg IV infusion (day 0), then every 14 days for four doses. Protocols may vary between centers.
CIs			
Cyclosporine (Sandimmune): 25-, 50-, 100-mg tablets; 100 mg/mL oral solution Cyclosporine microemulsion (Neoral): 25-, 100-mg tablets; 100-mg/mL oral solution (Gengraft): 25-, 100-mg tablets; 100-mg/mL oral solution	Binds to cyclophilin and inhibits calcineurin, leading to impaired T-cell activation	Nephrotoxicity, hypertension, hyperlipidemia, glucose intolerance, hyperkalemia, hyperuricemia, hypomagnesemia, tremor, paresthesias, seizures, thrombotic microangiopathy, hirsutism, gingival hyperplasia, hepatotoxicity	Usually given with antimetabolite/steroid or steroid alone. Initial dose is 6–10 mg/kg/day. For first 3 mo target 12-hr trough levels are 200–350 ng/mL and 80–200 ng/mL beyond 3 mo

Table 87-1 Immunosuppressive Drugs: Dose Forms, Mechanisms of Action, Adverse Effects, and Dosing Guidelines—cont'd

Drug	Mechanism of Action	Adverse Effects	Dosing Guidelines
CIs—cont'd			
Tacrolimus (Prograf): 0.5-, 1-, 5-mg capsules	Binds FK-binding protein, thereby inhibits calcineurin, leading to impaired T-cell activation	Similar as for cyclosporine but compared with cyclosporin A has less common hirsutism, hyperlipidemia, and gingival hyperplasia; more commonly alopecia, neurotoxicity, and glucose intolerance	Initial dose is 0.15–0.3 mg/kg/day. For first 3-mo target 12-hr trough levels are 8–15 ng/mL and 5–10 ng/mL beyond 3 mo
Antimetabolites			
Azathioprine Azasan: 75, 100 mg Imuran: 50 mg	Competitive inhibitor of purine synthesis	Leukopenia, thrombocytopenia, anemia, hepatotoxicity	Oral dose is 1–2 mg/kg/day when combined with a CI and corticosteroids. Dose adjustment with low WBC count
Mycophenolate mofetil (MMF) (CellCept): 250-, 500-mg tablets, 200-mg/mL oral suspension, enteric-coated mycophenolate sodium (EC-MPS) (Myfortic): 180-, 360-mg tablets	Noncompetitive inhibitor of inosine monophosphate dehydrogenase; inhibits purine synthesis. Impairs T-cell responses and decreases B-cell activity and antibody production	Nausea, vomiting, diarrhea, dyspepsia, leukopenia, anemia	When used with tacrolimus 0.5–1.0 g bid, and 1.0–1.5 g bid with Cyclosporin A. Dose adjustment with low WBC count; 500 mg of MMF corresponds to 360 mg EC-MPS
TOR Inhibitors			
Sirolimus (Rapamune): 1-, 2-mg tablets, 1-mg/mL oral solution Everolimus (Certican): 250-, 500-, 750-, 1000- μ g tablets	Sirolimus–FK binding protein complex inhibits mammalian TOR and blocks cytokine-mediated cellular proliferation at G ₁ to S phase	Increased nephrotoxicity when used with CI, proteinuria, hypokalemia, hypomagnesemia, thrombotic microangiopathy, thrombocytopenia, anemia, hyperlipidemia, lymphocele, impaired wound healing, oral ulcers, interstitial pneumonitis	Used with CI or antimetabolite. For sirolimus, starting dose is 2–5 mg/day. Target trough levels 5–10 ng/mL with CI, 12–20 ng/mL with MMF, and 15–25 ng/mL if CI is withdrawn. Everolimus is given twice daily (not available in U.S.)
Corticosteroids			
Prednisone, prednisolone, methylprednisolone (Solu-Medrol)	Inhibition of genes encoding proinflammatory cytokines	Glucose intolerance, hypercholesterolemia, hypertension, impaired wound healing, skin fragility, growth retardation, osteoporosis, central obesity, suppression of pituitary-hypothalamic axis, cataracts, glaucoma, psychosis	Initiated intraoperatively at 250–1000 mg of methylprednisolone followed by an oral taper to a maintenance dose, usually 5–10 mg/day by 2–6 mo after transplantation. Pulse steroids (250–500 mg/day for 3 days) are used to treat acute rejection.

Suggested target levels depend on use of concomitantly administered drugs, immunologic risk, transplanted organs, and assay used (range based on immunoassay).

ADCC, antibody-dependent cellular cytotoxicity; CDC, complement-dependent cytotoxicity; CI, calcineurin inhibitor; IL, interleukin; PTLT, posttransplantation lymphoproliferative disease; TCR, T-cell receptor; TOR, target of rapamycin; WBC, white blood cell.

the transplantation before reperfusion due to a decreased incidence of DGF rather than administered postoperatively.¹⁹ The duration is usually 3 to 5 days for induction treatment and 5 to 10 days for treatment of rejection. Polyclonal antibody preparations are foreign proteins and may cause a variety of adverse effects. Most common are fever, chills, and arthralgias. Allergic reactions can be avoided with premedication consisting of methylprednisolone, diphenhydramine, and acetaminophen. Anaphylaxis and serum sickness occur rarely. Leukopenia and thrombocytopenia are common and need dose adjustment. Patients with white blood cell counts between 2000 and 3000 or platelet counts between 50,000 and 75,000 require half-dose Thymoglobulin, and it should be held if the white blood cell count is less than 2000 or the platelet count is less than 50,000.¹⁸

Monoclonal Lymphocyte-Depleting Antibodies

Anti-CD3 Monoclonal Antibodies

Muromonab-CD3 (Orthoclone OKT3) was the first monoclonal antibody approved for human use by the U.S. Food and Drug Administration in 1986. A humanized anti-CD3 monoclonal antibody, hOKT3 γ 1 (Ala-Ala) was developed to eliminate some of the toxicities of OKT3. The current use of OKT3 as an induction agent is extremely rare (<1%) in the United States. OKT3 can be used for the treatment of acute rejection.

Mechanism of Action

OKT3 is a xenogeneic murine IgG₂ antibody directed against the ϵ chain of the human CD3 complex, which is a protein linked to the TCR. Within minutes after administration, CD3⁺ cells (T cells) disappear from the circulation, returning only after several days. This is a result of complement-mediated lysis and opsonization for clearance by phagocytic cells. OKT3 can also modulate the TCR-CD3 complex off the T-cell surface, thereby rendering T cells, even if present, incapable of antigen recognition.¹⁸

Dosing and Side Effects

The standard dose of OKT3 is 5 mg/day given as 7 to 14 single daily doses. Approximately 50% of patients develop anti-mouse antibodies and 20% of these have high titers (>1:1000) that may make a second course of OKT3 ineffective.²⁰ During an effective course, the percentage of CD3⁺ cells decreased from 60% to less than 5% within 24 to 48 hours. The most dangerous adverse effect of OKT3 administration is a cytokine release syndrome usually seen during the first few doses and characterized by high fever, chills, headache, arthralgias, nausea, diarrhea, and pulmonary edema. These reactions are due to the binding of OKT3 to proteins in the TCR complex leading to transient T-cell activation and cytokine release.¹⁸ The severity of these reactions may decrease by premedication with high doses of corticosteroids and antihistamines.²¹ To avoid the occurrence of life-threatening pulmonary edema, it is important to ensure that the patient is euvolemic before administration. OKT3 is associated with an increased incidence of posttransplantation lymphoproliferative disorders

and opportunistic infections, most commonly cytomegalovirus infection.^{22,23}

Alemtuzumab (Campath-1H)

Alemtuzumab (Campath-1H) is a monoclonal humanized rat monoclonal antibody (rat IgG2b) directed against the CD52 antigen, which is expressed on all blood mononuclear cells, including T and B lymphocytes, monocytes, macrophages, and eosinophils, as well as on the lining of the male reproductive system. It has been used to treat chronic B-cell lymphocytic leukemia since 1988, but was first used in organ transplantation in 1998. Due to its strong cytolytic activity, alemtuzumab has been mainly used in minimization of immunosuppressive protocols (rapid steroid withdrawal, calcineurin inhibitor (CI) free or reduced-dose CI).²⁴

Mechanism of Action

Alemtuzumab's proposed mechanism of action includes ADCC, CDC, and induction of apoptosis.²⁴ It causes profound and long-lasting lymphopenia and may take months to years for the depressed lymphocyte levels to return to normal levels.

Dosing and Side Effects

The protocol usually consists of one or two doses (total dose 30–40 mg) on the day of transplantation and the first postoperative days. Alemtuzumab traditionally has been administered intravenously over 2 hours but can be also given subcutaneously.²⁵ In theory, alemtuzumab should leave patients seriously immunocompromised due to profound and long-lasting CD4 T-cell depletion, but surprisingly few serious infections were encountered in all studies reported. Infusion-related toxicities are common and include fevers, rigors, hypotension, dyspnea, and nausea. These reactions are related to cytokine release during administration and can be minimized by premedication regimens.

Rituximab (Rituxan)

Rituximab is a chimeric anti-CD20 (B-cell) monoclonal antibody, approved for the therapy of B-cell lymphomas including posttransplantation lymphoproliferative disorders. It has not been evaluated in a rigorous fashion in kidney transplantation but has been employed in desensitization protocols of crossmatch-positive or ABO-incompatible kidney transplant recipients. Rituximab is also used in the treatment of acute antibody-mediated rejection.²⁶

Mechanism of Action

Rituximab eliminates B cells in a highly selective fashion via multiple mechanisms: directly by CDC and ADCC and indirectly by structural changes and apoptosis. B-cell recovery takes 6 to 12 months after the completion of the treatment.

Dosing and Side Effects

Rituximab has been used in kidney transplant recipients during desensitization protocols or for the treatment of acute antibody-mediated rejection as a single dose (325 mg/m²) and infused over 6 hours. For the treatment of posttransplantation lymphoproliferative disorders, it is given the same dose but for four consecutive weeks. The reactions include transient hypotension that responds to intravenous fluids, low-grade fever, mild tachycardia, and arthralgias.²⁷ Persistent hypogammaglobulinemia has been shown in patients with

autoimmune hemolytic anemia and bone marrow transplant recipients.

Monoclonal Nondepleting Antibodies (Anti-CD25)

The humanized antibody daclizumab (Zenapax) and the chimeric antibody basiliximab (Simulect) are two similar compounds that became available in 1998. They are not used for the treatment of acute rejection but rather to prevent rejection when used as an induction agent. These agents have been shown clinically to result in a lower incidence of acute rejection compared with standard three-drug therapy in renal transplantation and may allow for steroid sparing.

Mechanism of Action

IL-2 receptor antibodies target the α chain (CD25) of the IL-2 receptor, blocking the autocrine and paracrine survival and growth effects of IL-2, which play a central role in antigen-induced proliferation of T cells.²⁸

Dosing and Side Effects

Both drugs have a half-life of more than 7 days, which permits a long dose interval and results in diminished T-cell responses for at least 4 to 6 weeks. Basiliximab is given as two intravenous doses of 20 mg (days 0 and 4). Daclizumab is given as IV doses of 1 mg/kg starting on day 0 and then four times every other week.²⁸ Some recent studies demonstrated the efficacy of using two-dose courses of daclizumab. Neither IL-2 receptor antibody has significant serious adverse effects or first-dose reactions. There is no increased risk of posttransplantation infections or malignancy.

Calcineurin Inhibitors (Cyclosporine and Tacrolimus)

The introduction of CIs in kidney transplantation, first cyclosporin A (CsA) in 1983 and later tacrolimus (Prograf) in 1994, has significantly improved the 1-year graft survival, and they became the main immunosuppressive agents. The original formulation Sandimmune (cyclosporine) has been largely replaced by Neoral, the microemulsion formulation, due to improved gastrointestinal absorption and bioavailability. The generic formulations of cyclosporine microemulsion, Gengraf and cyclosporine USP, have been used widely in the United States. Tacrolimus is now the predominantly used CI in the United States (85% tacrolimus vs. 15% CsA).

Mechanism of Action

CsA and tacrolimus inhibit the expression of multiple genes involved in T-cell activation and proliferation, including IL-2 and other lymphokines. CsA and tacrolimus bind respectively to cytoplasmic immunophilins called cyclophilin and FK-binding protein, thereby producing a complex that inhibits the calcium-sensitive phosphatase calcineurin.²⁹ Calcineurin normally dephosphorylates transcription factors including nuclear factor of activated T cells, allowing their translocation into the nucleus where they are responsible for induction of gene transcription.³⁰

Dosing and Side Effects

The optimal maintenance doses of CIs are still not fully stratified. CsA is usually administered orally in doses of 6 to 10 mg/kg/day and tacrolimus in doses of 0.15 to 0.3 mg/kg/day, in two divided doses. Monitoring blood levels is important because of variation in interpatient and inpatient metabolism and a narrow therapeutic index. In patients receiving triple immunosuppressive therapy, the target 12-hour trough level (C0) for CsA and tacrolimus are 200 to 350 ng/mL and 8 to 15 ng/mL up to 3 months, 100 to 200 ng/mL and 5 to 10 ng/mL within 3 to 12 months, and 80 to 150 ng/mL and 4 to 8 ng/mL thereafter, respectively. There are several assays currently available to measure the CsA and tacrolimus levels, and physicians should know the type of method used at their center due to differences in results between the methods. Immunoassays using monoclonal antibodies against CsA and tacrolimus are the most common methods used. Recent attention has been given to 2-hour peak CsA levels (C2), which may predict clinical events such as acute rejection and nephrotoxicity better than 12-hour trough levels. Suggested target C2 levels are 1200 to 2000 ng/mL for the first 3 months, 800 to 1000 ng/mL months 4 through 6, and 800 ng/mL thereafter.³¹ However, there are no large, multicenter, randomized trials to compare the long-term effects of C2 with C0 trough levels on allograft outcome. After significant dose adjustment, levels of CsA and tacrolimus should be rechecked within 2 to 4 days.

Both CIs are associated with numerous adverse effects. Although there are minor differences in the incidence of individual adverse effects, the spectrum is essentially similar for both agents. Both CIs are nephrotoxic and cause acute and chronic renal insufficiency. Acute renal insufficiency may be related to renal vasoconstriction as well as tubular toxicity. The vasoconstriction can be marked, involving both the afferent and efferent glomerular arterioles and persisting with time. Long-term use of CIs leads to renal insufficiency due to chronic tubulointerstitial disease, which may be characterized by “striped” interstitial fibrosis or multinodular arteriolar hyalinosis. However, none of the pathologic changes are specific for CIs.³² CsA is associated with hypertension that appears to be salt sensitive and associated with low renin levels.³³ It also causes hyperlipidemia and glucose intolerance. Tacrolimus causes the same problems, but there seems to be a greater tendency to diabetogenicity with a slightly lower incidence of hypertension and hyperlipidemia. Posttransplantation diabetes mellitus was reported in 5% to 10% of CsA-treated and 10% to 20% of tacrolimus-treated patients. The mechanisms underlying the development of these adverse defects are not fully clear. Hyperkalemia is common, seen with both agents, and often associated with mild hyperchloremic acidosis (type 4 renal tubular acidosis). Hyperuricemia is more common with CsA. Both drugs lead to magnesium wasting and hypomagnesemia. Neurotoxicity may occur with both agents and manifests as paresthesias, tremors, convulsions, and encephalopathy. Thrombotic microangiopathy may develop secondary to CIs that may manifest with or without systemic features. Thrombotic microangiopathy mostly develops early after the introduction of a CI, but can be seen at later stages

as well. At high drug levels, hepatotoxicity manifested by hyperbilirubinemia and elevated transaminases may occur with both agents. Hirsutism, coarse facies, and gingival hyperplasia are troubling adverse effects that appear to occur only with cyclosporine, and patients may respond to a switch to tacrolimus. In contrast, tacrolimus may cause hair loss.

Antimetabolites

Azathioprine (Imuran, Azasan)

Azathioprine (Imuran, Azasan) was first synthesized in the late 1950s as a prodrug of 6-mercaptopurine and has been the most commonly used immunosuppressive agent first with steroids and later with CsA and steroids until the introduction of mycophenolate mofetil (MMF). Currently less than 1% of de novo renal transplant recipients are started on azathioprine. However, given the costs and clinical efficacy, it remains a reasonable alternative to MMF in immunologically low-risk recipients, pregnancy, and recipients unable to tolerate MMF due to side effects.³⁴

Mechanism of Action

Azathioprine is a prodrug, whose active metabolite, 6-mercaptopurine, competitively inhibits the formation of phosphoribosyl pyrophosphate, a key intermediate in purine synthesis. Lymphocytes are relatively unique in their dependence on de novo purine synthesis. Other cells are able to use a “salvage pathway” for recycling of purines. Thus azathioprine and related compounds are relatively selective for lymphocytes.

Dosing and Side Effects

The daily oral dose is 1.0 to 2.0 mg/kg/day when combined with a CI. Therapeutic drug monitoring is usually not necessary but possible by measuring 6-thioguanine levels in red blood cells. Myelosuppression is the most serious adverse effect leading to leukopenia, megaloblastic anemia, and thrombocytopenia in that order of frequency. It is important to be aware of a significant drug interaction between azathioprine and allopurinol. The latter drug impairs the degradation of the active metabolites of azathioprine, with the risk of profound and long-lasting neutropenia. Azathioprine should be switched to MMF in patients requiring allopurinol. Hepatotoxicity, reflected by a cholestatic picture, is another serious side effect.

Mycophenolate Mofetil (CellCept) and Enteric-Coated Mycophenolate Sodium (Myfortic)

MMF (CellCept) was introduced in clinical transplantation in 1995 and has almost completely replaced azathioprine in the United States.³⁵ Enteric-coated mycophenolate sodium (Myfortic) is an advanced formulation of mycophenolic acid characterized by a delayed release at the level of the small bowel and became available in 2004.³⁶

Mechanism of Action

MMF is metabolized to MPA, which causes noncompetitive inhibition of inosine monophosphate dehydrogenase, a key enzyme in the de novo synthesis of guanine nucleotides.³⁷ Due to their significant dependence on this pathway, in addition to salvage mechanisms for purine synthesis, proliferating lymphocytes are especially susceptible to inhibition of inosine monophosphate dehydrogenase. Consequently, exposure to MPA impairs T-cell proliferation in response to antigen stimulation, decreases B-cell

activity and antibody production, inhibits generation of cytotoxic T cells, and also decreases adhesion molecule function.³⁸

Dosing and Side Effects

The standard dose is 1.0 g twice daily for CellCept and 720 mg twice daily for Myfortic. Blacks require higher doses of CellCept (1.5 g twice daily) when used with CsA. Trough levels of MPA are not routinely measured in kidney transplant recipients. Pharmacokinetic studies demonstrated that the area under the curve 0-12 for MPA correlates with its clinical efficacy and side effect profile. This relationship with random or 12-hour trough levels is less consistent.³⁹ Trough levels of MMF seem to be lowered by concurrent administration of cyclosporine but not tacrolimus.⁴⁰ The optimal dose of MMF in long-term stable kidney transplant recipients (>1 year) on CsA or tacrolimus is not certain. MMF causes significant gastrointestinal adverse effects that may manifest as severe nausea, vomiting, and persistent diarrhea (infectious or noninfectious Crohn's disease–like enterocolitis).⁴¹ The only effective therapy for the noninfectious enterocolitis is to decrease the dose or even discontinue the drug, which is, however, associated with an increased risk of rejection. It is therefore important to reintroduce or increase the drug dose as soon as clinically possible. Enteric-coated mycophenolate sodium was developed as an alternative way to deliver MPA with the goal of reducing gastrointestinal adverse effects, but most clinical trials demonstrated a similar gastrointestinal side effect profile compared with MMF. The gastrointestinal side effects are due to systemic MPA and occur even when the drug is given intravenously. Other causes of diarrhea, such as infections, should be investigated before attribution to MMF or enteric-coated mycophenolate sodium and dose reduction of these agents. In clinical trials of MMF, leukopenia was found to occur at a frequency similar to that seen with the use of azathioprine, and may require dose adjustment.⁴² However, other causes of leukopenia, such as viral infections, or other drugs (ganciclovir, valganciclovir) should be considered before dose reduction due to increased risk of acute rejection in patients whose MMF dose was reduced due to leukopenia.⁴³ Those patients on a reduced dose of MMF require closer monitoring. Nephrotoxicity, neurotoxicity, and hepatotoxicity have not been observed with MMF.

The Target of Rapamycin Inhibitors: Sirolimus (Rapamune) and Everolimus (Certican)

Sirolimus, formerly known as rapamycin, was introduced to transplantation in 1999⁴⁴ and its derivate with a shorter half-life, everolimus, is approved for use in Europe but is not currently available in the United States.^{45–47} Since the approval of sirolimus by the U.S. Food and Drug Administration, this drug has been used in combination with CIs or MMF.

Mechanism of Action

Although TOR inhibitors bind to the same immunophilin FK binding protein as FK506 tacrolimus, they act through an entirely different mechanism. The resulting TOR inhibitor–FK binding protein complex does not bind to calcineurin phosphatase, but rather to cytosolic protein kinases known as TOR that are centrally involved in the regulation of cell proliferation and differentiation. Binding to this target results in inhibition of signal transduction through several growth factor receptors (such as the IL-2 receptor), thus preventing

cell-cycle progression and immune activation.⁴⁸ The net result of these actions is potent antiproliferative activity against T cells and smooth muscle cells. Due to actions at a later stage in the immune response, TOR inhibitors can prevent cell proliferation even after immune stimulation and may function synergistically with a CI.

Dosing and Side Effects

Sirolimus is given once daily due to its long half-life (62 hours). It is rapidly absorbed from the gastrointestinal tract, reaching peak concentrations within 1 to 2 hours. It is usually given as a loading dose (6–15 mg/day), which is three times the maintenance dose (2–5 mg/day). Therapeutic drug level monitoring is an important part of its use and provides a good reflection of drug exposure. The doses and the target levels for sirolimus depend on the concomitant immunosuppressive agent, whether it is a CI or MMF. CIs augment the blood concentrations of sirolimus and vice versa, potentiating the nephrotoxicity of the CIs when these two drugs are used in combination.⁴⁴ Sirolimus should be administered 4 hours after the morning CI dose. Current recommendations are sirolimus trough levels of 5 to 10 ng/mL, CsA levels 50 to 100 ng/mL, or tacrolimus levels 3 to 6 ng/mL, if used together. Sirolimus trough levels should be 15 to 25 ng/mL if the CI is withdrawn after 3 months or 12 to 20 ng/mL if used with MMF. Sirolimus has direct adverse effects on the kidney even in the absence of CI use, causing proteinuria,⁴⁹ hypokalemia, and hypomagnesemia as a result of kaliuresis, and magnesuria. Everolimus has a shorter half-life (23 hours) and is given twice daily. The adverse effect profile of sirolimus is better established than that of everolimus, although preliminary data suggest that they are similar. The major adverse effects of sirolimus appear to be related to higher concentrations of drug in the blood. In the early post-transplantation period, impaired wound healing and an increased tendency for lymphocele formation have been noted.⁵⁰ It may cause myelosuppression, especially anemia and thrombocytopenia. Hyperlipidemia, particularly with hypertriglyceridemia, is a common complication of TOR inhibitors.⁵¹ Other important complications described with sirolimus use include pulmonary toxicity (bronchiolitis obliterans organizing pneumonia) and painful oral ulcers.⁵²

Glucocorticoids

Glucocorticoids are potent anti-inflammatory and immunosuppressive agents and have been used for several decades. Rapid steroid withdrawal protocols have gained popularity and are discussed under “Immunosuppressive Protocols.” Pulse steroids are used to treat acute cellular rejection.

Mechanism of Action

Glucocorticoids bind to a cytosolic receptor that translocates to the nucleus, where the complex binds to DNA regulatory sequences, called glucocorticoid-responsive elements.⁵³ Glucocorticoids decrease the transcription of key cytokines, where glucocorticoid-responsive element sequences have been found in the critical promoter regions of several cytokine genes, or may also affect the transcription of genes that do not contain glucocorticoid-responsive elements.⁵⁴ As evidenced by the large number of target genes for glucocorticoids, their effects are exerted on a variety of cells, including lymphocytes and macrophages. Despite our understanding of the molecular mechanisms of these drugs, it is not certain which mecha-

nisms predominate *in vivo*, and this may depend on the drug dose. It is likely that for low doses used for daily maintenance therapy for prophylaxis of rejection, the nonspecific anti-inflammatory effects are most important. At higher doses, glucocorticoids are directly lympholytic, that is, they kill T and B cells, and this action may explain the rapid and potent immunosuppressive effects of pulse steroids.

Dosing and Side Effects

Steroids are given at high doses intravenously (250–1000 mg) starting before the transplantation surgery and gradually tapered over a few weeks, reaching maintenance doses of 5 to 10 mg/day at 2 to 3 months after transplantation. For rapid steroid withdrawal protocols, steroids are given for only 3 to 7 days after transplantation in a rapid taper. Glucocorticoids have multiple adverse effects that depend on the dose and duration of use, with the majority of effects becoming a serious problem only after prolonged use. These include impaired glucose tolerance, hyperlipidemia, and hypertension. These adverse effects can significantly enhance progression of atherosclerosis and cardiovascular morbidity and mortality. Glucocorticoids have devastating effects on connective tissues, causing poor wound healing, skin fragility, growth retardation in children, accelerated bone loss leading to osteoporosis, avascular necrosis of bones, cataracts, and proximal myopathy. Corticosteroid-induced osteoporosis may be diminished by the use of calcium and vitamin D supplements as well as agents to decrease bone resorption, including bisphosphonates and calcitonin.⁵⁵

Drug Interactions of Immunosuppressive Drugs

Cyclosporine, tacrolimus, and sirolimus are catabolized by the same hepatic cytochrome P-450 systems (CYP3A4/5) that are involved in the degradation of other commonly used drugs. CYP3A4/5 is also present in the intestinal wall,⁵⁶ and oral absorption is decreased by the multidrug resistance gene *MDR-1*. This gene produces a transmembrane protein, P-glycoprotein⁵⁷ that actively transports a large number of molecules (including cyclosporine, tacrolimus, and sirolimus) back into the intestinal lumen. Due to genetic and/or environmental factors, the activity of both of these systems varies greatly from individual to individual. Box 87-1 lists some of the more common drugs that are particularly prone to produce changes in blood levels. In any immunosuppressed patient who has developed impaired renal function or toxic drug side effects, it is important to ascertain whether there have been any changes in medications, including over-the-counter medications such as herbal and antioxidant supplements.

Intravenous Immunoglobulins

Intravenous immunoglobulin (IVIG) products have immunomodulatory effects and have been used in the treatment of inflammatory and autoimmune disease.⁵⁸ IVIG products are prepared from IgG derived from thousands of donors. IVIG has been used in the field of transplantation since the 1990s, after *in vitro* studies demonstrated the inhibition of anti-HLA lymphocytotoxicity of sera from highly sensitized patients, and later *in vivo* studies showing decreased titers of anti-HLA antibodies.⁵⁹ A randomized, double-blind, placebo-controlled, multicenter National Institutes of Health-sponsored trial

Box 87-1 Common Drugs That Alter Blood Levels of Cyclosporine, Tacrolimus, and Sirolimus**Increase Levels**

Diltiazem, nicardipine, verapamil
 Clarithromycin, erythromycin

involving 101 end-stage renal disease patients with PRA levels greater than 50% and on the transplant waiting list for more than 5 years have shown decreased PRA levels and an increased transplantation rate in patients receiving IVIG (2 g/kg monthly for 4 months).⁶⁰ IVIG is currently used in desensitization protocols of crossmatch-positive or ABO-incompatible kidney transplant recipients. IVIG is also used in the treatment of acute antibody-mediated rejection.

Mechanisms of Action

There are many proposed mechanisms of IVIG, involving different parts of the immune response, including inhibition of the activation and effector functions of complement, cytokine cascades, and T- and B-lymphocyte function, and modulation of dendritic cells. Anti-idiotypic antibodies binding to anti-HLA antibodies might be the immediate mechanism of IVIG, but the immunomodulatory effects of IVIG treatment persist well beyond its half-life, indicating ongoing active inhibitory mechanisms. IVIG interacts with Fcγ receptor IIB, which is a negative signaling receptor on B cells and inhibits the expression of CD19 on activated B cells.^{61,62}

Dosing and Side Effects

The dose of IVIG ranges from 100 to 2000 mg/kg depending on the type of protocol used. Desensitization protocols combining IVIG with plasmapheresis used lower doses of IVIG or 2.0 g/kg if used alone (maximum 140 g in a single administration). There are many IVIG products with different osmolality, pH, sodium, and sugar components, which results in specific side effect profiles. Adverse reactions to IVIG occur in less than 5% of patients. These side effects include headache, chills, nausea, myalgia, arthralgia, back pain, and increased blood pressure. Premedication with acetaminophen and diphenhydramine is required before infusion. A rare side effect is acute aseptic meningitis, which occurs 48 to 72 hours after the administration of IVIG and resolves spontaneously or can be prevented with nonsteroidal anti-inflammatory drugs. Renal failure secondary to osmotic injury to proximal tubular epithelium may occur due to sucrose or sorbitol components in some IVIG preparations. IVIG preparations that do not include sucrose or sorbitol are preferred to avoid renal failure (such as Gamimune-N, Gammagard, and Polygam). IVIG should be given during hemodialysis in end-stage renal disease patients or as a 6- to 8-hour infusion in nondialysis patients. Very rarely, serious anaphylactoid reactions occur within the first hour of administration of IVIG. In this situa-

tion, the infusion should be stopped and patients be treated with intravenous glucocorticoids.

New Immunosuppressive Medications

LEA29Y (belatacept) is a second-generation CTL-associated antigen 4 (CTLA4) immunoglobulin, a fusion protein combining CTLA4 with the Fc portion of IgG, which blocks costimulation (signal 2) of T cells by binding to CD80 and CD86. A phase II, randomized, multicenter trial comparing belatacept, mycophenolate mofetil, and prednisone to cyclosporine microemulsion, mycophenolate mofetil, and prednisone treatment showed similar rates of acute rejection but a better glomerular filtration rate and less chronic allograft nephropathy at 12-month protocol biopsies in the belatacept group.¹¹ All patients received basiliximab induction treatment, and belatacept was administered as a 30-minute intravenous infusion and divided into two groups, intensive and less intensive regimen, depending on the frequency of dosing. Efalizumab is a humanized IgG₁ monoclonal antibody that prevents LFA1–intracellular adhesions molecule interaction by binding to CD11a chain of leukocyte function antigen 1 (LFA1). In a phase I/II open-label, multidose, multicenter trial involving 38 patients, efalizumab was administered weekly for 12 weeks (0.5 or 2.0 mg/kg subcutaneously) after renal transplantation along with full-dose CsA, MMF, and prednisone or half-dose CsA, sirolimus, and prednisone.⁶³ The overall acute rejection rate at 6 months was 11%. However, three patients receiving high-dose efalizumab with full-dose CsA developed posttransplantation lymphoproliferative disease. Leflunomide (Arava) is metabolized to its active metabolite, A77 1726, which inhibits dihydroorotic acid dehydrogenase, an enzyme required for de novo pyrimidine synthesis in lymphocytes. It also inhibits selected tyrosine kinases involved in T- and B-cell activation. In addition, leflunomide seems to have antiviral activity against herpesviruses and polyomaviruses and has been used in the treatment of polyoma nephropathy.⁶⁴ FK778 is an analogue of A77 1726 with a shorter plasma half-life. It was used in a phase II multicenter trial in renal transplant recipients in combination with tacrolimus and steroids.⁶⁵ Anemia was the most frequently reported side effect of FK778 in this trial. Another phase II study comparing FK778 with MMF, along with tacrolimus and steroids, did not show efficacy of FK778 over MMF, and the manufacturer decided not to pursue the use of FK778 in renal transplantation. FTY720 is a novel immunomodulator agent with unique mechanisms of action. It is a sphingosine-

1-phosphate receptor agonist that modulates lymphocyte trafficking by reducing the recirculation of lymphocytes from lymph nodes to blood and peripheral tissues, including inflammatory lesions and graft sites. A phase II, multicenter, open-label study compared four different doses of FTY720 with MMF, in combination with cyclosporine and steroids.⁶⁶ Reversible bradycardia during the first doses of FTY720 raised concerns about the safety of the drug. Higher doses of FTY720 were found to be as effective as MMF, but the manufacturer decided not to pursue clinical use of FTY720 in renal transplant recipients. Janus kinase 3 is a tyrosine kinase associated with the cytokine receptor γ chain, which participates in the signaling of many cytokine receptors (IL-2, 4, 7, 9, 15, and 21). The Janus kinase 3 inhibitor CP-690,550 has been used in kidney transplant patients in a multicenter, randomized, phase II clinical trial comparing it with MMF in combination with tacrolimus and steroids. AEB071 is a highly potent and reversible inhibitor of all classic and novel protein kinase C isoforms. Protein kinase C isoforms are important mediators of intracellular signaling of T and B cells. AEB071 has completed phase I trials and is now in phase II trials in kidney transplant recipients. A modified extended-release tacrolimus formulation (Prograf XL, previously referred to as MR4) for once-daily administration has been shown to be safe in renal transplant patients converted from tacrolimus standard twice-daily dosing.⁶⁷ A large randomized, multicenter, phase III trial involving 638 de novo kidney transplant recipients comparing Prograf XL with twice-daily tacrolimus and cyclosporine microemulsion, along with MMF, steroids, and basiliximab induction has shown a similar patient and graft survival and safety profile.⁶⁸

IMMUNOSUPPRESSIVE PROTOCOLS

Conventional immunosuppressive protocols consist of a CI (tacrolimus or cyclosporine), an adjuvant agent (MMF, azathioprine, or sirolimus), and corticosteroids with or without an induction agent. Immunosuppressive regimens have significantly changed over the past decade in the United States (Table 87-2). Although 76.5% of patients undergoing transplantation in 1997 received cyclosporine and 12.5% received tacrolimus, this ratio was reversed in 2005 such that 78.7% received tacrolimus and 14.9% received cyclosporine. As an adjuvant agent, 81.8% of 2005 kidney transplant recipients received MMF, 9.1% sirolimus, 5.1% Myfortic (mycophenolate sodium), 0.6% azathioprine, and 0.3% everolimus. The tacrolimus/MMF regimen was the most common combination (80.4%), followed by CsA/MMF (9.4%). The remaining 10% of the recipients received sirolimus with tacrolimus (4.5%), CsA (2.8%), or MMF (3.0%). The induction regimen has also been changed over the past decade such that while 65.7% of transplant recipients in 1997 did not receive any induction treatment; this rate was only 26.4% for patients receiving a transplant in 2005. Thymoglobulin was the most commonly used induction agent in 2007 (38.6%), followed by basiliximab (16.4%), daclizumab (11.5%), and alemtuzumab (8.8%). The use of Atgam and OKT3 was extremely rare, 1.6% and 0.4%, respectively. The use of rapid steroid withdrawal protocol has also increased recently so that although 97.4% of transplant recipients in 1997 were discharged with steroids, this rate decreased to 73.5% in 2007, indicating that 26.5% of the patients underwent rapid steroid withdrawal or steroid avoidance protocol.

Table 87-2 Immunosuppressive Treatment of Kidney Transplant Recipients in 2005 (United States)

Agent	%
Induction	
Thymoglobulin	38.6
Basiliximab	16.4
Daclizumab	11.5
Alemtuzumab	8.8
Atgam	1.6
OKT3	0.4
No induction	26.4
Calcineurin Inhibitors	
Tac	78.7
Cyclosporine	14.9
Adjuvant Treatment (Antimetabolite)	
MMF	81.8
SRL	9.1
Myfortic (enteric-coated mycophenolate sodium)	5.1
Azathioprine	0.6
Everolimus	0.3
Steroids	73.5
Immunosuppressive Treatment Combinations	
Tac/MMF	80.4
CsA/MMF	9.4
Tac/SRL	4.5
SRL/MMF	3.0
CsA/SRL	2.8

CsA, cyclosporine; MMF, mycophenolate mofetil; SRL, sirolimus; Tac, tacrolimus.

What Type of Calcineurin Inhibitor? (Tacrolimus vs. Cyclosporine)

Both CsA and tacrolimus have similar efficacy but different side effect profiles. Randomized, controlled studies or large database analyses comparing tacrolimus with CsA revealed conflicting results.^{69,70} Initial randomized, multicenter, controlled trials showed decreased acute rejection rates in tacrolimus-treated patients compared with CsA-treated patients, but patients received Sandimmune (cyclosporine oral solution) instead of microemulsion CsA.⁶⁹ Follow-up studies comparing tacrolimus with Neoral showed similar patient and graft survival rates, but some advantages of tacrolimus in subgroups of patients, such as patients with DGF and black patients. Retrospective data analysis of patients

undergoing transplantation between 1996 and 2000 in the United States has showed a similar graft survival rate in tacrolimus- and CsA-treated patients.⁷¹ Another study analyzed deceased donor pairs between 1995 and 2002, in which one kidney was allocated to a patient receiving Neoral and the other kidney to a patient receiving tacrolimus to minimize the donor variability and selection bias.⁷² Multivariate analyses could not demonstrate a difference in 5-year patient survival or graft loss. More recent studies analyzing patients receiving a transplant between 2000 and 2005 using the Scientific Registry of Transplant Recipients database demonstrated a slight but statistically significant increase in risk for 6-month acute rejection rate and decreased graft survival in CsA/MMF-treated patients compared with tacrolimus/MMF-treated patients (relative risk, 1.16 for both parameters, $P < .01$).⁷³ Initial studies demonstrated a higher rate of posttransplantation diabetes mellitus in tacrolimus-treated patients compared with CsA-treated patients, especially in African American and Hispanic patients, but more recent studies targeting lower tacrolimus levels revealed a decreased incidence of posttransplantation diabetes mellitus. Although CsA decreases MPA levels, tacrolimus does not have any significant effect; thus, patients on tacrolimus/MMF may receive more overall immunosuppression that may affect allograft outcome. Tacrolimus is preferred in immunologic high-risk kidney transplant recipients, pancreas transplant recipients, and in patients receiving minimization of immunosuppressive protocols (rapid steroid withdrawal).

What Type of Adjuvant Agent? (Mycophenolate Mofetil vs. Sirolimus)

Sirolimus use peaked in 2001; 9.7% of kidney transplant recipients were treated with sirolimus with tacrolimus, 4.1% with CsA, and 4.2% with MMF. Despite a decrease in acute rejection rates in patients treated with the sirolimus and CI combination, the studies also demonstrated a significant decrease in the glomerular filtration rate, indicating increased nephrotoxicity with this combination. This synergistic nephrotoxicity was attributed to impaired tubular recovery from CIs and/or ischemia/reperfusion injury by sirolimus. A meta-analysis of the studies using lower dose sirolimus with standard dose CI or higher dose sirolimus with lower dose CI still demonstrated a lower glomerular filtration rate compared with patients receiving a CI and MMF.⁴⁴ This analysis also showed that patients on sirolimus and a CI developed more thrombocytopenia, anemia, hypercholesterolemia, hypertriglyceridemia, and lymphocele. Due to these adverse effects, later studies were designed to withdraw the CI from the sirolimus/CI combination after 3 months or use sirolimus with MMF without using a CI.⁷⁴ A meta-analysis analyzed six randomized, controlled trials that involved initial immunosuppression with CI and sirolimus, followed by CI withdrawal in stable patients at 3 months after transplantation. The results demonstrated an increased risk of acute rejection (6%), but a higher glomerular filtration rate at 1 year in patients with CI withdrawal compared with patients remaining on sirolimus/CI.⁷⁵ There was no difference in patient and graft survival. A single-center study using sirolimus and MMF with basiliximab induction found excellent patient and graft survival,

kidney function, and low acute rejection rates ($<10\%$).⁷⁶ The protocol biopsy specimens at 2 years also had significantly fewer chronicity findings in sirolimus/MMF-treated patients compared with patients treated with CI/MMF.⁷⁷ Another single-center study demonstrated similar acute rejection rates and graft function in sirolimus/MMF-treated patients compared with tacrolimus/MMF patients.⁷⁸ However, two multicenter, controlled, randomized trials were halted due to higher than expected acute rejection rates in patients receiving sirolimus/MMF. Analysis of patients receiving transplants between 2000 and 2005 using Scientific Registry of Transplant Recipients data showed the lowest 5-year graft survival in sirolimus/MMF-treated patients (57.7%) compared with patients treated with tacrolimus/MMF (73.8%), CsA/MMF (71.8%), CsA/sirolimus (68.9%), and tacrolimus/sirolimus (67.6%).⁷³ The risk of acute rejection was also the highest (relative risk = 1.53) compared with other combinations. Sirolimus is probably a more potent but also more toxic immunosuppressant compared with MMF. These studies raised questions regarding the safety of using sirolimus in kidney transplantation as a de novo agent with CIs or MMF. Use of sirolimus as a secondary agent in stable patients on a CI and MMF, in whom the CI will be switched to sirolimus after 3 months, in a multicenter trial is currently ongoing. However, another concern about sirolimus is proteinuria, and some studies found increased proteinuria in patients who were switched to sirolimus from a CI.

Sirolimus and everolimus have antiangiogenic and antiproliferative actions leading to inhibition of tumor growth in animal models. Maintenance immunosuppression with the TOR inhibitors is associated with a decreased risk of developing any posttransplantation de novo malignancy, using a large database analysis of kidney transplant recipients.⁷⁹ Conversion from CIs to sirolimus has been shown to cause regression of Kaposi's sarcoma.⁸⁰ These results indicate a potential use of sirolimus in transplant recipients with de novo malignancy.⁸¹

What Type of Induction Treatment?

A prospective, randomized trial comparing Thymoglobulin with Simulect in deceased donor recipients at high risk of acute rejection or DGF showed higher acute rejection rates in Simulect-treated patients (25.5% vs. 15.6%) but a similar incidence of DGF (44.5% vs. 40.4%).⁸² Another prospective, randomized trial demonstrated a significant decrease in DGF incidence in patients treated with intraoperative Thymoglobulin induction treatment compared with postoperative thymoglobulin administration.¹⁹ The main concerns using polyclonal or monoclonal lymphocyte-depleting agents are increased risk of developing opportunistic infections and malignancy after transplantation.⁸³ A meta-analysis of randomized trials using anti-IL-2R antibodies compared with placebo showed decreased acute rejection rates but no improvement in patient or graft survival at 1 year.⁸⁴ Using the Scientific Registry of Transplant Recipients database of patients receiving a transplant between 1998 and 2003, analysis demonstrated that anti-IL-2R antibodies decreased acute rejection at 6 months and decreased graft failure over a follow-up of 1059 days compared with no induction.⁸⁵ The benefit of anti-IL-2R antibodies in reducing acute rejection

increased significantly with greater HLA mismatch. However, despite a statistically significant decrease in acute rejection rate (10.2% vs. 8.1%) and graft failure (11.8% vs. 10.4%) due to the large number of the patients analyzed,^{49,50} the clinical meaning of these small differences is questionable. Anti-IL-2R antibodies were not found to increase the risk of cytomegalovirus infection or malignancy in this meta-analysis. The use of OKT3 as an induction agent has almost been completely eliminated due to cytokine-release syndrome as well as increased risk of infection and posttransplantation lymphoproliferative disorders. Alemtuzumab is a powerful cytolytic agent and has been used mainly for minimization of immunosuppressive treatment.²⁴ The first single-center study using alemtuzumab induction treatment with CsA monotherapy showed similar patient and graft survival and acute rejection rates compared with patients receiving triple immunosuppression.⁸⁶ Sirolimus monotherapy with alemtuzumab induction treatment showed increased acute antibody-mediated rejection.⁸⁷ A number of nonrandomized, retrospective, single-center studies with large patient numbers using alemtuzumab with rapid steroid withdrawal and low-dose tacrolimus and MMF found good patient and graft survival and acute rejection rates without increases in the incidence of infection and malignancy. However, there is a need for large, prospective, randomized, controlled studies with long-term follow-up of patients to determine the safety of alemtuzumab treatment as well as the advantages over the other induction agents.

Induction treatment has also been used to delay the initiation of CIs, but a recent randomized trial comparing early versus delayed CsA in renal transplant recipients with anti-IL-2R antibody showed similar DGF, graft function, and graft loss in both groups.⁸⁸ Patients receiving delayed CsA had higher rate of acute rejection (26.5% vs. 15.5%), but the difference was not statistically significant.

Steroid Withdrawal

The widely known adverse effects of long-term steroid treatment have stimulated interest in using lower doses of steroid in kidney transplant recipients. Although most recent transplant patients decrease their maintenance dose of steroids to 5 mg once daily at 3 months after transplantation, an increasing number of transplant recipients have been receiving rapid steroid withdrawal before discharge. Steroid-free protocols using CsA and azathioprine in kidney transplant recipients from the 1980s and early 1990s showed increased risks of acute rejection.⁸⁹ In the past decade, the paradigm for timing of steroid withdrawal has shifted from late withdrawal to early withdrawal, eliminating steroids within 7 days after transplantation, and using more potent immunosuppressive treatment along with induction treatment. Two retrospective studies using rapid steroid withdrawal with induction treatment have shown low acute rejection rates and good patient and graft survival and graft function up to 5 years in immunologically low-risk patients.^{90,91} However, randomized, controlled trials have shown increased acute rejection rates in steroid withdrawal groups.⁸⁹ Data on the beneficial effects of steroid withdrawal on posttransplantation diabetes mellitus, hyperlipidemia, osteopenia, weight gain, and blood pressure control have been mixed and could not be demon-

strated in all studies. Some investigators raised the question of whether low-dose maintenance steroid treatment can achieve similar outcomes in prevention of side effects without increasing the risk of acute rejection. Due to a lack of protocol allograft biopsy specimens and long-term follow-up, it is not clear whether steroid withdrawal may increase the risk of developing chronic allograft nephropathy. Despite the increased popularity of using steroid-free protocols and the good short-term outcome, there is still a need for additional research to investigate the safety of those protocols, which induction agent to use (Thymoglobulin, Campath-1H, or anti-IL-2R antibodies), and what patient population to use (immunologically high versus low risk) in multicenter, randomized, controlled trials incorporating protocol biopsies and bone densitometry compared with patients treated with a low maintenance dose of steroids.

Calcineurin Inhibitor Withdrawal

CI have been the cornerstone of immunosuppressive treatment and primarily responsible for increased 1-year graft survival rates of more than 90% in the past decade. However, CI-induced nephrotoxicity is still a hurdle to achieving better long-term graft survival. Other CI-related cardiovascular side effects, including posttransplantation diabetes, hyperlipidemia, and hypertension may decrease patient survival. CI withdrawal or dose reduction in patients receiving a transplant before 1996 and receiving CsA, azathioprine, and steroids have resulted in increased acute rejection.^{92,93} In a prospective, multicenter trial involving 212 stable kidney transplant recipients receiving CsA/MMF/steroids randomized at 6 months post-transplantation to either CsA withdrawal or to continue their triple-drug therapy,⁹⁴ the CsA withdrawal group had 22% and 11% biopsy-proven acute and chronic rejection compared with 1.4% and 0% in controls, respectively. CsA withdrawal or complete avoidance using sirolimus also increases the risk of acute rejection. Current ongoing trials using new immunosuppressive medications, such as LEA29Y (belatacept), Janus kinase 3 inhibitor (CP-690,550), and protein kinase C inhibitor (AEB071), along with MMF and steroids, compared with standard treatment with CI/MMF/steroids may show the safety of CI avoidance in the future.

Immunosuppression and Sensitization

Unsensitized recipients of HLA-identical living donor or zero antigen mismatched deceased donor kidney transplant recipients have a lower risk of acute rejection and much longer graft survival. Those patients need less immunosuppressive treatment with lower dose CIs and MMF and are also good candidates for rapid steroid withdrawal or CI avoidance protocols with anti-IL-2R antibodies. However, immunosuppressive management of sensitized recipients of HLA-identical living donor or 0-mismatched deceased donor kidney transplant recipients may require more immunosuppression. Recent findings by Opelz⁹⁵ suggest that the long-term outcome in kidney recipients from HLA-identical siblings depends on the degree of sensitization before transplantation. Although unsensitized HLA-identical siblings showed a 72% ten-year survival rate, recipients with

1% to 50% and more than 50% PRA had 63% and 55% graft survival rates after a decade, respectively. Whether PRA indicates a higher responsiveness or a reaction against a non-HLA antigen remains to be elucidated. In general, unsensitized living donor kidney transplant recipients usually receive standard triple immunosuppressive treatment with or without an induction agent per transplantation center preference. Unsensitized deceased donor kidney transplant recipients may require induction treatment along with standard triple immunosuppressive treatment, especially in patients at higher risk of developing DGF. Immunosuppressive management of the sensitized patients depends on the type of crossmatch result and the specificity of anti-HLA antibodies (i.e., whether it is donor specific). CDC T-cell crossmatch positivity is an absolute contraindication to transplantation and requires pretransplantation desensitization. Therapeutic strategies for desensitization protocols include combinations of plasmapheresis or immunoadsorption, IVIG, rituximab (anti-CD20), and splenectomy.

Currently, there are no randomized, controlled, prospective studies that compare different desensitization protocols, and all published studies are retrospective, single-center studies using high-dose IVIG or immunoadsorption alone or plasmapheresis with low- or high-dose IVIG.⁹⁶ The selection of the desensitization protocol also depends on the strength of the DSA, so that patients with high titers probably require pretransplantation plasmapheresis.⁹⁷ Patients with low DSA titers (<1:8) may require two to three sessions of plasmapheresis, whereas patients with high DSA titers (>1:128) may require six to 10 sessions to decrease the antibody titers. Patients undergo transplantation if the crossmatch becomes negative with an induction agent (anti-IL-2R antibody, Thymoglobulin, or alemtuzumab), IVIG, and continuation of posttransplantation plasmapheresis for two to five sessions depending on the titers of the DSA. Rituximab has been added to some desensitization protocols as a single dose (375 mg/m²) before or at the time of transplantation. However, early acute antibody-mediated rejection is an important obstacle seen in 30% to 40% of the recipients, despite the type of desensitization, whether they receive high-dose IVIG or low-dose IVIG/plasmapheresis protocol or rituximab is added to the protocol.

CDC B-cell or FC T-or B cell-positive crossmatch patients are at higher risk of developing acute antibody-mediated or cellular rejection as well as chronic rejection leading to decreased graft survival. Those patients also require desensitization protocols with IVIG and pre- and/or pertransplantation plasmapheresis depending on the titers of the DSAs.⁹⁸ All sensitized patients require induction agents along with triple immunosuppressive treatment and the CI levels should be kept at higher target levels plus standard doses of MMF and steroids. Those patients should be closely followed after transplantation with monitoring DSAs and probably with protocol allograft biopsies to diagnose acute or chronic antibody-mediated rejection. Future prospective, randomized, multicenter studies are required to define the most appropriate desensitization protocol for highly sensitized kidney transplant recipients.

IMMEDIATELY POST-TRANSPLANTATION

Delayed graft function (DGF) is defined as the requirement for dialysis within the first week after transplantation or as less than 25% decrease in creatinine within the first 24 hours after surgery.^{1,2} The term *primary nonfunction* describes the outcome of approximately 5% of kidneys that never work. The dominant cause of DGF is acute tubular necrosis consequent to ischemia and the events surrounding organ procurement.^{2,3} Acute tubular necrosis rarely occurs in living donor kidney recipients, although the incidence may be higher if the kidney is procured laparoscopically.⁴ The incidence of DGF increases when the cold ischemia time exceeds 24 hours and when calcineurin inhibitors (CIs) are included in the induction regimen.^{5,6}

The organ donor shortage has spawned several previously underused and innovative strategies to increase the donor pool from nontraditional sources. Over the past 10 years, there has been a marked increase in the number of donors whose death was defined by cardiac standstill (donation after cardiac death).⁷⁻⁹ Wider use of donation after cardiac death organs has the potential to greatly increase the number of organ transplants. Cooper and colleagues⁹ reported on the experience of the University of Wisconsin of 382 donation after cardiac death organ donors over a 16-year period starting in 1984 and compared the function of these kidneys to more than 1000 brain-dead donors over the same time period. They found that there was no statistical difference in cold ischemia time, rate of primary nonfunction, and short- or

long-term graft loss. However, the incidence of delayed graft function (DGF) was significantly higher in donation after cardiac death organ recipients compared with standard criteria recipients.

The United Network for Organ Sharing recently defined a class of deceased donor kidney grafts for special allocation procedures to enhance use of such organs. The criteria defining these expanded-criteria donor kidneys (ECDs) are donor age older than 60 years or donor age between 50 and 59 years plus two of the following characteristics: donor history of cerebrovascular accident, donor history of hypertension, and elevated creatinine (1.5 mg/dL) at any time during donor management.¹⁰ The risk of DGF is higher in expanded-criteria donor recipients, although the risk may be mitigated by pulsatile perfusion of the graft before transplantation.¹¹ Recipients older than the age of 60 years who receive an expanded-criteria donor kidney and experience DGF have a higher risk of death compared with other patient groups,¹² although overall survival is improved compared with dialysis.

Diagnosis

Renal ultrasonography should always be performed to exclude a vascular catastrophe such as thrombosis of the transplant renal artery or vein. Isotope renography may also detect functionally significant obstruction or a urine leak and exclude kidney infarction. The diagnosis of allograft rejection in patients with DGF who are maintained on dialysis can be made only histologically.

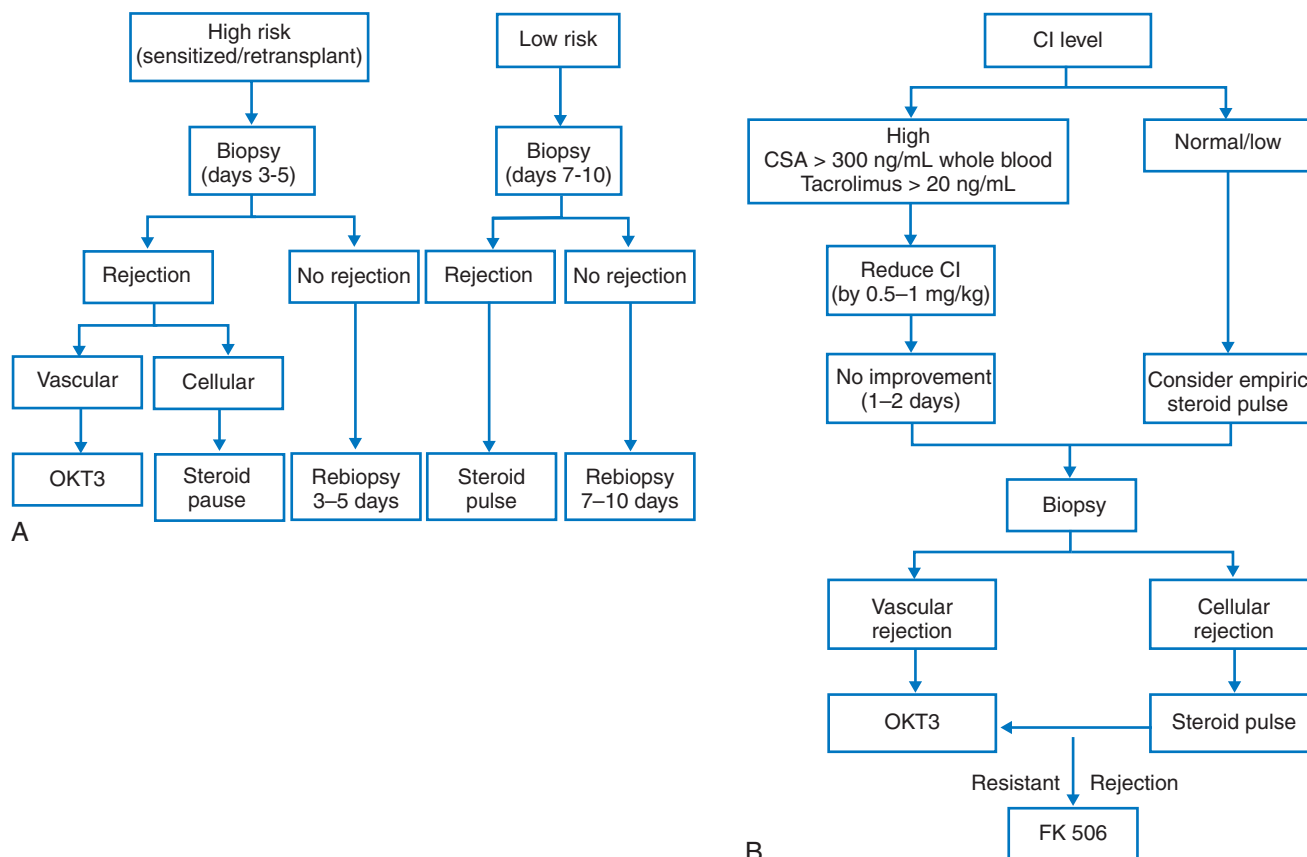

Figure 88-1 **A**, The approach to patients with delayed graft function. **B**, The approach to patients with rising creatinine levels after immediate graft function. The causes and approach to the management of renal allograft dysfunction vary with time after transplantation. Therefore, the differential diagnosis is best approached by considering the time periods separately. The surgical complications leading to allograft dysfunction that include obstruction and vascular thromboses are addressed in Chapter 86. The attention of the reader is directed to a recently published update of the Banff diagnostic categories for renal allograft biopsies that is discussed in detail in the text¹ (Table 88-1).

The approach to DGF varies with patient risk (Fig. 88-1). Factors indicating high-risk include sensitization, retransplantation, and cold ischemia time exceeding 24 hours. Such patients should have a renal biopsy performed on days 3 to 5 to rule out acute rejection. A repeat biopsy should be performed in 3 to 5 days if rejection is not seen and DGF persists. In the absence of antibody induction therapy, low-risk patients should have a biopsy performed on days 7 to 10, which can be repeated should DGF persist. For those patients receiving potent antilymphocyte antibody induction therapy, it may be reasonable to defer the biopsy as the risk of early rejection is low.¹³

Management

Prolongation of DGF by concurrent calcineurin inhibitor (CI) therapy has led to the use of sequential induction regimens with antilymphocyte antibody therapies. Provision of adequate immunosuppression while avoiding CI therapy is desirable during DGF as there is evidence to suggest that the incidence of acute rejection is increased by DGF.^{13,14} Initial studies suggested that DGF is associated with poorer long-term graft survival.¹⁵ More recent reports indicate that graft survival is not significantly different when comparing DGF versus no DGF for patients without rejection.^{16,17} Immunologic injury may play a role in some cases of DGF.¹⁸ Evidence to support this is provided by the ob-

servations that the incidence of DGF is increased in presensitized, retransplant patients.¹⁵ Therapy of DGF includes supportive care¹⁹ and minimizing nephrotoxins (notably CIs and some antibiotics). The use of vasodilators such as dopamine in the recipient with DGF has been largely discredited. However, a recent report of dopamine use in the donor before organ procurement suggests that such an approach may have a favorable impact on DGF rates after implantation.²⁰ Reports that rabbit antithymocyte globulin (thymoglobulin) may reduce the incidence of DGF²¹ have not been universally reproduced.^{13,22}

Hyperacute rejection is a rare and generally preventable cause of primary nonfunction.²³ It is caused by unrecognized ABO incompatibility or donor-specific antibody, both of which have long been deemed to be contraindications to kidney transplantation.²⁴ More recently, successful transplantation across such immunologic barriers has been described in which a pretransplant conditioning regimen involving plasmapheresis and intravenous immunoglobulin is used.²⁰ Other causes of hyperacute rejection include anti-HLA class II antibodies and antidonor endothelial/monocyte antibodies, which may cause a delayed-onset hyperacute rejection-like syndrome in HLA-identical grafts.^{19,25,26} The diagnosis of hyperacute rejection is usually made by the surgeon in the operating room. The initially pink kidney becomes mottled and cyanotic. There is little or no urine output, and the renal biopsy specimen

shows intrarenal coagulopathy and cortical necrosis. The differential diagnosis includes pulsatile perfusion-induced endothelial injury, cryoglobulinemia, disseminated intravascular coagulation, fat embolization, and antglomerular basement membrane disease.^{27,28} There is no effective therapy, and graft nephrectomy is necessary.

Accelerated rejection can occur in patients with or without DGF; it refers to rejection episodes occurring 2 to 5 days after transplantation.²³ It is caused by previous sensitization to donor antigens (occult T-cell crossmatch), a positive B-cell crossmatch, or a positive flow cytometry crossmatch in patients who underwent a repeat transplantation.²⁹ The differential diagnosis includes CI toxicity, thrombotic angiopathy, and urinary tract obstruction. The diagnosis of accelerated rejection is usually established by renal biopsy. The biopsy specimen may show predominantly either cellular rejection or vascular rejection. It is important to make this pathologic distinction because the approach to therapy is different.

EARLY POST-TRANSPLANTATION

The major causes of a decrease in graft function early after transplantation include acute rejection, which is most common, polyoma virus allograft nephropathy (PVAN) CI nephrotoxicity, thrombotic microangiopathy, and urinary tract obstruction or decreased renal perfusion due to effective circulating volume depletion, infection, and recurrent or de novo renal disease.

Approach to Diagnosis

Early allograft dysfunction is typically characterized by a blood creatinine concentration that is stable at an elevated level or is increasing. Unfortunately, the blood creatinine is a rather crude marker of allograft health, lacking sensitivity and specificity for rejection, especially in children.³⁰ Indeed, there is the growing realization that subclinical rejection exists as an entity that is treatable that affects long-term graft survival.³¹ Unless there is evidence suggestive of infection or recurrent disease, the evaluation of such patients is commenced by measuring the plasma CI concentrations (see Fig. 88-1). If the drug level is elevated, the cyclosporine or tacrolimus dose may be decreased. A renal biopsy is performed if no improvement is noted within 1 to 2 days or if the creatinine continues to increase. If, conversely, the CI level is normal or low, a biopsy is performed or empirical pulse steroid therapy may be given with the CI dose adjusted until the level is within the therapeutic range.

Acute Renal Allograft Rejection

Acute renal allograft rejection is defined as an acute deterioration in allograft function associated with specific pathologic changes in the transplant that have been categorized by the Banff consortium described in Figure 88-1.^{1,32} The incidence of acute rejection and the time at which it occurs vary with the induction and maintenance therapy protocol used for immunosuppression. Registry data indicate that the incidence of acute rejection has greatly decreased over the past decade and is now consistently less than 20% depending on donor and recipient characteristics and the immunosuppressive protocol.³³ Kidneys that recover function still have a 10% decrease in 1-year survival compared with rejection-free kidneys.³⁴

Acute rejection episodes also have a negative impact on long-term graft survival, being a major clinical predictor of chronic allograft nephropathy.³⁵

Diagnosis

The presence of acute renal allograft rejection should be suspected in every transplant recipient in whom the creatinine fails to settle or is increasing. Most patients are asymptomatic. Fever and graft pain are rarely encountered unless immunosuppression has been discontinued. Most episodes of acute rejection occur within the first 3 months post-transplantation. Only 8% of patients with functioning grafts have a first episode of rejection after 1 year,³⁶ often associated with noncompliance with medical therapy or low drug levels.³⁷ The differential diagnosis includes ongoing acute tubular necrosis, CI nephrotoxicity, and urinary tract obstruction. Obstruction can usually be ruled out by renal ultrasonography. Duplex Doppler ultrasonography, although noninvasive, is not sufficiently sensitive or specific for the diagnosis of acute rejection.³⁸

Percutaneous renal allograft biopsy is frequently necessary and may be complicated by macroscopic hematuria, transient anuria due to obstructing blood clots, perirenal hematoma, retroperitoneal hematoma, and rarely traumatic intrarenal arteriovenous fistula or bowel injury.³⁹ Fine-needle aspiration biopsy⁴⁰ has not been widely accepted as a replacement for core biopsy techniques.

Pathology

The 8th Banff Conference on Allograft Pathology held in 2005 represented the latest iteration of the international consensus meeting that develops standards for interpretation of allograft biopsy results.¹ The meeting is generally perceived to be an important force behind the standardization of slide interpretation for use in clinical trials. The current classification of renal allograft biopsy pathology is summarized in Box 88-1.⁴¹⁻⁴³ The characteristic pathologic changes that occur during acute cellular rejection include interstitial infiltration with mononuclear cells and disruption of the tubular basement membranes.⁴⁴ The presence of patchy mononuclear cell infiltrates without tubulitis is not uncommon in normally functioning renal allografts and is not sufficient to make the diagnosis of acute rejection. The presence of neutrophils is uncommon and should suggest the diagnosis of infection. Immunohistologic evaluation of rejecting renal allografts shows an increased number of infiltrating major histocompatibility complex (MHC) class II-positive and interleukin-2 receptor-positive mononuclear cells.⁴⁵ Acute vascular rejection, conversely, is characterized pathologically by capillary endothelial swelling, arteriolar fibrinoid necrosis, fibrin thrombi in glomerular capillaries, and frank cortical necrosis in severe cases. Glomerular involvement is associated with a worse prognosis.^{44,46}

Antibody-mediated rejection (AMR) has now been incorporated into the Banff schema and is summarized in Table 88-1. To satisfy current diagnostic criteria, three of the four parameters must be present⁴¹: allograft dysfunction, histology, positive immunofluorescence for C4d, and demonstration of donor-specific antibody. It should be noted that the histology in type 1 AMR is not typically thought of as being associated with rejection (minimal inflammatory infiltrate with microscopic evidence of tubular necrosis). Consequently, all allograft biopsy material should be processed for C4d with an additional search for donor-specific antibody performed as necessary.

Box 88-1 Banff 97 Diagnostic Categories for Renal Allograft Biopsies (2005 Revision)

1. Normal
2. Antibody-mediated rejection
- Acute antibody-mediated rejection (C4d⁺) type
 - I. Acute tubular necrosis-like
 - II. Capillary margination and/or thrombosis
 - III. Arterial
- Chronic Active Antibody-Mediated Rejection***
- Glomerular double contours, peritubular capillary basement membrane multilayering, interstitial fibrosis, tubular atrophy, fibrous intimal thickening
3. Borderline changes
4. T cell-mediated rejection
 - Acute
 - IA. Significant interstitial infiltration (>25% of parenchyma) and moderate tubulitis
 - IB. Significant interstitial infiltration (>25% of parenchyma) and severe tubulitis
 - IIA. Mild to moderate intimal arteritis
 - IIIB. Cases with severe intimal arteritis comprising >25% of the luminal area
 - III. Transmural arteritis
- Chronic Active T Cell-Mediated Rejection**
5. Interstitial fibrosis and tubular atrophy, no evidence of any specific etiology
 - Grade
 - I. Mild (<25% of cortex)
 - II. Moderate (26%–50% of cortex)
 - III. Severe (>50% of cortex)
6. Other: Categories not considered to be due to rejection; may coincide with categories 2–5.

Unusual Rejection Variants

Colovai and colleagues⁴⁷ reported three cases of hyperacute rejection and AMR of renal allografts in recipients who had received rabbit antithymocyte globulin (thymoglobulin) as induction therapy. A variety of studies failed to reveal either antilymphocytic or antiendothelial cell antibodies either pre- or post-transplantation. However, xenoantibodies that strongly bound to human lymphocytes to activated endothelial cells were identified in the sera obtained at the time of rejection. Campath-1H (alemtuzumab) is a humanized monoclonal antibody against CD52 that is being studied as an induction agent in transplantation. Although rejection rates with alemtuzumab treatment are low, a number of reports describe acute rejection dominated by monocytes.^{48–50} Such rejections tend to be steroid sensitive.

Management of Renal Allograft Rejection

Treatment of rejection should be started when the diagnosis is suspected and should not be unduly delayed until the results of the allograft biopsy are available. There are several thera-

peutic options available for rejection. The intensity of therapy will largely be dictated by the severity of the rejection episode as well as response to initial therapy (see Table 88-1). In this age of greatly reduced rejection risk, it is useful to investigate the root cause of a rejection episode (Box 88-2). Certainly, from a continuous quality improvement process viewpoint, every rejection should be evaluated to ascertain whether there was a program or patient failure that led to rejection.

Corticosteroids remain one of the cornerstones of most induction, maintenance, and rescue immunosuppressive regimens.^{51,52} Steroids are lympholytic when given in high doses (e.g., methylprednisolone 0.5–1g/day given over 3–5 days) and can reverse acute rejection in as many as 75% of cases.⁵¹ After completing the steroid pulse, oral steroids are restarted using the same dose that the patient had been taking. The urine output increases, and the serum creatinine starts decreasing within 3 to 5 days after initiating therapy. The major complication of pulse steroids is increased susceptibility to infection, especially oral candidiasis. Other potential problems include acute hyperglycemia, hypertension, peptic ulcer disease, and psychiatric disturbances including euphoria and depression. Prophylactic antacids/H₂ blockers as well as oral antifungal therapy are generally recommended.⁵³ Steroid resistance is defined as a lack of improvement in urine output or the plasma creatinine concentration within 5 days. In this setting, second-line therapy consists of the administration of tacrolimus and antilymphocyte antibodies, either as rabbit antithymocyte globulin (thymoglobulin) or OKT3.^{54–56}

Polyclonal Anti-T Cell Antibodies

Rabbit antithymocyte globulin (thymoglobulin) is prepared by immunizing rabbits with human lymphoid cells derived from cultured B-cell lines. Antithymocyte globulin, a preparation commonly used in Europe, is an equine hyperimmune globulin. Such agents have been used for prophylaxis and first- and second-line therapy of acute rejection. A typical recommended dose for acute rejection is 10 to 15 mg/kg/day for 7 to 10 days. The reversal rate has been between 75% and 100% in different series,^{57,58} with the plasma creatinine concentration returning to baseline several days after initiating therapy. Fever and chills develop in a majority of patients during the initial infusion. Anaphylactic reactions, including respiratory distress and hypotension, are rare. To minimize the allergic manifestations, patients are usually pretreated with corticosteroids, antihistamines, and acetaminophen.

OKT3 was the first murine monoclonal antibody licensed for use in humans.^{59,60} It is directed against the CD3 antigen causing complex, which is closely associated with the T-cell receptor modulation or clearing of CD3⁺ T cells.⁶¹ OKT3 has been used as the primary treatment of acute rejection and also as rescue therapy for resistant rejection.⁶² The usual dose of OKT3 is 5 mg/day intravenously for 10 to 14 days. As many as 94% of steroid- or ALS-resistant rejections can be expected to reverse with OKT3 treatment.⁵⁹ The plasma creatinine concentration typically increases for the first 2 to 3 days of OKT3 therapy and then decreases. OKT3 is also used as primary therapy in patients who have vascular rejection, a process that is generally resistant to steroids.⁵⁹ In vitro, OKT3 acts as a T-cell mitogen, and many of the first dose reactions commonly seen are generally thought to be due to initial binding to the CD3 complex, mediating T-cell release of cytokines. These reactions include fever, rigors, nausea, vomiting, diarrhea, hypotension,

Table 88-1 Rejection Rescue Protocol

Rejection (Banff 1997 Classification)		Treatment Options
Borderline Change		Optimize immunosuppressive drug levels
Grade IA	Moderate tubulitis (>4 mononuclear cells in >25% of biopsy sample)	1. Optimize immunosuppressive drug levels
Grade IB	Severe tubulitis (>10 mononuclear cells in >25% of biopsy sample)	2. Consider switch to tacrolimus or mycophenolate mofetil or sirolimus
Grade IIA	Mild to moderate arteritis in at least one blood vessel	3. Adjunctive therapy (statin)
Grade IIB	Severe arteritis (>25% loss of luminal area)	4. Recycle oral steroids or pulse intravenous steroids
Grade III	Transmural arteritis with fibrinoid necrosis and perivascular inflammation	5. If unresponsive: Polyclonal anti-T cell antibody therapy or OKT3
Antibody-mediated rejection		Optimize immunosuppressive drug levels Switch to tacrolimus OKT3 Therapeutic plasma exchange until donor-specific antibody is removed

chest pain, dyspnea and wheezing, and occasionally frank pulmonary edema.⁶³ This latter complication is rarely seen unless the patient is volume overloaded, and, thus, patients should be dialyzed or diuresed before OKT3 therapy. Dyspnea may also be related to complement activation and subsequent pulmonary vascular neutrophil sequestration.⁶⁴ Antihistamines, acetaminophen, and steroids are usually given before OKT3 to minimize adverse effects, all of which should decrease with repeated exposure. Higher steroid doses should be avoided to prevent a potential increase in the procoagulant effect of OKT3.⁶⁵ Other serious complications that can occur after the administration of OKT3

include graft thrombosis⁶⁶ and thrombotic microangiopathy.⁶⁶ OKT3 can predispose to potentially life-threatening infections, especially those due to cytomegalovirus.⁶⁷ Total exposure is an important determinant of risk, with almost 100% of patients experiencing an episode of infection after three courses.⁶³ There is also evidence that OKT3 may be associated with an increased risk of certain malignancies such as Epstein-Barr virus–related lymphoproliferative disorders.⁶⁰ Aseptic meningitis characterized by lymphocytosis and elevated cerebrospinal fluid protein occurs in as many as 5% of patients who receive OKT3 and is usually self-limiting, although differentiation from other causes of infectious meningitis is essential.

Box 88-2 Preventable Causes of Rejection

Inadequate drug: azathioprine
 Inadequate dose: failure to aggressively optimize CI or SRL levels in the early post-transplantation period
 Noncompliance: failure to take medication
 Youth
 Side effects (especially cosmetic such as weight gain, acne, and hirsutism)
 Drug or alcohol abuse
 Financial
 Drug interaction: various drugs can reduce CI and SRL drug levels
 Dilantin
 Phenobarbital
 Rifampin
 St. John's wort

CI, calcineurin inhibitor; SRL, sirolimus.

Recurrent Rejection

Approximately 15% to 20% of transplant patients have recurrent episodes of acute rejection. The success rate of retreatment with OKT3 in this setting is related to its ability to modulate/clear CD3⁺ T cells.⁶⁸ This in turn is determined by two important factors: circulating anti-mouse antibody titers and timing of the rejection episode. Approximately 50% to 60% of patients who receive OKT3 will produce human anti-mouse antibodies,⁶⁹ generally in low titers (<1:100). Low antibody titers do not affect the response to retreatment (reversal rate almost 100%) if the rejection episode occurs within 90 days after transplantation. Conversely, titers of more than 1:100 or recurrent rejection beyond 90 days is associated with a reversal rate of less than 25%. The reversal rate is essentially zero when both high human anti-mouse antibodies titers and late rejection are present. OKT3 is also indicated in primarily vascular rejection.⁵⁹ It is important to confirm the diagnosis of rejection by renal biopsy before starting antilymphocyte therapy.

Recent uncontrolled trials suggest that tacrolimus may be effective as rescue therapy for refractory rejection. One report, for example, switched 77 patients with biopsy-proven ongoing acute rejection from cyclosporine to tacrolimus.⁷⁰ The overall response rate was 74%, with responders having a mean plasma creatinine concentration of 2.35 mg/dL (207 μ mol/L) at 14 months. Even dialysis-dependent patients had a 50% response rate. Preliminary data on the role of mycophenolic acid as rescue therapy for biopsy-proven acute rejection revealed a response rate of 69% in patients who failed standard pulse steroid or OKT3. Tacrolimus is currently the dominant CI at the time of discharge from hospital in the United States.⁵²

Antibody-Mediated Rejection Therapy

The optimal therapy for antibody-mediated rejection remains to be defined, although an aggressive approach with plasmapheresis and intravenous immunoglobulin to remove donor-specific antibodies is gaining support. In a retrospective study of nine patients with AMR, White and colleagues⁷¹ reported that eight grafts were successfully rescued with mean serum creatinine levels at 3 and 12 months of 1.9 and 1.8 mg/dL, respectively. Another group described a series of seven patients with AMR who received approximately seven plasmapheresis treatments combined with rabbit antithymocyte globulin (thymoglobulin).⁷² One graft was lost to rejection. Renal function improved to baseline in the remaining six patients. Lehigh and colleagues⁷³ described a retrospective analysis of 23 patients with AMR treated with plasmapheresis and intravenous immunoglobulin. Two-year graft survival was numerically worse in patients with AMR versus acute cellular rejection (ACR) (78% vs. 85%), but the difference was not statistically significant.

LATE ACUTE DYSFUNCTION

When acute allograft dysfunction develops more than 3 months after transplantation, the differential diagnosis should include prerenal azotemia due to volume depletion, CI nephrotoxicity, urinary tract infection or obstruction, acute rejection—possibly due to reduction in immunosuppression or noncompliance, recurrent or de novo renal disease, and renal artery stenosis.⁷⁴ The risk of late acute rejection is increased in patients who are tapered off cyclosporine³⁷ or steroids.⁷⁵ Bearing in mind that renal transplant recipients rarely achieve a glomerular filtration rate (GFR) exceeding 55/60 mL/min, a creatinine level less than 2 mg/dL represents good, although certainly not normal, renal function. Thus, under circumstances of volume depletion or infection, the creatinine can increase alarmingly quickly and still reflect small decreases in the GFR. Dehydration secondary to diarrhea can occur rapidly on exposure to enteropathogens in immunosuppressed transplant recipients. The principal aim of therapy under these circumstances is to ensure adequate volume and electrolyte replacement and maintain drug levels to prevent intercurrent rejection. Long-term transplant patients who miss several doses of steroids risk adrenal insufficiency.

Polyomavirus Nephropathy

The polyomaviruses that are known to cause disease in humans include BK, JC, and, much less commonly, SV40.⁷⁶ It is known that as many as 85% of adults in the general population are seropositive for BK and JC viruses as a consequence

of exposure during childhood.⁷⁷ By themselves, polyomaviruses tend not to be overtly pathogenic. However, in the setting of immunosuppression, malignancy, or acquired immunodeficiency syndrome, BK virus can cause nephropathy and hemorrhagic cystitis and JC virus can cause progressive multifocal leukoencephalopathy.

BK virus is the dominant pathogen causing polyomavirus nephropathy (PVN), although occasional cases have been reported due to JC and SV40. BK virus generally remains latent in kidney tissue and can induce inflammatory changes when the immune system is suppressed after transplantation. It has generally been assumed that PVN is due to reactivation of recipient disease. More recent data cast doubt on this premise. In a longitudinal study of almost 200 transplant recipients, pretransplant donor and recipient samples were analyzed for BK virus antibody titer and HLA alleles.⁷⁸ The donor antibody titer was found to be inversely proportional to onset of viruria, directly proportional to duration of viruria, and directly proportional to peak urine viral titer. Recipient pairs receiving kidneys from the same donor were concordant for BK virus infection and had matched sequences of segments of the defined genes that tend to vary among recipients of kidneys from different donors. All 11 recipients with sustained BK viremia received kidneys from donors lacking HLA C7, and 10 recipients also lacked C7.

The incidence of polyomavirus infection may differ among different organ recipients. For example, in a study of 263 heart, kidney, liver, and pancreas transplant patients, BK virus and JC virus DNAemia were observed most commonly in kidney and/or pancreas transplant patients (26%), although they were also observed, to a lesser extent, in heart (7%) and liver (4%) transplant patients.⁷⁹ As many as 8% of kidney transplant recipients will develop PVN with a concomitant risk of graft loss at 1 year ranging from 35% to 65%.⁸⁰ PVN has been described rarely in recipients of nonkidney transplants and can cause nephrosis and end-stage renal disease.^{76,81,82}

The incidence of PVN seems to be increasing, although it remains unclear whether this observation is related to enhanced recognition or more potent immunosuppression. Currently recognized risk factors include length of time after transplantation, rejection rescue therapy, type of immunosuppression, and co-infection with cytomegalovirus.^{83–85} Brennan and colleagues⁸³ examined 200 adult renal transplant recipients who were randomized to either tacrolimus or CsA. Urine and blood samples were collected at defined intervals for BK polymerase chain reaction. At 1 year, 35% had developed viruria and 11.5% viremia. Viral replication was not affected independently by tacrolimus, cyclosporin A (CsA), mycophenolate mofetil (MMF), or azathioprine, although viruria was highest with tacrolimus/MMF (46%) and lowest with cyclosporin/MMF (13%). After reduction of immunosuppression, viremia resolved in 95%, without increased acute rejection, allograft dysfunction, or graft loss. No BK nephropathy was observed. More recently, a significant association between BK virus nephropathy and HLA mismatching has been suggested.⁸⁶ This study also showed that BK virus nephritis was associated with a greater number of rejection episodes and a higher incidence of steroid-resistant rejection requiring antilymphocyte treatment. There was no association between BK virus nephropathy and any specific HLA allele. Active infection starts typically within the first 3 months in 80% of patients.⁸⁴ Cold ischemia time that exceeded 24 hours and the

administration of tacrolimus were identified as significant risk factors for viruria. The risk of viremia was greatest in patients with viruria (especially when the viral load exceeded 4 log/mL) and those treated with tacrolimus. No relationship was found between the development of nephropathy and genetic variability in the viral sequence.

Diagnosis

Many transplantation programs now routinely screen allograft recipients for polyomavirus infection either by urinary cytology or, more frequently, the more sensitive polymerase chain reaction assay in which viral DNA can be quantified in urine and blood.^{78,87,88} A consensus conference was recently held, and the report recommended that all renal transplant recipients should have their urine screened for BK virus replication⁸⁹ every 3 months during the first 2 years post-transplantation, when allograft dysfunction is noted, and when an allograft biopsy is performed. It should be noted that polyoma viruria is demonstrable as early as 4 weeks post-transplantation, and some programs initiate screening earlier than 12 weeks post-transplantation. They also recommended that positive screening results should be confirmed and assessed by quantitative assays and that a definitive diagnosis of PVAN requires allograft biopsy. In a simulation model in which patients positive for blood DNA polymerase chain reaction had their immunosuppression reduced, screening saved \$1912 and produced 0.02 more quality-adjusted life years than not screening.⁸⁸

The impact of the histologic features on the diagnosis and outcome of PVN was described in 90 patients.⁹⁰ Viral cytopathic changes, tubular atrophy (TA) and interstitial fibrosis (IF) as well as inflammation were scored and classified into defined histologic patterns. The histologic findings were correlated with viruria, viremia, and graft survival. PVAN lesions were found to be random and multifocal and affected both cortex and medulla. Areas with PVAN coexisted with areas of unaffected parenchyma. In 36.5% of biopsies with multiple tissue cores, discordant findings with PVAN-positive and -negative cores were observed. However, all patients with PVAN had decoy cells in urine as well as significant viruria and viremia. Biopsy specimens showing lesser degrees of renal scarring at the time of diagnosis were associated with, more likely, resolution of the infection, in response to decrease of immunosuppression. More advanced tubulointerstitial atrophy, active inflammation, and higher creatinine level at diagnosis correlated with a significantly worse graft outcome. Due to the focal nature of PVAN, correlation of biopsy results with viruria and viremia is required for diagnosis.

Treatment

Therapeutic options for established PVN include reducing immunotherapy, conversion to leflunomide, treatment of intercurrent infection, if present, with cidofovir, and retransplantation. It is generally agreed that decreasing immunosuppression is the primary therapy for PVN and alone is effective in reducing viremia and viruria in most cases.^{83,91} Leflunomide is an antimetabolite immunosuppressive agent that inhibits pyrimidine synthesis. The drug is licensed for the treatment of rheumatoid arthritis and is known to have antiviral and immunosuppressive properties. Williams and colleagues⁸⁰ provided a brief, nonrandomized report of 17 patients with biopsy-proven PVN in whom MMF was stopped and leflunomide commenced initially with a loading dose of 100 mg/day for 5 days

followed by a maintenance dose of 20 to 60 mg/day. Treatment was monitored by serial measurements of viral load as well as that of an active metabolite of leflunomide, A77 1726. This is an important point because leflunomide is P-450 metabolized and has an extremely long half-life. All patients who achieved a drug level in excess of 40 µg/mL either cleared or reduced their viral load. Two patients also required cidofovir.

Cidofovir is a monophosphate nucleotide analogue of deoxycytidine that competitively inhibits viral DNA polymerase. In vitro activity against a number of DNA viruses, including adenovirus, polyomavirus, papillomavirus, and herpesviruses has been demonstrated. Cidofovir also retains activity against thymidine kinase–negative herpes simplex virus and cytomegalovirus that are resistant to acyclovir and ganciclovir. Eighty percent of the drug is excreted unchanged in the urine within 24 hours. However, cidofovir diphosphate is an active metabolite that is eliminated more slowly with first- and second-phase intracellular half-lives of 24 and 65 hours, respectively, permitting the drug to be dosed every 2 weeks. Kuypers and colleagues⁹² reported a nonrandomized study of 8 of 21 patients who were treated with weekly adjuvant low-dose cidofovir in addition to reduction of immunosuppressive therapy. PVN caused irreversible deterioration of graft function in all patients, but renal function stabilized after antiviral treatment and no graft loss occurred in cidofovir-treated recipients during 25 months of follow-up. No cidofovir-related renal toxicity occurred. In contrast, 9 of 13 patients who received no adjuvant cidofovir therapy lost their graft after approximately 8 months.

The outcomes of 10 patients from 5 transplantation centers who had lost their primary renal allografts to PVN who underwent retransplantation were described.⁹³ Repeat transplantation occurred approximately 13 months after failure of the first graft. Allograft nephrectomy had been performed in 7 of the 10 patients. PVAN recurred in one patient 8 months after retransplantation, but stabilization of graft function was achieved with a decrease in immunosuppression and treatment with low-dose cidofovir. After a mean follow-up of 34 months, all patients were found to have good graft function with a mean creatinine level of 1.5 mg/dL. The authors concluded that patients with graft loss caused by PVN can safely undergo retransplantation. Initial results suggesting that ciprofloxacin may be useful in treating PVAN have not been confirmed.

LATE CHRONIC DYSFUNCTION

Many patients have slowly progressive azotemia over a period of years after kidney transplantation. The major etiologic considerations in this setting include chronic rejection, chronic CI nephrotoxicity, hypertensive nephrosclerosis, chronic urinary tract obstruction, and recurrent or de novo renal disease. The use of the nonspecific term chronic allograft nephropathy has now been formally abandoned by the Banff consortium due to concerns that this term “undermines recognition of morphologic features enabling diagnosis of specific causes of chronic graft dysfunction.”¹

Interstitial Fibrosis and Tubular Atrophy

IF/TA, previously referred to as chronic allograft nephropathy, is one of the most common causes of end-stage renal disease, accounting for 20% of kidney transplantations performed in

the United States and as many as 30% of patients awaiting renal transplantation.⁹⁴ Various terms have been used to describe this condition over time, although the acronym IF/TA is that chosen by the most recent iteration of the Banff consortium. The syndrome is clinically associated with progressive loss of graft function and hypertension with variable degrees of proteinuria. Approximately 2.6% of kidney grafts are lost yearly due to IF/TA.^{94,95}

Pathogenesis

The exact mechanisms responsible for the pathogenesis of IF/TA are varied and are summarized in Table 88-2. It has been postulated, however, that chronic graft dysfunction is mediated by both alloantigen-dependent and alloantigen-independent factors.^{96,97} Data from experimental models indicate a role for all elements of the immune system, including cell-mediated immune responses (delayed-type hypersensitivity responses mediated by macrophages and CD4⁺ T cells), humoral alloantibody responses against donor antigens, inflammatory cytokines, fibrogenic growth factors (such as platelet-derived growth factor and transforming growth factor β), and possibly the vasoactive and mitogenic peptide endothelin.

T-cell recognition of alloantigen in the presence of the appropriate costimulatory signal is the central and primary event that initiates the immunologic component of the rejection process that ultimately leads to chronic allograft loss. Such antigen is recognized either directly in the form of intact allo-major histocompatibility complex (MHC) on the surface of donor cells or indirectly in the form of processed peptide(s) that is itself derived from donor MHC presented by recipient antigen-presenting cells. There is increasing interest in this indirect pathway as peptide antigens are relatively simple structures that are readily synthesized.⁹⁸ This novel experimental approach permits the investigation of the molecular mechanisms of allograft rejection. Recent evidence indicates that allopeptide-primed T cells are present during both acute and chronic rejection.⁹⁹ Although primary immune responses are characterized by T-cell proliferative responses to a limited number of immunogenic MHC allo-

peptides under experimental circumstances, secondary responses, such as those that occur in chronic or late acute rejection, are associated with T-cell proliferative responses to a more variable repertoire.¹⁰⁰ This repertoire includes responses to peptides that were previously immunologically silent. Such a change in the pattern of T-cell responses has been termed epitope switching or spreading and can occur to peptides representing alternative regions within a given MHC β chain hypervariable region (intramolecular spreading) or, alternatively, peptides representing different MHC chains (intermolecular spreading). The precursor frequency of such MHC allopeptide reactive T cells is typically low, as evidenced by studies in humans with chronic renal allograft rejection. However, such a finding is not unexpected given the indolent nature of chronic rejection. Recent studies have provided a link between MHC allopeptide primed T cells and the development of acute vascular type rejection mediated in part by accelerating the production of alloantibodies. Such studies suggest that chronic allograft vasculopathy, the sine qua non of experimental chronic rejection, may also be mediated by T cells primed by the indirect pathway. Additional evidence of the importance of T-cell activation in chronic rejection is provided by experimental observations that inhibiting costimulatory signals such as the CD28:B7 pathway using cytotoxic T lymphocyte antigen 4 immunoglobulin or blockade of the CD40:CD40L pathway can prevent or even interrupt progression of chronic rejection in experimental models of cardiac and renal allograft rejection.⁹⁸ The development of the C4d assay in which the complement component gets covalently bound to endothelial structures in response to antibody activity has also cast a new light on immunopathogenesis. For example, glomerular C4d deposits were found in a cohort of 10 of 11 biopsies with IF/TA and in only 2 of 13 controls.¹⁰¹

Therapeutic Options for Interstitial Fibrosis and Tubular Atrophy

Despite the frequency of IF/TA as a cause of premature graft failure and the frequency with which clinical research papers are published annually, therapeutic options are limited. Treatment strategies include prevention and management of established disease and are summarized in Box 88-3.

Prevention

Most programs strive to minimize acute rejection rates based on the understanding that either clinical or subclinical rejection is a major risk factor for the development of IF/TA.³⁵ Data are accumulating that some of the newer immunosuppressive medications currently in clinical practice are associated with a lower incidence of IF/TA compared with older regimens. For example, in a small single-center study, the incidence of biopsy-confirmed IF/TA was 31% in patients treated with MMF compared with 63% in those treated with azathioprine when both groups also received prednisone and cyclosporine.¹⁰² Meier-Kriesche and colleagues¹⁰³ performed an analysis of registry data and found that continued therapy with MMF compared with azathioprine was associated with a protective effect against declining renal function at 1 year. Continued therapy with MMF at 2 years was associated with a further reduction in the risk of decreased renal function.

Protocols that avoid the deleterious effects of CI continue to be pursued. Renal function, structure, and gene expression were studied in a prospective, randomized trial that compared a CI-free to CI-based immunosuppressive regimen.¹⁰⁴ Kidney

Table 88-2 Interstitial Fibrosis and Tubular Atrophy: Morphology and Causes of Specific Chronic Renal Allograft Diseases

Etiology	Morphology
Chronic hypertension	Arterial thickening with reduplication of elastica and hyaline arteriosclerosis
Calcineurin inhibitor toxicity	Arteriolar hyalinosis and tubular cell injury with vacuolization
Chronic obstruction	Marked tubular dilatation
Bacterial pyelonephritis	Intratubular neutrophils
Viral infection	Viral inclusions on histology, immunohistochemistry, and electron microscopy

Adapted from Solez K, Colvin RB, Racusen LC, et al: Banff '05 Meeting Report: Differential diagnosis of chronic allograft injury and elimination of chronic allograft nephropathy ('CAN'). *Am J Transplant* 2007;7:518–526.

Box 88-3 Interstitial Fibrosis and Tubular Atrophy Therapeutic Strategies**Prophylactic Interventions**

- A. Alloantigen-dependent mechanisms
- Optimize HLA match
 - Long term benefit greatest with matching for HLA-A>HLA-B>HLA-DR
 - Avoidance of sensitization to HLA
 - As much as 6% differential in 3-year graft survival in patients who are highly sensitized versus nonsensitized (treated with cyclosporin A)
 - Blood transfusion effect
 - 1-DR matching
 - Donor-specific transfusion
 - As much as 10% improvement in 3-year graft survival in those who did not become sensitized to HLA
 - Avoidance of acute rejection
 - Mycophenolate mofetil
 - Neoral versus cyclosporin A (?)
 - Tacrolimus
 - Antibody induction therapy
 - Impact of newer immunosuppressive agents and antibody induction protocols on chronic graft loss remains unproven. Tacrolimus can negate impact of sensitization on long-term graft loss.
- B. Alloantigen-independent mechanisms
- Nephron undersupply
 - Donor-recipient age matching
 - Donor-recipient weight matching
 - Double kidney transplants
 - Theoretical benefits from providing adequate nephron dose. Optimizing this variable may conflict with organ procurement.
 - Renal Injury
 - Minimize cold ischemia time
 - Preservation solution
 - Risk of ATN is greatly increased when cold ischemia exceeds 24 hours. Risk of CAD increases if ATN is complicated by acute rejection.

Therapeutic Interventions

- Cytomegalovirus
- Potential benefits of antiviral chemotherapy
- Hyperfiltration
- Potential benefits of preventing/treating hyperfiltration
- Hypertension
- Calcium channel blockers probably of maximal benefit in early posttransplantation period when calcineurin inhibitor dose is highest
- Proteinuria
- Potential benefit of reducing proteinuria (unproven)
- Hyperhomocysteinemia
- Potential benefit of reducing homocysteine levels (unproven)
- Hyperlipidemia
- 3-Hydroxy-3-methylglutaryl coenzyme A reductase inhibitors reduce risk of acute rejection. Unproven benefit in preventing coronary artery disease

recipients were treated with basiliximab, MMF, and prednisone and were randomly assigned to either sirolimus (SRL) or cyclosporine. Renal function as measured by iothalamate GFR was 60 mL/min in the SRL group compared with almost 50 mL/min in the CsA group. Regression analysis of calculated GFRs yielded a positive slope for SRL of 3.36 mL/min per year and a negative slope for CsA of -1.58 mL/min per year. Gene expression profiles from kidneys with higher Banff IF/TA scores confirmed significant up-regulation of the genes responsible for inflammation, fibrosis, and tissue remodeling.

Vincenti and colleagues¹⁰⁵ reported a study in which patients were randomized to either cyclosporine-based immunotherapy or a novel costimulatory blockade molecule, belatacept (LEA29Y). Various animal studies have previously indicated that such a strategy can effectively prevent allograft rejection and in some cases induce tolerance.⁹⁸ In this protocol, patients received conventional immunosuppression with basiliximab, MMF, and steroid along with either cyclosporine or two different dosing regimens of belatacept. At 6 months, the incidence of acute rejection was similar among the groups and at 12 months, the GFR was significantly higher in both belatacept groups compared with cyclosporine. Biopsy-confirmed IF/TA was less common in both belatacept groups compared with the cyclosporine group. Lipid levels and blood pressure values were similar or slightly lower in the belatacept groups, despite the greater use of lipid-lowering and antihypertensive medications in the cyclosporine group.

Treatment of Established Interstitial Fibrosis and Tubular Atrophy

The limited therapeutic options for established chronic allograft nephropathy include inhibition of the renin-angiotensin system and altering the immunosuppressive drug strategy. One retrospective European study found that renal allograft outcome was influenced by the relative change in renal function over time, urinary protein excretion, hypertension, and renin-angiotensin system blockade.¹⁰⁶ In this nonrandomized cohort, renal allograft survival after treatment with renin-angiotensin system blockade was significantly longer at 6.3 years as opposed to 1.8 years in untreated patients. It has also been suggested that 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor therapy may have an impact on renal allograft survival. Unfortunately, the null hypothesis was supported in a post hoc analysis of the ALERT (Assessment of Lescol in Renal Transplantation) study.⁹⁵ More than 2000 renal transplant recipients were randomized to receive either fluvastatin or placebo and followed for as long as 6 years. Although fluvastatin treatment significantly lowered cholesterol, no significant effect on the incidence of renal graft loss or GFR was seen. It should be noted that fluvastatin had no impact on total mortality or graft loss.¹⁰⁷ However, fluvastatin was a safe and effective agent for reducing low-density lipoprotein cholesterol and was associated with a reduced risk of major adverse cardiac events in kidney transplant recipients.

A variety of immunosuppressive strategies for treatment of established IF/TA have been studied over time. Such approaches have included the addition of MMF, withdrawal of CIs, and the addition of SRL.

Most transplantation centers routinely use MMF as part of their standard induction and maintenance immunosuppressive protocol. Nevertheless, a limited number of patients continue to take azathioprine as the antimetabolite component of

their immunosuppressive regimen. It has been suggested that such patients may benefit from switching to MMF. In a non-randomized study of renal allograft recipients with biopsy-proven chronic allograft nephropathy, MMF was substituted for azathioprine.¹⁰⁸ At inclusion, each group received 2 g/day of MMF and azathioprine was stopped. Before the introduction of MMF, renal function had been deteriorating progressively. After the introduction of MMF, renal function stabilized and a significant change in the slope of the GFR was observed.

The long-term nephrotoxic potential of both CIs has been well characterized. Although tacrolimus may be less nephrotoxic than cyclosporine, elimination of either drug remains an attractive strategy in patients with established IF/TA who are losing graft function. The withdrawal of a nephrotoxin must be balanced against the risk of rejection and, consequently, CI withdrawal strategies usually employ the introduction of a potent, nonnephrotoxic agent such as MMF or SRL. A prospective, randomized study compared the introduction of MMF with or without CI withdrawal in long-term transplant recipients with histologically proven IF/TA and deteriorating renal function.¹⁰⁹ An interim analysis found a greater than expected difference between groups in terms of renal function deterioration, and the study was stopped prematurely. There were 20 patients in the MMF/CI continuation and 19 patients in the MMF/CI withdrawal groups. Renal function and blood pressure control improved in the dual-therapy compared with the triple-therapy group, and no acute rejections occurred. In a controlled, multicenter study, CsA-treated renal allograft recipients with IF/TA were randomized to have their CsA discontinued with the concomitant addition of MMF to their regimen or to continue treatment with CsA.¹¹⁰ Fifty-eight percent of patients who had the CsA withdrawn achieved the primary endpoint defined as a stabilization or reduction of serum creatinine, as evidenced by an improvement in slope of the 1/SCr plot and no graft loss compared with 32% of patients who continued CsA. There were no acute rejections in CsA withdrawal group during the study period.

Various studies have indicated that SRL is equally effective as cyclosporine in preventing early allograft rejection. Adverse effects of SRL include edema, thrombocytopenia, hyperlipidemia, and delayed wound healing. The pivotal trials that studied SRL in place of CsA indicated that SRL-treated patients had a significantly higher GFR at the end of the first posttransplantation year. It is now also recognized that SRL is associated with at least some nephrotoxicity as evidenced by prolongation of DGF immediately post-transplantation and the development of long-term proteinuria in some patients. In an analysis of pretransplantation and 1-year renal allograft biopsies of patients enrolled in a multicenter trial, patients who received cyclosporine and SRL during the first 3 months post-transplantation were randomly assigned to continue cyclosporine or have it withdrawn.¹¹¹ The proportion of patients in whom chronic pathologic lesions progressed was lower in the cyclosporine elimination group. There was significantly less chronic interstitial and tubular disease, whereas no differences were observed in rejection. In a study of 59 renal transplant patients with IF/TA who were converted to SRL, renal function improved in 54% and deteriorated in 46%.¹¹² Patient and graft survival rates were 100% and 92%, respectively, at 1 year. In a multivariate analysis, proteinuria less than 800 mg/day was the only independent variable that predicted a favorable outcome.

Calcineurin Inhibitor Nephrotoxicity

The toxic effects of CI therapy can be divided temporally and pathogenically into two discrete categories. Acute nephrotoxicity manifests as azotemia, which is largely reversible after dose reduction and is due predominantly to vasoconstriction. Chronic CI toxicity manifests as irreversibly progressive renal disease and hypertension and is due to fibrogenesis. Most of the literature devoted to the mechanisms of CI nephrotoxicity examines the effects of cyclosporine as opposed to the newer agent tacrolimus. Although it is now generally agreed that tacrolimus is less nephrotoxic compared with cyclosporine, this drug can have a significant impact on kidney function in both the short and long term via mechanisms that are largely presumed to be the same as those of cyclosporine.

Acute Toxicity

Renal transplant patients treated with cyclosporine may develop nephrotoxicity that can manifest in many ways. In addition to azotemia, other renal effects of cyclosporine include tubular dysfunction with concomitant electrolyte and acid base disturbances and rarely thrombotic microangiopathy. A similar pattern of renal injury associated with the use of tacrolimus may be less severe.^{113,114} Attention must also be paid to drug dose and to drug interactions to minimize toxicity and maximize efficacy. In the earliest clinical renal transplantation trials using cyclosporine, a high incidence of oliguric acute tubular necrosis and primary nonfunction was observed; the risk was greatest with prolonged ischemia time of the donated kidney before transplantation. Subsequent trials using lower doses of cyclosporine showed that these problems were dose related. Studies in experimental animals have demonstrated that cyclosporine causes vasoconstriction of the afferent and efferent glomerular arterioles and decreases in renal blood flow and GFR. Cyclosporine is not a direct vasoconstrictor, however, and the exact mechanism of vasoconstriction is unclear, but there appears to be substantial impairment of endothelial cell function, leading to decreased production of vasodilators (prostaglandins and nitric oxide) and enhanced release of vasoconstrictors (endothelin and thromboxane).¹¹⁵⁻¹¹⁸ Increased sympathetic tone also may be present, although renal vasoconstriction occurs even in denervated kidneys.¹¹⁹ The increase in renal vascular tone induced by cyclosporine does not attenuate with time. Maintenance cyclosporine therapy is associated with transient reductions in renal plasma flow and GFR, which correlate with both dose and peak cyclosporine levels reached 2 to 4 hours after the oral dose and reverse when reasonable drug levels are attained. Administration of a calcium channel blocker can prevent the renal vasoconstriction.^{120,121} This observation constitutes part of the rationale for the use of calcium channel blockers to treat hypertension in cyclosporine-treated transplant recipients. The increase in vascular resistance may be reflected clinically by an elevated plasma creatinine concentration and hypertension. Acute cyclosporine nephrotoxicity is usually reversible with cessation of therapy, as both the plasma creatinine concentration and systemic blood pressure decrease toward baseline values for that patient. The important clinical problem is to differentiate cyclosporine-induced renal dysfunction from acute rejection. The only definitive diagnostic test is biopsy of the renal allograft. Although there are no specific pathologic changes induced acutely by cyclosporine, the absence of cellular or vascular rejection, coupled with tubular

damage including vacuolization of the tubular epithelial cells, strongly suggests cyclosporine nephrotoxicity. In addition, the presence of rejection does not exclude concomitant cyclosporine toxicity. Rarely, vascular lesions similar to those seen in the thrombotic microangiopathies are seen. This lesion is idiosyncratic and presumably initiated by cyclosporine-induced injury to the vascular endothelial cells.

Chronic cyclosporine nephrotoxicity manifests as renal insufficiency due to glomerular and vascular disease, abnormalities in tubular function, and an increase in blood pressure. The biopsy specimen reveals an obliterative arteriopathy, ischemic collapse or scarring of the glomeruli, vacuolization of the tubules, and focal areas of IF/TA.¹²² These changes are typically seen with high-dose cyclosporine therapy (>6 mg/kg/day). The factors responsible for chronic cyclosporine nephrotoxicity are not well understood. It has been proposed that the arterial lesions are the primary abnormality, with ischemia being responsible for the tubular and interstitial lesions. However, animal studies have shown that the vascular and interstitial findings can be dissociated. It is now accepted that transforming growth factor β , a cytokine with both potent immunosuppressive and fibrogenic properties, is up-regulated by cyclosporine in an experimental model of chronic cyclosporine nephropathy.^{123–125} The development of IF is also associated with increased expression of osteopontin, a potent macrophage chemoattractant, by the tubular epithelial cells.¹²⁶ Other evidence that supports an alternative mechanism for cyclosporine toxicity is the observation that administration of either an endothelin A receptor antagonist or calcium channel blocker can prevent hypertension and decreases in renal plasma flow and yet have no impact on the development of arteriopathy.¹²⁷

Perhaps the best information available to support the hypothesis of chronic cyclosporine nephrotoxicity comes from nonkidney solid organ transplant patients in whom the nephrotoxic potential of cyclosporine can be evaluated in the absence of coexisting acute or chronic renal allograft rejection.¹²⁸ During a median follow-up of 36 months, chronic kidney disease developed in 16.5% of almost 70,000 recipients of (non-kidney) solid organ transplants.¹²⁸ Almost 30% required maintenance dialysis or renal transplantation. The 5-year risk of chronic renal failure varied according to the type of organ transplanted, from 7% among recipients of heart-lung transplants to 21% among recipients of intestine transplants. Factors associated with an increased risk of chronic kidney disease included increasing age, female sex, hepatitis C infection, hypertension, diabetes mellitus, and postoperative acute kidney injury. The applicability of these findings to renal allografts is uncertain; it has been suggested, for example, that the denervated kidney may be less susceptible to cyclosporine-induced renal injury.¹²⁹

Calcineurin Inhibitor Dosing

There are few studies that clearly define the optimal dose of cyclosporine in renal transplantation. More recently, a number of investigators have focused on tailoring cyclosporine to a 2-hour peak (C₂) level as against the traditional 12-hour trough (C₀) level.^{130–134} Some such studies have indicated that targeting higher peak levels may be associated with delivery of higher doses of cyclosporine in the early posttransplantation period and lower early rejection rates.^{130,134} However, C₂ monitoring has not been shown to have an impact on patient or

graft survival, and the whole endeavor has been eclipsed by the emergence of tacrolimus as the dominant CI over the past few years.⁵² It should also be noted that the introduction of cyclosporine microemulsion preparations in the mid-1990s has had no appreciable impact on patient or graft survival rates.

Tacrolimus is 100 times more potent than cyclosporine on a milligram-per-milligram basis. As such, the starting dose is generally in the range of 0.05 to 0.1 mg/kg twice daily. As the bioavailability of tacrolimus is more predictable than cyclosporine, 12-hour trough levels are deemed sufficient for monitoring.¹³⁵ The desired target level within the first 3 months is generally 8 to 15 ng/mL.¹³⁶ Thereafter, levels are allowed to run at a lower level.

In view of the utility of calcineurin inhibition in transplantation and autoimmune diseases, there has been a great deal of interest in developing novel therapeutic strategies to minimize their nephrotoxic potential. Animal data and preliminary observations in humans that suggested that fish oil may be beneficial were never confirmed.^{137,138} Animal and human data also suggest that concurrent administration of calcium channel blockers may be protective against cyclosporine nephrotoxicity, at least in part by minimizing renal vasoconstriction.^{120,121} However, there is at present no proof that these agents increase graft survival. The likely explanation for the inability to demonstrate a long-term benefit with calcium channel blockers in patients treated with cyclosporine is that reversal of renal vasoconstriction, although beneficial, does not affect the concurrent up-regulation of transforming growth factor β , and, therefore, fibrosis can proceed uninterrupted.

RECURRENT AND DE NOVO RENAL DISEASE POST-TRANSPLANTATION

Virtually all primary renal diseases can recur in a kidney transplant with the exception of polycystic kidney disease, hereditary nephritis, and chronic tubulointerstitial nephritis.^{139–141} The diagnosis of recurrent glomerular disease post-transplantation depends on an initial complete and accurate histologic evaluation of the primary nephropathy leading to renal failure and the documentation of the same disease in the transplanted kidney. Although disease recurrence is relatively common post-transplantation, the precise incidence is unknown and recurrence accounts for only 2% to 5% of all graft failures.^{139,142,143} Clearly, recurrent primary and secondary glomerulonephritides are a cause of concern for patients and their physicians, and there is some evidence to suggest that recipients of living related donor transplants¹⁴⁴ and pediatric recipients are at greater risk. Recurrent glomerular disease in the allograft is the third most common cause of premature graft failure after death with function and chronic allograft nephropathy.¹⁴¹

The presence of focal glomerulosclerosis on the transplant biopsy specimen must be distinguished from recurrent disease in those patients in whom primary focal glomerulosclerosis was responsible for the initial renal failure.¹³⁹ The onset of proteinuria typically occurs within hours or days in recurrent focal glomerulosclerosis, whereas in the chronic de novo disease, protein excretion does not begin to increase until 3 or more months after transplantation and then increases slowly. Early data indicated that staphylococcal protein A immunoabsorption can induce partial or complete remission in such

patients with recurrent disease. More recent reports have focused on the use of plasmapheresis for recurrent focal segmental glomerulosclerosis post-transplantation.¹⁴⁵

Patients with Alport syndrome can develop antiglomerular basement membrane nephritis post-transplantation.^{146,147} These patients lack the $\alpha 5$ chain of type IV collagen and presumably mount a humoral response on receiving an allograft that contains the offending collagen structure. Interestingly, the antibodies produced are directed against the $\alpha 3$ chain, the reason for which is not known.¹⁴⁸ The frequency with which this complication arises is unclear due to variable reporting; however, it appears to be uncommon. It is more often associated with graft failure in patients who have undergone retransplantation, probably due to previous sensitization to the glomerular basement membrane antigen.

Metabolic diseases that recur include diabetes mellitus, oxalosis, amyloidosis, and, to a lesser extent, cystinosis. There is in these patients clearly a milieu that is not altered per se by renal transplantation. When a patient with diabetes receives a kidney, typical histologic changes generally can be seen within 2 years. The clinical course is variable, however, and progression does not correlate with donor age, human leukocyte antigen match, recipient age, or chronic rejection.¹⁴⁹ Simultaneous pancreas-kidney transplantation may prevent such complications.¹⁵⁰

Pessimism resulted from early reports of rapid recurrence of oxalosis after renal transplantation alone. However, better results have been achieved more recently.¹⁵¹ Combined liver and kidney transplantation in this setting, however, may be curative.

MALIGNANT DISEASE	1018		

Recommendations for outpatient surveillance of renal transplant recipients have been provided by the Clinical Practice Guidelines Committee of the American Society of Transplantation.¹ Three useful points should be kept in mind when prescribing medications for renal transplant recipients. First, because most renal transplant recipients have renal function at stage 3 chronic kidney disease (CKD) (i.e., glomerular filtration rate [GFR] 30–59 mL/min), dosage adjustments will be necessary for many medications (see Chapter 91). Second, because cyclosporine, tacrolimus, and sirolimus are metabolized by the cytochrome P450 3A4 (CYP3A4) pathway, and many other drugs share this pathway, their various drug interactions need to be considered² (see the section on Hyperlipidemia in this chapter). Third, tablet splitting should not be used for special formulations such as enteric-coated and unscored extended release tablets, nor for certain combination tablets (e.g., amoxicillin/clavulanic acid, irbesartan/hydrochlorothiazide, ezetimibe/simvastatin).³

CARDIOVASCULAR DISEASE

Cardiovascular disease (CVD; see also Chapter 70) remains the leading cause of mortality in recipients of renal allografts, and its proportion of total deaths in these patients has increased. Moreover, CVD accounts for 36% of patients dying with a functioning graft in the first 10 years after transplantation. By 15 years after renal transplantation, approximately 23% of patients develop coronary heart disease (CHD), 15% develop cerebrovascular disease, and 15% develop peripheral arterial disease.¹ “The annual risk of a fatal or nonfatal CVD event of 3.5% to 5% in renal transplant recipients is 50-fold higher than in the general population.”⁴

Coronary Heart Disease

The annual mortality from CHD in renal transplant recipients age 25 to 34 years is equivalent to mortality from CHD in those age 45 to 54 years in the general population; CHD mortality for renal transplant recipients age 45 to 54 years is comparable to that of those age 55 to 64 years in the general population, with mortality rates converging at age 75 to 84 years.⁵ When compared with CHD in renal transplant recipients before 1986, the relative risk of CHD decreased to 0.60 between 1986 and 1992, and even further, to 0.27, after 1992.⁶ Moreover, in patients who suffered an acute myocardial infarction (MI) between 1990 and 1996, compared with those who suffered an acute MI between 1977 and 1984, there has been a 51% reduction in the risk of cardiac mortality.⁷

Three important new themes in CHD have recently emerged. (1) Patients in high-risk and very high-risk categories for CHD (this could apply to many renal transplant recipients) had a low-density lipoprotein cholesterol (LDL-C) goal set at less than 70 mg/dL as a therapeutic option (Treating to New Targets, TNT study)^{8,9}; based on a meta-analysis of studies in nontransplant patients with either stable CHD or acute coronary syndrome, a 16% to 22% event reduction can be expected.^{8,10} (2) In patients with stable CHD, percutaneous coronary intervention, when added to optimal medical therapy, did not reduce the risk of death, MI, or other major cardiovascular events.¹¹ (3) In 40,450 patients with established CHD, those who had not undergone either percutaneous coronary intervention or coronary artery bypass graft (CABG) and were dependent on medical therapy only, were the *least* likely to be receiving evidence-based therapies.¹²

The management of CHD can be directed at two levels: medical treatment of CHD risk factors and diagnosis of CHD, and medical and interventional treatment of established CHD.

Level I: Medical Treatment of CHD Risk Factors and Diagnosis of CHD

Posttransplantation risk factors for CHD may be classified as not modifiable, difficult-to-modify, in transition, and modifiable (Box 89-1).⁶ In one major study, hypertension and LDL-C could no longer be identified as CHD risk factors, apparently because of intensive treatment.¹³ Applying the Framingham Heart Study CHD Risk Score (Framingham Risk Score) to renal transplant recipients tends to underestimate the risks, especially for diabetics.^{6,14} CHD risk factors in renal transplant recipients, when compared with those in the nontransplant population, include risks specific to transplantation (e.g., acute rejection, use of certain immunosuppressants [see Box 89-1], pretransplant splenectomy), risks disproportionately accentuated by transplantation (e.g., diabetes mellitus, age, cigarette smoking),⁶ risks of similar magnitude (e.g., male gender, hypertension, decreased high-density lipoprotein cholesterol [HDL-C] and high LDL-C), risks related to CKD and proteinuria, and risks that may reflect another process (e.g., hypoalbuminemia reflecting increased interleukin-1 and interleukin-6 inflammatory activity).^{6,13,15-19} A recent study of 643 patients with a bone mineral density (BMD) T-score of -1.0 or less quantitated the known risk that created for CHD.²⁰ Overall, patients with a BMD T-score of -1.0 or lower had a 43% greater hazard of CHD compared to those with normal BMD (see Box 89-1).

minemia reflecting increased interleukin-1 and interleukin-6 inflammatory activity).^{6,13,15-19} A recent study of 643 patients with a bone mineral density (BMD) T-score of -1.0 or less quantitated the known risk that created for CHD.²⁰ Overall, patients with a BMD T-score of -1.0 or lower had a 43% greater hazard of CHD compared to those with normal BMD (see Box 89-1).

Risk Assessment

The first step in risk management is risk assessment. The 10-year risk for developing CHD can be assessed by a risk scoring system that expands the original three major risk categories for CHD—high risk (10-year risk $> 20\%$ mortality); moderately high risk (10-year risk 10% – 20%); moderate risk ($<10\%$ risk)—by adding two new groups: very high risk and lower risk.^{9,21} The new designation of a very high-risk patient includes the following criteria: the presence of established CVD plus (1) multiple major risk factors (especially diabetes mellitus); (2) severe and poorly controlled risk factors (especially cigarette smoking); (3) multiple risk factors of the metabolic syndrome (especially high triglycerides ≥ 200 mg/dL plus non-HDL-C ≥ 130 mg/dL with low HDL-C < 40 mg/dL); and (4) patients with acute coronary syndrome.⁹

Box 89-1 Posttransplantation Risk Factors* for Coronary Heart Disease

Not Modifiable

Increasing age^{‡,§}
 Male gender^{‡,§}
 Pretransplantation CHD
 Atherosclerotic disease

- In carotid arteries^{‡,§}
- In peripheral vessels^{‡,§}

 Plaque burden in coronary arteries
 Pretransplantation diabetes mellitus^{‡,§}
 Family history of premature CHD
 Pretransplantation splenectomy[†]

Difficult-to-Modify

Smoking[†]
 Excess weight
 Sedentary lifestyle
 HDL-C (each 10 mg/dL)[†]
 Lipoprotein (a)
 Stages 3–5 CKD proteinuria

In Transition[†]

Modifiable

Hypertension[¶]
 Elevated total cholesterol[§]
 LDL-C ≥ 130 mg/dL[¶]
 Left ventricular hypertrophy

*Not all risk factors have been subjected to analysis.

[†]Arrow indicates direction of change based on frequency of occurrence (acute rejection), trends to treatment minimization or avoidance (prednisone, cyclosporine), trends to increased use (tacrolimus, sirolimus), and evolving evidence that hyperuricemia, hyperparathyroidism, and osteoporosis are, and hyperhomocysteinemia is not, likely to be significant coronary risk factors.

[‡]Independent risk factor for post-transplantation CHD identified by multivariate analysis.

[§]Risk factor for posttransplantation CHD identified by discriminate analysis. (Kasiske BL, Chakkeria HA, Roel J: Explained and unexplained ischemic heart disease risk after renal transplantation. *J Am Soc Nephrol* 2000;11:1735–1743.)

[¶]These traditional risk factors did not appear in some analyses presumably because they were aggressively treated.

[¶]Although each of these immunosuppressants has not been subjected to specific analysis as a coronary risk factor, they may be considered risk factors because each has potential significant risk(s) for provoking known coronary risk factors: prednisone (hypertension, hypercholesterolemia, diabetes); cyclosporine (hypertension, hypercholesterolemia, diabetes); tacrolimus (hypertension, diabetes); sirolimus (hypercholesterolemia and more frequent rejection).

The diagnosis of CHD is usually based on a description of angina pectoris or MI, but many patients have atypical pain; those with diabetes mellitus often are asymptomatic. Clinical suspicion and use of the expanded Framingham Risk Score will often lead the clinician to consider stress imaging. Imaging stress testing is usually either nuclear-based (assessing perfusion) or echo-based (assessing myocardial contractility); each of these may use either exercise or pharmacologic stressors (i.e., dipyridamole, adenosine, or dobutamine). From a practical point of view, dipyridamole and adenosine stress tests are not heart-rate dependent. Screening for CHD by electron beam computed tomography and coronary calcium scoring remains unproved.^{22,23} Although plaque burden is a coronary risk factor²⁴ and coronary calcium scoring reflects plaque,²⁵ calcified plaques are relatively stable.²⁶ The threshold for performing coronary arteriography rests with the interventional cardiologist, but generally it is based on the presence of ischemic symptoms or evocable ischemia.

Hypertension

Hypertension is a well-established risk factor for CHD (see Chapters 58 and 59).

Hyperlipidemia

Hyperlipidemia occurs in 50% to 80% of renal transplant recipients treated with prednisone and calcineurin inhibitors. It usually consists of elevated LDL-C, apolipoprotein B, triglycerides (particularly when sirolimus is used), and very low-density lipoproteins; and low, normal, or even slightly elevated serum HDL-C levels.²⁷⁻²⁹ Elevated LDL-C levels have been identified as a risk factor for cardiovascular disease in several, but not all, studies, probably because of treatment effects.^{13,30} Glucocorticoids, cyclosporine, and sirolimus promote hyperlipidemia.^{28,31} Severe hypercholesterolemia and hypertriglyceridemia were 3 to 4 times more frequent with sirolimus than with cyclosporine and were maximal after approximately 2 months of therapy.³² The Framingham Risk Score has been used to estimate that sirolimus in doses of 2 or 5 mg/day would cause an increased incidence of two or three new cases of CHD per thousand renal transplant recipients per year, respectively.^{32,33} Hypercholesterolemia tends to improve within the first 6 to 12 months after transplantation, when prednisone and cyclosporine, sirolimus, or tacrolimus doses are being tapered, as may hypertriglyceridemia when sirolimus and prednisone doses are decreased. Nevertheless, significant persistent hyperlipidemia warrants treatment (Table 89-1).

It is important to consider secondary causes of dyslipidemias: for hypercholesterolemia these include hypothyroidism, nephrotic syndrome, obstructive liver disease, and use of prednisone, cyclosporine, and sirolimus; for hypertriglyceridemia these include diabetes mellitus, chronic excessive alcohol consumption, prednisone, and sirolimus. Other drugs that can cause dyslipidemias include anticonvulsants, isotretinoin, β -blockers, diuretics, androgens/anabolic steroids, oral contraceptives, and highly active antiretroviral agents.³¹

Lowering LDL-C is achieved by therapeutic lifestyle changes and drug therapy (see also Chapter 63).³¹

Drug therapy includes statins, ezetimibe, bile acid sequestrants, nicotinic acid, fibric acid derivatives, and omega-3-acid ethyl esters. A complete description of lipid-lowering agents, their mechanisms of action, and side effects is given in Chapter 63. However, their use in renal transplant recipients often requires modification because of impaired renal func-

tion and the use of certain immunosuppressants. Cyclosporine can cause significant blood level elevations of those statins metabolized by the CYP3A4 pathway (i.e., atorvastatin, lovastatin, and simvastatin), as well as pravastatin, metabolized in the liver by sulfation, and rosuvastatin, metabolized by the CYP2C9 pathway.^{31,34} Cyclosporine may not raise the level of fluvastatin, which has multiple metabolic pathways, including CYP2C9.^{31,34,35} Ingestion of food increases the bioavailability of lovastatin.³⁶ Cyclosporine levels can be increased by pravastatin, simvastatin and, to a minor degree, by atorvastatin.^{34,36} Recommended daily statin doses need to be adjusted for the level of renal function and certain immunosuppressants (Table 89-2).³¹ "It is recommended that the maximum doses of statins be reduced in patients receiving either cyclosporine or tacrolimus. The effects of sirolimus on statins are unknown."³¹ It has not been established that the addition of coenzyme Q10 to statin treatment reduces its potential for causing myopathy.³⁷ The phosphate binder sevelamer binds bile acids and can lower LDL-C.³⁸

The only prospective, randomized, controlled trial of statin therapy in renal transplant recipients is the Assessment of Lescol in Renal Transplantation (ALERT) study, which compared 40 to 80 mg/day of fluvastatin with placebo in 2102 cyclosporine-treated stable recipients followed for 5 to 6 years.³⁹ The primary endpoint of a composite of cardiac death, definite or probable MI, and coronary revascularization was reduced 17% by fluvastatin.³⁹ Although the difference in this endpoint did not achieve statistical significance, a post hoc analysis using cardiac death or definite nonfatal MI did show a significant decrease with fluvastatin from 104 to 70 events ($P = .005$).⁴⁰ In a study of 12 cyclosporine-treated patients with elevated LDL-C levels, atorvastatin was more effective in reducing LDL-C than was a change from cyclosporine to tacrolimus, although a combination of atorvastatin and a change to tacrolimus had the greatest effect.⁴¹ Reviews of 13 statin trials in renal transplant recipients, including the ALERT study, confirmed in 6 of 7 studies their benefit in reducing cardiac events, but in 3 of the largest and most recent studies, there was no evidence that they reduced acute rejection.⁴²⁻⁴⁴ Additional benefits of statins include a reduction in the level of circulating endothelin 1; decreases in systolic, diastolic, and pulse pressure⁴⁵; reduced CRP and reduction of acute primary coronary events⁴⁶; and antiproliferative^{47,48} and immunomodulatory effects.⁴²

Patients should be monitored every 3 to 6 months, or as clinically indicated, with alanine aminotransferase (ALT) levels for hepatic toxicity and creatine kinase (CK) enzymes for muscle toxicity (although dose-related myopathy can occur with or without CK elevation),⁴⁹ and at more frequent intervals with serum creatinine and blood levels of the immunosuppressants that can be affected by statins.^{31,34} Proteinuria was associated with the use of 80 mg of rosuvastatin, a dose no longer marketed.⁵⁰ The possibility that proteinuria is actually a statin-class effect with a renal tubular mechanism involving blocked endocytosis by megalin and cubilin has been analyzed in meta-analyses^{51,52} and will be further elucidated in ongoing trials.⁵³

Ezetimibe was used as additional therapy for 18 renal transplant patients receiving cyclosporine ($N = 11$), tacrolimus ($N = 6$), or sirolimus ($N = 1$) plus 7.5 prednisone, and whose LDL-C levels were uncontrolled by high-dose statin therapy (80 mg fluvastatin in 14, 40 mg fluvastatin in 1, 40 mg pravastatin in 2, 80 mg simvastatin in 1).⁵⁴ LDL-C levels were reduced from 178 ± 41 mg/dL to 117 ± 40 mg/dL after 3 months of additional ezetimibe 10 mg daily. There were no significant changes

Table 89-1 Adult Treatment Panel III Low-density Lipoprotein Cholesterol (LDL-C) Goals and Cutpoints for Therapeutic Lifestyle Changes (TLC) and Drug Therapy in Different Risk Categories and Proposed Modifications Based on Recent Clinical Trial Evidence

Risk Category	LDL-C Goal	Initiate TLC	Consider Drug Therapy*
<i>Very high risk:</i> (10-yr risk >20% plus other features) (see text)	<100 mg/dL (optional goal: <70 mg/dL [†])	≥70 mg/dL	≥70 mg/dL
<i>High risk:</i> CHD ^{‡,¶} or CHD risk equivalents [§] (10-yr risk > 20%)	<100 mg/dL (optional goal: <70 mg/dL) ^{†,§}	≥100 mg/dL [¶]	>100 mg/dL (<100 mg/dL: consider drug options)*
<i>Moderately high risk:</i> 2+ risk factors** (10-yr risk 10%–20%) ^{††}	<130 mg/dL ^{††}	≥130 mg/dL [¶]	≥130 mg/dL (100–129 mg/dL: consider drug options) ^{§§}
<i>Moderate risk:</i> 2+ risk factors** (10-yr risk < 10%) ^{††}	<130 mg/dL	≥130 mg/dL	≥160 mg/dL
<i>Lower risk:</i> 0–1 risk factors ^{¶¶}	<160 mg/dL	≥160 mg/dL	≥190 mg/dL (160–189 mg/dL: LDL-lowering drug optional)

*When LDL-lowering drug therapy is employed, it is advised that intensity of therapy be sufficient to achieve at least a 30%–40% reduction in LDL-C levels.

[†]Very high risk favors the optional LDL-C goal of < 70 mg/dL, and in patients with high triglycerides, non-HDL-C < 100 mg/dL (see Risk Assessment in this chapter). However, there are increased risks with this approach, which is not universally accepted (Hayward RA, Hofer TP, Vijan S: Narrative review: Lack of evidence for recommended low-density lipoprotein treatment targets: A solvable problem. *Ann Intern Med* 2006;145:520–530; Grundy SM: Promise of low-density lipoprotein-lowering therapy for primary and secondary prevention. *Circulation* 2008;117:569–573).

[‡]CHD includes history of myocardial infarction, unstable or stable angina, coronary artery procedures (angioplasty, stenting, or bypass surgery), or evidence of clinically significant myocardial ischemia.

[§]CHD risk-equivalents include clinical manifestations of noncoronary forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and carotid artery disease [transient ischemic attacks or stroke of carotid origin or > 50% obstruction of a carotid artery]), diabetes, and 2+ risk factors with 10-year risk for hard CHD > 20%.

[¶]Any person at high risk or moderately high risk who has a lifestyle-related risk factor (e.g., obesity, physical inactivity, elevated triglyceride levels, low HDL-C, or metabolic syndrome) is a candidate for TLC to modify these risk factors regardless of LDL-C level.

^{||}If baseline LDL-C is < 100 mg/dL, institution of an LDL-lowering drug is a therapeutic option on the basis of available clinical trial results. If a high-risk person has high triglycerides or low HDL-C, combining a fibrate or nicotinic acid with an LDL-lowering drug can be considered.

**Risk factors include cigarette smoking, hypertension (BP ≥ 140/90 mm Hg or on antihypertensive medication), low HDL-C (<40 mg/dL), family history of premature CHD (CHD in male first-degree relative < 55 years of age; CHD in female first-degree relative < 65 years of age), and age (men ≥ 45 years; women ≥ 55 years).

^{††}Electronic 10-year risk calculators are available at www.nhlbi.nih.gov/guidelines/cholesterol.

^{†††}Optional LDL-C goal is < 100 mg/dL.

^{§§}For moderately high-risk persons, when LDL-C level is 100–129 mg/dL, at baseline or on TLC, initiation of an LDL-lowering drug to achieve an LDL-C level < 100 mg/dL is a therapeutic option on the basis of available clinical trial results.

^{¶¶}Almost all people with 0 or 1 risk factor have a 10-year risk < 10%, and 10-year risk assessment in people with 0 or 1 risk factor is thus not necessary.

Modified from Grundy SM, Cleeman JI, Merz CN, et al: Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III guidelines. *Circulation* 2004;110:227–239.

in cyclosporine or tacrolimus blood levels or in liver or muscle enzymes, although two patients stopped treatment because of nausea and muscle pain without CK enzyme elevation.⁵⁴ In the Canadian experience with nontransplant patients, some taking ezetimibe without a statin did develop rhabdomyolysis.⁵⁵ The use of the combination drug ezetimibe/simvastatin has been reported in nontransplant patients, and there are indications of a higher frequency of adverse effects.⁵⁶

Hypertriglyceridemia, when associated with sirolimus, may diminish as the dosage of sirolimus declines, but treatment may be necessary for severe elevations (see Chapter 63). The use of fibric acid analogs (e.g., gemfibrozil, bezafibrate, fenofibrate, and ciprofibrate) or nicotinic acid may be indicated. Bezafibrate, fenofibrate, and ciprofibrate may increase serum creatinine in cyclosporine-treated patients, and fenofi-

brate and bezafibrate may increase plasma homocysteine.^{27,57} Fibric acid analogs should be avoided in those with severe renal disease or severe hepatic disease, and the dose should be reduced in patients with impaired renal function.^{27,31} The use of omega-3-acid ethyl esters has not been tested in renal transplant recipients, but in nontransplant patients doses of 3 to 12 g daily can decrease fasting triglycerides by 20% to 50% and do not interact with statins to cause rhabdomyolysis.^{58,59}

Combined lipid abnormalities characterized by both high LDL-C and triglyceride levels are more difficult and riskier to treat. Statins can reduce triglycerides modestly,⁵⁹ but the addition of a second agent may be necessary. Under such circumstances, very close clinical and laboratory follow-up are warranted. Pharmacologic approaches to raising HDL-C as a means to reduce cardiovascular risk and disease are just emerging.⁶⁰

Table 89-2 Modification of Statin Doses According to Glomerular Filtration Rate (GFR) and Cyclosporine Use

Statin	LEVEL OF GFR (mL/min/1.73 m ²)		
	≥30	<30 or Dialysis	With Cyclosporine
Atorvastatin	10–80 mg	10–80 mg	10–40 mg
Fluvastatin	20–80 mg	10–40 mg	10–40 mg
Lovastatin	20–80 mg	10–40 mg	10–40 mg
Pravastatin	20–40 mg	20–40 mg	20–40 mg
Simvastatin	20–80 mg	10–40 mg	10–40 mg

Most manufacturers recommend once-daily dosing, but consider giving 50% of the maximum dose twice daily.

Adapted from Executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *JAMA* 2001;285:2486–2497, and Kasiske B, Cosio FG, Beto J, et al: Clinical practice guidelines for managing dyslipidemias in kidney transplant patients: A report from the Managing Dyslipidemias in Chronic Kidney Disease Work Group of the National Kidney Foundation Kidney Disease Outcomes Quality Initiative. *Am J Transplant* 2004;4(Suppl 7):13–53.

Transplant-Associated Hyperglycemia: New-Onset Diabetes Mellitus and Prediabetic Conditions

Current criteria from the American Diabetes Association (ADA) classify patients with a fasting plasma glucose of ≥126 mg/dL as having diabetes, and those with values between 100 and 125 mg/dL as having impaired fasting glucose.⁶¹ When a 2-hour 75-g oral glucose tolerance test is used, a 2-hour plasma glucose level greater than 200 mg/dL represents diabetes, and a 2-hour level between 140 and 200 mg/dL defines impaired glucose tolerance.⁶¹ Because varying criteria were used for the diagnosis of new-onset diabetes mellitus (NODM), its frequency within the first year after transplantation was reported to be from 4% to 20%.⁶² In subsequent studies diabetes occurred at a 6% annual rate while patients were on the waiting list for a deceased donor kidney transplant, increased to 14% to 16% as NODM in the first year after transplant, and then settled at an annual incidence of 4% to 6%, so that the cumulative incidence of NODM 3 years after transplantation was 24%.^{63–65} In addition to patients with overt NODM, approximately a third to a half of the others have either impaired fasting glucose or impaired glucose tolerance 1 year after transplantation.^{65–67} Impaired fasting glucose and insulin resistance are components of a cluster of CVD risk factors designated the *metabolic syndrome* that also includes triglycerides greater than 150 mg/dL, HDL-C less than 40 mg/dL, blood pressure greater than 130/80 mm Hg, and obesity.²¹

Risk factors for NODM include most of the major immunosuppressants (glucocorticoids, tacrolimus, cyclosporine, and sirolimus, but not mycophenolate mofetil or azathioprine), excess weight, age older than 45 years, male gender, African-American and Hispanic race, family history of diabetes mellitus, hepatitis C, possibly cytomegalovirus, and autosomal dominant polycystic kidney disease (ADPKD).^{63,65,68–70} Acute rejection episodes, which are often treated with high-dose IV

methylprednisolone and conversion to tacrolimus, also raise the risk of NODM.⁶⁵

Complications of NODM are essentially the same as those seen in patients with pretransplant diabetes mellitus.⁷¹ At least 10 cases of de novo diabetic nephropathy evolving from NODM have been reported, with a time from onset to histologic diabetic nephropathy of approximately 6 years, similar to that with recurrent diabetic nephropathy.^{72,73}

A recent expert opinion recommends that “a 75-g 2-hour oral glucose tolerance be performed at 3 to 6 months after transplantation and annually thereafter in all kidney recipients without diabetes. Testing should be repeated in all patients who meet diabetic criteria to confirm a diagnosis of NODM. NODM should be treated with medical nutrition therapy and, as required, by drug therapy to target American Diabetes Association–defined glycemic goals for patients with diabetes: fasting plasma glucose 90 to 130 mg/dL, 2-hour postprandial glucose less than 180 mg/dL, and glycosylated hemoglobin (HbA_{1C}) less than 7%.”^{61,65,74}

Patients with new-onset diabetes mellitus require diabetes education and diet instruction. They should monitor their glycemic control with a home glucose diary; have their HbA_{1C} levels checked every 3 months; have annual ophthalmologic evaluations, regular foot care, and regular evaluation of complications from a variety of neuropathies (i.e., autonomic neuropathy with orthostatic hypotension, peripheral neuropathy, gastroenteropathy, bladder dysfunction, neuropathic bone disease); and receive appropriate periodic cardiovascular evaluation of the coronary arteries, carotid arteries, and peripheral vascular system.^{61,71}

Because of the dramatic increase in new drugs with new mechanisms of action that now constitute nine classes of antidiabetes medications for treating diabetes, patients with NODM are usually best managed by collaborative care with an endocrinologist or diabetologist.⁷⁵ However, lifestyle changes can achieve a 58% risk reduction for diabetes in patients at high risk for the disease.^{76,77} The nine classes of antidiabetes classes are insulin, sulfonylureas (oral), biguanides/metformin (oral), alpha-glycosidase inhibitors (oral), thiazolidinediones (TZDs; rosiglitazone and pioglitazone; oral), meglitinides/glinides (nateglinide, repaglinide; oral), glucagon-like peptides (GLP analogs; exenatide; parenteral), amylin analogs (pramlintide; parenteral), and dipeptidyl peptidase-IV (DPP-IV) inhibitors (sitagliptin; oral).⁷⁵ Selection of NODM treatment and dosing will be influenced by the level of renal function, which may fluctuate; intermittent courses of IV methylprednisolone; use of drugs, including immunosuppressants, that share metabolism by the CYP3A4 pathway; and compromised cardiopulmonary situations that may not permit the fluid retention often seen with TZDs. The four commonly used groups of oral agents have been sulfonylureas (glipizide and glyburide), biguanides (metformin), TZDs (pioglitazone and rosiglitazone), and meglitinides/glinides (repaglinide and nateglinide).⁷⁵ A consensus algorithm for initiation and adjustment of therapy has recently been published, but it was developed before the availability of DPP-IV inhibitors.⁷⁸ Various combinations of these drugs also are available, and dose modification or avoidance is required according to the more hazardous component. Sulfonylureas, which act by stimulating insulin, cannot be used for type 1 diabetes mellitus; they are renally excreted and should generally be avoided with significant

allograft dysfunction because of the risk of protracted hypoglycemia. Biguanides act by decreasing hepatic glucose production and increasing muscle glucose uptake and utilization, may aid in avoiding further weight gain, and are usually titrated from doses of 500 mg up to a maximum of 2000 mg; they are contraindicated with either transient renal insufficiency or fixed elevations of the serum creatinine or impaired liver function. TZDs are agonists for peroxisome proliferator-activated receptor-gamma receptors in target tissues for insulin action, such as adipose tissue, skeletal muscle, and liver, an effect that translates into enhanced sensitivity to insulin. An interim analysis of 4437 nontransplant type 2 diabetic patients (RECORD study) confirmed rosiglitazone's risk for congestive heart failure and had insufficient data to determine whether there was an increased risk of MI,⁷⁹ a provocative finding reported in a recent meta-analysis.⁸⁰ Durability of therapy is an important consideration in medication selection. In A Diabetes Outcome Progression Trial (ADOPT), which evaluated rosiglitazone, metformin, and glyburide as initial treatment for recently diagnosed type 2 diabetes mellitus in 4360 patients treated for a median of 4 years, the cumulative incidence of monotherapy failure at 5 years was 34% with glyburide, 21% with metformin, and only 15% with rosiglitazone.⁸¹ In studies done before concerns were raised about an increased risk of myocardial infarction,⁸⁰ rosiglitazone had been used with apparent safety and efficacy for NODM after renal transplantation and did not appear to have any significant effect on calcineurin dosing.^{65,82} However, concerns do exist about its risk for MI based on a recent meta-analysis.^{80,83} Meglitinides/glinides that act by stimulating insulin secretion cannot be used for type 1 diabetic patients, are dosed 15 minutes before each meal, and appear to have less of a hypoglycemic potential than sulfonylureas. Nateglinide is metabolized by several pathways, including CYP3A4, which is involved in the metabolism of cyclosporine, tacrolimus, and sirolimus. Because approximately 75% of the administered dose appears in the urine within 6 hours, the dose effect should be monitored in patients with impaired renal function. In a single study of NODM after renal transplantation, repaglinide was reported to be safe and efficacious.⁸⁴ The newest drugs that either mimic, and thereby compensate for deficient production of the incretin hormone glucagon-like peptide-1 (GLP-1) in type 2 diabetic patients (e.g., the GLP analog exenatide), or limit proteolysis of native GLP-1 (e.g., the DPP-IV inhibitor sitagliptin) have not been evaluated in renal transplant recipients.^{75,85-87} A recent review of oral medications for type 2 diabetes in nontransplant patients concluded, "Compared with newer, more expensive agents (thiazolidinediones, α -glucosidase inhibitors, and meglitinides), older agents (second-generation sulfonylureas and metformin) have similar or superior effects on glycemic control, lipids, and other intermediate endpoints."⁸⁸ Insulin therapy is an alternative for treating NODM. Insulin analogues in both long-acting (glargine, detemir) and short-acting (lispro, aspart, and glulisine) forms have a reduced risk for hypoglycemia compared to older formulations.

The transplant nephrologist needs to carefully evaluate the medications being used because of the potential for adverse effects that include edema and congestive heart failure (the TZD derivatives pioglitazone and rosiglitazone), possible risk for MI⁸⁰ and fractures in women⁸¹ (rosiglitazone), higher

blood levels of drugs because of decreased renal function (insulin, metformin, sulfonylurea derivatives, exenatide, and sitagliptin), lactic acidosis (metformin), competitive metabolism by CYP3A4 (the meglitinides repaglinide and nateglinide to a lesser extent and the DPP-IV inhibitor sitagliptin), and the effect of hepatic insufficiency on drug metabolism. Control of the edema associated with TZDs has been more effectively accomplished with spironolactone or thiazide diuretics than it has with furosemide.⁸⁹

In 1994, a 5-year, randomized, controlled clinical trial of kidney transplant recipients who had type 1 diabetes mellitus as their original disease compared standard insulin therapy with optimized glycemic control.⁹⁰ The standard therapy group had more than a twofold increase in the volume of the mesangial matrix per glomerulus, a threefold increase in arteriolar hyalinosis, and greater thickening of the glomerular basement membrane. In this early study that did not have currently available insulin formulations, severe hypoglycemic episodes were more frequent in the optimized group. Very recently, it has been shown that "in at-risk patients with type 2 diabetes, intensive intervention with multiple drug combinations and behavior modification has sustained beneficial effects with respect to vascular complications and on rates of death from any cause and from cardiovascular causes."⁹⁴

Ancillary but possibly important contributors to glucose control are statins and drugs that block the renin-angiotensin system, both angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers. Statins increase insulin sensitivity; in a retrospective study of 300 Canadian renal transplant recipients, statins were associated with a 70% decrease in the occurrence of NODM.^{65,91} There is suggestive evidence from studies in nontransplant patients that blockade of the renin-angiotensin system may be associated with a reduction in the occurrence of diabetes.^{65,92-94} The avoidance or withdrawal of diabetogenic immunosuppressants is discussed in Chapter 87. It is worthwhile to note that "trials that reduce one drug often improve the effects of that drug, but not graft and patient survival."⁹⁵

Cigarette Smoking

In a study of 1334 transplant recipients, 24.7% of whom smoked, the relative risk for a major cardiovascular event was 1.56 for those smoking 11 to 25 pack-years at transplant and 2.14 for those smoking for more than 25 pack-years ($P < .001$).⁹⁶ For smokers, the relative risk of invasive malignancy was 1.91 and of death with a functioning graft 1.42. Adverse renal hemodynamic effects, coagulation alterations, and endothelial injury result from smoking and are particularly injurious in diabetic patients.^{97,98} Cigarette smoking is also an independent risk factor for type 2 diabetes mellitus.⁹⁹

There are basically three ways in which smoking cessation may be achieved: self-motivated spontaneous cessation, counseling and behavioral therapies, and pharmacotherapies.¹⁰⁰ One or more of these should be offered to every smoker. It has been estimated that approximately 50 million Americans have stopped smoking, 95% of whom have stopped of their own accord.^{100,101} Individuals who stop smoking typically experience physical withdrawal symptoms, which peak in 2 to 4 days and generally disappear in 10 to 14 days. Even years later, many individuals will continue to experience the periodic desire to smoke. Smoking even a single cigarette in response to these urges can frequently lead to an extended relapse. When

conducted by a psychologist or physician experienced in smoking cessation therapy the next most effective methods after spontaneous cessation are behavior-oriented programs.¹⁰⁰

Pharmacologic aids to smoking cessation include nicotine replacement therapy (gum, lozenge, transdermal patch, nasal spray, and inhaler), bupropion, and varenicline.^{100–112} Recommended dosage schedules for transdermal nicotine patches are widely available. If patients continue to smoke while using nicotine replacement therapy, there is an increased risk of adverse effects and higher peak nicotine levels. Up to 23% of patients using nicotine replacement therapy complain of sleep disturbances; nausea is also common, as is skin irritation with transdermal patches.

Bupropion's mechanism for smoking cessation is unknown. Under the brand name Zyban, bupropion is approved by the U.S. Food and Drug Administration (FDA) for smoking cessation with a prescription, but under the brand name Wellbutrin, bupropion is FDA-approved for the management of depression. Because bupropion takes 5 to 8 days to reach steady-state concentrations, patients must select a quit date for smoking.¹⁰⁵ The initial dose of bupropion is usually 150 mg orally for several days that may be followed by an increase to 150 mg twice daily for a total treatment period of 7 to 12 weeks. Bupropion 150 mg each morning for 9 weeks, when compared with a nicotine patch alone, a combination of the nicotine patch and bupropion, or placebo, resulted in abstinence rates after 1 year of 30.3%, 16.4%, 35.5%, and 15.6%, respectively, clearly indicating greater success with combination therapy that included bupropion or bupropion alone.¹⁰³ Sustained-release bupropion reduced the relapse rate and weight gain after smoking cessation.¹⁰⁴ Bupropion appears to be metabolized in the liver by enzyme systems other than CYP3A4 (which is involved in the metabolism of cyclosporine, tacrolimus, and sirolimus). Bupropion has not been studied in patients with renal insufficiency, but dose reduction may be needed in these patients. Adverse effects of bupropion include seizure and other neurological symptoms (insomnia [21%], headache, abnormal dreams, dizziness, disturbed concentration), dry mouth, and nausea. Contraindications include seizure disorder, prior or current bulimia or anorexia nervosa, and monoamine oxidase inhibitor use.

Varenicline has a dual effect in smoking cessation because it binds to the $\alpha_4\beta_2$ neuronal nicotinic acetylcholine receptors and acts as an agonist to enhance dopamine release and curb nicotine withdrawal; it also prevents the binding of nicotine to these receptors.^{105–110} Because varenicline does not reach steady state for 4 days, patients must have a quit date, just as with bupropion. Varenicline doses begin with 0.5 mg once daily on days 1 to 3, 0.5 mg twice daily on days 4 to 7, and 1 mg twice daily from day 8 to the end of treatment, which is usually 12 weeks. In a randomized, double-blind, parallel-group, placebo-controlled trial that compared varenicline titrated to 1 mg bid ($N = 352$), sustained-release bupropion titrated to 150 mg bid ($N = 329$), or placebo ($N = 344$) orally for 12 weeks, continuous abstinence rates from weeks 9 to 12 (the primary endpoint) were 44%, 29.5%, and 17.7%, respectively.¹⁰⁸ However, continuous abstinence rates for these same three groups for weeks 9 to 52 fell to 29.9%, 16.1%, and 8.4%, respectively. At 1 year varenicline was not superior to sustained-release bupropion.^{106,108} However, in a study of relapse after quitting, addition of another 12 weeks of varenicline versus placebo in those who were abstinent at week 12 in-

creased the continuous abstinence rates to 43.6% versus 36.9% at week 52, respectively ($P = 0.02$). Weight gain in the two groups was comparable.¹¹⁰ Serious neuropsychiatric symptoms including agitation, depression, and suicidal behavior have been reported with varenicline. Other adverse effects from varenicline with greater than 5% frequency include nausea (28%), sleep disturbance, constipation, vomiting, frequent arthralgia, diarrhea, chest pain, edema, polyuria, psychiatric disturbances, flushing, and abnormal liver function tests. Varenicline must be used with caution in patients with impaired renal function and creatinine clearances less than 50 mL/min because blood levels increase by 1.5- to 2.1-fold. Varenicline's place in therapy is still evolving, but "it might prove to be particularly appropriate for those in whom other therapies have failed."¹⁰⁶ Multi-component behavior-oriented programs can improve the long-term cessation rates of pharmacologic therapies.^{102,111}

Level II: Medical and Interventional Treatment of Established CHD

Four evidence-based medical therapies have been proven to decrease morbidity and mortality in nonrenal transplant patients with documented CHD.^{12,113} These are antiplatelet agents (aspirin, adenosine diphosphate receptor antagonists, or dipyridamole), β -blockers, inhibitors of the renin-angiotensin system, and statins or certain other lipid-lowering agents. Compliance with recommendations for medical therapy was evaluated in 40,450 patients from the REduction of Atherothrombosis for Continued Health (REACH) International Registry who had documented CHD (previous MI, percutaneous coronary intervention, CABG, or angina pectoris), approximately 33% having had previous CABG, 33% percutaneous coronary intervention, and 33% no revascularization.¹² When compared to those who had no intervention and were medically managed, the groups who had previous CABG (usually older, male, and diabetic) or percutaneous coronary intervention (usually younger) were significantly more likely to be receiving antiplatelet therapy (79% vs. 86% and 91%, respectively), a lipid-lowering agent (70% vs. 86% and 86%, respectively), or a β -blocker (55% vs. 64% and 66%, respectively). The use of ACE inhibitors and angiotensin II receptor blockers was comparable in the three groups (50% vs. 48% and 46%, respectively, for ACE inhibitors; and 19% vs. 21% and 21%, respectively, for angiotensin receptor blockers). These data clearly indicate that "those patients with CHD managed only with medications appear to be receiving the *fewest* evidence-based pharmacologic treatments."¹² To paraphrase Shakespeare, "the fault, . . . is not in our stars, but in ourselves. . ." (Julius Caesar, Act I, Scene II). In the TNT study of 10,001 patients with clinically evident CHD and LDL-C less than 130 mg/dL who were randomly assigned to receive either 80 mg or 10 mg of atorvastatin, a primary event (CHD death, nonfatal nonprocedure-related MI, resuscitation after cardiac arrest, or fatal or nonfatal stroke) occurred in 8.7% of those receiving the 80-mg dose vs. 10.9% of those given a 10-mg dose, a 22% relative reduction in risk ($P < .001$).⁸ Persistent elevation of liver enzymes was seen in 0.2% of those receiving 10 mg atorvastatin versus 1.2% of those on 80 mg atorvastatin.⁸ Among 15,603 nontransplant patients in the Clopidogrel for High Atheroembolic Risk and Ischemia Stabilization, Management and Avoidance (CHARISMA) study) who had either clinically evident CVD or multiple risk factors and received either 75 mg clopidogrel plus low-dose aspirin (75–162 mg) daily or placebo plus

low-dose aspirin, there was no significantly greater effect with clopidogrel plus aspirin than with aspirin alone in reducing MI, stroke, or death from CVD over 28 months.¹¹⁴ However, in the CREDO study of 2116 higher-risk cardiac patients, long-term (1 year) clopidogrel plus aspirin versus placebo plus aspirin was associated with a 26.9% relative reduction in the combined risk of death, MI, or stroke ($P = .02$).¹¹⁵

Experimental and clinical data suggest that at least part of the benefit of renin-angiotensin-aldosterone system blockers and statins is related to their additional secondary antiproliferative or antifibrotic effects. ACE inhibitors block transforming growth factor- β -mediated extracellular matrix protein synthesis by fibroblasts,¹¹⁶ and angiotensin receptor blockers shunt angiotensin II to binding sites on AT₂ receptors that inhibit endothelial cell proliferation.¹¹⁷ Spironolactone (25 mg/day) reduced morbidity and mortality in patients with severe congestive heart failure who were also receiving ACE inhibitors, probably because it reduced myocardial and vascular fibrosis.¹¹⁸ Careful attention to spironolactone dosing, concurrent medications, and level of renal function should permit its safe use in some patients without serious hyperkalemia.¹¹⁹ Statins can block the proliferative effect of epidermal growth factor,⁴⁸ have an antihypertensive effect,¹²⁰ and have no clearly defined benefit for osteoporosis.¹²¹

Coronary artery stenting (CAS) using drug-eluting stents (DES) (sirolimus or paclitaxel) has decreased restenosis from approximately 15% to 6% (9 events per 100 patients) whereas the risk of thrombosis has increased from 0.2% to 0.4% (2 events per 1000 patients).¹²²⁻¹²⁵ Prolonged use of clopidogrel has improved the outlook.¹²⁶ In an observational study from the Duke Heart Center, patients with DES who were event-free at 6 months and received clopidogrel ($N = 637$), when compared to those not receiving clopidogrel ($N = 579$), had significantly lower death rates (2.0% vs. 5.3%) and death or MI (3.1% vs. 7.2%) at 24 months.¹²⁶ Among patients who had bare metal stents, clopidogrel was beneficial for the first 3 to 6 months but not beyond.

In a 25-year single-institution experience examining outcome after CABG among 2989 renal transplant recipients, 83 required myocardial revascularization (percutaneous transluminal coronary angioplasty [PTCA] or CABG) before or after renal transplantation.¹²⁷ None of the 45 patients revascularized after transplantation experienced allograft loss or significant change in renal function. Survival rates of the 45 patients were 93%, 78%, and 60% at 1, 3, and 5 years, respectively.¹²⁷ Early-phase risk factors for death included hypertension and revascularization carried out before 1989. Late-phase risk factors for death included diabetes mellitus, a greater number of pre-CABG myocardial infarctions, renal transplantation before 1984, older age, and unstable angina before CABG. These authors concluded that coronary angiography, PTCA, and CABG are safe in patients with functioning renal allografts.¹²⁷ In another series of 31 patients who received CABG after renal transplantation, there was one early postoperative death and two episodes of renal transplant dysfunction.¹²⁸ A retrospective U.S. Renal Data System (USRDS) database search from 1995 to 1998 identified 912 patients who were hospitalized for CABG, 613 hospitalized for PTCA, and 626 for PTCA/CAS.¹²⁹ In-hospital deaths were 4.9% for CABG, 4.2% for PTCA, and 2.2% for CAS. At 3 years, event-free survival from combined cardiac endpoints (cardiac death and acute MI) was 88.9% for

CABG, 84.8% for CAS, and 80.2% for PTCA.¹²⁹ After comorbidity adjustment, renal transplant patients in the United States have similar 3-year survival after PTCA, CAS, and CABG (75.8%, 78.9%, and 77.0%, respectively), but fewer serious cardiac events after CABG.

Cerebrovascular Disease

A duplex ultrasound or imaging study of the carotid arteries should be performed if a decreased carotid arterial pulse, a bruit over the carotid artery, or a neurological syndrome consistent with carotid artery disease is present. A systematic review and meta-analysis involving more than 90,000 nontransplant patients that examined the effect of statins on incident strokes concluded that statin use was associated with a 21% reduction for stroke and no increase in hemorrhagic stroke; for every 10% reduction in LDL-C a 15.6% decrease in all strokes and 0.73% decrease in carotid intima-media thickness was seen.¹³⁰ However, in 69 nontransplant patients (CKD $N = 38$; CHD $N = 31$) there was no significant reduction in carotid intima-media thickness after 2 years in the CKD group despite lowering LDL-C to 70 ± 27 mg/dL with atorvastatin 80 mg/day.¹³¹ Recently a randomized, double-blind, placebo-controlled study (Measuring Effects on Intimal-Media Thickness: an Evaluation Of Rosuvastatin [METEOR]) of 984 nontransplant patients with an average age of 57 years and Framingham Risk Score less than 10% demonstrated that rosuvastatin 40 mg, when compared to placebo, significantly reduced carotid intima-media thickness over 2 years.¹³²

If carotid artery stenosis 80% or larger (but not total occlusion) is detected in asymptomatic patients, intervention should be considered.¹³³ In the Asymptomatic Carotid Atherosclerosis Study (ACAS), the estimated incidence of ipsilateral strokes within 5 years and perioperative strokes or death within 30 to 42 days of randomization was reduced with surgical intervention by 66% in men and by 17% in women.¹³³

As secondary prevention, in the Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) study of 4731 nontransplant patients, 80 mg of atorvastatin, initiated within 6 months of a stroke or transient ischemic episode, significantly reduced recurrent stroke by 16% and fatal stroke by 43% when compared to placebo.¹³⁴ Although atorvastatin decreased ischemic strokes significantly more than placebo (218 vs. 274), with a 5-year 3.5% absolute reduction in risk of a major cardiovascular event, atorvastatin was associated with a nonsignificant increased frequency of hemorrhagic strokes (55 vs. 33). Overall mortality rate was similar in the two groups, but elevated liver enzyme values were more common in those taking atorvastatin. The SPARCL results differed somewhat from those of the Heart Protection Study (HPS), in which 40 mg of simvastatin or placebo was used.¹³⁵ Patients with preexisting cerebrovascular disease in the HPS study ($N = 3280$ adults) had no significant reduction in stroke rate. A major protocol difference in the HPS study was that patients were enrolled an average of 4.3 years after the index event, a period well after the highest risk of stroke recurrence.¹³⁶ However, in the HPS study there was a significant reduction in the first event rate for stroke, from 5.7% to 4.3%, a 28% reduction in presumed ischemic strokes with no apparent difference in hemorrhagic strokes.¹³⁵ Data are conflicting as to whether

low cholesterol levels represent a risk for hemorrhagic stroke.^{137–140} The combined use of intensive LDL-C-lowering and antiplatelet drugs has not been specifically studied for either primary or secondary prevention, and not in transplant recipients. The combination of these two treatment modalities might be hazardous because of the suggestion of an increase in hemorrhagic strokes in one study with high-dose statin therapy.¹³⁴

The choice of endarterectomy over stenting has become clearer.^{141–143} Both a review of five randomized trials that compared stenting to endarterectomy¹⁴¹ and a recent Endarterectomy Vs. Angioplasty in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S) study support using carotid endarterectomy as the standard treatment because of lower rates of death and stroke at 1 and 6 months when compared to stenting: 3.9% versus 9.6%, and 6.1% versus 11.7%, respectively.¹⁴² Expert commentary on these findings stated: “the only widely accepted indication for carotid artery stenting remains its use in symptomatic patients who have stenosis of the internal carotid artery exceeding 70% and who also have a high surgical risk. All other patients should be treated medically, undergoing carotid endarterectomy if indicated, or should be placed in a clinical trial.”¹⁴⁴

Patients with ADPKD require special attention for CVD because the overall prevalence of an asymptomatic intracranial aneurysm as determined by magnetic resonance angiography is approximately 12% and increases to about 20% in those with a positive family history of an intracranial aneurysm or subarachnoid hemorrhage in conjunction with ADPKD.^{145,146} Magnetic resonance angiography with gadolinium has recently been associated with the risk of nephrogenic systemic fibrosis in some patients with severely impaired renal function, but cerebral MRA can be done without it.^{147–149} For those patients with ADPKD and a family history of intracranial aneurysm or subarachnoid hemorrhage, or who have neurological symptoms suggestive of an intracranial aneurysm, magnetic resonance angiography is usually the initial study. Repeat scanning for those with a history of intracranial aneurysm has been recommended every 5 to 10 years.^{150,151} These patients should know the significance of for those with a history of intracranial aneurysm a “sentinel” headache relating to the initial intracranial bleed and the need to seek immediate medical/surgical treatment. Control of hypertension and timely neurosurgical judgment and skill are the main elements of treatment.

Peripheral Arterial Disease

A report based on data from the Atherosclerosis Risk In Communities (ARIC) study in 14,280 middle-aged adults with either normal kidney function, mildly decreased kidney function, or stages 3 to 4 CKD indicated by multivariate analysis, that CKD created a 1.56 relative risk for peripheral arterial disease (PAD).¹⁵² Among 43,427 adult renal transplant recipients and 53,309 adults on the renal transplant waiting list, the 3-year cumulative incidence of de novo PAD in diabetics was 24% for those on the waiting list versus 20% after transplantation, and for those without diabetes mellitus, 9% on the waiting list versus 5% after transplantation.¹⁵³ For both diabetic and nondiabetic patients a diagnosis of PAD on the waiting list was associated with approximately a threefold increase in the relative risk for death. After transplantation in both groups the development of de novo PAD increased the relative risk

for death approximately twofold. Nondiabetic patients with renal allografts functioning for longer than 20 years also can have vascular calcification and lower limb ischemia requiring amputation.¹⁵⁴

Diminished femoral and/or pedal pulses; iliofemoral bruits; the presence of coronary, carotid, or renal arterial disease; a high-risk CHD profile, and claudication are indications to measure the ankle-brachial index ratios. An ankle-brachial index value less than 0.90 at rest, or more than 0.90 at rest but that decreases by 20% after exercise, represents the earliest diagnostic assessment of PAD.¹⁵⁵ The presence of vascular calcification prevents the interpretation of the ankle-brachial index but at times may be circumvented by using a toe-brachial index rather than the ankle-brachial index.^{155,156} About one third of patients with PAD in the general population have typical claudication, resulting in amputation in 5% of patients within 5 years, and about 5% to 10% of patients have critical leg ischemia with major risk of limb loss. However, more than 50% of patients having PAD on the basis of abnormal ankle-brachial index ratios do not have typical claudication or critical leg ischemia, but they do have reduced ambulatory activity and quality of life.¹⁵⁵

For patients with PAD in the general population, risk factors should be assessed and treated (e.g., smoking cessation, reduction of LDL-C to less than 100 mg/dL or in very high-risk individuals possibly to less than 70 mg/dL, control of hypertension to less than 130/80 mm Hg, and diabetes control with HbA_{1c} less than 7%).¹⁵⁷ Further treatment includes an exercise program, antiplatelet and other pharmacologic therapy and, when indicated, revascularization that may take the form of open surgical procedures, angioplasty, and stents.^{155,157} Currently drug treatment of PAD includes aspirin in daily doses of 75 to 150 mg, which has been shown to be as effective as higher doses and less likely to cause gastrointestinal (GI) bleeding complications.^{157–159} Although aspirin has not been shown to improve claudication, it does delay the rate of progression, lessens the need for intervention, and reduces graft failure in patients who have undergone revascularization procedures.¹⁵⁷ Clopidogrel was compared with aspirin in the Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) trial, in which clopidogrel's greatest benefit occurred in the 6452 patients with PAD who had nearly a 24% reduction (4.9%/year with clopidogrel vs. 3.7%/year with aspirin) in the risk of MI, stroke, or cardiovascular death.¹⁶⁰ Clopidogrel is usually given in doses of 75 mg once daily. It is extensively metabolized by the liver. Although there are lower metabolite levels and reduced adenosine diphosphate-induced platelet aggregation in patients with stage 5 CKD, prolongation of bleeding time was similar to that in healthy treated volunteers. Nevertheless, clopidogrel should be used with caution in those with significant liver or kidney disease. Its use is contraindicated in patients with active bleeding or hypersensitivity. Adverse effects include bleeding, thrombotic thrombocytopenic purpura, hypersensitivity reactions, anaphylactoid reactions, serum sickness, neurological symptoms, hepatobiliary disorders, myelotoxicity, and skin lesions, including angioedema, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

Angiographic studies in renal transplant patients, who typically have stage 3 or 4 CKD, are problematic both for the use of intravenous (IV) iodinated contrast agents with their risk of acute kidney injury as well as magnetic resonance

angiography employing gadolinium with its risks for nephrogenic systemic fibrosis and possible need for dialysis.^{147–149} Because contrast loads are typically larger for the study of PAD, if iodinated contrast agents are to be used, it is still advisable to try to keep the amount of reagent as low as possible, prehydrate patients intravenously according to their cardiopulmonary parameters, and use acetylcysteine before and after the procedure.¹⁶¹ (See also Chapter 40.)

POSTTRANSPLANTATION ERYTHROCYTOSIS

Posttransplantation erythrocytosis, defined as a persistently elevated hematocrit higher than 51%, used to be seen in about 15% of renal transplant patients (range, 4%–22%), usually within the first 2 years after transplantation.¹⁶² However, in clinical practice since about 2000, it has become an unusual finding. This may be due to the expanding use of sirolimus, with its anemia effect,²⁸ as well as widespread use of ACE inhibitors or angiotensin receptor blockers. In fact, posttransplant anemia has become a significant issue, initially because it contributed to the risk of CVD, especially in diabetics,¹⁶³ and then because its treatment with erythropoietin products after transplantation could create a new risk, as reflected in the CHOIR and CREATE trials in nontransplant patients (see Chapters 67 and 68).^{164–166}

The consequences of posttransplantation erythrocytosis (PTE) are primarily thromboembolic events, which may be seen in up to 22% of patients. Remarkably, the development of PTE does not correlate with serum erythropoietin levels.¹⁶⁷ Instead, angiotensin II stimulates the proliferation of normal early erythroid precursors that have increased numbers of AT₁ receptors and correlate with the hematocrit in patients with PTE.^{168,169} Consequently, ACE inhibitors and angiotensin receptor blockers are the treatments of choice for PTE, although phlebotomy may be useful at times. Because some patients may have a rapid fall in hematocrit, or less commonly a spontaneous remission, careful monitoring is necessary. Intermittent therapy may be effective in some patients.

MALIGNANT DISEASE

It has been stated that “cancer will surpass cardiovascular complications as a leading cause of death in transplant patients within the next two decades.”¹⁷⁰ Skin cancer is the most frequent malignancy seen in renal transplant recipients, and post-transplant lymphoproliferative disease (PTLD) is the second most common, occurring in about 11%.¹⁷⁰ A study of malignancy among 35,765 first-time recipients of deceased or living donor kidney transplants from 1995 to 2001 revealed a twofold increase in common tumors (i.e., colon, lung, prostate, stomach, esophagus, pancreas, ovary, and breast); approximately a fivefold increase in melanoma, leukemia, hepatobiliary tumors, cervical, and vulvovaginal cancers; a threefold increase in testicular and bladder cancers, a 15-fold increase in kidney cancers, and more than a 20-fold increase in Kaposi’s sarcoma, non-Hodgkin’s lymphoma, and nonmelanoma skin cancers.¹⁷¹ In data obtained by record linkage between the Australia and New Zealand Dialysis and Transplant Registry and the Australian National Cancer Statistic Clearing-

house, it was noted that among the 18 specific cancers with greater than a threefold increase in risk, five were at sites affected by human papillomavirus (tongue, mouth, vulva, vagina, penis), two were related to Epstein-Barr virus (EBV) (Hodgkin’s disease, non-Hodgkin’s lymphoma), one was related to hepatitis B and C (hepatocellular carcinoma), and one is universally associated with human herpes virus 8 (HHV-8) (Kaposi’s sarcoma).¹⁷² Only five of the high-risk cancers did not have viral infection as a generally accepted primary cause. Azathioprine, cyclosporine, and tacrolimus have been associated with an increased risk of post-transplant malignancies, whereas sirolimus especially, and possibly mycophenolic acid, may lower malignancy frequency.^{170,173–180} The full extent of post-transplant malignancies is beyond the scope of this chapter.

When a renal transplant recipient develops a malignancy, the transplant physician/surgeon will need to work closely with the oncologist to develop a plan of therapy that will involve modification of immunosuppressant medication, as well as selection of chemotherapy, radiotherapy, and surgery. The risks of the malignancy itself and each component of therapy must be compared to the morbidity and mortality risks for the patient and stability of renal allograft function. Perhaps the strongest trend in immunosuppression management of post-transplant malignancies has been the use of sirolimus, which followed reports of a reduced incidence of *de novo* malignancies when it is used.^{28,175,178–180} A decreased incidence of both skin and nonskin malignancies 5 years after renal transplant was reported in 430 adult renal transplant recipients randomly assigned to either remain on sirolimus/cyclosporine/steroids or to have cyclosporine withdrawn at 3 months and sirolimus trough levels increased.¹⁷⁹ It should be noted, however, that the prescribed trough levels for sirolimus are ones that have more frequent and serious adverse effects. Mycophenolic acid appears to have a neutral to possibly beneficial effect on the occurrence of post-transplant *de novo* malignancies.^{175–177} Two major studies of antibody induction therapy and subsequent PTLD are in agreement that PTLD rates were highest with monoclonal OKT3 and polyclonal Atgam and thymoglobulin, with the least risk from interleukin-2 receptor antibodies.^{180,181} Somewhat at variance with these results is the SRTR report, which attributes the highest risk for PTLD to rabbit thymoglobulin and then clusters interleukin-2 receptor antibodies, OKT3, and equine antithymocyte globulin in the second tier.^{182,183} Thus far, alemtuzumab does not appear to create a higher risk.¹⁸⁴

Several clinical risk profiles for individuals prone to developing certain malignancies after renal transplantation are: (1) PTLD occurring within the first 12 months after transplantation in a white male (often younger than age 18 years) who is seronegative for EBV, human leukocyte antigen (HLA)–mismatched for both HLA-B locus antigens, lacks HLA-DR7, and receives antithymocyte globulin induction or possibly belatacept^{185–189}; (2) Kaposi’s sarcoma in a person of Arabic, Jewish, black, or Mediterranean ancestry with evidence of HHV-8 or human immunodeficiency virus infection^{174,190}; (3) vulvar and vaginal carcinomas in women with papillomavirus types 16 and 18¹⁹¹; (4) hepatocellular carcinoma in those with persistent hepatitis B antigenemia, cirrhosis, or hepatitis C of long duration¹⁹²; (5) carcinomas of the skin in fair-skinned or older individuals with unprotected sun exposure and long-duration use of azathioprine with its metabolite thioguanine^{173,193}; (6) recurrent

malignant disease in those who before transplantation had a malignant neoplasm with a medium or high rate of recurrence.^{194,195} Other nondrug risk factors associated with increased frequency of post-transplantation malignancy are increasing age, a past history of cancer, cigarette smoking, previous splenectomy, and polycystic kidney disease.^{175,183}

Recommendations of the American Cancer Society are used for cancer surveillance, but they may need to be applied with increased frequency or with invasive testing in high-risk individuals.^{1,195}

Two of the most frequently encountered malignancies after transplantation are PTLD and squamous cell carcinomas of the skin and lip. PTLD occurs within 5 years of renal transplantation in approximately 1.2% of adult renal transplant recipients at a median of 1000 days.¹⁹⁶ Poor prognostic factors include multiple organ involvement at the time of diagnosis, graft organ failure at diagnosis, age greater than 40 years, and lactic dehydrogenase level 2.5 times or more above the upper limit of normal.¹⁹⁷ If none of these risk factors is present, response to treatment can occur in as many as 89% of patients, whereas with two or three factors present, the response rate is essentially zero.¹⁹⁷ Also influencing the prognosis is the clonality of the PTLD. Polyclonal B-cell PTLD has an early onset, is EBV-positive, and offers a better prognosis, whereas monoclonal B-cell PTLD has a late onset, may be EBV-positive or EBV-negative, and is more aggressive. B-cell PTLD constitutes approximately 85% to 90% of PTLD cases, and T-cell PTLD, which carries a worse prognosis, the other 10 to 15%.

Three special characteristics of PTLD after transplantation are its extranodal involvement in 70% of patients, compared with 35% of nontransplant controls, central nervous system involvement in 26% (63% confined to the brain), and microscopic or gross involvement of the allograft in 20% of patients, sometimes simulating rejection. In an early study of 435 patients, total remissions were achieved in 29%, and approximately 25% of the remissions were induced by the decrease or elimination of nonsteroidal immunosuppressants.¹⁷⁴

Treatment still begins with a reduction in immunosuppression, according to the risks of each noted in this chapter, that will usually involve discontinuation of azathioprine, discontinuation or at least a 50% reduction in cyclosporine or tacrolimus, and often an increase in maintenance prednisone to the 10- to 15-mg range for protection of the allograft. In some cases surgical resection may be indicated.¹⁹⁷ Whether the second step in treatment of B-cell lymphoma should be chemotherapy or rituximab is currently being reassessed.¹⁹⁸ Conventional chemotherapy has a rapid response (days) but significant toxicity, whereas rituximab is slower (weeks) but generally safer.^{197,199,200} The usual course had been to proceed with conventional chemotherapy, namely, the CHOP protocol (cyclophosphamide, doxorubicin, vincristine [Oncovin], and prednisone), sometimes with irradiation. However, more recently the anti-CD20 B-cell monoclonal antibody rituximab has been gaining favor for use before chemotherapy.^{198,201,202} In a key study, complete remissions were achieved in 13 (59%) of 22 patients who received rituximab and in 13 (57%) of 23 patients who received chemotherapy.²⁰¹ No fatalities occurred in the rituximab-treated group, whereas a quarter of those treated with chemotherapy died of treatment-related toxicities. Because failure with one mode of therapy can often be salvaged by the other, the use of rituximab as initial therapy appears to be reasonable.^{198–200} Rituximab also has the advan-

tage of being a standardized dose of 375 mg/m² usually given weekly for 4 weeks. No adjustment appears to be needed for the level of renal function, although “no formal studies were conducted to examine the effects of either renal or hepatic impairment” on rituximab. Adverse effects of rituximab include fatal infusion reactions, 80% of which occurred with the first dose, tumor lysis syndrome with acute kidney injury and some fatalities seen when treating PTLD, severe mucocutaneous reactions, and severe infection, also with fatalities, reported. One should be thoroughly familiar with the adverse effects before using this agent.

T-cell PTLD is typically aggressive and poorly responsive to conventional therapy centered on reduction of immunosuppression and chemotherapy. However, one case recently reported in a recipient of a combined kidney/pancreas transplant achieved clinical remission after treatment with a novel synthetic retinoid analog, bexarotene.¹⁹⁹

Although antiviral therapy has been used as adjunctive therapy, it would only be active during the lytic stages of EBV infection. It may well have a more important role in reducing the risk of PTLD in recipients seronegative for EBV.²⁰³

Newer therapies in limited testing include the use of EBV-specific cytotoxic lymphocytes²⁰⁴ and arginine butyrate, which may render EBV more susceptible to ganciclovir.¹⁹⁹

Remarkably, because PTLD is a result of a primary EBV infection, renal retransplantation is acceptable for those who have had a complete remission. The median time from PTLD diagnosis to retransplantation has been 1300 days.¹⁹⁶ Often the same immunosuppressants that were used at the time of the initial PTLD can be used for the next renal transplant.¹⁹⁸

The second malignancy of particular interest after renal transplant is squamous cell carcinoma (SCC) of the skin and lip, which constitutes about one third of all new malignant neoplasms after renal transplantation. After renal transplantation SCCs tend to be multiple, have a more aggressive course, and are a more common cause of cancer death than in the general population. Transplant recipients developing SCC are about 30 years younger than their counterparts in the general population. Renal transplant recipients at increased risk include those with a history of skin cancer, actinic keratoses, chronic sun exposure or sunburns, or human papillomavirus infection, those who are fair skinned (Fitzpatrick types I to III), older age, those with CD4 lymphocytopenia, and those whose immunosuppression has been either intense or of long duration.²⁰⁵

A dermatologist should examine and treat the patient at intervals appropriate to the risks.^{205,206} Treatment of SCC may require varying types of surgery. Patient education, guidelines of care, and other aspects of posttransplantation skin cancer are in the process of being placed on the new International Transplant Skin Cancer Collaborative website for AT-RISC Alliance. (After Transplantation Reduce Incidence of Skin Cancer at www.at-risc.org). In addition to information about SCC in allograft recipients, there will also be information about the diagnostic management of basal cell carcinoma, melanoma, and rare carcinomas of the skin.

Skin cancer risk can be lessened by wearing protective clothing, avoiding direct sun exposure, and using appropriate sun block. Sunscreens should have a sun protection factor of at least 15 and be applied 15 to 30 minutes before sun exposure. They do not necessarily avoid all photodamage from prolonged sun exposure even though they prevent erythema.²⁰⁷

The first new sunscreen approved by the FDA in 18 years contains ecamsule, which is particularly effective in UVA2 absorption.²⁰⁷ Medical treatment of recurrent SCC includes cautious decreases in overall immunosuppression, specifically elimination of azathioprine (if being used), careful use of low-dose retinoids, and possible substitution of sirolimus for a calcineurin inhibitor.^{179,180,206,208,209} The frequency of SCC of the skin is reported to be reduced by sirolimus.^{179,180,208,209} In a series of 23 renal transplant recipients with multiple skin cancers who were treated in 70% of the cases with cyclosporine, azathioprine, and prednisone, 2 mg daily of sirolimus was initiated with rapid withdrawal of cyclosporine or tacrolimus, and azathioprine or mycophenolic acid.²⁰⁹ With sirolimus levels maintained at 4 to 10 ng/mL and prednisone sustained at 5 to 10 mg/day, the average frequency of skin cancer episodes (predominantly SCC) decreased from 3.2 to 0.7 ($P < .001$) over mean follow-up of 22.4 months, and 16 patients had no new skin cancers. However, one patient with malignant melanoma and another with Kaposi's sarcoma died within 1 year of conversion. A delay in the onset of the first skin cancer was also seen in a multicenter trial in which 215 renal transplant recipients, who had cyclosporine withdrawn from a cyclosporine/sirolimus/steroid regimen, had the first cancers appearing at an average of 1126 days after transplant compared to 491 days in those who remained on the triple therapy, which included cyclosporine ($P = .007$).¹⁷⁹

Other modes of therapy for SCC include topical 5-fluorouracil, and more recently low-dose oral acitretin, whose oral absorption is optimal with food. In collaboration with our dermatologists we have initiated treatment with low doses of 10 mg acitretin daily with careful monitoring for the numerous adverse effects, which include hepatotoxicity, pancreatitis, pseudotumor cerebri, ophthalmologic complications, inflammatory bowel disease, hyperglycemia, hypertriglyceridemia, decreased HDL-C, hyperostosis, osteoporosis, alopecia, mucocutaneous lesions, elevated CK levels, and depression. Postmarketing adverse effects include cardiovascular events, neuropathy, myopathy, and thinning of the skin. Acitretin may require dose adjustment in renal insufficiency and end-stage renal disease. It should not be used in women who are or intend to become pregnant. If this medication is to be used, the manufacturer's drug information should be carefully reviewed.

The treatment of local/regional advanced SCC of the head and neck with a monoclonal antibody against epidermal growth factor receptor (cetuximab) plus radiotherapy significantly lengthened overall survival from approximately 29 months to 49 months.²¹⁰

Sirolimus has demonstrated a remarkable capacity to control Kaposi's sarcoma in renal transplant recipients.¹⁹⁰ Because Kaposi's sarcoma is invariably associated with HHV-8, this implies that sirolimus has activity against HHV-8, as well as against EBV, as noted in the discussion of PTLD.²¹¹ The anti-neoplastic and antiviral effects of sirolimus, as well as the comprehensive overview of its therapeutic efficacy and tolerability, have recently been reviewed.^{28,180} A detailed discussion of malignant melanoma is beyond the scope of this discussion, but a recent comprehensive review is available.²¹²

Patients who are hepatitis B carriers or have nonhepatitis B cirrhosis should be monitored at 6- to 12-month intervals for development of hepatocellular carcinoma with liver ultrasound and alpha fetoprotein determinations.¹⁹² Abstinence from alcohol is recommended for those with hepati-

tis. Treatment of hepatitis B and C and other infections of the liver are discussed in Chapter 90. Of particular interest are recent studies evaluating cyclosporine as therapy for hepatitis C.^{213–215}

GASTROINTESTINAL DISEASE

The primary causes of GI disease after renal transplantation are infections, malignancies, and adverse effects due to immunosuppressant drugs. GI infections, which include tissue-invasive cytomegalovirus, herpes simplex, fungal, bacterial, and parasitic infections, are discussed in Chapter 90 and have been reviewed elsewhere.²¹⁶ In addition to creating the susceptibility to infection, use of immunosuppressants produces other complications, including mucosal injury and ulceration associated with atypical chest pain, nausea, vomiting, aphthous ulcers of the mouth and tongue, and diarrhea. Diarrhea has been a major problem with the use of mycophenolate mofetil (MMF), and attempts to avoid it with enteric-coated mycophenolate sodium in two studies showed no significant difference between MMF or enteric-coated mycophenolate sodium in the occurrence of GI symptoms.^{217,218} In some patients, changing the MMF dosing schedule from bid to tid dosing may control the diarrhea. Reduction of MMF dose is an option, but it has been reported that when compared to those with no MMF dose reduction or discontinuation, the risk of renal allograft failure increased after MMF dose reduction equal to or greater than 50% (hazard rate, 2.36), and with MMF discontinuation (hazard rate, 2.72).²¹⁹ Sirolimus has also been noted to be associated with diarrhea in as high as 38% of renal transplant recipients with elevated trough levels of sirolimus.²²⁰ Other causes of diarrhea include diverticular disease, pancreatitis, unsuspected celiac disease, continued stool softener and laxative use, and other medications such as cinacalcet for hyperparathyroidism, colchicine for gout, and high doses of magnesium supplements.

A nonrandomized multicenter study to identify nonimmunosuppressant factors causing severe diarrhea in renal transplant recipients followed these seven steps: (1) Discontinue or replace any nonimmunosuppressant drug that could cause diarrhea (e.g., antiarrhythmics, antibiotics, antihypertensives, diuretics, diabetic medications, laxatives, proton pump inhibitors, protease inhibitors). (2) Perform a microbiologic stool examination (cultures for pathogenic bacteria, examination for ova and parasites, assays for fungi, and assay for *C. difficile* toxin). (3) Screen for viruses, including CMV, adenovirus, enterovirus, and rotavirus. (4) Test for bacterial overgrowth and treat as indicated. If diarrhea did not resolve after these four steps, (5) adjust the immunosuppressive regimen. If diarrhea persists, (6) perform a colonoscopy. If, after all of the above steps, the diarrhea has not resolved, (7) treat with antidiarrheal drugs, supplemental bacteria, or diets.²²¹ In this protocol MMF was associated with the largest number of dose reductions or stoppages ($N = 34$), and the remission rate of diarrhea was 65% in these patients. Tacrolimus was adjusted in 12 patients, with a 42% remission rate; all 3 of the patients who had cyclosporine stopped or reduced had remission of diarrhea; glucocorticoids were reduced in 10 patients, with a 60% remission rate. After the first five steps of this protocol, 67 of the 108 patients had resolution of diarrhea,

and 41 patients went on to require colonoscopy and empirical treatment.²²¹

Esophagitis and gastritis are most frequently associated with infectious causes, but cyclosporine, tacrolimus, sirolimus, and MMF have been associated with upper GI lesions, and glucocorticoids remain a controversial cause of these lesions.²¹⁶ Once again, it is necessary to identify other drugs that might be causing the symptoms, such as nonsteroidal anti-inflammatory drugs (NSAIDs), bisphosphonates, potassium supplements, and alcohol. There should be a low threshold for endoscopy of the upper GI tract. Identification of early malignancy and *H. pylori*-positive ulcers are obvious benefits of this approach. A search for iron-deficiency anemia and occult blood testing in three or more stool specimens are also indicated. Surprisingly, one still encounters patients who have upper GI symptoms that completely disappear when they stop taking all of their morning medications in a single batch and separate them by about 1 hour into two or three groups. Esophageal reflux disease may be an especially difficult problem for those whose original kidney disease was ADPKD and have very large kidneys and an enlarged liver, provoking reflux symptoms. Setting aside the treatment of *H. pylori*-positive peptic ulcer disease, which involves triple therapy (2-week course of two antibiotics [e.g., amoxicillin 1000 mg bid and clarithromycin 500 mg bid]), along with lansoprazole 30 mg bid), and other lesions caused by infection, the treatment of esophagitis and gastritis includes the use of proton pump inhibitors, H₂ receptor antagonists, and coating agents.²²² The use of clarithromycin for treatment of *H. pylori*-positive peptic ulcers can increase blood levels of immunosuppressants metabolized by the CYP3A4 pathway. Prolonged use of proton pump inhibitors has been associated with an increased risk of fractures.²²³

When a colonoscopy is to be done, whether for screening purposes over age 50 or for a specific indication, special care needs to be exercised in bowel preparation. Oral phosphate solutions should be avoided to prevent “phosphate nephropathy.”^{224,225} Nonphosphate-containing preparations should be used.²²⁶

When a disease process leads to perforation of the colon, it can be managed with low mortality and often maintenance of allograft function, when there is a high clinical index of suspicion leading to prompt treatment with appropriate antibiotics, exteriorization of the perforated colon, and reduction of immunosuppression to minimal levels.²²⁷ In a series of 1000 renal transplant recipients, the incidence of colon perforations was 1.1%. Diverticulitis was the cause in approximately 70%, with smaller contributions from iatrogenic factors, ischemia, impaction, colonic ulcers, and colitis.²²⁷ More than half of the cases of perforation of the colon occurred within 3 months of renal transplantation.

Aphthous ulcers occurring in the course of treatment with sirolimus have been reported to be manageable with clobetasol.^{228,229}

Acute pancreatitis and biliary tract diseases are more serious events in renal transplant recipients than in the general population. Cyclosporine has been associated with a higher frequency of cholelithiasis,²³⁰ although this was in an era when higher cyclosporine dosing was common.²³¹ Some have recommended “eradication of all biliary calculi, electively, before

transplantation and on diagnosis after transplantation before the patients get really sick.”²¹⁶

OSTEOPOROSIS

Many renal transplant recipients have unrecognized osteopenia or osteoporosis at transplantation. Compounding that problem is the fact that “as many as 60% of renal transplant recipients treated with corticosteroids may lose sufficient BMD to meet the definition of osteoporosis in the first 18 months after transplantation.”²¹ Glucocorticoids suppress bone formation (inhibiting synthesis of insulin-like growth factor, transforming growth factor- β action on bone, and osteocalcin) without suppressing, and possibly even stimulating, bone resorption.²³² By 6 months after renal transplant, patients receiving therapy with cyclosporine, azathioprine, and low-dose prednisone had a 2.8% decrease in BMD of the lumbar vertebrae and a 4.2% decrease in BMD of the femoral neck.²³³ When the prednisone dose was less than 7.5 mg/day, subsequent decreases in BMD appeared to parallel those for age-matched individuals.²³⁴ However, prednisone doses as low as 5 mg/day have been associated with significant reduction in indices of bone formation in postmenopausal females,²³² and doses of 2.5 to 7.5 mg/day with higher hip and vertebral fracture risks in nontransplant patients.^{235,236} Duration of steroid treatment, as well as dose, influence BMD. Moderate use of steroids for 4 months after transplantation when compared to rapid steroid withdrawal had no significant effect on bone mass at 1 year.²³⁷ In a study of 364 renal transplant recipients, all of whom were treated with tacrolimus, MMF, and 3 days of 100 mg/day IV prednisolone, 186 of these patients were randomized to receive either daclizumab and no further steroid, whereas 178 patients had a limited 4-month steroid regimen beginning at 0.3 mg/kg and tapered to zero.²³⁷ Although lumbar BMD decreased significantly in the first 3 months in both the steroid-free (−1.3%) and steroid groups (−2.3%), recovery to baseline occurred at 12 months in both groups. Both regimens prevented accelerated bone loss. In a randomized, controlled study of 92 renal transplant recipients receiving cyclosporine, azathioprine, and prednisone who had stable graft function for at least 1 year (average, 7 years), those who had prednisone withdrawn at a rate of 1 mg/month, when compared to controls maintained at an average of 5.6 mg/day, demonstrated a significant 2.54% per year increase in L1–L4 BMD, a rise in osteocalcin, and no significant change in serum creatinine.²³⁸

Lumbar spine and hip bone mineral densities should be measured by dual x-ray absorptiometry at the time of transplantation, after 6 months, and then every 12 months if results are abnormal. Bone mineral density measurements are “specific but not necessarily sensitive” and, as a single method, are inadequate for identifying all patients at risk for osteoporosis and in need of treatment.²³⁹ Consequently, a new evaluation scheme is being developed that combines BMD and clinical risk factors to quantitate the absolute probability of risk for hip or clinical fracture over a 10-year period, an approach that resembles estimation of 10-year risk for CHD.²³⁹ Overall, the most important clinical risk factors appear to be patient age, previous fracture, and use of glucocorticoids, although many other risk factors have been described by at least seven sources.^{239,240} Disease states relevant to the renal transplant population are diabetes

mellitus, hyperparathyroidism, vitamin D deficiency, chronic metabolic acidosis, and hypogonadal states, as well as use of glucocorticoids and possibly other immunosuppressants.^{235,240–243} It remains unclear as to whether cyclosporine and tacrolimus, independent of other immunosuppressants, cause osteoporosis.²³⁵ Sirolimus thus far does not appear to significantly affect BMD, but its testosterone-lowering effect may pose a long-term risk for males.^{28,235,244,245} Azathioprine, MMF, and cyclophosphamide have not been shown to cause bone loss.²³⁵ There have been recent reports of an increased risk of fractures with prolonged use of proton pump inhibitors,²²³ and with pioglitazone in females, but without other indications of osteoporosis.^{79,246}

“Multiple current guidelines generally agree that patients with T-scores lower than -2.5 should be treated, and those with T-scores higher than -1.5 should not”; however, glucocorticoid use may modify this statement.^{239,240} Treatment of osteoporosis in renal transplant recipients has paralleled that in the general population and is conjoined with adequate calcium (1500 mg daily) and vitamin D (800 IU cholecalciferol) supplementation, after deficiencies have been corrected; blood levels should be monitored. These treatments include bisphosphonates (oral agents: alendronate, ibandronate, and risedronate; IV agents: ibandronate [FDA approved],²⁴⁷ pamidronate, and zoledronic acid [FDA approved]), calcitonin, estrogen, the selective estrogen receptor modulator raloxifene in postmenopausal females, testosterone in hypogonadal males, and possibly recombinant human parathyroid hormone (teriparatide).^{235,248–258} Bisphosphonates have been used in renal transplant recipients because of BMD-documented osteoporosis or glucocorticoid therapy^{259,260} and often a plethora of other risk factors. One of the early guidelines for the prevention and treatment of glucocorticoid-induced osteoporosis is given in Box 89-2, and will be updated.^{259–261} However, there are reports pointing to the need to reassess both the routine use and duration of bisphosphonate therapy in such renal transplant recipients.^{251,262–267} This emerging uncertainty is generated by the diversity of pretransplant bone diseases and their uncharted courses after transplantation even before bisphosphonate use, now further complicated with the use of bisphosphonates.^{253,262–269} A meta-analysis²⁵¹ of five randomized, controlled trials of bisphosphonates in 180 glucocorticoid-treated renal transplant recipients concluded that bisphosphonates, usually given IV in two to four doses with and soon after transplantation, significantly reduced bone loss by 0.06 g/cm^2 in the lumbar spine and nonsignificantly in the femoral neck by 0.05 g/cm^2 . Three of the five studies used pamidronate (two IV^{264,270} and one orally,²⁷¹ one IV ibandronate,²⁷² and one IV zoledronic acid²⁷³)—all with supplemental calcium and three with supplemental vitamin D. Three of these studies reported the number of fractures, and they were nearly identical in the bisphosphonate-treated versus control patients (4 vs. 3). In a more definitive randomized, prospective, controlled study of 72 renal transplant recipients (21 with bone biopsies at baseline and 14 with 6-month follow-up biopsies) who received glucocorticoids and cyclosporine or tacrolimus, 36 received pamidronate IV within 48 hours after transplantation and at months 1, 2, 3, and 6, as well as oral calcitriol and calcium carbonate, the latter two medications being the ones received by the 36 control patients.²⁶⁴ Pamidronate-treated

Box 89-2 Guidelines for the Prevention and Treatment of Glucocorticoid-Induced Osteoporosis (see comments in text)

- Patient receiving long-term glucocorticoid therapy (prednisone equivalent of $\geq 5 \text{ mg/day}$)
- Modify lifestyle risk factors for osteoporosis
 - Smoking cessation or avoidance
 - Reduction of alcohol consumption if excessive
 - Instruct in weight-bearing physical exercise
 - Initiate calcium supplementation as needed
 - Initiate supplementation with vitamin D (plain or activated form) as needed
 - Prescribe treatment to replace gonadal sex hormones if deficient or otherwise clinically indicated
 - Measure BMD at lumbar spine and/or hip
 - If BMD is not normal (i.e., T-score below -1), then:
 - Prescribe bisphosphonate (use with caution in premenopausal women; avoid in patients with $\text{GFR} < 30 \text{ mL/min/1.73 m}^2$ or high-risk condition)
 - Reevaluate at least annually the safety and duration of bisphosphonate therapy because of new information on possible adverse effects of these drugs on different underlying pretransplant bone diseases
 - Consider calcitonin as second-line agent if patient has contraindication to or does not tolerate bisphosphonate therapy
 - If BMD is normal, followup and repeat BMD measurement either annually or biannually

Modified from the American College of Rheumatology Ad Hoc Committee Guidelines on Glucocorticoid-Induced Osteoporosis—2001 Update. *Arthritis Rheum* 2001;44:1496–1503.

patients preserved bone mass at 6 and 12 months whereas the control patients had decreases in vertebral BMD at 6 and 12 months of 4.8% and 6.1%, respectively. However, at baseline 50% of the patients in the subset studied with bone histology had low-turnover bone disease; this increased to 100% at 6 months in all the patients who received IV pamidronate but remained at 50% in control patients.²⁶³ As noted by Cunningham,²³⁵ “These observations are very important, raising the question of whether preservation of BMD, possibly in the face of deteriorating and adynamic bone histology is a reasonable objective in its own right. The overall balance in terms of achieved bone health remains uncertain.” These divergent findings of improved BMD and the development of universal adynamic bone histology are unsettling. Furthermore, among 20 renal transplant recipients randomized to receive either two infusions of 4 mg of zoledronic acid or placebo at 2 weeks and 3 months after transplantation, as well as 1000 mg of daily calcium citrate for the first 6 months (also used in the controls), zoledronic acid when compared to placebo showed no sustained benefit at 3 years despite an early decrease in bone loss by the bisphosphonate.²⁶⁶ The potential use of teriparatide to increase BMD has not been tested in renal transplant recipients in whom preexisting bone disease, probable hyperparathyroidism, and use or nonuse of glucocorticoids and bisphosphonates will create a highly complex picture.^{229,255} When nontransplant patients were treated with alendronate the improvement of BMD by teriparatide was blunted, but

no interference was exerted by raloxifene.²⁶⁵ None of the renal transplant studies performed with bisphosphonates have been sufficiently powered to determine the hard endpoint of fracture occurrence. In a long-term retrospective cohort study of 86 renal transplant recipients followed for a median of 10.6 years, the only overall predictors of fracture risk were age and diabetic nephropathy.²⁶⁷ There were 117 fractures observed in this long-term group with a cumulative incidence of 60% for any fracture at 15 years (compared to the expected 20%), but cumulative corticosteroid dose was remarkably not associated with an increased fracture risk.²⁶⁷

No guidelines have been established regarding when to stop bisphosphonate therapy, but a “holiday” period at 5 years is being evaluated in low-risk nontransplant patients.^{257,258}

Adverse effects reported with oral bisphosphonates are dysphagia, esophagitis, esophageal and gastric ulcers, decreases in serum calcium and phosphorus, and osteonecrosis of the jaw, most often occurring when bisphosphonates are given IV to patients with cancer, dental disease, or to those undergoing dental surgery.²⁷⁴ Because bisphosphonates are renally excreted and can accumulate in patients with stages 5 and 4 CKD, their use is avoided under these circumstances because of potential renal and other toxicities. The nephrotoxic effects of bisphosphonates appear to be most closely associated with IV use. Pamidronate given IV has been associated with hypocalcemia, febrile reactions, and collapsing focal segmental glomerulosclerosis reported in seven patients receiving high doses in the course of treatment for malignancy.²⁷⁵ As noted above, bisphosphonates may aggravate preexisting low-turnover bone disease and hyperparathyroidism.^{235,264,276}

A once-yearly infusion of zoledronic acid over a 3-year period in a double-blind, placebo-controlled nontransplant trial of 3889 postmenopausal females with osteoporosis (Health Outcomes and Reduced Incidence with Zoledronic acid ONce yearly [HORIZON]) showed a benefit in terms of a reduction in the risks of vertebral, hip, and other fractures, a similar effect on renal function as in the controls, but significantly more episodes of serious atrial fibrillation more than 30 days later in the zoledronic acid group (50 vs. 20 patients).^{255,256}

Calcitonin nasal spray 200 once daily, which reduced new vertebral fractures by 33% in 1255 postmenopausal osteoporotic women,²⁷⁷ has adverse effects that include allergy and nasal irritation. Raloxifene for postmenopausal women at a dose of 60 mg/day can reduce vertebral fractures by 30%,²⁷⁸ and it does not interfere with the use of teriparatide.²⁶⁵ Adverse effects of raloxifene include flushing and hot flashes, leg cramps, and thromboembolic events.

HYPERPARATHYROIDISM

Parathyroid function improves in approximately 50% of patients with pretransplant hyperparathyroidism. However, hyperparathyroidism persists in 17% to 50% of patients if the parathyroid glands have developed nodular hyperplasia or if renal allograft function is impaired; hypercalcemia is present in approximately 10% of recipients at 1 year.^{279–281} The majority of functioning renal allografts have a GFR of 30 to 59 mL/min/1.73 m² (stage 3 CKD) accompanied by decreas-

ing phosphorus excretion and lower serum calcium and 1,25-dihydroxyvitamin D₃ levels that promote secondary hyperparathyroidism.²⁸² For interpretation of parathyroid hormone (PTH) function and assays, see Chapter 69.

Hyperparathyroidism can cause osteoporosis (particularly evident as decreased bone density in the forearm), osteitis fibrosa cystica, lytic bone lesions (Brown tumors), pathologic fractures, vascular calcification, ectopic calcification, calciphylaxis, renal stones, and pancreatitis. The K/DOQI guidelines provide a framework for treating renal transplant recipients even though they have not been specifically tested in that population (see Chapter 69).

Treatment of hyperparathyroidism can be medical or surgical. Medical therapy includes vitamin D analogs, the calcimimetic cinacalcet, which suppresses PTH and lowers serum calcium and phosphorus and, if still needed, oral phosphate binders (see Chapter 69).

When secondary hyperparathyroidism is present, typically with hypercalcemia, and 1,25-dihydroxyvitamin D₃ levels are in a normal range with or without vitamin D supplementation, the use of cinacalcet can be considered.²⁸³ Seven small short-term studies totaling 81 kidney-only transplant recipients who received 30 to 180 mg of cinacalcet daily generally demonstrated safety and efficacy, reflected in decreases in serum calcium, elevation of depressed phosphorus levels, and usually decreases in PTH levels.^{281,284–289} An extended study of 170 nontransplant patients with secondary hyperparathyroidism who were treated with 30 to 180 mg of cinacalcet daily for 2 years demonstrated control of PTH levels in approximately 60% of patients.²⁹⁰ Nausea, vomiting, and diarrhea are the most common GI effects and may occur even at the lowest dose. This author has found that dosing on a Monday-Wednesday-Friday schedule can sometimes relieve these symptoms while still retaining partial effectiveness. Diarrhea is a particularly difficult adverse effect because it is also likely to be attributed to mycophenolate mofetil, sirolimus, or colchicine, if one of these drugs is also being used. Cinacalcet is metabolized by multiple enzymes, including CYP3A4. In a recent report cinacalcet reduced the AUC of tacrolimus by 14% and increased formation of the nephrotoxic cyclosporine metabolite AM19.²⁹¹ These findings may help to explain the reduced allograft function reported by some when cinacalcet was used. A more complete list of pharmacokinetic interactions with cinacalcet is given in Chapter 69. Those prescribing the drug should read the manufacturer’s information thoroughly. Hypocalcemia and excessive reduction of PTH need to be avoided, and monitoring of serum calcium, phosphorus, and PTH is advisable at 3-month intervals. Re-lapsing hypercalcemia and elevated PTH levels have been reported when cinacalcet is stopped.^{281,286,287}

When 1,25-dihydroxyvitamin D₃ was given for various reasons to 26 deceased donor renal allograft recipients with functioning grafts more than 1 year after transplantation, there was evidence of immunosuppressive properties, reflected in deceleration in the loss of graft function and instances of stabilization or slight improvement in function. These clinical results extended findings from animal studies of transplantation in which vitamin D prevented rejection and prolonged graft function.^{292,293} The fact that blacks have lower levels of vitamin D than do whites may be relevant to the high risk that blacks have for allograft rejection. Vitamin D has also been reported to have antifibrotic and antirenin effects.^{294,295}

Indications for parathyroidectomy have generally been the occurrence of acute hypercalcemia greater than 12.5 mg/dL in the immediate post-transplant period, asymptomatic hypercalcemia greater than 12 mg/dL for more than 1 year after transplantation, and symptomatic hypercalcemia.²⁹⁶ It should be noted that if cinacalcet was being used in a patient before transplantation and then discontinued, rebound hypercalcemia may occur.²⁸⁶ The surgical guidelines reported by Kerby were developed before the availability of cinacalcet. The major single-center study by Kerby, extending over a 29-year period, resulted in only 38 of 4344 renal transplant recipients requiring a parathyroidectomy for hyperparathyroidism at a mean of 2.7 years after transplantation. In addition to surgical complications, parathyroidectomy incurs risk for hypocalcemia (*hungry bone syndrome*), hypoparathyroidism that requires resetting “normal” serum calcium levels to 8.0 to 8.5 mg/dL to avoid nephrocalcinosis (because the absence of PTH decreases calcium reabsorption), adynamic bone disease, and a significant decline in renal allograft function.²⁹⁷ A summary of various forms of vitamin D is given in Chapter 69 and has been reviewed.²⁹⁸

ACUTE VASCULAR NECROSIS

When glucocorticoids were the major immunosuppressant, the prevalence of acute vascular necrosis was 3% to 41%, but in the cyclosporine and tacrolimus eras it has generally been less than 5%. Risk factors for acute vascular necrosis include deceased donor transplants, repeat transplants, frequent acute rejections, alcohol consumption, glucocorticoids, severe hypertriglyceridemia, and osteoporosis. However, an analysis of 27,772 solitary renal transplant recipients in the USRDS database indicated that acute vascular necrosis was significantly more common when cyclosporine was used.²⁹⁹ Unfortunately, the study was unable to determine if the effect was due to differences in the amount of glucocorticoid therapy, hyperlipidemia, or microvascular thrombosis. The weight-bearing long bones are the most frequently affected sites. Diagnosis is confirmed by magnetic resonance imaging, although such imaging now raises concerns for gadolinium toxicity if it has to be used.^{147–149}

Initial conservative measures for the hip include avoidance of weight-bearing on the symptomatic side and orthopedic consultation. Orthopedic surgical procedures for acute vascular necrosis include core decompression (with uncertain benefit) before collapse of the femoral head and total hip replacement for more extensive disease. Once the disease has occurred, an abrupt decrease or discontinuation of glucocorticoids does not appear to be helpful and may jeopardize the allograft.

A syndrome of severe, episodic bone pain involving primarily both knees and ankles that is often worse at night and in recumbency has been associated with the use of cyclosporine.³⁰⁰ The pain often responds to calcium channel blockers, but a small number of patients may develop acute vascular necrosis in the affected knee.

GOUT

Risk factors for the development of gout in the general population include obesity, weight gain, hypertension, and diuretic use, as well as high-purine diets in males.³⁰¹ Impaired renal

function, treatment with cyclosporine, and the use of diuretics are major contributing factors in renal transplant recipients. In patients receiving cyclosporine, the prevalence of hyperuricemia was 30% to 80%, and 2% to 28% developed symptomatic gout.^{302,303} In the era before cyclosporine use, hyperuricemia developed in 19% to 55%, and gout occurred in only 0% to 8% within 10 years of transplantation, although it increased to 23% after 20 years.^{241,302,304} The diagnosis of acute gout can be made with a good history, physical examination and, when needed, an examination of the joint fluid for monosodium urate monohydrate crystals during an acute attack. However, gout in transplant patients has differences that include involvement of proximal joints, including the sacroiliac joint³⁰⁵ a shorter lead time from onset of hyperuricemia to the first gout attack, with a mean time of approximately 1.5 to 2 years; and the more frequent occurrence of tophi.³⁰¹ Glucocorticoids may mute the full expression of acute gout.

Treatment of acute gout in renal transplant recipients involves modification of the American College of Rheumatology guidelines used in the general population.³⁰⁶ These guidelines recommend the use of NSAIDs, colchicine, or corticosteroids for treatment of acute gout in patients who do not have significant renal impairment or peptic ulcer disease. However, in renal transplant recipients both cyclooxygenase-1 and cyclooxygenase-2 NSAIDs are not recommended as first-line treatment for acute gout because of adverse effects on renal hemodynamics, including renal vasoconstriction, with reduced renal blood flow and decreased GFR, sodium and water retention, hyperkalemia, hypertension, and in some cases acute renal failure. Colchicine appears to be a useful medication for acute attacks, but it too must be used with caution and in modified dose (Box 89-3).³⁰⁷ This author does not recommend titrating colchicine to the point of diarrhea; one of the goals of colchicine therapy should be to avoid diarrhea. Among the adverse effects of colchicine noted in Box 89-3 is myoneuropathy, which can cause elevated serum creatine kinase levels and changes seen on electromyography, particularly when used for long periods of time in patients with impaired renal function or also receiving statins, cyclosporine, or clarithromycin.^{301,308–311} Colchicine 0.6 mg may be continued on an every-other-day basis if necessary for a short time with close monitoring for toxicity until acute gouty attacks cease and the serum uric acid has been reduced to a safe level.

An alternative treatment is the use of glucocorticoids at doses of 0.5 to 1.0 mg/kg of prednisone for 3 to 7 days with tapering to a maintenance dose within 14 days.³¹² Adrenocorticotropic hormone 40 to 80 IUs given intramuscularly has also been used.³¹² A low-purine diet can be a useful adjunct in males.^{313,314} In patients receiving cyclosporine, a change to another immunosuppressant not having such adverse renal hemodynamic and hyperuricemic effects may be appropriate. Diuretics should be avoided if possible or used in reduced doses because of their hyperuricemic effects.

According to guidelines for the general population, therapy to lower elevated serum uric acid levels should be undertaken in patients who have hyperuricemia and gouty arthritis with tophi, gouty erosive changes on radiograph, or two or more attacks/year; however, one attack has been deemed sufficient in the transplant population.^{301,306} Reduction of serum uric

Box 89-3 A Modified Protocol for Colchicine in the Treatment of Acute Gout in Stable Renal Transplant Recipients**Day 1**

Colchicine 0.6 mg orally q1h \times 2 maximum, but stop if any dose causes diarrhea

Days 2–8

Colchicine 0.6 mg orally daily, but stop if any dose causes diarrhea

Days 10, 12, 14

Colchicine 0.6 mg orally every other day, but stop if diarrhea occurs

Note: The objective is to terminate the acute painful inflammatory joint symptoms while minimizing the risk of toxicity. One should be thoroughly familiar with each patient's drug sensitivities and with other potential adverse effects, including myopathy, neuropathy, alopecia, myelosuppression and, rarely, fatality, and with drug interactions, especially with immunosuppressants. Lower doses or drug avoidance are necessary for those with a GFR $<$ 50 mL/min/1.73 m². The risks and benefits of treatment, alternative treatment, or nontreatment must be carefully evaluated for each patient. Prudent clinical judgment and careful monitoring are essential. Also adjust allopurinol, azathioprine, diuretics, and diet as needed.

Modified from Braun WE: Modification of the treatment of gout in renal transplant recipients. *Transplant Proc* 2000;32:199.

acid levels can be achieved through inhibition of uric acid production by means of the xanthine oxidase inhibitor allopurinol or by cautiously employing a uricosuric agent such as probenecid if there is good renal function. Adverse effects of allopurinol, especially the hypersensitivity syndrome, and its interaction with azathioprine, are noted in Box 89-4.

Losartan also has a uricosuric effect that is more pronounced the higher the serum uric acid level.^{315–317} Uricosuria could pose a risk for uric acid stone formation, but the solubility of uric acid rises significantly even with a urine pH of 6.0. Renal allografts with impaired function may not be capable of acidifying the urine to a pH of 5.0 where urate stones can form. Nevertheless, urine pH should be kept at 6.0 or above. It has been my experience that the uric acid level does not have to be driven down below 6 mg/dL to suppress acute gouty attacks, and often a reduction from a range of 11 to 13 mg/dL to 8 to 9 mg/dL, which may be achievable with losartan, is sufficient to avoid acute attacks. However, hyperuricemia may still be a cardiovascular risk factor (see the section Coronary Heart Disease in this chapter).^{317,318}

Two new agents are under study for the treatment of hyperuricemia: urate oxidase (uricase), which catalyzes the conversion of uric acid to allantoin, and febuxostat, a nonpurine selective inhibitor of xanthine oxidase.^{301,311,319} These drugs have not been studied in renal transplant recipients. A single report from Italy in 1997 described the use of urate oxidase in six heart transplant patients receiving cyclosporine, azathioprine, and prednisone; their acute gouty symptoms subsided and plasma uric acid levels normalized with apparently no change in serum creatinine or blood counts.^{301,320} Febuxostat has been shown in a randomized, controlled trial of nontransplant pa-

Box 89-4 A Modified Protocol for Managing Tophaceous Gout in Stable Renal Transplant Recipients**For Patients on Azathioprine**

Allopurinol 50 mg/day; azathioprine reduced by 50%–75% (no more than 50 mg/day)

Monitor complete blood count, serum uric acid, and liver and renal function. Leukopenia would be the most likely sign of toxicity and would require discontinuation of both drugs.

Reduce or eliminate diuretic, if possible; diet as needed (males)

For Patients on Mycophenolate Mofetil

Allopurinol 100 mg/day

Monitor complete blood count, serum uric acid, and liver and renal function

Reduce or eliminate diuretic if possible; diet as needed (males)

For All Patients Being Treated for Gout

Ultrasound of renal allograft for obstruction or stones; treat as indicated

Urine alkalinization to pH of \approx 6.0–6.5*

Appropriate hydration

If no adverse effects or toxicity are encountered, except for patients on azathioprine, cautiously increase allopurinol toward 200 mg/day if necessary, and continue close monitoring

If GFR is $>$ 50 mL/min/1.73 m², probenecid 250 mg bid may be initiated

Addition of losartan for its uricosuric effect can be considered

Note: The objective is to decrease urate deposits while minimizing drug toxicity or damage to the allograft. One should be thoroughly familiar with each patient's drug sensitivities and with the potentially serious adverse effects of each component of treatment, medications, and fluids, including the broad range that may be seen with allopurinol and probenecid. One should also be aware of any potential drug interactions, especially with immunosuppressants. With impaired renal function (GFR $<$ 50 mL/min/1.73 m²), azathioprine doses are often reduced, and allopurinol and probenecid may need to be avoided entirely. The risks and benefits of treatment, alternative treatment, or nontreatment must be carefully evaluated for each patient. Prudent clinical judgment and careful monitoring are essential.

*Approaches to alkalinizing the urine (and some of their risks) when clinically safe include the use of potassium citrate (hyperkalemia, alkalosis); sodium citrate, sodium bicarbonate (hypertension, fluid retention, possibly nephrocalcinosis and nephrolithiasis), and acetazolamide (paresthesias, renal stones) may be more problematic.

Modified from Braun WE: Modification of the treatment of gout in renal transplant recipients. *Transplant Proc* 2000;32:199.

tients with gout to reduce serum uric acid levels to 6 mg/dL or lower in 81% of cases, compared to 39% of those receiving 300 mg of allopurinol.³²¹ Emerging problems with febuxostat include hepatotoxicity, diarrhea, musculoskeletal symptoms, and a high frequency (70%) of gouty flares that developed despite concurrent colchicine or naproxen therapy.³¹⁹

HYPOPHOSPHATEMIA

Hypophosphatemia may be caused by massive diuresis immediately after transplantation, persistence of secondary hyperparathyroidism early post-transplantation, defective proximal tubular phosphate reabsorption because of glucocorticoid therapy or Fanconi-like syndrome, glycosuria, acyclovir (in rat studies),³²² and even the inadvertent use of phosphate binders as antacids. A recent study of the phosphaturic hormone FGF-23, an inhibitor of renal 1- α -hydroxylase activity, in 41 patients at the time of renal transplantation and 3 months after transplant demonstrated that the persistence of FGF-23 after transplant contributed to hypophosphatemia and suboptimal calcitriol levels.²⁹⁷ Complications of severe hypophosphatemia include rhabdomyolysis, impaired left ventricular function and possibly ventricular arrhythmias, impaired pulmonary function presumably related to respiratory muscle impairment, defects in erythrocyte metabolism with possible hemolysis, insulin resistance, and osteomalacia. Oral supplementation with phosphorus-containing compounds may be needed. Dipyridamole at a dose of 75 mg qid has been reported to increase low Tm PO₄/GFR and improve hypophosphatemia.³²³

HYPOMAGNESEMIA

Cyclosporine, tacrolimus, and sirolimus may cause renal magnesium wasting and hypomagnesemia. Magnesium depletion is associated with intracellular calcium overload, cardiac arrhythmias, and changes in the coronary vasculature similar to those seen in accelerated atherosclerosis, as well as neurological and GI symptoms. The hypomagnesemia caused by cyclosporine is typically not accompanied by hypocalcemia or hypokalemia. Oral magnesium supplements with substantial elemental magnesium content include magnesium oxide, as Mag-Ox 400 (241 mg), Slow-Mag enteric-coated (64 mg), and Uro-Mag (84 mg).

Acknowledgments

I am indebted for helpful suggestions to Dr. Michael Limhoff (Coronary Heart Disease and Medical Interventional Treatment of Established CHD), Dr. Byron Hoogwerf (New-Onset Diabetes Mellitus and Prediabetic Conditions), and Dr. Angelo Licata (Hyperparathyroidism and Osteoporosis).

Mrs. Sandra Bronoff provided excellent editorial assistance.

Despite advances in immunosuppression, surgical techniques, and donor and recipient screening that have increased the life expectancy of renal transplant recipients, infectious complications remain a significant cause of morbidity and mortality among renal transplant recipients.¹ A recent analysis of the U.S. Renal Data System database found that for patients who received a transplant between 1991 and 1998, 51% had a hospital discharge diagnosis that included infection during the first year after transplantation.² Unfortunately, the incidence of infection in the post-transplant period seems to be increasing; total infection-related hospital discharge diagnoses have increased each year since 1999.³

For the clinician, the challenge lies in both the prevention of and the early diagnosis and treatment of infection in this population. This is hampered by the lack of standardized diagnostic testing for many pathogens and the often atypical presentation of infectious diseases in immunocompromised patients. Additionally, many of the more commonly used antimicrobials have significant drug interactions with immunosuppressive medications, putting the patient at risk for allograft rejection or toxic adverse effects.⁴ Some drug-drug interactions of importance are listed in Table 90-1; however, the clinician should always check for drug interactions before prescribing any antimicrobial, preferably with the input of a clinical pharmacist, if available.

Although the list of pathogens that may cause disease in the transplant recipient continues to increase, each broad class of infection contains several “typical” organisms with which the practitioner should be familiar. One helpful method of thinking about infection in the transplant patient is to consider how much time has elapsed since the transplant occurred, because some infections tend to manifest during certain time windows after surgery. This finding has been

summarized in chart form by Fishman⁵ (Fig. 90-1). In the first month post-transplant, nosocomial infections tend to predominate, including wound and catheter-related bacterial and fungal infections, and flares of prior latent or allograft-transmitted viruses if no prophylaxis is given (i.e., herpes simplex virus [HSV], hepatitis B, hepatitis C). During the following 5 months, viral infections predominate, including reactivation or primary infection with varicella-zoster virus (VZV), Epstein-Barr virus (EBV), or cytomegalovirus (CMV), although if the patient is receiving antiviral prophylaxis, disease may be delayed until prophylaxis is discontinued. Patients are also increasingly susceptible to community-acquired respiratory viruses, environmental fungi, and parasites as they begin to travel and congregate with others outside the healthcare setting. After 6 months, the risk of opportunistic infections declines as the period of maximum immunosuppression passes, and community-acquired pathogens and post-transplant lymphoproliferative disease (PTLD) tend to be more common.

The use of vaccines before transplantation and selected prophylaxis regimens after transplantation, along with good infection control practices and common sense guidelines for the recipient to minimize high-risk exposures after discharge, will greatly reduce the risk of infectious complications.^{6,7} However, there are still many pathogens for which there are no vaccines or effective prevention strategies. This chapter discusses the more common infections encountered in the transplant setting; however, an exhaustive review of infectious diseases is beyond the scope of this chapter. An excellent resource containing comprehensive guidelines for the majority of infectious diseases encountered by the clinician is available in a recent supplement to the *American Journal of Transplantation*.⁸

Table 90-1 Important Drug-Drug Interactions

	Drugs By Class	Cyclosporine Interaction	Tacrolimus Interaction	Nephrotoxic?
Antifungals	Amphotericin B/lipid amphotericin B	—	—	Yes
	Caspofungin	*	↓	
	Fluconazole/itraconazole	↑↑	↑↑	
	Ketoconazole	↑↑↑	↑↑↑†	
	Voriconazole	↑↑↑	↑↑↑†	
Antibacterials	Erythromycin/clarithromycin	↑↑↑	↑↑↑	
	Nafcillin	↓↓	—	Yes
	Aminoglycosides	—	—	Yes
	Rifampin	↓↓↓	↓↓↓	
	Trimethoprim/sulfamethoxazole	—	—	Yes
	Dapsone	—	↑	
	Chloramphenicol	↑↑	↑↑	
	Quinupristin/dalfopristin	↑↑	—	
	Metronidazole	↑↑	↑↑	
Antivirals	Foscarnet	—	—	Yes
	Cidofovir	—	—	Yes
	Protease inhibitors	↑↑	↑↑	
	Tenofovir	—	—	Yes

*Combination may increase caspofungin levels and induce hepatotoxicity.

†Use with sirolimus contraindicated.

VIRAL INFECTIONS

Cytomegalovirus

Cytomegalovirus is the most important viral infection that develops after solid organ transplant and is associated with significant morbidity and mortality.⁹ CMV is a member of the Betaherpesvirus family; its seroprevalence in the general adult population ranges from 50% to 80% by age 40, and the virus establishes lifelong latency in the host.¹⁰ Primary infection with CMV in the immunocompetent host may be asymptomatic or may manifest as fever, malaise, and a mononucleosis-type syndrome. After primary infection, the virus typically remains latent with no systemic signs or symptoms of reactivation. However, in the transplant recipient, the effects of CMV are myriad, including a *viral syndrome* with fever, leukopenia, and thrombocytopenia that may be compounded by immunosuppressive medications, and also tissue-invasive disease, potentially involving the transplanted organ as well as the lungs, liver, gastrointestinal tract and, rarely, the retina.¹¹ CMV also has been associated with several indirect effects in solid organ transplant patients, including increased risk of rejection, reduced long-term survival, increased risk of other opportunistic infections, bacterial infections, and allograft dysfunction.¹²

Prior to the widespread use of antiviral prophylaxis, most CMV disease occurred in the first 3 months after solid organ

transplantation, with donor-seropositive/recipient-seronegative patients at the highest risk for disease. In addition to donor seropositivity, other major risk factors for CMV infection and disease include the degree of immunosuppression, including the use of antilymphocyte and OKT3 monoclonal antibody therapy for induction or treatment of rejection, rejection itself, and other concurrent viral infections (e.g., human herpesvirus 6 [HHV-6] infection).⁹ Primary CMV infection via the transplanted organ in the seronegative recipient, reactivation of latent disease in the seropositive recipient, and superinfection of donor virus in the seropositive recipient can all cause symptomatic disease. Two strategies have been used for CMV prevention in at-risk patients: universal prophylaxis and preemptive therapy.

Universal CMV prophylaxis involves giving antiviral therapy to all “at-risk” patients (i.e., those with either a CMV-seropositive donor or recipient) at the time of transplantation or immediately afterward for a specified period with the goal of preventing CMV disease during the period of maximum immunosuppression. This approach may be preferable in patients in whom close monitoring for CMV disease is not possible or practical. Although numerous approaches (including acyclovir, valacyclovir, and CMV immunoglobulin) have been associated with a reduction in CMV disease, ganciclovir has been the mainstay of both CMV treatment and prophylaxis in solid organ transplant recipients after studies showed improved efficacy over acyclovir in this population.^{13–15} The

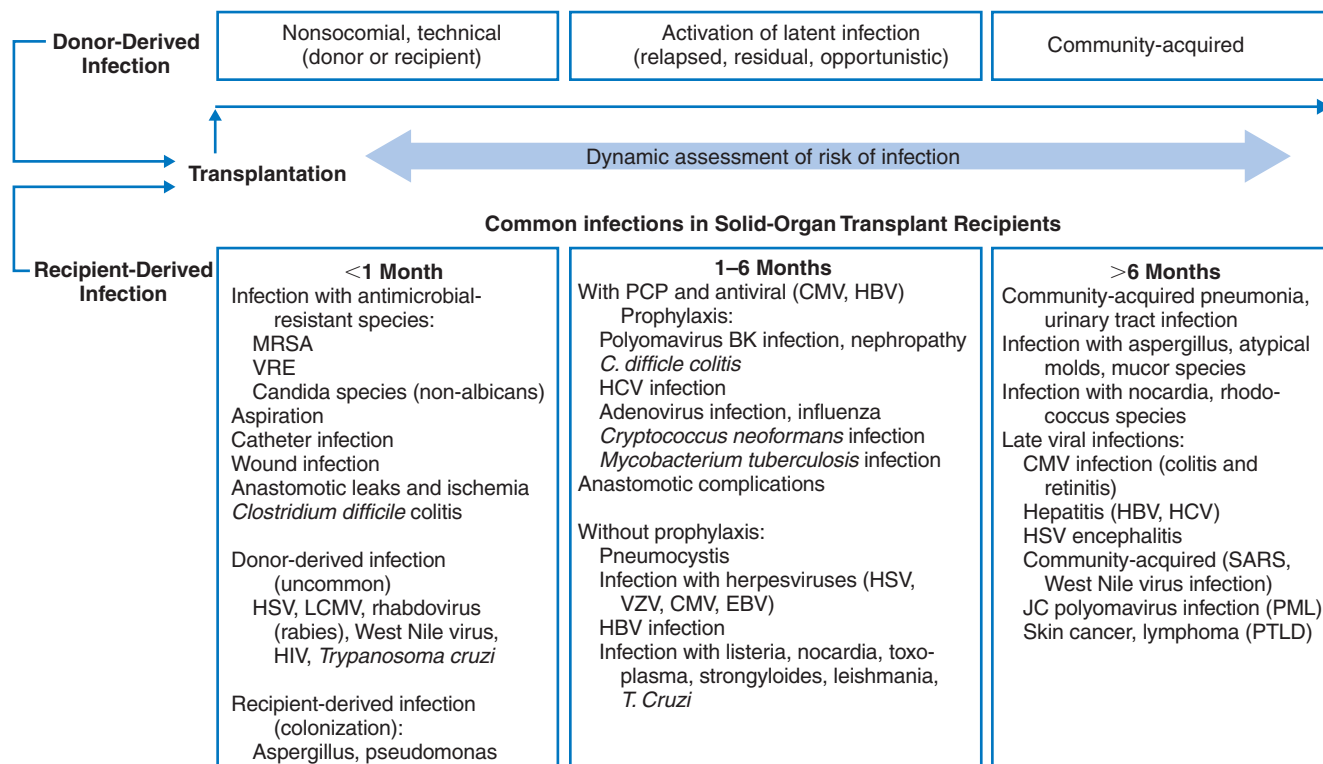

Figure 90-1 Timeline of infection after solid organ transplantation, summarizing typical donor-derived and recipient-derived infections. CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; LCMV, lymphocytic choriomeningitis virus; MRSA, methicillin-resistant *Staphylococcus aureus*; PCP, *Pneumocystis carinii* pneumonia; PML, progressive multifocal leukoencephalopathy; PTLD, post-transplant lymphoproliferative disorder; SARS, severe acute respiratory syndrome; VRE, vancomycin-resistant *Enterococcus faecalis*; VZV, varicella-zoster virus. (From Fishman JA: Infection in solid-organ transplant recipients. *N Engl J Med* 2007;357:2601–2614.)

intravenous form of ganciclovir has given way to oral formulations at many centers due to ease of administration. Oral ganciclovir has a significantly lower bioavailability than the intravenous form, but at doses of 1 gram three times a day it has proven efficacy in reducing the incidence of CMV disease.¹⁶ The valine ester prodrug of ganciclovir, valganciclovir, has improved bioavailability compared to oral ganciclovir, and at doses of 900 mg daily has been shown to be equally efficacious in renal transplant patients,¹⁷ with a slightly increased incidence of neutropenia compared to ganciclovir (8.2% vs. 3.2%). Valganciclovir is not indicated for patients undergoing combined liver and kidney transplantation due to reports of breakthrough CMV disease in liver transplant recipients receiving valganciclovir prophylaxis.¹⁸

Preemptive therapy requires close monitoring of patients for signs of CMV reactivation or primary infection, with prompt initiation of anti-CMV therapy to prevent progression to CMV disease. Blood CMV DNA or RNA levels or CMV antigenemia assays can be utilized at weekly intervals for the initial post-transplantation phase, and then at longer intervals as immunosuppression is reduced. Culture techniques, including shell vials, have fallen out of favor due to long turnaround times or poor sensitivity. A randomized trial of prophylactic or preemptive oral valganciclovir was published in 2006, comparing prophylactic valganciclovir 900 mg daily for 100 days posttransplant and preemptive valganciclovir 900 mg twice a day for 21 days; the trial measured whether

CMV DNA levels rose above 2000 copies/mL in blood samples assessed weekly for the first 16 weeks and then at 5, 6, 9, and 12 months post-transplant. There were no significant differences in efficacy in the prevention of CMV disease, and a cost-sensitivity analysis was similar for both approaches.¹⁹

The optimal duration of CMV prophylaxis remains unclear. Now that many centers use prophylaxis for the first 3 months after transplant, CMV disease typically occurs later after transplantation, most often at a median of 5 months post-transplant in donor-seropositive/recipient-seronegative patients.^{20,21} Unfortunately, extension of prophylaxis beyond 3 months raises concerns of drug toxicity or the development of drug resistance, although a study of 301 high-risk solid organ transplant patients who received 100 days of valganciclovir prophylaxis failed to show the development of drug resistance.²² Monitoring immune markers of CMV also does not appear to be predictive of the development of CMV disease, as a recent study by LaRosa and colleagues²³ suggests. This study examined interferon gamma release from T cells at biweekly intervals between 4 and 6 months after transplant. No association was found between presence or absence of T-cell response and development of CMV disease.²³ However, the failure to develop IgG antibodies at 6 months' post-transplant in patients seronegative at the time of transplant may be predictive of late-onset CMV disease (10% developed disease vs. 1.3% of patients with CMV IgG by 6 months).²⁴

Standard treatment of CMV disease uses intravenous ganciclovir, 5 mg/kg twice daily (with dose adjustments for renal

insufficiency) and reduction of immunosuppression until resolution of symptoms and CMV viremia. Unfortunately, ganciclovir-resistant CMV has emerged as an uncommon but growing problem in the solid organ transplant population, perhaps due to prolonged use of oral ganciclovir prophylaxis and more potent immunosuppression regimens.²⁵ Although this has not been commonly reported in recipients of kidney transplants alone, it may occur more frequently in pancreas transplant recipients; a major risk factor for this is prolonged exposure to low-dose ganciclovir during periods of asymptomatic infection. Resistance can be detected via phenotypic or genotypic testing, but usually requires additional time. Failure to respond to adequate dosing of ganciclovir should raise a suspicion of ganciclovir resistance, and substitution of another antiviral agent may be warranted. Options for the treatment of resistant CMV include foscarnet with or without ganciclovir and cidofovir, both of which may be highly nephrotoxic, especially when used in the context of calcineurin inhibitors. Adjunctive intravenous immunoglobulin (CMV specific or nonspecific) has been used for treatment of refractory CMV disease, although there are no large-scale trials or specific guidelines for its use.¹¹

Epstein-Barr Virus

Similar to CMV, EBV is a ubiquitous herpesvirus that also establishes latent infection in the host. EBV is a member of the Gammaherpesvirus family along with human herpesvirus 8 (HHV-8)/Kaposi's sarcoma-associated herpesvirus (KSHV). EBV infection in the immunocompetent host may be asymptomatic if acquired during childhood or may result in infectious mononucleosis in young adults. More than 90% of the population is seropositive by adulthood. In the transplant recipient, EBV is associated with PTLD, a group of disorders involving varying degrees of abnormal B-cell and T-cell proliferation. Patients at highest risk for PTLD are seronegative recipients who acquire primary infection after transplantation, making pediatric patients especially vulnerable. The virus is efficiently transmitted via saliva and other body fluids, but may also be transmitted by lymphocytes in the transplanted allograft. The risk of PTLD varies by the organ transplanted, with small-bowel transplant recipients at highest risk; lung, heart, pancreas, and liver patients at moderate risk; and renal transplant recipients at lowest risk (approximately 1%).^{26–28} Other risk factors include the type and duration of immunosuppression, including OKT3 and polyclonal antibody use. A recent analysis of the French Registry of PTLD in renal transplant recipients demonstrated an incidence of 1.18% after 5 years, with a 61% survival rate at 5 years after diagnosis.²⁹ Infection with hepatitis B or C was also noted to be a risk factor for patient death, in addition to the more commonly recognized risk factors.

The diagnosis of PTLD initially requires clinical suspicion, because the presentation may be variable, ranging from an infectious mononucleosis-like syndrome to localized or diffuse lymphatic tissue involvement or even isolated allograft involvement. The standard test for diagnosis is biopsy of the involved site with examination of cellular phenotype and clonality, as well as examination for the presence of EBV gene products, such as EBER, via *in situ* hybridization. Staging should be performed with special attention paid to allograft involvement, the presence of multifocal disease, including

involvement of the central nervous system, and the category of PTLD (i.e., monomorphic vs. polymorphic, B cell vs. T cell). EBV viral load testing has not yet been established as an accepted diagnostic test for PTLD because viremia is variable and does not correlate specifically with the presence or absence of PTLD. A low viral load has good negative predictive value, but a high viral load is nonspecific, and certain subtypes of PTLD are EBV-negative.^{30,31} Studies are currently underway examining different EBV antigens as markers for patients at risk for developing PTLD and possibly also as surrogate markers for global immunosuppression levels.

Prevention strategies for PTLD are limited, because systematic study of various modalities is lacking. Identification of high-risk recipients is recommended, specifically EBV-seronegative recipients and those at risk for CMV disease. Avoidance of overzealous immunosuppression should be encouraged as well, because this has been shown to be a risk factor for development of PTLD. The benefit of antiviral prophylaxis specifically targeted toward EBV has not been established, but CMV prophylaxis regimens may have some benefit in reducing the risk for PTLD. The use of prophylactic CMV intravenous immunoglobulin (IVIg) did not prove efficacious in a small clinical trial.³²

Treatment of early PTLD begins with reduction of immunosuppression, which may result in spontaneous regression in 23% to 50% of cases. In renal transplant patients, confirmed PTLD should prompt cessation of immunosuppression, even at the expense of rejection of the allograft. Retransplantation after recovery from PTLD is possible, with a recent OPTN/UNOS database study showing retransplantation patient survival of 100% and graft survival of 88.9% at a mean follow-up of 742 ± 107 days.³³ Other treatment modalities include surgical debulking of the tumor or explant of the allograft, if involved; referral to an oncologist for monoclonal B-cell antibody therapy (rituximab) if the tumor cells are CD20+; and cytotoxic chemotherapy for refractory disease. A variety of other treatment modalities are under investigation, including anti-interleukin-6, interferon alfa, and adoptive immunotherapy using the patient's own lymphocytes activated *ex vivo*.²⁷ Late-onset or EBV-negative PTLD typically does not respond as well to reduction of immunosuppression and thus requires more aggressive therapeutic measures, so early consultation with an oncologist is prudent in these patients.

Herpes Simplex Viruses 1 and 2 and Varicella-Zoster Virus

Herpes simplex virus-1, HSV-2, and VZV are members of the Alphaherpesvirus family and, like other herpesviruses, establish lifelong latency after primary infection. Seroprevalence of HSV-1, the common etiological agent for orolabial lesions, is >60% in the United States, whereas seroprevalence of HSV-2 (genital ulcer disease) exceeds 20%.³⁴ Antibodies to VZV, the cause of chickenpox and zoster/shingles, are present in more than 90% of adults, although the epidemiology of this virus may change in the future due to the adoption of universal vaccination of children in the United States in 1995. Most disease caused by these viruses is secondary to reactivation of latent infection; however, in seronegative patients primary infection may be acquired rarely via transmission from the allograft or more commonly from community spread, usually early in the post-transplant course if prophylaxis is not given.

Reactivation of HSV-1 and HSV-2 may present as localized orolabial or genital ulcers, but disseminated disease may occur, causing pneumonitis and hepatitis. Similarly, VZV may reactivate as dermatomal zoster, but can also cause more generalized skin disease as well as invasive disease involving the lungs, gastrointestinal tract, and central nervous system.

Most centers use oral acyclovir 400 to 800 mg orally bid to tid³⁵ or valacyclovir 500 mg daily as prophylaxis against HSV-1, HSV-2, and VZV in patients who are not receiving prophylaxis for CMV; regimens for CMV prophylaxis using ganciclovir or valganciclovir are also effective.³⁴ The VZV serostatus of prospective transplant recipients should be assessed early in the evaluation process so the live, attenuated varicella vaccine can be administered well before transplantation occurs. In the previously infected, immunocompetent host, varicella vaccine has been shown to reduce the incidence of zoster.³⁶ Whether varicella vaccine is safe and effective for the prevention of zoster after transplantation is unknown.

Human Herpesviruses 6 and 7

The Betaherpesviruses HHV-6 and HHV-7 were identified in 1986 and 1990, respectively. Both tend to cause primary infection in childhood, such as roseola infantum, exanthema subitum, or other nonspecific febrile illnesses, and then establish latency in adults, with 90% of adults demonstrating seropositivity for the viruses.³⁴ The role of reactivation of these viruses in the post-transplantation period is still under investigation, but it appears that they may have immunomodulatory effects either independently or in combination, especially in that reactivation of HHV-6 and HHV-7 is often found in the context of CMV disease. Primary disease caused by HHV-6 has been reported to include bone marrow suppression, encephalitis, hepatitis, colitis, pneumonitis, and fatal hemophagocytic syndromes,^{34,37–39} whereas primary HHV-7 syndromes have been less well-described. In a prospective study of Betaherpesvirus viremia after renal transplantation, CMV was the most commonly detected virus, occurring in 58% of patients; HHV-7 occurred earliest (in 47%) of patients, and HHV-6 occurred in 23% of patients.⁴⁰ Interestingly, the authors found a correlation between HHV-7 viremia and increased number of rejection episodes in an analysis restricted only to patients with rejection (overall there was no association between presence of Betaherpesvirus viremia and occurrence of rejection), and there was an increased incidence of CMV disease in patients who demonstrated infection with both CMV and HHV-7.⁴⁰

Detection of HHV-6 and HHV-7 can be accomplished by nucleic acid testing, but prevention strategies remain undefined. Ganciclovir may be effective for HHV-6 prophylaxis, but variability of susceptibility to this agent may exist between the A and B variants of the virus. HHV-7 does not appear to be affected by ganciclovir prophylaxis,⁴¹ and both viruses appear to be resistant to acyclovir. Optimal treatment of these viruses is clouded by frequent coinfection with CMV. Ganciclovir, foscarnet, and cidofovir appear to reduce HHV-6 and HHV-7 viremia when used for coincident CMV disease, but it is unclear if this reduction is due to clearance of CMV and resolution of its immunomodulatory effects, or direct antiviral effects on HHV-6 or HHV-7. Individual case reports of reduction of immunosuppression and ganciclovir treatment for HHV-6 infection have been published.³⁷

Human Herpesvirus 8/Kaposi's Sarcoma-Associated Herpesvirus

Human herpesvirus 8 is a Gammaherpesvirus related to EBV that similarly establishes latency after primary infection, and is the cause of Kaposi's sarcoma (KS), primary effusion lymphoma, and some forms of multicentric Castleman's disease. Seropositivity for HHV-8 is more geographically restricted than for other herpesviruses, with highest prevalence rates in Africa and the Middle East. In the United States, seroprevalence is estimated to be less than 5%, although in certain populations (i.e., men who have sex with men) the rates may be higher.⁴² Seroconversion post-transplant appears to depend on the donor status and perhaps the geographical location of the recipient, although a study of 100 solid organ transplant recipients in Pittsburgh showed seropositivity rose from 5.3% to 15.8% after transplantation with presumed donor-negative organs (90% documented as negative via serum sample), regardless of patient age or type of organ received.⁴³ Incidence of KS has been estimated to be up to 500 times higher in solid organ transplant recipients as compared to the general population,⁴⁴ and rates in the United States have been reported to be from 0.5% to 6%. Most U.S. patients present with cutaneous KS, and disease occurs a median of 30 months after transplantation.³⁴

Detection of HHV-8 antibodies is useful for establishing seroconversion, and an assay for the detection of serum nucleic acid is available for detection of viremia. No guidelines exist for prevention of disease, although the replicating virus appears to be susceptible *in vitro* to ganciclovir, foscarnet, and cidofovir.³⁴ Treatment of post-transplantation KS depends on the extent of disease (i.e., cutaneous or visceral involvement), but typically begins with reduction of immunosuppression; if necessary radiotherapy and chemotherapy may be added for more extensive disease. Recently a series of 15 renal transplant recipients with post-transplantation KS were successfully treated with discontinuation of cyclosporine and mycophenolate mofetil and addition of sirolimus.⁴⁵ Sirolimus, an immunosuppressive medication that targets mTOR and prevents interleukin-2-induced proliferation of T cells, inhibits the growth of several tumor cell lines *in vitro*, and inhibits Akt, a protein kinase in the mTOR signaling pathway that has been implicated in KS pathogenesis. Sirolimus trough levels were maintained between 6 and 10 ng/mL, and no episodes of rejection occurred in any of the patients.⁴⁵

Respiratory Viruses (Adenovirus, Respiratory Syncytial Virus, Influenza, Parainfluenza)

Recipients of renal transplants are at risk of contracting common community-acquired respiratory viruses from household contacts and others. In many cases, these viruses may be seasonal (e.g., respiratory syncytial virus [RSV], parainfluenza, and influenza), and the impact on the patient varies with the proximity to the transplant and the degree of immunosuppression of the recipient. Polymerase chain reaction (PCR) techniques have made the rapid diagnosis of most of these pathogens possible (fluorescent antibody detection is also available in many centers), but prevention strategies and treatment are limited for many of these viruses. Infection control practices to prevent nosocomial spread and hand hygiene in and outside of

the hospital are the primary means of prevention of these viruses, along with yearly influenza vaccination for all transplant recipients, household contacts, and healthcare workers.

Adenovirus can cause symptomatic and invasive disease (i.e., hemorrhagic cystitis, gastroenteritis, pneumonitis) that can occasionally be fatal in transplant recipients, more commonly in pediatric patients. No vaccine or prophylaxis is currently available against adenovirus, and definitive treatment recommendations have not been established. Several case reports suggest that cidofovir may be efficacious in treating hematopoietic stem cell transplant patients, although dosing recommendations are unclear.⁴⁶ Dosing of cidofovir at 5 mg/kg every 1 to 2 weeks may cause nephrotoxicity, but dosing at 1 mg/kg three times per week may cause breakthrough CMV or HSV infections.^{46,47} Ribavirin has also been used for treatment of tissue-invasive adenoviral disease, but its antiviral activity is limited to certain serotypes of adenovirus, there are significant toxicities associated with its use, and convincing efficacy data has not been shown to warrant recommendation of its use.^{46,47} Ganciclovir has in vitro activity against adenovirus, but there is no definitive data supporting its use for treatment of adenoviral disease, and conflicting data exist regarding prophylactic benefits. Insufficient evidence exists for the use of other agents, such as zalcitabine and vidarabine, for treatment.⁴⁷ Reduction of immunosuppression should be attempted in all cases along with supportive care.

RSV is a common pediatric pathogen that causes seasonal disease in the winter months, usually among children age 2 and younger. It appears that immunity to the virus is not lifelong, and transplant recipients may manifest more severe disease than immunocompetent hosts. Manifestations are typically pulmonary, and the development of lower respiratory tract disease portends a worse prognosis.⁴⁸ The benefit of prophylaxis with palivizumab or RSV-IVIG in adult transplant recipients has not been proven. Data are limited for treatment of established RSV disease in solid organ transplant patients, but some benefit may exist for the use of aerosolized ribavirin in combination with palivizumab or RSV-IVIG early in lower tract disease.⁴⁸

The mainstay of prevention of influenza A and B is the yearly vaccination of the transplant recipient and their close contacts.^{6,49} The preferred vaccine is a combination of inactivated antigens from strains of influenza A and B that are predicted via epidemiological studies to circulate for a given year; thus, the composition may change on a yearly basis. Although the response of transplant patients is lower than that of healthy immunocompetent individuals, sufficient levels of protection are likely to occur in most individuals. Early concerns about an increased risk of graft rejection as a result of the immune response to vaccination have not been supported by the literature, and a recent multicenter retrospective analysis of rejection in more than 3000 heart transplant recipients found no association between influenza vaccination and episodes of rejection.⁵⁰ If infection is suspected, rapid treatment should be initiated within 48 hours of symptom development concurrently with a diagnostic test such as nucleic acid detection. Neuraminidase inhibitors (oseltamivir, zanamivir) have become the mainstay of therapy because they are efficacious against both A and B strains of influenza; however, studies specifically evaluating their efficacy in transplant recipients have yet to be conducted.⁴⁸ Treatment dosing of oseltamivir is 75 mg orally twice a day for 5 days (zanamivir is only available as an inhaled agent). Prophylaxis with oseltamivir may also be beneficial within 48 hours in cases of known or suspected exposure to influenza at a dose of

75 mg orally once a day for a minimum of 10 days. The use of amantadine or rimantadine has fallen out of favor due to the lack of efficacy against influenza B and the recent reports of resistance of influenza A during the 2006 influenza season.⁵¹

Parainfluenza viruses 1 and 2 tend to circulate in the fall and winter months, and typically produce nonspecific upper respiratory tract symptoms. There is currently no vaccine, prophylaxis, or accepted treatment regimens for these viruses.⁴⁸

Hepatitis B

The incidence of new acquisition of hepatitis B during the hemodialysis period has been markedly reduced since the adoption of improved infection control practices in 1977. Widespread use of the hepatitis B vaccine was adopted in 1982, further reducing the incidence of hepatitis B acquisition.⁵² Vaccination of all patients with compensated renal disease well in advance of dialysis dependence should be encouraged using a four-dose vaccine schedule (0, 1, 2, and 6 months), and yearly monitoring of HBsAb titers should be conducted, with booster vaccination given as needed.⁵³ Currently the prevalence among hemodialysis patients is approximately 1.6%. Among dialysis patients who seroconvert, 80% may develop chronic hepatitis B, and a subset of patients who undergo transplantation after becoming HBsAg-negative will reactivate after the transplant.⁵⁴ Patients who receive a transplant when HBsAg-positive have a poorer prognosis with high rates of chronic hepatitis by 10 years (85%) and also an increased likelihood of sepsis and hepatocellular carcinoma in the posttransplant period.⁵⁴ A high risk of HBV transmission exists when grafting an HBsAg-positive organ into a seronegative recipient, so this circumstance should be avoided. Transplantation of a hepatitis B surface antigen (HBsAg)-negative/core antibody (cAb)-positive kidney may be undertaken in a seronegative recipient if the recipient is fully vaccinated and the donor is HBV DNA-negative; although the recipient may seroconvert based on the presence of new HBcAb, this did not affect patient survival or graft function.⁵⁵ Close follow-up of these recipients with monitoring for transmission of hepatitis B is important; the use of hepatitis B immunoglobulin and pharmacotherapy may be warranted in this situation.

For recipients with hepatitis B, close monitoring of viral load and HBeAg is warranted, and a liver biopsy before transplantation to assess the extent of hepatitis or cirrhosis should be performed, because the more extensive the liver disease present before transplantation, the higher the liver-associated mortality after transplantation.⁵⁴ Treatment of these patients may include use of the nucleoside analogs lamivudine, adefovir, entecavir, and telbivudine, and nucleotide analogs such as tenofovir. Treatment with lamivudine typically results in a large reduction in HBV DNA, but resistance may develop with prolonged use of the drug (>1 to 2 years).⁵⁶ This approach is advocated before transplantation to suppress the viral load and should be continued after transplantation in nonhepatic recipients with chronic hepatitis B. Tenofovir and adefovir have both been associated with nephrotoxicity in patients who are not transplant recipients, raising concerns about their safety in renal transplant recipients. Recent data regarding the use of long-term (up to 5 years) adefovir in chronic hepatitis B patients was recently published, suggesting that this agent is well tolerated, with a small risk of renal insufficiency at 1 to 3 years and a low risk of development of resistance after 5 years.⁵⁷ A smaller analysis of renal

transplant recipients with chronic hepatitis B resistant to lamivudine was reported that showed a significant reduction in hepatitis B DNA with no evidence of adefovir-related renal toxicity after a median of 15 months of treatment, although several patients required phosphorus supplementation.⁵⁸ Pretransplant treatment with interferon- α to reduce viral load and promote seroconversion has been investigated in renal transplant recipients, but specific guidelines regarding its use have not been published; this approach is not currently recommended.

Hepatitis C

Infection with hepatitis C leads to chronic infection in 85% of exposed individuals, and cirrhosis develops after approximately 20 years in 10% to 30% of these individuals.⁵⁴ Fortunately, the rates of HCV infection in the hemodialysis population have declined due to improved infection control measures and screening of blood products.⁵² However, de novo infection still occurs in the dialysis setting, with a seroconversion rate of 2.5% per 100 person-years in a recent prevalence study.⁵⁹ Screening of potential renal transplant recipients and donors is critical, because discovery of chronic infection with HCV has implications for treatment and surveillance.

Hepatitis C can be efficiently transferred via the transplanted organ, with seroconversion occurring in 67% of recipients of an HCV-positive organ and detection of HCV RNA in 96% of recipients.⁶⁰ This result underscores the difficulty of relying solely on serological testing in transplant recipients, and nucleic acid testing for HCV is required for the immunocompromised host, including both dialysis patients and transplant recipients. Because transmission of the virus occurs frequently, HCV-seropositive donors now are considered extended-criteria donors and are typically reserved for HCV-positive recipients or other special circumstances. Nucleic acid testing for hepatitis C RNA in antibody-positive renal donors can help identify those donors who are viremic and therefore likely to transmit hepatitis C.⁶¹

The effects of HCV positivity on graft and patient survival have been variable. In a cohort of patients on a renal transplant waiting list, HCV-positive patients had a higher risk of death compared to HCV-negative patients regardless of whether they remained on dialysis or underwent transplantation.⁶² However, HCV-positive recipients who underwent transplantation or seronegative recipients who received a HCV-positive kidney had improved long-term survival compared to patients who remained on dialysis after 6 months.^{60,63–65} HCV infection in the post-transplant period is associated with increased chance of new-onset diabetes mellitus, sepsis, and HCV-related glomerulonephropathy; long-term mortality; and graft failure.^{54,66–69} Recent studies have suggested that hepatitis C infection in renal transplant patients may not necessarily predispose recipients to rapid progression of liver disease.⁷⁰ Increased variability of the hypervariable region (HVR-1) of HCV E₂ glycoprotein may be a predictor of lack of progression of fibrosis.^{70,71}

Because of the implications of chronic hepatitis C infection in the post-transplant period, efforts should be made to stage the extent of disease in transplant candidates. Serum transaminases do not reflect the extent of liver fibrosis or cirrhosis, so a liver biopsy should be performed during the transplant evaluation to determine the extent of liver damage. Treatment of hepatitis C in the pretransplant period should also be considered in an effort to eradicate the virus.⁶⁶ Ribavirin and

PEG-interferon- α combinations are the treatments of choice, but adverse effects such as anemia prevent the use of ribavirin in this population. After transplantation, interferon- α has been associated with an increased risk of renal failure and possible graft rejection, so it is generally not recommended for use after renal transplantation.^{54,72,73}

BK Virus

The BK virus is a double-stranded DNA polyoma virus that infects up to 90% of the adult population and appears to be primarily asymptomatic in the immunocompetent host, although upper respiratory symptoms and cystitis have been reported.⁷⁴ In the renal transplant recipient, BK virus can be transmitted by the transplanted organ or can reactivate from latency in seropositive recipients. Typically the virus causes asymptomatic viremia in this population, but in some patients nephropathy with allograft dysfunction or ureteral stenosis or stricture develops as a result of BK disease. The risk factors for development of BK viremia or viremia are unclear, but the extent of immunosuppression appears critical, as does antirejection treatment.⁷⁵

The methods and screening intervals used for the diagnosis of BK virus infection are not well-defined, but include frequent urine cytological examination looking for abnormal epithelial *decoy cells* and more sensitive PCR methods of detection of both urine and blood specimens.⁷⁶ Nucleic acid techniques also can provide a quantitative assessment of viral load and are able to differentiate between BK virus infection and other viruses that may produce a similar cytological appearance of epithelial cells (i.e., JC virus). Plasma viral loads greater than 10⁴ copies/mL and urine viral loads greater than 10⁷ copies/mL are suggestive of underlying BK virus nephropathy (BKVN).⁷⁷ The diagnosis and staging of BKVN requires renal biopsy, and the incidence of BKVN appears to range between 1% and 10% of renal transplant recipients. Recent research has examined the utility of nucleic acid-based detection techniques as screening tools for the development of BK viremia, viremia, and nephropathy.⁷⁸ Both the level of BK viremia and the presence of recurrent viremia have been correlated with the presence of BKVN.^{75,79}

Treatment and prevention of BK virus is still evolving. Reduction of immunosuppression remains the mainstay of prevention and therapy of BK viremia, viremia, and nephropathy. Antiviral agents have not been uniformly efficacious in the prevention or treatment of BK viremia, but several have been anecdotally reported, including cidofovir and leflunomide. Unfortunately, no randomized, controlled clinical trials have been performed with either of these agents, but their use may be warranted in patients who have severe BKVN with concurrent rejection that may limit reduction of immunosuppression.⁸⁰ Cidofovir has activity against polyoma viruses in vitro, but its nephrotoxicity has led to reduced dosing in renal transplant patients for treatment of BK virus infection (0.25–1 mg/kg given intravenously every 1–3 weeks), and clinical results remain mixed.⁸⁰ Of 26 patients with BKVN treated with cidofovir at the University of Pittsburgh, viremia cleared in 25 patients, and 15% lost the graft, compared to a historical graft loss rate of 45% without cidofovir.⁸¹

Leflunomide, a drug used for the treatment of rheumatoid arthritis, also has antiviral activity against BK virus in vitro, and a limited amount of data is available regarding its clinical utility.

A series of 17 patients with biopsy-proven BKVN was treated with leflunomide at a loading dose of 100 mg/day for 5 days and then 20 to 60 mg per day titrated to maintain blood levels higher than 40 µg/mL.⁸² Those patients who achieved blood levels greater than 40 µg/mL had reduction or clearance of the virus in the urine and blood by 6 months, with persistence of response beyond that time.⁷⁸ However, the pharmacokinetics of leflunomide are unpredictable, making uniform dosing recommendations difficult and serum drug level monitoring necessary.

Quinolones and IVIG have also been explored for the treatment of BK virus infection, but limited clinical data is available on efficacy, and no recommendations can be made about these agents until further studies are performed.^{80,81}

Retransplantation after BKVN is feasible, with a low risk of recurrence of BKVN, regardless of transplant nephrectomy before retransplantation or the presence of active BKVN and viremia.^{83,84}

FUNGAL INFECTIONS

The morbidity and mortality of fungal infections in transplant recipients remains high despite recent advances in antifungal medications and diagnostic testing. Compared with other transplant recipients, renal transplant patients are at lower risk for fungal infections unless they are receiving a simultaneous pancreas transplant.⁸⁵ Despite this reduced risk, clinicians need to remain vigilant for unexplained fever, respiratory symptoms, or skin lesions as possible manifestations of fungal disease. The unpredictability of the clinical signs and symptoms of fungal infections, the difficulty of interpreting radiological studies and biopsies, and the limited number of laboratory-based markers of fungal infection often result in the dissemination and invasion of fungal disease before proper treatment can be initiated. The added difficulties of managing the interactions between immunosuppressive medications and many antifungal medications increase the complexity of treating these infections.

Fungal infections in the early transplant period (<1 month) typically involve *Candida* species or, in rare instances, nosocomial transmission of other environmental fungal pathogens, such as *Cryptococcus neoformans* or *Aspergillus* species.^{9,85} A variety of risk factors have been associated with early invasive fungal infections after transplant, including simultaneous pancreas transplant or pancreas transplant after kidney transplant, enteric or bladder drainage procedures, primary allograft dysfunction, prolonged transplantation surgery, high intraoperative blood loss, prolonged intensive care unit stay, chronic graft dysfunction/rejection, presence of immunomodulating viruses, prolonged use of antibiotics, artificial stents, donor fungemia, and prior or concurrent fungal infection in the recipient.⁸⁵ Care must be taken to identify the species of *Candida* isolated for therapeutic reasons, because *Candida albicans* remains susceptible to fluconazole, but other *Candida* species are becoming more frequent pathogens and are not uniformly susceptible to fluconazole (i.e., *Candida glabrata* may be resistant or have dose-dependent susceptibility, *Candida krusei* is intrinsically resistant). The choice of empirical therapy for life-threatening candidal infections depends on the epidemiology of isolates at an individual institution and may include high-dose fluconazole, voriconazole or an echinocandin.

In the later post-transplant period, patients are at risk for environmental pathogens and endemic mycoses, both via primary exposure and reactivation of latent disease.^{9,85} *Aspergillus* and *Cryptococcus neoformans* infections are the most commonly encountered fungal pathogens during this period. Risk factors for fungal infection include diabetes, prolonged pre-transplant dialysis, use of tacrolimus, and treatment for rejection.⁸⁶ A careful history, including travel, workplace and home exposures (i.e., construction or remodeling, pets), and hobbies such as gardening or spelunking should be elicited, and a careful review of systems performed. Radiological studies may be warranted, and any suspicious skin lesions should be biopsied. Suggested diagnostic testing and treatment regimens for *Candida*, *Aspergillus*, and *Cryptococcus* are summarized in Table 90-2.

PNEUMOCYSTIS JIROVECI INFECTIONS

Pneumocystis jiroveci (formerly *Pneumocystis carinii*) remains an important cause of respiratory disease in transplant recipients despite excellent prophylaxis regimens. The use of more potent immunosuppression and the ultimate cessation of prophylaxis at approximately 6 months post-transplant require the physician to consider *Pneumocystis* infection in any transplant recipient with flulike symptoms and persistent respiratory complaints, including dry cough and dyspnea. Radiographic findings may be atypical in transplant recipients and can manifest as diffuse ground-glass infiltrates, more focal consolidation, or pneumothorax.⁸⁷

Prophylaxis with trimethoprim-sulfamethoxazole for the first 6 months after transplant is strongly recommended, because it also reduces the risk of other opportunistic infections, such as toxoplasmosis, listeriosis, and nocardiosis, as well as bacterial urinary tract infections (UTIs). If the patient cannot tolerate trimethoprim-sulfamethoxazole, other agents can be used, such as aerosolized pentamidine, atovaquone, and dapsone, but care must be taken to monitor for compliance and adverse effects of the medications.⁸⁷ Treatment of *Pneumocystis* disease should be with trimethoprim-sulfamethoxazole 15 to 20 mg/kg daily in four divided doses, with corticosteroids given if hypoxia with a PO₂ lower than 70 mm Hg by arterial blood gas is documented. A minimum 14-day course of trimethoprim-sulfamethoxazole is often sufficient if immunosuppression can be reduced, and 40 to 60 mg of prednisone for 5 to 7 days followed by a taper is recommended for concomitant hypoxemia.

BACTERIAL URINARY TRACT INFECTIONS

Urinary tract infections, especially involving the transplanted kidney, are the most commonly encountered bacterial infections in renal transplant recipients. The incidence of UTI in this population has been estimated to be between 35% and 79%, and this infection is the most common source of gram-negative bacteremias.⁸⁸ The high rate of infection is likely due to several factors, including surgical factors (e.g., refluxing vs. nonrefluxing anastomosis of the ureters, ureteral stent placement, impaired bladder emptying), presence and duration of bladder catheters, and immunosuppression.^{88,89} Of increasing concern is the number of highly resistant gram-negative

Table 90-2 Suggested Diagnostic Testing and Treatment Regimens for *Candida*, *Aspergillus*, and *Cryptococcus*

Pathogen	Prophylaxis	Diagnosis	Treatment of Invasive Disease	Special Considerations
<i>Candida</i> species	Candiduria: fluconazole 400 mg/day until eradication SPK: fluconazole 400 mg/day or liposomal amphotericin B 3–5 mg/kg/day for ≥4 wks until risk factors resolved	Smear/culture of blood or sterile site Nucleic acid detection (not universally accepted) Radiology: CT of viscera, MRI of brain Histopathology	Fluconazole 200–800 mg/day depending on site and isolate MIC, renal function Amphotericin B lipid formulations: 1–5 mg/kg/day Amphotericin B: 0.5–1.5 mg/kg/day Echinocandins: caspofungin 75 mg × 1 loading dose then 50 mg/day, dose reduction for liver disease Anidulafungin 200 mg × 1 loading dose, then 100 mg/day Triazoles: voriconazole 6 mg/kg IV q12h × 2 doses, then 4 mg/kg q12h; 400 mg PO q12h × 2 doses, then 200 mg q12h for patients >40 kg; dose reduction for liver disease; itraconazole 200 mg PO or IV q12–24h Other options not yet FDA approved for this indication: micafungin, posaconazole	<i>C. glabrata</i> MICs/resistance increasing to fluconazole, <i>C. krusei</i> intrinsically resistant <i>C. lusitaniae</i> intrinsically resistant; monitor renal function and electrolytes Monitor renal function and electrolytes May be hepatotoxic if given with cyclosporine; may decrease tacrolimus levels IV form not recommended if renal impairment, significant drug interactions, including contraindication of voriconazole use with sirolimus; reduce dose of tacrolimus by two thirds and reduce cyclosporine by one half; monitor levels
<i>Aspergillus</i> species	None recommended	Culture of sterile site Antigen detection: galactomannin assay not universally accepted, false positives with concurrent piperacillin use Radiology: CT of viscera with nodules, cavities; halo sign, crescent sign may be seen/MRI of brain Histopathology	Voriconazole: dosed as above Liposomal amphotericin B: 5 mg/kg/day Amphotericin B: 1–1.5 mg/kg/day Caspofungin: dosed as above Role of combination therapy unclear Other options not yet FDA approved for this indication: micafungin, posaconazole	As above As above As above As above
<i>Cryptococcus neoformans</i>	None recommended (fluconazole may provide some protection)	Smear/culture of blood, CSF, sterile site (transplant patients <i>must</i> have CSF evaluation, may have elevated opening pressure) India ink preparation of CSF Antigen detection in CSF, blood (false-negatives if nonencapsulated strain, prozone effect) Nucleic acid detection (not universally accepted) Radiology: CT of viscera, MRI of brain Histopathology	Liposomal amphotericin B: 5 mg/kg/day OR Amphotericin B: 0.5–1 mg/kg/day PLUS 5-flucytosine 100 mg/kg/day divided q6h; renal dosing required × 14 days THEN Fluconazole 400 mg/day, duration unknown	As above As above Monitoring serum creatinine and 5-flucytosine levels suggested, goal 30–80 μg/mL 2 hr after dose

CSF, cerebrospinal fluid; CT, computed tomography; FDA, Food and Drug Administration; MRI, magnetic resonance imaging; SPK, simultaneous pancreas-kidney transplantation.

Adapted from Fungal infections. Am J Transplant 2004;4(Suppl 10):110–134, Tables 3 and 4.

organisms isolated from these patients and the limited number of antimicrobial options for treatment.

The impact of early UTI in renal transplant recipients has been associated with pyelonephritis, bacteremia/septicemia, and increased mortality compared to the general population^{88–91}; late UTI may also be associated with increased mortality,⁹² although most tend to mimic UTIs in the immunocompetent host. Most centers provide prophylaxis against early UTI using either trimethoprim-sulfamethoxazole or a quinolone for the first 6 to 12 months after transplant.^{93–95} Use of trimethoprim-sulfamethoxazole is not only inexpensive, but also provides prophylaxis against *Pneumocystis*, toxoplasmosis, listeriosis, and nocardiosis, although quinolones may be better tolerated.⁹³ Most centers use low-dose trimethoprim-sulfamethoxazole daily, but some studies have suggested that higher doses (320 mg/1600 mg) may be more efficacious in the prevention of UTI during the first month after transplant.^{95,96} Whether higher doses may be associated with increased toxicity is unknown.

Treatment of UTI in this population requires that close attention be paid to the susceptibilities of the isolate, because rates of highly resistant gram-negative pathogens appear to be increasing.^{97,98} Most centers use a longer duration of treatment in transplant recipients, typically 14 days.⁸⁸ Candidal UTIs in this population are also problematic because they may lead to the formation of fungal balls and resultant urinary obstruction, so the finding of yeast in a sterile urine specimen should prompt further investigation.

TUBERCULOSIS AND NONTUBERCULOUS MYCOBACTERIA

Although tuberculosis (TB) remains a relatively rare disease after renal transplantation, the complexities of treatment and high associated mortality require vigilance of the provider during both the pretransplant and posttransplant periods. The incidence of TB after renal transplantation in the United States is estimated to be less than 1%, but the mortality rate in these patients approaches 25% to 30%.^{99,100} Most patients develop symptomatic disease within the first year after transplantation.

Evaluation of the transplant recipient should include a detailed history of prior TB, possible exposure to the disease, or travel to endemic areas. Tuberculin skin testing is recommended for all potential recipients, and should be interpreted as positive if greater than 5 mm of induration is detected.¹⁰¹ If no prior prophylaxis has been given, or if the patient's response to the test has recently converted to positive, the patient should be treated as having latent TB infection. Unfortunately many patients with severe renal disease may be anergic, rendering the test unreliable if negative. The recent release of a blood test for interferon-gamma release from patient's sensitized lymphocytes after exposure to purified protein derivative (QuantiFERON test) is promising, but as yet is not indicated for use in immunosuppressed individuals.¹⁰² Chest radiographs may be useful for finding evidence of prior or active disease that would warrant further evaluation, especially if no prior treatment or prophylaxis was given. In patients in whom latent TB infection is suggested, treatment with 300 mg of isoniazid daily for 9 months is recommended after evaluation for underlying liver disease. Ideally, prophylaxis should be completed before transplantation and the

onset of more severe immunosuppression; however, if the donor had risk factors for latent TB infection, the recipient should receive prophylaxis after transplantation to reduce the risk of transmission of disease.¹⁰¹ Liver function tests should be monitored every 2 weeks for the first 6 weeks of therapy, then monthly, looking for elevations of transaminases greater than 4 times normal.

Diagnosis and treatment of active tuberculosis after transplantation is complex; the involvement of an infectious diseases specialist is recommended, as well as involvement of local public health departments. Patients are likely to present in the first year after transplantation and are more likely to present with disseminated disease than immunocompetent patients, although pulmonary disease remains the most common manifestation.^{99,100} Diagnosis may require extensive imaging and multiple specimens from suspicious areas for microbiological culture and susceptibility testing. The use of the QuantiFERON test has not been validated for diagnosis of active infection in immunosuppressed patients.¹⁰³ The standard four-drug regimen typically initiated at diagnosis of TB (isoniazid, rifampin, pyrazinamide, and ethambutol) is problematic in the transplant recipient due to the interaction between rifampin and calcineurin inhibitors that induces the metabolism of these agents. Substitution with rifabutin or a quinolone such as levofloxacin is a common approach to eliminate this problem, although rifabutin is still associated with significant drug interactions.¹⁰¹ Once susceptibility of the isolate to isoniazid and rifampin is confirmed, therapy should continue for a minimum of 6 months, if isoniazid and rifampin or rifabutin are used, and longer with other regimens or more severe disease.

Nontuberculous mycobacterial infections in transplant recipients are rare and not well-studied. Many of these organisms are environmental contaminants and can cause disease as a result of nosocomial transmission or exposure in the community. Again, a high index of suspicion must be maintained, and early involvement of an infectious diseases specialist is helpful, because many of these organisms require special growth conditions in the microbiology laboratory and do not have uniform susceptibilities to antimicrobial agents. More detailed recommendations can be found in recently published guidelines.^{104,105}

HUMAN IMMUNODEFICIENCY VIRUS AND RENAL TRANSPLANTATION

The widespread use of highly active antiretroviral therapy (HAART) has changed the prognosis for patients with human immunodeficiency virus (HIV) infection, allowing these patients to be considered for renal transplantation.¹⁰⁶ Prior to the widespread use of HAART, a retrospective analysis of HIV-positive renal transplant recipients suggested a slightly worse 3-year survival compared to HIV-negative patients during the same 10-year period (83% vs. 88%).¹⁰⁷ More recently, several case series have reported encouraging results after renal transplantation in HIV-positive patients, showing similar graft survival and mortality at 1 year compared to controls from the UNOS database.^{108,109} Unfortunately, graft rejection rates appear to be higher in the HIV-positive groups. Currently a prospective, multicenter trial is underway to study HIV-positive renal and liver transplant recipients to study the

effects of immunosuppressive medications on patient survival and how HIV infection and HAART affect graft survival.

Ideally, HIV-positive patients being considered for transplantation should have CD4⁺ cell counts greater than 200 cells/ μ L and an undetectable viral load for 3 months on stable antiretroviral therapy.¹¹⁰ Comorbid conditions should be assessed, including the presence of other viral infections (i.e., HBV, HCV) that may have accelerated courses in the presence of both HIV and immunosuppression, and history of opportunistic infections that may reactivate post-transplantation. After transplantation, these patients require close monitoring, because the pharmacokinetics and drug interactions of antiretroviral medications and immunosuppressive medications may be complex; notably, there are significant drug interactions between calcineurin inhibitors and antiretroviral agents, including both protease inhibitors and nonnucleoside reverse transcriptase inhibitors.^{108,111} Frequent assessment of serum drug levels of the calcineurin inhibitors is therefore mandatory for patients on protease inhibitor-based HAART. More comprehensive guidelines have been established by the Cooperative Clinical Trials in Adult Transplantation group and include specific recommendations regarding inclusion and exclusion criteria and pharmacological considerations for HAART, immunosuppression, and prophylaxis regimens.¹¹¹

Management of infectious disease complications continues to pose a challenge for physicians treating transplant recipients. As the use of newer, more potent immunosuppressive regimens becomes more common, the risk for opportunistic pathogens and more severe manifestations of both community-acquired and nosocomial pathogens increases. Continued attention to improved preventive, diagnostic, and treatment strategies to minimize the impact of infections on outcomes is required.

Many drugs are eliminated by the kidney and therefore require dose adjustment in patients with renal insufficiency.¹⁻⁴ Other drugs that themselves are not dependent on the kidney for excretion are converted in the liver to active metabolites that accumulate in patients with diminished renal function.^{5,6} Thus, to avoid toxicity doses of many drugs must be diminished in patients with decreased renal function. The precision required depends on the therapeutic index of individual drugs. For example, penicillins and cephalosporin antibiotics have wide margins of safety. Dosing does not require the same precision as with drugs having narrow therapeutic indices, such as aminoglycoside antibiotics or digoxin, in which, in some instances, serum concentrations are measured to assure attainment of therapeutic, yet nontoxic, levels.

Patients treated with hemodialysis, hemofiltration, or peritoneal dialysis present an additional challenge. Drug may be removed by the procedure itself, thereby requiring compensatory dose supplementation, the extent of which is a function of the amount of drug removed.¹ The ability of dialysis to remove drugs is influenced by the binding of the drug to protein, which limits dialyzability, and molecular size, for example. These factors are highly variable among drugs, even those in the same chemical class, rendering a priori predictions impossible. Published data from appropriate patient populations guide therapy, which should be complemented with measurements of serum drug concentrations when assays are available.

This chapter discusses principles of drug dosing as a framework for adjustment in dosing regimens in patients with renal insufficiency. Dosing guidelines for patients with renal dysfunction, including dialysis, are offered in the appendix (Tables A91-1 to A91-3).

It is possible to anticipate some of the effects that renal disease and dialysis will have on drug disposition. Renal insufficiency will cause drugs eliminated by the kidney to accumulate. In general, accumulation sufficient to be of clinical concern occurs if 30% or more of the drug is eliminated in the urine unchanged. A characteristic of renal insufficiency is accumulation of endogenous organic acids in plasma, which compete with acidic xenobiotics for binding to albumin and thereby diminish protein binding. Hypoalbuminemia results in diminished binding of drugs bound to albumin. Thus, changes in protein binding influence the concentration of unbound, pharmacologically active drug in plasma.

All forms of dialysis require passage of the removed substance across a membrane. Certain characteristics of a drug predict its removal by dialysis. Avid binding to circulating proteins prevents dialytic removal. Theoretically, large size also restricts removal, but most xenobiotics are sufficiently small that this is only rarely important. A drug that is widely distributed in tissues, with only a small component of the total body burden circulating in plasma, may readily cross a dialysis membrane. However, the amount removed during dialysis will be clinically unimportant.

Understanding the pharmacokinetic characteristics of a drug is the framework on which the following discussion is based. This allows predictions that can be helpful in clinical situations in which insufficient dosing information is available.

PRINCIPLES OF DOSE ADJUSTMENT

Loading Dose

Use of some drugs entails administration of a loading dose to rapidly attain therapeutic drug concentrations.⁷⁻⁹ This approach is usually employed when an effective drug concentration is needed quickly. Whether to give a loading dose depends on the urgency to achieve a pharmacologic effect compared to the half-life of the drug. If a loading dose is not given, the time needed to reach plateau drug concentrations is 4 times the half-life. If this time is long relative to the clinical need, a loading dose strategy should be employed. The loading dose needed is a function of the *volume of distribution* (V_d) of the drug and its *initial blood concentration* (C_{initial}):

$$\text{Loading dose} = (C_{\text{initial}}) (V_d)$$

For example, if the V_d for a drug such as an aminoglycoside antibiotic is 0.25 L/kg and the desired peak serum concentration is 8 mg/L, the necessary loading dose can be calculated as follows:

$$\text{Loading dose} = (8 \text{ mg/L}) (0.25 \text{ L/kg}) = 2 \text{ mg/kg}$$

It is customary for clinicians to consider a standard loading dose rather than calculating it from V_d and the desired

concentration. This can be hazardous in settings in which the patient's disease may influence V_d and thereby mandate a change in the loading dose. For example, if the V_d of a drug in a patient with renal insufficiency is one-half that in a patient with normal renal function, and the patient with renal disease received a "standard" loading dose, the resulting initial concentration would be twice that expected, with a consequent risk of toxicity. To illustrate this from the previous example, if the "normal" loading dose of 2 mg/kg were administered to a patient whose V_d was 0.125 L/kg (i.e., one-half the usual value), a concentration of 16 mg/L would result:

$$2 \text{ mg/kg} = (C_{\text{initial}}) (0.125 \text{ L/kg})$$

$$C_{\text{initial}} = 2 \text{ mg/kg} \div 0.125 \text{ L/kg} = 16 \text{ mg/L}$$

It should be clear that clinicians need to be alert to changes in the V_d of drugs. Such data are provided in the appendix (see Table A91-1) for patients with renal disorders. The loading dose can be calculated as shown above. Alternatively, if the clinician knows the usual loading dose, the data in Table A91-1 can be used to calculate a modified dose:

$$\text{Usual loading dose/Modified loading dose} = \frac{\text{Normal } V_d/\text{Patient's } V_d}$$

or,

$$\text{Modified loading dose} = \frac{(\text{Patient's } V_d/\text{Normal } V_d) \times \text{Usual loading dose}}$$

The direct proportionality between loading dose and V_d makes such dose adjustments quite easy. A caution is the influence of changes in drug protein binding, which in many drugs is decreased in patients with renal insufficiency,^{10,11} particularly for acidic drugs bound to serum albumin, wherein accumulated endogenous organic acids can displace drug from albumin binding sites.¹²

For highly protein-bound drugs, such as phenytoin, valproate, and warfarin, a decrease in binding to albumin might be expected to cause an increase in the unbound concentration, thereby resulting in increased drug effect. However, the increased free drug is also readily available for metabolism by the liver, such that the unbound concentration is no different from that in patients with normal renal function.^{10,11,13,14} As an example, in a patient with normal renal function, a total serum concentration of phenytoin of 10 mg/L yields 1 mg/L of free drug. In contrast, in a patient with end-stage renal disease, the same dose results in a lower total concentration of 5 mg/L but the same free, pharmacologically active phenytoin concentration (Table 91-1).

The lesson is that for phenytoin (and valproate) the same pharmacologically active unbound serum concentration occurs at a lower total concentration. Clinical laboratories usually measure total drug concentration. Hence, in a patient with renal insufficiency or hypoalbuminemia, the "therapeutic" serum concentration, expressed as total drug, is less than in patients with normal renal function. This may prompt the physician to administer inappropriately larger doses to increase the total drug concentration. The result is a concomitant increase in the unbound concentration to potentially toxic levels. Although there is a similar scenario for warfarin,

Table 91-1 Phenytoin Concentration in Patients with Normal Renal Function and Those with End-stage Renal Disease

Concentration	Bound	+	Free	=	Total	Percentage Bound
Normal renal function	9	+	1	=	10 mg/L	90
ESRD	4	+	1	=	5 mg/L	80

ESRD, end-stage renal disease.

physicians normally monitor this drug's effect using the International Normalized Ratio as opposed to measuring the drug concentration. This spares the need to contemplate the role of protein binding with this agent.

Maintenance Dose

A maintenance dose maintains the desired steady-state drug concentrations,⁷⁻⁹ as determined by the target *average drug concentration*, C_{average} , and the *clearance* (Cl) of the drug from the body:

$$\text{Maintenance dose} = (C_{\text{average}}) (\text{Cl})$$

If a drug is administered as a continuous intravenous infusion, the maintenance dosing rate is the infusion rate of the drug. If a drug is administered as separate, intermittent intravenous doses, the dosing rate is expressed as:

$$\text{Dosing rate} = \text{Individual dose}/\text{Dosing interval}$$

If a drug is administered by mouth, a term to account for incomplete bioavailability must be incorporated, with the *fraction of the dose absorbed* (F). The maintenance dosing rate becomes:

$$\text{Dosing rate} = (F) (\text{Individual dose})/\text{Dosing interval}$$

Hence, depending on the route of administration, any of the following relationships may apply:

$$\text{Infusion rate} = (C_{\text{average}}) (\text{Cl})$$

$$\text{Dose}/\text{Dosing interval} = (C_{\text{average}}) (\text{Cl})$$

$$F \times \text{Dose}/\text{Dosing interval} = (C_{\text{average}}) (\text{Cl})$$

Thus, a change in clearance mandates a proportional change in the rate of drug administration to maintain a constant average drug concentration. The clearance of drugs or their metabolite(s) in patients with renal insufficiency is often diminished; consequently, maintenance doses must be adjusted. Guidelines for doing so are offered in the appendix (see Table A91-3).

Half-life

The *half-life* ($t_{1/2}$) of a drug refers to the time required for the serum concentration to decrease by 50%. The rate of elimination of most drugs (exceptions being phenytoin and salicylate)

is linear and independent of the drug serum concentration. This implies that the $t_{1/2}$ is independent of the serum concentration. Therefore, the time for a drug's concentration to decrease from 100 to 50 units of concentration is the same as for a decrease from 10 to 5 units.

Many clinicians use $t_{1/2}$ synonymously with clearance of a drug. This presumes that an increase in $t_{1/2}$ indicates a proportional decrease in clearance, which thereby requires a compensatory and proportional decrease in the maintenance dose. This misconception can lead to errors in dose adjustment in patients with renal insufficiency because $t_{1/2}$ is a function of both V_d and Cl and does not solely reflect the clearance of a drug:

$$t_{1/2} = 0.693 V_d/Cl$$

A change in $t_{1/2}$ can reflect a change in V_d , a change in Cl , or both. The correct dosing regimen adjustment depends on whether an alteration in V_d or in Cl is responsible for the change in $t_{1/2}$. If $t_{1/2}$ increases solely because of an increase in V_d , the loading dose should be increased, while the maintenance dose should remain unchanged. If it is assumed that the $t_{1/2}$ increased because Cl decreased, a "normal" loading dose and a diminished maintenance dose would be administered. This would result in a loading dose that is too small, which would fail to attain the desired initial concentration, and an inappropriately diminished maintenance dose, which would maintain a lower drug concentration than desired. The result could be lack of efficacy.

A good example of this is the use of digoxin in patients with renal insufficiency. In patients with mild to moderate renal insufficiency, the V_d of digoxin is little changed, whereas Cl may be reduced to about one-half to two-thirds normal.¹⁵ In such patients, the $t_{1/2}$ rises in proportion to the diminished Cl . However, in patients with severe renal insufficiency, the V_d is decreased to one-half to two-thirds normal, and Cl is decreased further to about one-third normal.^{15,16} In this setting, the $t_{1/2}$ is influenced by both parameters. Although the half-life is prolonged in severe renal dysfunction, it is little different from that in the patient with mild to moderate renal insufficiency. If the change in $t_{1/2}$ in the patient with severe renal insufficiency compared to normal subjects was erroneously presumed to reflect only the decrease in digoxin clearance and thereby to affect only the maintenance dose, a serious dosing error would occur. Because no downward adjustment in loading dose would be made, the initial concentration would be higher than desired. The decrease in maintenance dose would be underestimated so that the patient's steady-state serum concentration would be maintained at a higher concentration than desired. The hazards of such an error are obvious.

A realization of the limitations of using $t_{1/2}$ to predict dosing adjustments mandates the need to dissect it into its component parts of V_d and Cl . Of what use, then, is $t_{1/2}$? Knowing $t_{1/2}$ allows one to determine the time necessary for serum drug concentrations to reach a steady state. Steady state is reached after administering the drug for 4 to 5 times the $t_{1/2}$. This delay in attaining plateau drug concentrations can be avoided by giving a loading dose designed to attain the desired drug concentration quickly.

The attainment of steady state applies to a change in dose. For example, if a maintenance dose is doubled, 4 to 5 times the $t_{1/2}$ is required for the serum concentration to reach the new plateau. Similarly, if the maintenance dose is decreased, 4 to

5 times the $t_{1/2}$ must elapse for the new, lower steady-state concentration to be reached. Lastly, if a drug is stopped, 4 to 5 times the $t_{1/2}$ is needed for concentrations to become negligible.

In summary, the half-life should be used to predict the time for a drug to reach steady-state concentrations. It is a hybrid value influenced by both V_d and Cl and provides no direct information about loading or maintenance dose.

Dosing Regimens

Changes in loading dose entail giving a larger or smaller dose depending on whether V_d is increased or decreased. The need to modify a loading dose may be unclear, in which case a decision must be made concerning whether a loading dose strategy is necessary. In such cases it is wise to err on the side of caution and administer a smaller loading dose. If monitoring of clinical endpoints or serum drug concentrations shows the dose to have been too low, a supplementary dose can be given. In contrast, too large a loading dose can lead to iatrogenic drug toxicity.

Several strategies can be employed for adjusting maintenance doses of a drug. The primary objective is to maintain the same average drug concentration in a patient without renal disease. Because the majority of drugs obey linear or first-order elimination kinetics, change in clearance can be compensated for by a proportional change in the dosing rate:

$$\text{Usual maintenance dose/Modified maintenance dose} = \frac{\text{Usual clearance/Patient's clearance}}{\text{Usual clearance/Patient's clearance}}$$

or,

$$\text{Modified maintenance dose} = (\text{Patient's clearance/Usual clearance}) \times \text{Usual maintenance dose}$$

Hence, if the clearance of a drug in a patient with renal insufficiency is one-half the "normal" value, the patient's maintenance dose should be one-half that usually administered. Such dose modifications will maintain a normal average steady-state drug concentration.

If a patient is receiving a drug by continuous intravenous infusion, maintenance dose modification simply requires a modified infusion rate. If the patient is receiving intermittent doses, reduction of the total dose administered can be accomplished in three ways:

1. Decreasing each individual dose and maintaining the same dosing frequency. This is referred to as the *variable dose method*.
2. Maintaining the same individual dose but administering each dose less frequently. This is referred to as the *variable frequency method*.
3. Modifying both individual doses and the frequency of their administration, which is a combination method.

All three methods attain the same average drug concentration. For example, if 2400 mg of a drug is administered to a patient with normal renal function as 600 mg every 6 hours, and one wished to administer one half as much total drug to a patient with renal insufficiency, options include the following:

- 300 mg every 6 hr (variable dose)
- 600 mg every 12 hr (variable frequency)
- 400 mg every 8 hr (combination)

The total drug administered with each of these regimens is the same (1200 mg). It is half that administered to a patient with normal renal function. These regimens differ in the profile of serum drug concentrations. Regimens with closer dosing frequencies and smaller individual doses result in less difference between peak and trough drug concentrations. Determining which option is best is a function of the drug and the disease being treated. For example, having low serum concentrations for a considerable period of time with an antibiotic with a long postantibiotic effect may not be worrisome. In contrast, for a drug that must be maintained within a narrow concentration range to maximize efficacy (e.g., an antiarrhythmic or anticonvulsant), a regimen would be needed that minimizes fluctuations in serum concentrations.

No general rule can be applied to the maximum length of a dosing interval; 24 hours seems a reasonable rule of thumb and would likely be helpful for patient adherence. If a patient is not responding to a drug, the clinician should anticipate a possible inappropriate dosing regimen. Signs of toxicity shortly after administration of an individual dose may indicate a need to give the drug more frequently in smaller doses to optimize the dosing regimen.

Dialysis

Patients with endstage renal disease treated with dialysis (including hemofiltration) have an additional mechanism by which drugs can be eliminated.^{17–20} If substantial elimination by these routes occurs, supplemental dosing must be given. This is most easily accomplished by administering a supplemental dose of drug at the completion of dialysis. The dose given is the amount of drug removed during the procedure.

With continuous ambulatory peritoneal dialysis (CAPD), drug removal is continuous. The patient's total clearance of a drug is the sum of the clearance by residual renal function and clearance via CAPD. The dosing regimen (individual dose, dosing interval, or both) should be adjusted upward in proportion to the added increment in clearance from CAPD.

Where information on dialytic removal of the agent is lacking, insight into the dialyzability of a drug may be appreciated from its pharmacokinetic parameters. If a drug such as vancomycin or amphotericin is too large to pass across the dialysis membrane (including the peritoneum), it will not be removed by dialysis. If a drug is bound in excess of 90% to plasma proteins, it is unlikely that dialysis will contribute appreciably to its elimination. Drugs that are water soluble are more readily dialyzed. A clue that a drug is water soluble is that these drugs are usually eliminated predominantly by the kidney as unchanged drug. Lastly, drugs with large volumes of distribution have minimal dialyzability because, of the total amount of drug in the body, only a small portion resides in the vascular space where it can be removed. Once dialysis ends, the large amount of drug in the tissues can refill the vascular compartment. The dialysis procedure therefore removes only an insignificant quantity of the total amount of drug in the body.

Specific examples can be used to illustrate these principles. Aminoglycoside antibiotics are water soluble, eliminated primarily by the kidney (100% of the dose is normally excreted unchanged in the urine), have negligible protein binding, have a small volume of distribution (0.25 L/kg), and are removed by dialysis procedures sufficiently to require dose supplementation. In contrast, cefonicid also has a small V_d (0.10 L/kg), but is

highly bound to serum proteins (98%) and therefore is not removed by hemodialysis or CAPD. Cefadroxil, on the other hand, despite having a somewhat larger V_d than cefonicid (0.30 L/kg) is only 16% bound to serum proteins. Dialytic removal is sufficient with this cephalosporin to require supplemental dosing. Last, drugs such as phenothiazines and tricyclic antidepressants that have large V_d values (>10 L/kg) are not eliminated by dialysis even if they are negligibly bound to serum proteins.

Table A91-2 in the appendix lists the amount of a drug removed by dialysis (as a percentage of a "normal" dose in a patient with normal renal function). This value allows calculation of the increment in dosing that must be given to compensate for removal by dialysis. The table does not include removal of drugs by hemoperfusion, hemofiltration, or hemodiafiltration. Hemoperfusion is applicable to toxicologic settings and is discussed in Chapter 92.

Hemofiltration removes unbound drug in the serum. The amount removed (and thereby the dose increment needed) can be calculated as:

$$\text{Amount removed (mg)} = \text{Serum concentration (mg/L)} \times \\ \text{Unbound fraction} \times \text{Ultrafiltration rate (L/min)} \times \\ \text{Time of procedure (min)}$$

The ultrafiltration rate and the duration of hemofiltration are known. The unbound fraction can be found in the published literature.¹ Serum concentration can be directly measured for many drugs. Alternatively, the average concentration at steady state can be reasonably estimated as:

$$\text{Average concentration (mg/L)} = \\ \text{Dosing rate (mg/min)} / \text{Clearance (mL/min)}$$

Active Metabolites

Although many drugs are not themselves eliminated by renal routes, they are converted by the liver to active metabolites that depend on the kidney for excretion. Hence, in patients with renal disease, the metabolite can accumulate, causing its own pharmacologic effect(s).^{5,6} For example, meperidine is converted to normeperidine, which unlike the parent drug is not an analgesic but rather a central nervous system stimulant. The metabolite is excreted by the kidney and accumulates in patients with renal insufficiency. Even in elderly patients with mild decrements in renal function, this metabolite can reach sufficient concentrations to cause seizures. Its use in patients with renal compromise requires lower doses of meperidine (which may limit its efficacy). A better alternative is to use another analgesic such as morphine for which the parent drug and metabolite(s) do not depend on the kidney for elimination. For many drugs, it is not known whether there are active metabolites or if these accumulate in renal disease. Unanticipated responses to drugs should raise the consideration of active metabolites and may prompt discontinuation of a drug in the hope that an adverse response dissipates.

DOSING RECOMMENDATIONS

When renal insufficiency affects the volume of distribution of a drug (see Table A91-3 in the appendix), the loading dose must be modified. More commonly, one needs to compensate

for decreased clearance of drugs by adjusting the maintenance dose. Principles for doing so have been discussed previously, the most important of which is the proportionality that exists between clearance, dose, and steady-state serum drug concentration. Hence, a clearance that is one-half that of normal can be compensated for by decreasing the dose to one-half normal. Different strategies for dose adjustment have also been discussed. The clinician can change each individual dose, the interval between them, or both. Which strategy to use depends on the drug and the individual patient, but a reasonable starting point for most drugs is to first lengthen the interval until a maximum of 24 hours is reached, after which further modification of the individual dose is appropriate.

Table A91-3 in the appendix offers recommendations for modification of the maintenance dose in patients with various degrees of renal insufficiency. These guidelines should serve only as starting points of therapy. Subsequent dosing requires tailoring the regimen to each individual patient, which in turn must be based on clinical endpoints or measurement of serum concentrations of drugs.

"Decrease" indicates a need to decrease the dose in patients with renal insufficiency, but data are not sufficient to offer quantitative guidelines.

Dialysis and Hemoperfusion in the Treatment of Poisoning and Drug Overdose

Nikolas B. Harbord, Zachary Z. Brener, Donald A. Feinfeld, and James F. Winchester

CHAPTER CONTENTS

INITIAL APPROACH 1073

ENTERIC DECONTAMINATION: GASTRIC LAVAGE, EMETICS, WHOLE BOWEL IRRIGATION, AND ORAL SORBENTS/CATHARTICS 1074

ENHANCED ELIMINATION: ALTERING URINE PH 1074

INDICATIONS FOR EXTRACORPOREAL TECHNIQUES IN POISONING 1075

DIALYSIS TECHNIQUES FOR REMOVING POISONS 1075
Principles of Dialysis 1075
Factors Governing Drug Removal with Dialysis 1075

Sorbent Hemoperfusion and Complications of Hemoperfusion 1076

Plasma Exchange and Exchange Blood Transfusion 1076

Hemoperfusion and Hemodialysis with Chelation 1076

IMMUNOPHARMACOLOGY 1079

In 2004, the American Association of Poison Control Centers (AAPCC) reported approximately 2.43 million human poison exposures.¹ Although incidence far exceeds mortality, fatal ingestions occurred in 1183 patients.

The nephrologist is often consulted in poisoning cases for assistance in drug removal. The 2004 AAPCC data show that 8654 patients were treated with urine alkalinization, 1726 received hemodialysis, and 62 received either hemoperfusion or another extracorporeal intervention.

This chapter outlines the approach to the poisoned subject. It covers initial management, enteric decontamination, enhanced drug elimination, and principles and application of dialysis and related procedures. Emphasis is given to clinical criteria for use of dialysis and extracorporeal techniques, decision making among available modalities, and recent advances.

INITIAL APPROACH

The algorithm in Figure 92-1 provides a reasonable approach to the treatment of all poisoned patients, in combination with appropriate triage and disposition. Initial assessment should include evaluation of the airway and breathing status, with administration of supplemental oxygen, intubation, and mechanical ventilation as necessary. Impaired circulatory status requires hemodynamic support with intravenous fluids or pressor agents. Core temperature should be frequently assessed, because autonomic dysfunction is possible. Hyperthermia or hypothermia should be corrected by passive external cooling or warming or peritoneal lavage. Hypoglycemia should also be assessed and corrected if present.

Although all patients require a complete neurological examination, comatose patients and those with seizures need immediate intervention. With coma or altered consciousness, dextrose (25 g) should be administered empirically in combination with thiamine (100 mg) given before the dextrose in alcoholics and malnourished patients.^{2,3} Empiric administration of naloxone should be reserved for patients with signs of opiate intoxication, such as respiratory depression and pupillary miosis. Empirical flumazenil can precipitate seizure. It should be used only for reversal of conscious sedation and not for presumed benzodiazepine overdose.² Treatment of seizures after poisoning is similar to treatment of seizures from other causes. If intravenous access is difficult, intranasal midazolam or rectal administration of diazepam is an effective treatment for acute seizures, particularly in children.⁴ Seizures and coma after acute overdose of isoniazid are typically unresponsive to conventional antiepileptics and should be treated with pyridoxine (vitamin B₆) in doses equivalent to ingested isoniazid.^{5,6} Physostigmine should be used to treat anticholinergic poisonings even without seizures. It may be safer and more effective than benzodiazepines.⁷

Subsequent evaluation should include an investigation of the offending or suspected drug or chemical. This should include the route, estimated dose, quantity, and timing of ingestion. Multiple drugs should be considered, especially with intentional or suicidal ingestions. Further information might be obtained from physician and pharmacy records, family members, paramedics, and medication containers. An accurate and thorough medical history with regard to chronic illness or organ dysfunction, medications, and allergies should be attempted. A complete physical examination with attention to pupillary size, breath odors, skin changes, unusual vital signs, and respiratory pattern should be performed.

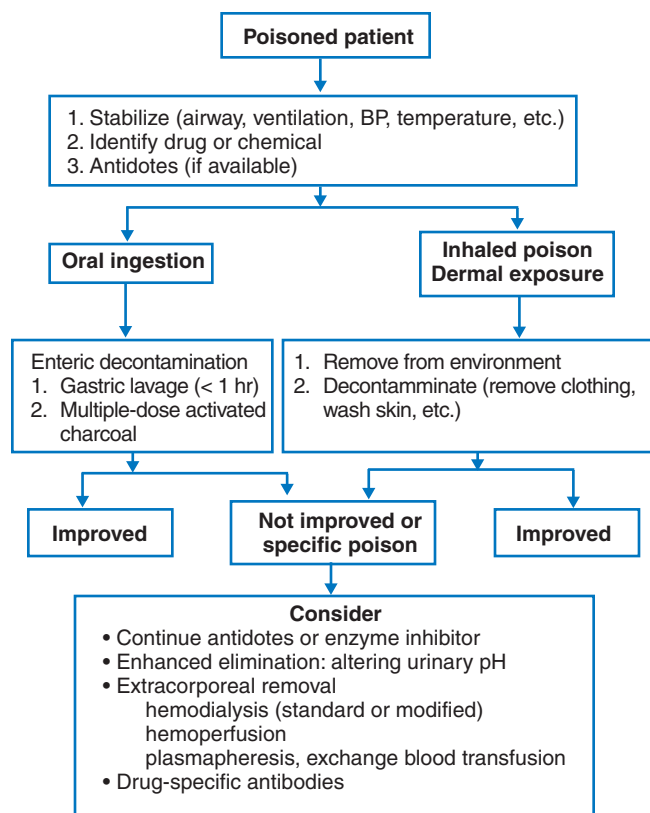

Figure 92-1 Simplified management of the poisoned patient.

Finally, laboratory studies should include toxicology panels with serial blood levels of identified ingestions. Metabolic panels with electrolytes and an arterial blood gas should be obtained to determine acid-base status and identify an increased anion gap or electrolyte disturbance. Calculation of the serum osmolal gap and examination of urine for crystals may further aid in the identification and treatment of ingestion. Additional laboratory tests should include calcium, magnesium, liver function tests, ketones, lactate level and, if applicable, a urine pregnancy test.

ENTERIC DECONTAMINATION: GASTRIC LAVAGE, EMETICS, WHOLE BOWEL IRRIGATION, AND ORAL SORBENTS/CATHARTICS

Use of lavage, induction of emesis, bowel irrigation, and oral sorbents should be preceded in unconscious patients by airway intubation with a cuffed tube to prevent aspiration of gastric contents. Enteric decontamination is contraindicated in petroleum distillate ingestions and caustic ingestions because of the risk of hydrocarbon aspiration pneumonitis and gastrointestinal rupture, respectively. Gastric lavage is recommended only up to 1 hour after ingestion. Lavage provides limited total drug removal and may increase the risk of aspiration or hasten the passage of drug into the small bowel.^{8–10} Syrup of ipecac is not recommended for routine use for induced emesis of ingestions.¹¹ Gastric lavage and ipecac may, however, be useful for drugs that delay gastric emptying, such as tricyclic antidepressants and large quantities of aspirin or barbiturates.¹² Whole-bowel irrigation with large volumes of polyethylene glycol is an effective method for clearing the bowel of poisons, particularly if the in-

gestion is an enteric-coated drug (e.g., aspirin), a slow-release preparation (e.g., lithium, theophylline, verapamil), iron tablets, foreign bodies, or ingested packets of illicit drugs.^{13–15} Multiple-dose activated charcoal is the most effective method of enteric decontamination. It is recommended for a wide variety of ingestions.¹⁶ Oral charcoal (50 g q2–6h) reduces oral bioavailability by preventing drug absorption and also significantly shortens drug half-life through interruption of the enterohepatic circulation of some agents (e.g., barbiturates, digitalis preparations, and theophylline). The cation exchange resin kayexalate is an oral sorbent that may be effective in the prevention of gastrointestinal absorption of ingested lithium.¹⁷ The addition of the cathartic sorbitol to oral sorbents prevents constipation and increases passage of the charcoal–poison complex.

ENHANCED ELIMINATION: ALTERING URINE pH

Elimination is the irreversible removal of a drug from the body. It refers principally to excretion and biotransformation. In patients with renal function, excretion involves drug concentration movement in (and out of) the urine through three processes: glomerular filtration, tubular secretion, and tubular reabsorption. With an understanding of drug properties, clinicians can increase renal excretion of drugs through modulation of urine pH.

Drugs that are weak acids or bases exist in solution as mixtures of ionized and nonionized species. The dissociation of a weak acid or base is determined by its *dissociation constant* (pKa). At a pKa equal to the pH, the concentrations of nonionized drug and ionized drug are equivalent. In the renal tubule, the nonionized molecules are generally lipid soluble, readily diffuse across cell membranes, and are reabsorbed. In contrast, the ionized form is reflected from cell membranes and excreted. Because the dissociation constant is a logarithmic function, small alterations of the pH of tubular fluid increase ionization greatly and have a disproportionately larger effect on drug clearance. In short, excretion of weak acid drugs with pKa in the range of 3.0 to 7.5 can be increased with urinary alkalinization. Conversely, excretion of weak bases with pKa 7.5 to 10.5 can be increased with urinary acidification. Drugs that will respond to urine pH manipulation are renally excreted, with pKa in the weakly acidic and basic range, confined to the extracellular fluid compartment, and minimally protein bound. For example, phenobarbital (pKa 7.2) and thiopental (pKa 7.6) have similar dissociation constants, but, due to differences in distribution, 25% to 50% of phenobarbital is excreted unmetabolized in the urine compared with less than 1% of thiopental. In this case, alkalinization of the urine will clearly not increase the excretion of the weak acid thiopental.

The administration of alkali to raise urine pH above 7.5 increases the urinary excretion of chlorpropamide, 2,4-dichlorophenoxyacetic acid, diflunisal, fluoride, mecoprop, methotrexate, phenobarbital, and salicylate.¹⁸ Urinary alkalinization is recommended for salicylate poisoning when the plasma level exceeds 50 mg/dL, even when alkalemia is initially present. In salicylate poisoning, estimating the severity of poisoning with the assistance of serum levels and a nomogram will help in the decision to use alkalinization. However, clinical deterioration, pulmonary edema, development of renal failure or severe acid-base disorders, and

salicylate levels greater than 100 mg/dL should prompt a change to hemodialysis to remove salicylate and correct acid-base status. Urinary alkalization remains first-line therapy for treatment of salicylate intoxication when hemodialysis is not appropriate.¹⁸ Acetazolamide is not recommended as the method of urinary alkalization due to competitive inhibition of protein binding and risk of increase in salicylate levels.¹⁹ Urinary alkalization for drug removal in phenobarbital poisonings is not likely to be as effective as multiple-dose activated charcoal.^{18,20} Intravenous bicarbonate solutions should be administered as a bolus followed by a constant infusion. Urine pH should be maintained within the range of 7.5 to 8.5. Urinary modulation is the objective of treatment.

“Forced” diuresis or alkaline diuresis with large quantities of intravenous fluids is recommended for chlorophenoxy herbicides, 2,4-dichlorophenoxyacetic acid, and mecoprop.¹⁸ Furthermore, forced diuresis (achieving urine outputs of 300–500 mL/hr) may be complicated by the development of hyponatremia and water intoxication, pulmonary edema, and cerebral edema. Salicylate excretion has been found to be similar after urinary alkalization without forced diuresis.²¹ Although alkalization is well tolerated, hypokalemia after potassium shifts is frequent. Severe alkalemia with tetany and hypocalcemia may occur.¹⁸ Urine pH, serum pH, and electrolytes should be measured frequently in the initial period of treatment.

Urinary acidification, to pH less than 5.5, has been attempted to increase the excretion of weakly basic drugs such as amphetamines, fenfluramine, phencyclidine (PCP), and quinine. However, acidification is not recommended in the management of poisoning with these agents because most patients recover with supportive care.²² Furthermore, lowering urine pH increases PCP excretion only modestly and is only of benefit for deeply comatose patients.²² Acidification has been performed using arginine- or lysine-hydrochloride, ammonium chloride, or ascorbic acid. There is a risk of acidemia and hyperkalemia. Serum potassium should be monitored closely and urine pH measured at least hourly. Bromide intoxication, often with high serum chloride levels and negative anion gap at presentation, may follow ingestion of dextromethorphan bromide, bromide salts in sleeping draughts, and colas.^{23–25} Chloride loading with ammonium chloride increases the elimination of bromide, which can be increased further with the administration of mannitol, loop diuretics, or dialysis.²⁵

INDICATIONS FOR EXTRACORPOREAL TECHNIQUES IN POISONING

Extracorporeal techniques deserve special consideration for removal of agents with delayed toxicity, such as mushrooms, paraquat, methanol, and ethylene glycol; when endogenous clearance is impaired (e.g., cardiac, renal, or hepatic failure); or when the agent can be removed at a rate exceeding endogenous elimination.

The decision to use dialysis modalities for drug removal is made on clinical criteria. Symptoms to consider include abnormalities in vital signs suggesting hemodynamic instability, deterioration despite adequate supportive treatment, mental status alteration (including confusion, lethargy, stupor, and

coma), pneumonia due to coma, and midbrain dysfunction (i.e., hypothermia, hypotension, and bradycardia). Dialysis may not only remove the offending agent, but also improve electrolyte abnormalities and correct concomitant acid-base disorders.

Hypotensive patients requiring hemodynamic support with an indication for extracorporeal drug removal should receive an infusion of pressors distal to the dialyzer or sorbent cartridge. Careful monitoring of circulatory status is essential as dialysis may enhance the clearance of the pressor agents.

DIALYSIS TECHNIQUES FOR REMOVING POISONS

Many substances can be removed from the body by hemodialysis, peritoneal dialysis, hemofiltration, hemoperfusion, and combined modalities.²⁶ The underlying principles of dialysis for drug removal, and the potential problems associated with it, are reviewed first.

Principles of Dialysis

Hemodialysis is the most commonly used method of extracorporeal drug removal for the treatment of poisoning.¹ In conventional practice, the apparatus consists of a blood circuit (arteriovenous or venovenous), electronic and mechanical devices (blood pump, pressure monitors and alarms, and transmembrane pressure controller), a dialyzer cartridge containing the synthetic (or semisynthetic) membrane, and a countercurrent dialysate circuit of purified water and added electrolytes. In dialysis, solutes and poisons are removed from blood by diffusion across the porous membrane and into the dialysate.

Hemofiltration is a related procedure that does not employ dialysate but removes drugs and poisons by convective clearance. Blood within the filtration cartridge is subject to pressure across the porous membrane, creating an ultrafiltrate of plasma and solutes. Hemofiltration requires both anticoagulation of the blood circuit and continuous replacement of fluid and electrolytes lost into the ultrafiltrate. Ultrafiltration dialysis provides efficient clearance of large-molecular-weight intoxicants. It requires lower rates of blood and dialysate flow but a prolonged or continuous treatment protocol.

Hemodiafiltration combines ultrafiltration across a high-flux (large-pore) dialysis membrane with countercurrent flow of dialysate for combined diffusive and convective clearance.

Factors Governing Drug Removal with Dialysis

Drug characteristics that increase removal by dialysis are small molecular size (molecular weight < 500 Da), high water solubility, low protein binding, small volume of distribution (<1 L/kg), and rapid equilibration of plasma and tissue to maintain a concentration gradient.^{27,28} Characteristics that limit dialysis clearance include high lipid-solubility, tight tissue binding, large volume of distribution, and slow plasma equilibration with other body compartments. For example, amitriptyline is tightly bound to albumin and muscle protein, resulting in a large apparent volume of distribution (8.3 L/kg of body weight). Consequently, it is poorly dialyzable. In

contrast, lithium distributes in whole body water and is not protein bound. Consequently, it is eminently dialyzable. Although protein binding is an important factor, some drugs, such as salicylates, are reversibly protein bound and are highly dialyzable. Dialysis factors that determine drug removal include access type, blood and dialysate flow rates, and dialyzer properties (i.e., material, surface area, and pore size). Low blood flow may prevent hemodynamic instability but necessitates longer or continuous treatments for adequate clearance. Although higher flow rates increase diffusive clearance, this plateaus above a blood flow rate of 200 to 300 mL/min and a dialysate flow rate above 1.5 times that of blood. For drugs of high molecular weight, removal can be increased by increasing the dialyzer surface area, pore size, and length of the treatment.

As the molecular weight of a drug increases, its removal becomes less dependent on diffusion and more on *convection* (the creation of an ultrafiltrate).²⁶ Therefore, the efficient clearance of large-molecular-weight intoxicants is best accomplished with hemofiltration and hemodiafiltration. Depending on the pore size of the dialyzer, these modalities can remove drugs with molecular weight up to 50,000 Da. The degree of protein binding also limits drug clearance with ultrafiltration. The *sieving coefficient* (SC) is a measure of the ability of a molecule to pass convectively across a membrane. The drug clearance is the product of the sieving coefficient and the ultrafiltration rate. For molecules that pass completely (an SC of 1), the clearance is equal to the ultrafiltration rate. Increasing the ultrafiltration rate will thus increase clearance of any intoxicant with an SC greater than 0.

The complications of extracorporeal elimination include hypotension, blood loss, metabolic disequilibrium, catheter problems such as hematomas, and mechanical problems such as air embolism. Dialysis is most frequently employed to remove alcohols, lithium, and salicylate. Prolonged (or repeat) dialysis may be required to remove lithium, ethchlorvynol, glutethimide, and midazolam to avoid rebounds in drug concentration and relapse of intoxication. Box 92-1 lists drugs and chemicals that are removed by dialysis.

Sorbent Hemoperfusion and Complications of Hemoperfusion

Although first introduced in the 1940s²⁹ and adopted for clinical use in the 1970s and 1980s,^{30–32} hemoperfusion is used infrequently to treat acute intoxications.¹ The apparatus consists of a blood circuit identical to that of hemodialysis, including blood pumps and pressure monitors, but with a cartridge containing a large surface area column of charcoal or resin. The column is primed with saline solution. Anticoagulated blood is pumped through the cartridge, where drugs with molecular weight between 100 and 40,000 Da are removed by adsorption. Table 92-1 lists several available hemoperfusion devices.

Available columns include activated charcoal and resin columns, and antibody- or antigen-coated columns for specific states (e.g., lupus erythematosus,³³ cytotoxic antibody removal before renal transplantation,³⁴ or endotoxin binding³⁵). Activated charcoal has greater affinity for water-soluble molecules, whereas resins (e.g., XAD-4) have greater affinity for lipid-soluble molecules (e.g., glutethimide and methaqualone).³⁶ The sorbent column may become saturated during use, leading

to a progressive decline in extraction ratios. The use of short, intermittent treatments provides several advantages: less clinical “rebound” effect as the drug redistributes from tissues into plasma, reduction in hematologic side effects, and improved drug clearance.

Drug clearance with hemoperfusion exceeds that seen with dialysis for lipid-soluble drugs, cardiac glycosides, barbiturates, and other types of hypnotics, sedatives, and tranquilizers. For example, the extraction ratio of theophylline is 99%, as compared to 50% with hemodialysis. If there is near-equivalent clearance, dialysis is preferred because it is less expensive and can address any superimposed metabolic disorder (e.g., those that complicate salicylate poisoning).³⁷ Box 92-2 lists drugs that have been reported to be removed by various types of hemoperfusion.

The specific complications of hemoperfusion include thrombocytopenia, leukopenia, hypocalcemia, and hypoglycemia. Transient platelet depletion (average loss 30%) occurs with both coated and uncoated charcoal and resin sorbent columns. More severe thrombocytopenia, flushing, and dyspnea were reported with the original resin columns, but changes to preparatory methods and coatings have made resins more biocompatible.³⁸ A transient reduction in body temperature of several degrees can be expected. However, hypotension is less likely with hemoperfusion than with dialysis modalities.

Plasma Exchange and Exchange Blood Transfusion

Plasma exchange and exchange blood transfusion are used infrequently in the treatment of poisoning³⁹ but can remove highly protein-bound drugs. With a 3- to 4-L plasma exchange, the maximal quantity of drug removed is the plasma concentration multiplied by the volume of plasma removed. Attempts to use plasma exchange to treat chromic acid and chromate poisoning have not been fully successful,⁴⁰ whereas treatment of acute cyclosporine⁴¹ and cisplatin⁴² intoxications have been more successful. Exchange blood transfusion is employed with hemolysis when methemoglobinemia complicates the poisoning (e.g., sodium chlorate poisoning).

Hemoperfusion and Hemodialysis with Chelation

Intoxication with aluminum in dialysis patients can be treated with desferoxamine (DFO) chelation combined with hemodialysis or hemoperfusion to remove the DFO–aluminum complex. Dialysis with high-flux membranes and charcoal hemoperfusion are superior to cuprophane membranes in removing the DFO–aluminum complexes.⁴³ Recently, in an aluminum-intoxicated patient, we demonstrated higher clearances with a 1.8 m² high-flux dialyzer than with a 300-g charcoal sorbent column. Steady clearance was observed throughout a 4-hour treatment with the dialyzer; the sorbent saturated by 2 hours.⁴⁴ Clinical improvement of osteomalacia, encephalopathy, and anemia have also been reported in aluminum-intoxicated dialysis patients treated with DFO chelation combined with extracorporeal elimination.⁴⁵

Desferoxamine chelation and hemoperfusion or hemodialysis also effectively clears iron from acutely intoxicated and overloaded patients.⁴⁶ Heavy metals and their salts are not removed efficiently by dialysis or hemoperfusion alone. During

hemodialysis, metal removal may be enhanced with certain antioxidants (*N*-acetylcysteine, cysteine, zinc, or methionine) when used in conjunction with chelating agents.⁴⁷ In contrast, the modest removal of mercury and thallium by hemoperfusion can be enhanced with high-dose vitamin C and intravenous glutathione.^{48,49}

IMMUNOPHARMACOLOGY

Immunopharmacologic treatment of poisonings is limited to digoxin toxicity,⁵⁰ scorpion sting,⁵¹ and snakebite.⁵² Fab (fragments of antibodies to drugs or venom) fragment preparations for treating acute colchicine and tricyclic antidepressant poisonings have been developed but are not available commercially.⁵³ When injected, Fabs combine specifically with their antigenic targets. Digoxin Fabs are effective in the treatment of toad venom poisoning⁵⁴ and after ingestion of yellow oleander, which is a frequent source of natural cardiac glycoside poisoning in South Asia.⁵⁵

When given in potentially fatal cases of cardiac glycoside poisoning, digoxin Fabs can improve outcomes.⁵⁶ Digoxin Fabs should not be dosed differently in patients with renal impairment,⁵⁷ although renal failure delays clearance of both Fab and total digoxin.⁵⁸ Digoxin poisoning can relapse in patients with renal failure 24 to 48 hours after receiving Fab antibodies. This may relate to dissociation of Fab from the glycoside (C. Ronco, personal communication). The risk of rebound toxicity necessitates prolonged monitoring in patients with renal failure. Although immobilized antibody on hemoperfusion devices is logical,⁵⁹ successful treatment of digoxin toxicity with hemoperfusion and hemofiltration has not been well substantiated. Newer resin hemoperfusion devices (BetaSorb) have been shown to remove digoxin *in vitro*.⁶⁰

Computers have a mystique that either attracts or repels prospective users. Regardless, they have become a necessity for the health profession. This chapter will deal with the practical aspects of applying the Internet to problems clinicians commonly encounter.

The history of computing and the Internet, though beyond the scope of this chapter, is fascinating.¹⁻³ What started as a tabulating machine to enable a burgeoning nation to compute the 1890 census grew into a mammoth device that provided a military advantage during World War II. After the invention of the transistor and solid-state circuitry, the computer shrank in size and cost, resulting in the digital transformation that erupted in the last part of the 20th century. Modern users carry computers in their pocket that have the computing power of the most sophisticated machines of 50 years ago.

BASICS

It is impossible to understand the Internet without a brief introduction to computer basics. One can easily become confused by the terminology and jargon used in this industry, and getting started may be difficult because of the learning curve required to master computer skills. Keeping in mind that the software of today is engineered to create ease of use and that skills gained are cumulative may alleviate the reader's trepidation.

The general principle of computing is the same regardless of use and can be divided in terms of hardware, software, or

location. With respect to *hardware* (machinery), there must always be input devices (i.e., the keyboard and mouse), a processor with storage devices such as the server or workstation, and output devices, such as the monitor or printer. The *software* is divided into the operating system, a specific application, and data management. Regarding *location*, processing may be done by a stand-alone machine, connected within an office to a network, or extended off-site via the Internet. Details of how each of these components work are discussed elsewhere.^{4,5}

The Internet is a worldwide network of computers communicating with each other through standard protocols. It became popular in 1990 when scientists at CERN, the European Organization for Nuclear Research, conceptualized and developed the World Wide Web. Several books are available to give the reader an in-depth view of how the Internet developed and information about the technical side of its management.⁶

INTEGRATING THE INTERNET WITH THE WORD PROCESSOR

Word processing replaced the typewriter; the only remnant left is the QWERTY keyboard developed in the 1860s.⁷ Word processing programs also feature a toolbar menu, enabling users to change and adapt styles, layouts, and font size easily. They also allow the nephrologist to generate manuscripts in the format required by the publisher, saving time and costs.

Specifically, users can add pictures, charts, tables, or diagrams into text by using the Insert dropdown menu.

Microsoft Word integrates with EndNote and Reference Manager, applications that allow users to create a library of bibliographic data downloaded from the Internet sources such as the National Library of Medicine's (NLM) PubMed. The author simply drags a selected reference from the End-Note or Reference Manager library, which consists of references the user has entered into the program, onto the document. It is automatically formatted in the selected style required by the publisher.⁸ Chickenfoot, a Mozilla Firefox Browser extension, enables users to automate web browsing functions on their personal computers. A script to automate EndNote use with PubMed can be found at <http://szf.com>.⁹

SPREADSHEETS: FROM LIST MANAGEMENT TO FORECASTING

Soon after the advent of personal computing in the late 1970s, software emerged that could modify data stored in the cells of computer-generated tables. This advance is known as the *spreadsheet*. Today, Microsoft Excel, the most heavily used spreadsheet application, enables users to add values to a cell, specify mathematical arguments for each value, and relate the results of the manipulation to any other cell or to an entire row or column of cells. Consequently, large bodies of data can be summed or averaged, and projections and regression analyses can be modified within milliseconds. With very little learning time, complex statistical manipulations of data can be performed by physicians as well as researchers. Changing one value in the spreadsheet will change all values that depend on it, giving users the power to design prediction and simulation templates. For instance, a practice that projects a 20% increase in patient services per year can simulate future requirements for employees, supplies, office space, and other expenses. Likewise, data transferred between large databases can be manipulated, reformatted, and shared with other applications.¹⁰

Useful accounting tools are also available; in Microsoft Excel, the *net present value* (NPV) formula enables users to predict whether it is more advantageous to place capital in an interest-bearing account than to invest it in a new enterprise; this can be used for clinical purposes. Take, for example, a nephrology practice that is trying to determine whether it will be economical to purchase a new electronic health record system. The system being investigated will allow the group to examine additional patients, eliminate dictation services and, when the practice becomes paperless, eliminate the chart room. They also will be able to reduce the time staff spends filing reports, laboratory reports, and imaging studies. The group carefully calculates how much they will reduce expenses and what revenue and additional services can be incorporated. But the application has fixed costs: purchasing the basic software application, the required computers and server, and the operating system licensing fee. In addition, there also is a hefty monthly service charge. With a spreadsheet containing all expenses and projected revenue, the practice can use the NPV formula, taking into account the current prime interest rate for investments, to ascertain if it would be more feasible just to place the money in the bank or to purchase the new electronic health record. A positive NPV means that the profits from capitalizing a system are greater

than placing funds in an interest-bearing account, giving the practice solid data on which to base their decision.^{9,11}

Patient List Management

By placing dates into spreadsheet columns and patient names in rows, a nephrologist can track which of his or her list of dialysis patients has been visited. A PDA (*personal digital assistant*) spreadsheet can be synchronized over the Internet to the main computer used by the billing and coding department to generate bills.

The spreadsheet can also keep track of laboratory information. The physician can refer to the spreadsheet during future visits to seek trends in patient care, as in this example: A patient with chronic kidney disease (CKD) is prescribed a 0.6 g/kg protein-restricted diet. Every 3 months the physician measures the 24-hour urine nitrogen, tracks the urine nitrogen, and uses it to calculate the patient's protein intake. The urine protein-to-creatinine ratio is also entered in the spreadsheet so the physician can determine if the patient is following the dietary restriction and if there are changes in proteinuria.

In clinics with large numbers of patients, this activity would be impractical, and other physicians would want to share this information. In addition, the visit needs to be tied to billing. In such clinics, the database, a large repository of structured information, should be useful for patient management.

CREATING PRESENTATIONS

Although most nephrologists use Microsoft PowerPoint for creating slide presentations, a few "tricks" can make any user appear professional. For example, a photograph of a saddle-nose deformity can be downloaded from the web to a desktop computer. This image is taken from the screen by pressing the "alt" and "PrtSc" buttons simultaneously, allowing the photograph to be immediately pasted into Microsoft PowerPoint. The "crop" tool on the "picture" toolbar can then be used to tailor-fit the photograph perfectly into a slide.^{12,13} In addition, highly complex tables created in Microsoft Excel can be converted to charts or graphs and imported into PowerPoint. Mastering a few simple keystrokes can allow one to create complex diagrams and figures because the PowerPoint program uses a technology that enables the embedding of practically any kind of binary data. Consequently, movies, charts, and photographs can be portrayed with equal ease.¹¹

THE OFFICE SYSTEM

The use of the computer as a practice management tool and electronic health record is gaining in popularity, but still only one in four physicians uses computers in this manner.¹⁴ Although computer systems are expensive and require sophisticated programming and upkeep, they can be an invaluable tool to increase the quality of health care delivered.¹⁵ Without computers, 30 minutes of care requires on average 1 hour of paperwork.¹⁶ Multiple benefits of using a computer include a reduction in redundant data entry; once entered, data is permanently available for future use.¹⁷ Next, a well-designed system can provide checkpoints for patient safety. An example is the medication list: Should two agents have the potential to interact, the

physician can be warned to make necessary changes. If a computer is at the point of service, whether a hospital room or a dialysis station, the physician will have instant access to data, and patient entries can be made on site. This reduces reliance on faulty physician memory. Once entered, other physicians and health personnel will have access to the information.

The computer is an Internet-based, patient-centered tool. Some health care providers, such as the Palo Alto Medical Foundation, allow patients to review their medications and laboratory values online.¹⁸ Patient organizations such as the American Association of Kidney Patients (AAKP) have developed patient health records that enable a patient to enter medical information, check definitions, and share data with their physician. Based on these advances, it is obvious that physician use of computers will decrease inequities in medical care and reduce administrative costs (presently 31 cents of each dollar¹⁹) while helping to make medical care accessible to the growing number of uninsured patients.

A well-designed health information system takes into account the need to protect patient confidentiality. Data must be sent from computer to computer over a secure network (a so-called *virtual private network*), which must be established on the physician's workstation or laptop computer. By using strong encryption algorithms when storing data on the server and allowing Internet access only directly to that server's address, the private network is not needed, so information can be securely viewed from any website. Physician passwords must be designed so that hackers cannot easily guess them; security is compounded by each letter or number added to the password, and when numbers and shifted numbers (characters and capitals) are added. Other security items, such as no repudiation, and digital signatures must be in place to prevent the record from being nefariously altered. Data security is beyond the scope of this chapter, but the Health Insurance Portability and Accountability Act (HIPAA) spells out specific requirements for using a computer online to share information. Information about a patient's health records must also follow these rules.

Selection of an office system should never be a decision made in haste. It requires time and energy and is often accompanied by periods of frustration; a purchase should be preceded by understanding the workflow of the office and by determining how a computer can speed each step, as in the following example: A group practice with offices at several locations is trying to decide whether to own or lease a computer system. If owned, it will reside on a local server, offering heightened security, but if leased, it will reside on the vendor's server and will be Internet-based. This offers the advantage of data access from remote sites. The group approaches the choice systematically, comparing costs, benefits, risks, and tradeoffs to make an ideal choice. Several outstanding resources, including the Hartley book,²⁰ can help clinicians select office systems.^{21–24}

PRACTICE ANALYSIS

Well-designed software enables the physician to gather and manipulate data. The physician can analyze growth patterns, define demographic and geographic centers where patients live, and give attention to areas for new recruits to practice. For example, a practice group can sort its end-stage renal

disease patients by ZIP code and rank them according to the first date of dialysis. Using a commercially available software package, Microsoft MapPoint, they can visualize their patients' homes by ZIP code. In one practice, it was noted that over the past 3 years there had been a steady growth of patients from the northwest side of the city, yet there were no dialysis centers in that area and patients were driving long distances for dialysis care. It became obvious that placing a dialysis facility near the heaviest density of patients would yield a financial "break-even" point in 2 years and would enhance the ability of the practice to deliver care. When presented with these data, the group decided to build a facility to accommodate patients based on the patterns recognized during their analysis.

THE COMPUTER AND CLINICAL RESEARCH

With expansive technology, particularly as we utilize knowledge of the human genome to create better therapies, there will be a greater demand for clinical trials. The office computer is an ideal analytic tool to help detect, recruit, and screen study subjects,²⁵ as in this example: The opportunity to screen patients with stage 4 CKD and diabetic nephropathy arose; one nephrology practice group promised to enroll 30 patients over a 12-month period to study a more aggressive lipid-lowering regimen. The inclusion criteria were patients over age 18 years with an estimated glomerular filtration rate (GFR) value of less than 30 mL/min, serum cholesterol levels lower than 200 mg/dL, and a negative history of myocardial infarction. The practice queried its database using these variables and notified patients of the possibility of participating in screening for enrollment or exclusion. Meanwhile, the physician group generated a list of referring physicians likely to send patients meeting these criteria, and in cooperation with the study sponsor, arranged educational seminars to help recruit additional patients. This computer-driven exercise allowed them to fulfill the recruitment goal.

INTERNET TOOLS FOR NEPHROLOGISTS

In the United States, 70.8% of the population uses the Internet.²⁶ The advent of mobile telephones and PDAs allow Internet access without carrying a large device. Technology adds dimension to effectiveness, knowledge, and confidence²⁷ to the physician's decision-making powers through instant access and sharing of patient data, guidelines, clinical trials results, and publications.

The Nephron Information Center

Nephron.org has embedded formulas for calculating the Modification of Diet in Renal Disease study (MDRD) GFR (eGFR) and has text boxes to link to PubMed, Google, and Wikipedia in its header. It receives 17,000 unique visits each day because users are searching for news or literature pertinent to patients with kidney disease. Newsdesk, a technology built for Nephron.org, aggregates and syndicates resources about kidney disease that are published on the Internet each

day. The information is organized and displayed on the front page of the site as “news.”

The site also has calculators for body mass index, mean arterial pressure, and conversions for laboratory values as well as direct access to the National Kidney Foundation’s K/DOQI guidelines (also available at <http://kidney.org>).

Finding Drug Reactions from a PDA

The site epocrates.com enables physicians to look up medication dosing, indication, drug interactions, and adverse events using a PDA. The package also includes several handy calculators. This information is available at <http://www.epocrates.com>.

Calculating Protein Intake

An online protein intake calculator (http://nephron.org/protein_intake) allows a nephrologist to advise a patient. It can be used as in this example: A mechanical engineer was prescribed a 0.6 g/kg protein-restricted diet in an effort to help preserve kidney function. The patient collected a 24-hour urine, and the urea nitrogen content in the collection was 4.5 g/day; his weight was 70 kg. The calculator converted these data into a protein intake of 41.69 g/day, which is on target with the prescribed diet.^{28,29}

Tracking Dialysis Units during a Catastrophe

The site dialysisunits.com enables users to search for dialysis facilities and details. Based on the Centers for Medicare & Medicaid Services (CMS) national provider list, it is updated monthly. Search can be made by name, city, ESRD Network, state, ZIP code, or dialysis modality. After Hurricane Katrina, the program informed dialysis patients which dialysis units were operating when they returned to Louisiana. CMS and the ESRD Networks control portions of the site to track facility closures during emergencies.

How to Calculate the MDRD GFR

The four-variable MDRD study equation is a popular method of predicting the GFR from serum creatinine, age, race, and gender. It is based on stepwise multiple linear regression analyses of the demographic and laboratory data from the Modification of Diet in Renal Disease clinical trial.^{30–33} To correct for the variation in the calibration of laboratory instruments that leads to a variation in performance of the equation at higher levels of GFR, serum creatinine levels measured using the original laboratory equipment were recalibrated to a Roche/Hitachi enzymatic assay traceable to serum samples analyzed at the National Institute of Standards and Technology (NIST) using isotope-dilution mass spectrometry. The original GFR equation is used when laboratory creatinine values have not been standardized. The formula, which gives users the option to choose which creatinine methodology was used, is available online at <http://mdrd.com> and is used by both the National Kidney Foundation (<http://www.kidney.org>) and the Nephron Information Center (<http://nephron.org>). A third site, that of the National Kidney Disease Education Program (<http://nkdep.nih.gov>), also gives users this option. The formula can be used as in this example: A 55-year-old Hispanic female with a creatinine of 2 mg/dL 4 months ago now has a creatinine of 2.1, both traceable to diabetic nephropathy. Her GFR has declined from 26 to 24 mL/min/1.73 m², indicating that she has stage 4 CKD.

gov), also gives users this option. The formula can be used as in this example: A 55-year-old Hispanic female with a creatinine of 2 mg/dL 4 months ago now has a creatinine of 2.1, both traceable to diabetic nephropathy. Her GFR has declined from 26 to 24 mL/min/1.73 m², indicating that she has stage 4 CKD.

Wikikidney

Wikikidney.org is a collaborative nephrology encyclopedia patterned after Wikipedia. Information is not copyrighted and is reviewed or edited by other volunteer professionals. The *wiki concept*³⁴ is that placing information in open view facilitates peer review, editing, and upgrading until contributors are satisfied with the content. Wiki etiquette dictates that all articles uploaded must have references. The wikis allow for broad dissemination but lack the structured peer review of conventional publications. This source can serve as a first-line resources for medical information.

Search Articles on PubMed, HighWire, and HubMed

The NLM’s PubMed enables searching for publications by keyword, author, date, or medical subject heading. It is also available for PDAs or phones at <http://pubmedhh.nlm.nih.gov>. One can enter keywords into a text field on a cell phone, for instance, and scroll through the same database of references and abstracts used with conventional computers. PubMed is invaluable during rounds, conferences, and in the midst of patient care. Many other features are listed on the ncbi.nlm.nih.gov website.

HighWire Press, a large repository of peer-reviewed content, hosts more than 4.2 million full-text articles, of which nearly 1.7 million are free. Surprisingly, it receives the overwhelming majority of its referrals from Google, not from PubMed.³⁵ HubMed.org also uses the NLM database, but it allows direct transfer to reference managers such as EndNote. In addition, it takes advantage of a standardized Web format that syndicates published articles that can be viewed on an individual’s website. This new format, RSS (Really Simple Syndication³⁶), is becoming highly popular in the news publishing industry and is widely used by CNN and the *New York Times*. In the past special software was required to read files sent in this format, but lately this functionality is available on freely accessible web browsers such as Mozilla Firefox (<http://firefox.com>).

An example will serve to illustrate how these searches work: A new faculty member was interested in learning more about CKD. By searching for “chronic kidney disease” on hubmed.org and then clicking the “feeds” button, all NLM articles on CKD were fed to her Firefox browser. Each time a new article appears on PubMed or HubMed, the feed distributes the reference to her computer, and it is available for viewing.

SHIFTS: Tracking Dialysis Patients between Center, Hospital, and Office

Tracking a visit to a patient in a dialysis unit is possible using a spreadsheet format, but there are disadvantages; it is not secure and may be difficult to send across the Internet. Using online programs enables users to log in and track their

visits. A well-designed computer program should automatically stamp the date, place, and physician's initials and generate a report for billing. The program should be encrypted so that the data are secure. To see an example of the SHIFTS program, go to <http://interoperablessoftware.com>.

NEPHROL: The Nephrology Discussion Group

NEPHROL, sponsored by the National Kidney Foundation, is an e-mail listserv, or discussion group, that comprises 2000 nephrologists from around the world. Subjects vary, and discussions can be lively. Many of the participants are experts in their field, and erudite discussions enable physicians in practice to get answers to difficult clinical problems from colleagues. This group can be found at <http://kidney.org/professionals/cyber.cfm>.

How to Look Up a Lecture from HDCN

The site hdcn.com (Hypertension, Dialysis and Clinical Nephrology) publishes key lectures from national meetings, offering streaming video as well as a PDF handout. Lectures can be downloaded and "burned" on a CD-ROM. The site requires a subscription.

USRDS

The USRDS (U.S. Renal Data System) is a database of information on every dialysis patient in the Medicare program. As patients become eligible for enrollment, their facilities must complete a Federal 2728 form. Using this and claims data, the registry makes available statistics about the incidence, prevalence, morbidity, and economics of end-stage renal disease (<http://usrds.org>).

Google

This popular search engine also accesses 3 billion medical articles. In a recent study of 26 *New England Journal of Medicine* weekly clinical pathologic conferences, three to five keyword Google searches had a 58% success rate of making the correct diagnosis.³⁷ Google Scholar is a refined version of Google that, by allowing a more selective search of scientific articles, filters out extraneous information. An additional feature of Google is the ability to automatically find images for keywords. This comprehensive tool is indispensable when trying to find charts and diagrams.

For example, a renal fellow was asked to give a talk on WNT signaling. She was working on a set of MS PowerPoint slides and needed another image. By going to <http://google.com>, typing "wnt signaling" into the textbox, and clicking the "images" menu item above the logo, she retrieved 3800 images in 0.02 seconds. She double-clicked on one of them, saved it to the desktop, and imported it into her PowerPoint presentation using the Insert:picture menu.

PHYSICIAN QUALITY REPORTING INITIATIVE (PRQI)

As part of the Tax Relief and Health Care Act of 2006, CMS has created the Physician Quality Reporting Initiative as the

initial step toward a shift in payment strategy to value or performance-based payments. This phase enabled providers to earn bonus payments of up to 1.5% of total allowed Medicare charges by voluntarily reporting codes that reflect quality of care with their claims. These "zero dollar quality-data codes" are specific for measures pertinent to one's practice.

This scheme forced physicians to review how they capture data related to clinical events, generate appropriate codes and include them with billing information. It is the first step toward tying claims processing to an outcomes-based reimbursement model.

Figure 93-1 is an algorithm for high blood pressure control in patients with diabetes. This algorithm can be converted into a simple software applet that, when integrated into one's electronic health system, simplifies the capture and analysis of relevant information and, after being reviewed by the provider, passes it along to the billing department.

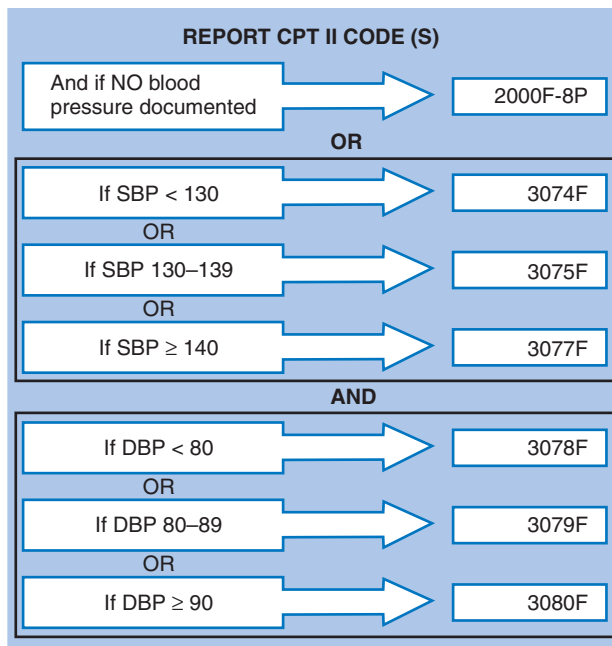

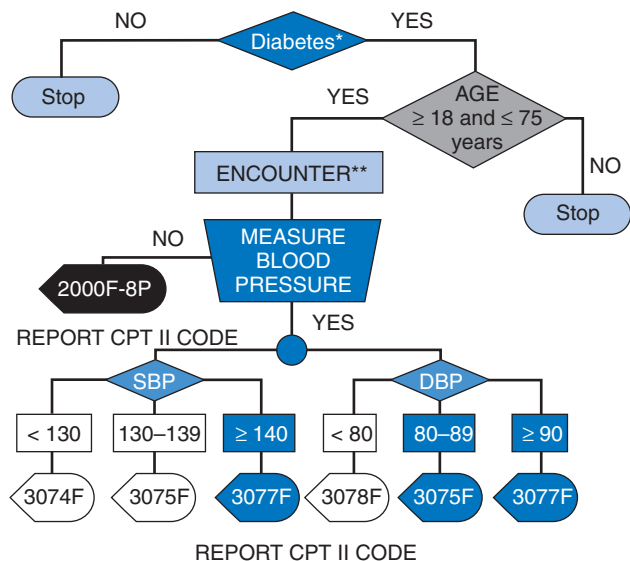

A PRACTICAL TIP ON INTERNET SECURITY

Standard e-mail uses nonencrypted protocols. For example, secure e-mail used within a university only assures privacy when the sender and user are in the same institution. Consequently, an email that is sent unencrypted is not secure for patient communication.^{38,39} Patients should be advised of this fact, and physicians should use caution when sending sensitive laboratory data to their patients.

The Health Insurance Portability and Accountability Act of 1996 specifies that patient health information sent over the Internet must be secure and encrypted. The CMS has authority over HIPAA and has created guidance documents on their website, <http://cms.hhs.gov/SecurityStandard>. They have pointed out risks and vulnerabilities associated with the use of laptops, backup devices, flash drives, and e-mails. These include the potential for stolen passwords, malicious stealing of sensitive data off a server, inappropriate access by an employee, workstations being left unattended, and corruption of a system due to a virus. Rules are complex, but in principle, specify that practices must have sound security policies and ongoing risk management initiatives and that electronic personal health information should always be protected from access by nonauthorized users through the use of strong encryption. CMS points out the risk of not using a strong encryption system when sending or receiving e-mails containing sensitive patient information.

CONCLUSIONS

A complete discussion of the resources and applications available to nephrologists would require much more space, but this chapter should serve as an introduction and review of some of the more practical web and computer applications, and as a starting point for those in the field to discover other available sites. Tables 93-1 to 93-3 list several sites useful to nephrologists.

PERFORMANCE IS MET IF 3074F, 3075F, 3078F
 PERFORMANCE IS NOT MET IF 3079F, 3080F, 3077F, 2000F-8P

Both a systolic and diastolic code are required
 SBP—systolic blood pressure in mm Hg
 DBP—diastolic blood pressure in mm Hg

<p align="center">DIABETES ICD-9 CODES</p> <p>*ICD-9 CODES FOR THIS MEASURE 250.00, 250.01, 250.02, 250.03, 250.10, 250.11, 250.12, 250.13, 250.20, 250.21, 250.22, 250.23, 250.30, 250.31, 250.32, 250.33, 250.40, 250.41, 250.42, 250.43, 250.50, 250.51, 250.52, 250.53, 250.60, 250.61, 250.62, 250.63, 250.70, 250.71, 250.72, 250.73, 250.80, 250.81, 250.82, 250.83, 250.90, 250.91, 250.92, 250.93, 648.00, 648.01, 648.02, 648.03, 648.04</p>	<p>If these 3 conditions are met</p> <p>AND</p> <div style="border: 1px solid black; padding: 5px; background-color: #e0f0ff; margin: 5px auto; width: 80%;"> <p align="center">AGE ≥ 18 and ≤ 75 years on encounter date</p> </div> <p>AND</p>	<p align="center">Encounter during reporting period</p> <p>CPT **CPT/HCPCS CODES FOR THIS MEASURE 97802, 97803, 97804, 99201, 99202, 99203, 99204, 99205, 99211, 99212, 99213, 99214, 99215, 99304, 99305, 99306, 99307, 99308, 99309, 99310, 99324, 99325, 99326, 99327, 99328, 99334, 99335, 99336, 99337, 99341, 99342, 99343, 99344, 99345, 99347, 99348, 99349, 99350 HCPCS G0270, G0271</p>
---	---	---

Figure 93-1 Algorithm for Physician Quality Reporting Initiative, Measure 3 (see text). Diabetic patients must have one of the listed ICD-9 codes, meet age criteria, and have a recent encounter during the reporting period that meets the listed CPT or HCPCS codes. If no documented blood pressure, use CPT II code 2000F-8P. Both a systolic and diastolic code are required. Performance is met if CPT II codes are 3074F or 3075F and 3078F. Performance is not met if code is 3079F or 3080F or 3077F. CPT, Current Procedural Terminology; DBP, diastolic blood pressure in mm Hg; HCPCS, Healthcare Common Procedure Coding System; ICD-9, International Statistical Classification of Diseases; SBP, systolic blood pressure in mm Hg.

AA amyloidosis, 257, 259t, 263
AAPCC (American Association of Poison Control Centers), 1073
AASK (African American Study of Kidney Disease and Hypertension), 614, 615t, 701
AAV (ANCA-associated vasculitis). *See* Systemic vasculitis.
Abacavir, in renal failure, 1060t
Abacteriuria, symptomatic, 449
ABCD (Appropriate Blood Pressure Control in Diabetes) trial, 612, 612t, 614, 615t, 639
Abdominal angiography, acute renal failure due to, dopamine for, 18t–19t
Abdominal aorta surgery, acute renal failure due to, dopamine for, 16t–17t
 fenoldopam for, 24t–25t
Abecarnil, in renal failure, 1054t
Abilify (aripiprazole), in end-stage renal disease, 803t, 813
ABO incompatibility, in renal transplantation, plasmapheresis for, 134
Abruptio placentae, hypertension and, 480
Abscess(es)
 perinephric, and autosomal dominant polycystic kidney disease, 541
 visceral, glomerulonephritis due to, 144
Acamprosate, in renal failure, 1064t, 1072t
ACAS (Asymptomatic Carotid Atherosclerosis Study), 1016
Access flow rate (Qa) monitoring, 864, 865b, 866
Access recirculation, 881, 888
ACCOMPLISH trial, 613
ACCORD (Action to Control Cardiovascular Risk in Diabetes) study, 639
Accounting tools, 1084
ACD-A (acid citrate dextrose-A) solution
 with hemodialysis, 65t
 with plasmapheresis, 127
ACE (angiotensin-converting enzyme), 602
Acebutolol
 with dialysis, 685, 685t, 1061t
 in renal failure, 1070t
Acecaimide, in renal failure, 1069t
ACEIs. *See* Angiotensin-converting enzyme inhibitors.
Acetaminophen, for pain management, in end-stage renal disease, 832t
Acetaminophen intoxication, hemodialysis for, 62t
Acetate dialysis, 851–852
 dialysis reactions with, 895–896
Acetate-based dialysate, 63
Acetazolamide
 in combination, 402b, 403
 dosage of, 390t
 for metabolic alkalosis, 383–384
 in renal failure, 1071t
 for salicylate toxicity, 373
Acetohexamide, in renal failure, 1072t
Acetylcysteine, for hyperhomocysteinemia, 727–728
N-Acetylcysteine, for chronic kidney disease, 732, 733, 733t
N-Acetylprocainamide, in renal failure, 1061t
Acetylsalicylic acid toxicity, respiratory alkalosis due to, 386, 386t
Acid citrate dextrose-A (ACD-A) solution
 with hemodialysis, 65t
 with plasmapheresis, 127
Acid-base disorders
 mixed, clinical settings for, 370
 pathophysiology of, 368–370, 369f, 370t
Acid-base regulation, in pregnancy, 487t
Acidosis
 drug-induced, 373
 lactic
 with contrast agents, 44
 D-, 373
 L-, 372–373
 due to metformin, 9
 metabolic (*See* Metabolic acidosis)
 renal response to, 368–370
 renal tubular, 375–378
 differential diagnosis of, 375b
 distal, 376–378
 classic, 375t, 376–377, 376b
 generalized, 375t, 377–378, 378b
 proximal, 375–376, 375t
 respiratory, 378–379
 causes of, 378
 compensation for, 368, 370t
 diagnosis of, 378–379, 379b
 treatment of, 379
 toxin-induced, 373–374
Acifran, in renal failure, 1055t, 1071t
Acquired immunodeficiency syndrome (AIDS). *See* Human immunodeficiency virus (HIV).
Acral calciphylaxis, 419
Action myoclonus–renal failure syndrome, 224t
Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, 639
Activated charcoal, for poisoning, 1074, 1076
Active metabolites, and dose adjustment, 1052
ACTN4 gene, 223, 224t
Acupuncture, for hypertension, 576t, 578
Acute dialysis, 58–69
 hemodialysis as (*See* Acute hemodialysis)
 peritoneal, 59, 67–69
Acute Dialysis Quality Initiative, 487
Acute hemodialysis, 58–67
 access for, 61–63
 anticoagulation with, 63, 64t–65t
 complications of, 66
 dialysate for, 63
 dialyzer for, 63
 factors influencing delivery of, 61–63
 indications for and timing of, 59–60
 for isolated fluid removal, 61
 modalities of, 58–59
 prescription for, 60–63, 61t
 quality assurance for, 66–67
 for toxin/drug removal, 61, 62t
Acute interstitial nephritis (AIN), 313–318
 background of, 313
 classification of, 313
 diagnosis of, 314
 drug-induced, 313, 314
 epidemiology of, 313
 histology and pathophysiology of, 313
Acute interstitial nephritis (AIN) (*Continued*)
 infection-related, 313–314
 in systemic immune disorders, 314
 therapy of, 314–318
 corticosteroids for, 314–315
 cyclophosphamide and cyclosporine for, 316–317
 future directions for, 318
 mycophenolate mofetil for, 315–316
 specific recommendations on, 317–318, 317f, 318t
 withdrawal of offending agent for, 314
Acute kidney injury (AKI)
 dialysis for (*See* Acute dialysis)
 diuretics in, 7, 35–39, 394–395
 ceiling dosage of, 401t
 for complications, 37–38
 for established disease, 36–37, 37t, 395
 pharmacology and dose recommendations for, 38–39
 for prevention, 35–36, 36t, 394–395
 early diagnosis of, 95, 95b
 experimental strategies for, 92–96, 95b
 pathophysiology of, 93–95
 prevention of, 95–96, 95b
 treatment of, 95–96, 95b
Acute Kidney Injury Network, 3
Acute peritoneal dialysis, 59, 67–69
Acute poststreptococcal glomerulonephritis (APSGN), in children, 507–508
Acute renal failure (ARF)
 acidosis due to, 374
 complications of, 9–10
 diagnostic criteria for, 3–4, 4b, 4f
 dialysis for (*See* Acute dialysis)
 dopaminergic agents for, 13–23
 dopamine as, 13–22
 in cardiovascular surgery, 15–20
 effect on renal hemodynamics and sodium excretion of, 14–15, 15
 in established disease, 20–21
 in high-risk patients, 15–20, 16t–19t
 in liver transplantation and hepatobiliary surgery, 20
 meta-analysis of trials of, 21
 potentially deleterious effects of, 21–22, 21t
 in radiocontrast-induced nephropathy, 20
 in renal transplantation, 20
 fenoldopam as, 22–23, 24t–27t
 drug dosing in (*See* Drug dosing, in renal failure)
 electrolyte disturbances in, 8–9
 fluid challenge in, 7, 7f
 with multiple myeloma, plasmapheresis for, 133–134, 134t
 myoglobinuria in, 7–8
 nutritional management of, 81–90
 amino acid/protein metabolism in, 82, 86, 87t
 antiacidotic strategies in, 82–83, 82b
 carbohydrate metabolism in, 83
 clinical experience with, 84–86
 complications and monitoring of, 89, 89t
 electrolytes in, 84
 energy metabolism and energy requirements in, 82, 87t
 enteral nutrition in, 86–87, 86t
 impact of, 85
 lipid metabolism in, 84

- Acute renal failure (ARF) (*Continued*)
 metabolic alterations and nutritional requirements in, 81–84, 82b
 metabolic impact of extracorporeal therapy in, 84, 84b
 micronutrients in, 84
 nutrient administration in, 85f, 85–89
 oral feedings in, 86, 86t
 parenteral nutrition in, 87–89, 88t
 patient classification for, 85, 86t
 protein/amino acid requirements in, 83, 85, 86t, 88t
 pregnancy-related, 487–488, 488t
 vs. prerenal azotemia, 3–4, 4b
 prevention of, dopamine for, 15–20, 16t–19t
 recovery from and prognosis for, 10
 renal replacement therapy for, 9–10
 vasopressor agents for, 23–30
 epinephrine as, 27–28
 norepinephrine as, 26–27, 28t–29t
 phenylephrine as, 28–29
 vasopressin as, 29–30
 volume replacement for, 4–8
- Acute tubular necrosis (ATN), dopamine for, 20–21
- Acute urethral syndrome, 449
- Acute vascular necrosis, posttransplantation, 1024
- Acylovir
 for posttransplant HSV and VZV, 1038
 in renal failure, 1060t, 1068t
- Adalat. *See* Nifedipine.

 for IgA nephropathy, 179, 180t, 507
 for membranoproliferative glomerulonephritis, 251
 for posttransplant coronary heart disease, 1015–1016
 for renal artery stenosis, 654–655, 656, 656f
 in renal failure, 1056t, 1064t
 for thrombotic microangiopathy, 306t, 308
 thrombotic microangiopathy due to, 302
 for vascular access thrombosis, 762
- Antipsychotics, in end-stage renal disease, 802t–804t, 813
- Antispasticity agents, in renal failure, 1068t
- Anti-T lymphocyte globulin (ATG-Fresenius), for renal transplantation, 979
- Antithrombotic agents, for thrombotic microangiopathy, 306t
- Antithymocyte globulin, for systemic vasculitis, 191
- Anti-T-lymphocyte antibodies, for systemic vasculitis, 191
- Anti-transforming growth factor- β (anti-TGF- β), for focal segmental glomerulosclerosis, 230t
- Antituberculous agents, in renal failure, 1060t, 1068t
- Anti-tumor necrosis factor- α (anti-TNF- α) monoclonal antibodies, for familial Mediterranean fever, 554t
- Antiulcer agents, in renal failure, 1068t
- Antiviral agents
 for posttransplant infections, 1035t
 in renal failure, 1060t, 1068t–1069t
- Anxiety disorders, in end-stage renal disease, 804t–806t, 811
- Anxiety-hyperventilation syndrome, respiratory alkalosis due to, 386, 386t
- Anxiolytics
 in end-stage renal disease, 804t–806t
 in renal failure, 1054t, 1055t–1056t, 1064t
- Aortic aneurysm
 dissecting, hypertension with, 630f, 631–632, 631t
 due to renal artery stenosis, 651t
- Aortic dissection, hypertension with, 630f, 631–632, 631t
- APCs (antigen-presenting cells), 977
- APD. *See* Automated peritoneal dialysis.
- Apheresis, double-filtration, 126–127
- Aphthous ulcers, posttransplantation, 1021
- Apnea, sleep, 681, 791–793, 809
- Apnea-hypopnea index (AHI), 791
- Apolipoprotein A1 amyloidosis, 259t, 263
- Apoptosis, in acute kidney injury, 94
- Apparent mineralocorticoid excess, hypokalemia in, 360t, 361
- Appropriate Blood Pressure Control in Diabetes (ABCD) trial, 612, 612t, 614, 615t, 639
- Appropriate Blood Pressure in Diabetes Study, 325
- APSGN (acute poststreptococcal glomerulonephritis), in children, 507–508
- Aquadex system, 61
- Aquaretics, 390t, 391, 403
- Arachidonic acid (AA), 114–116, 115f
- Arava. *See* Leflunomide.
- ARBs. *See* Angiotensin receptor blockers (ARBs).
- ARF. *See* Acute renal failure (ARF).
- Argatroban, with hemodialysis, 65t
- Arginine vasopressin receptor antagonists, 390t, 391, 403
- ARIC (Atherosclerosis Risk in Communities) study, 1017
- Aripiprazole (Abilify), in end-stage renal disease, 803t, 813
- Arrhythmias, in hemodialysis patients, 898
- Arterial monitor, for hemodialysis, 845
- Arteriovenous bridge graft (AVG), for hemodialysis vascular access, 860, 864, 866
 blood sampling with, 887b
- Arteriovenous fistula (AVF), for hemodialysis vascular access, 861–866
 blood sampling with, 887b
 complication(s) of, 864–867
 heart failure and pulmonary hypertension as, 867
 infections as, 860, 866, 868
 stenosis as, 863–866, 863t, 865b
 thrombosis as, 761–762, 864, 866, 867–868
 vascular steal as, 867
 maturation of, 863–864, 863b
 preoperative evaluation for, 861–862
 process improvement for, 862–863, 863b
 types of, 860
 in unique situations, 862
- Arteriovenous hemodiafiltration, continuous, 73
- Arteriovenous hemodialysis, continuous, 73
- Arteriovenous hemofiltration, continuous, 73
- ASB (asymptomatic bacteriuria), 449
 in pregnancy, 486
- Ascites, diuretics for, 394f, 397–398
- Ascorbic acid, for contrast-induced nephropathy, 43
- ASCOT (Anglo-Scandinavian Cardiac Outcomes Trial), 612t, 613
- ASCT (autologous stem-cell transplantation)
 for AL amyloidosis, 260t, 262–263, 264, 462–463
 for cast nephropathy, 464–465
 for light-chain deposition disease, 265
- ASDN (aldosterone-sensitive distal nephron), 389, 402
- ASFAST (Atherosclerosis and Folic Acid Supplementation Trial), 725
- Aspergillus* spp, posttransplant infections with, 1041, 1042t
- Aspirin
 for membranoproliferative glomerulonephritis, 251
 posttransplantation
 for coronary heart disease, 1015–1016
 for peripheral arterial disease, 1017
 for renal artery stenosis, 654–655, 656, 656f
 for thrombotic microangiopathy, 306t
 for vascular access thrombosis, 762
- Aspirin toxicity
 metabolic acidosis due to, 373
 respiratory alkalosis due to, 386, 386t
- Assessment of Lescol in Renal Transplantation (ALERT) study, 1002, 1011
- Asymmetric dimethylarginine (ADMA), 731, 733
- Asymptomatic bacteriuria (ASB), 449
 in pregnancy, 486
- Asymptomatic Carotid Atherosclerosis Study (ACAS), 1016
- Atenolol
 with dialysis, 685, 685t, 1061t
 for hypertension, 597t
 in children, 514t
 in pregnancy, 482t
 in renal failure, 1061t, 1070t
 renal protective effects of, 614, 615t
- Atgam (thymoglobulin), for renal transplantation, 979–982, 980t, 988

- ATG-Fresenius (anti-T lymphocyte globulin), for renal transplantation, 979
- Atherogenic dyslipidemia, 715, 717b, 718–720
- Atherosclerosis and Folic Acid Supplementation Trial (ASFAST), 725
- Atherosclerosis Risk in Communities (ARIC) study, 1017
- Atherosclerotic renal artery stenosis, 647, 650, 651t
angioplasty and stenting for, 664, 668–670, 668t, 669t, 670f
- Atherosclerotic renal vascular disease, in living kidney donor, 966
- Ativan (lorazepam), in renal failure, 805t
- ATN (acute tubular necrosis), dopamine for, 20–21
- Atorvastatin
for cardiovascular risk reduction, in hypertension, 637t
for chronic kidney disease, 733t
for lipid management, 719t
posttransplantation
for cerebrovascular disease, 1016
for coronary heart disease, 1015
for hyperlipidemia, 1011, 1013t
- ATP III (Adult Treatment Panel III) report, 715–722
- ATRA (angiotensin receptor antagonists).
See Angiotensin receptor blockers (ARBs).
- Atrial natriuretic peptide (ANP)
for acute kidney injury, 37, 37t
for edema, 403
mechanism of action of, 389f, 391
- Atypical hemolytic-uremic syndrome (aHUS), 249
in children, 510–511
- Autoimmune disease(s), 105
renal tubular acidosis due to, 376t
- Autologous stem-cell transplantation (ASCT)
for AL amyloidosis, 260t, 262–263, 264, 462–463
for cast nephropathy, 464–465
for light-chain deposition disease, 265
- Automated peritoneal dialysis (APD), 913, 919, 920, 921
demographics of, 913
guidelines for clearance with, 943
peritoneal transport status in, 938, 939
prescription for, 921, 939
small solute clearance in, 935, 937, 938
volume status in, 939, 940, 943
- Autoregulation, total body, 682
- Autosomal dominant hypophosphatemic rickets, 549t, 550
- Autosomal dominant polycystic kidney disease (ADPKD), 539–544
defined, 539
epidemiology of, 539
extrarenal manifestations of, 539–541, 540t
kidney pain in, 542, 543t
in living kidney donor, 966
management of complications of, 540t
posttransplant cerebrovascular disease with, 1017
renal manifestations of, 540t, 541–542
slowing of progression of, 544
- AVE 7688, for focal segmental glomerulosclerosis, 230t
- Aventyl (nortriptyline), in renal failure, 800t, 812
- AVF. See Arteriovenous fistula (AVF).
- AVG (arteriovenous bridge graft), for hemodialysis
vascular access, 860, 864, 866
blood sampling with, 887b
- Azapropazone, in renal failure, 1054t, 1056t, 1065t
- Azathioprine (Azasan, Imuran)
for anti-GBM antibody disease, 199, 199t, 200
for glomerular and tubulointerstitial disease, 106
for IgA nephropathy, 175, 177t, 507
for lupus nephritis, 159b, 160b, 161–162, 164b, 166f
for minimal change disease, 215
in children, 215, 500
for renal transplantation, 979f, 981t, 984
gout due to, 1025b
for systemic vasculitis, 190, 191t, 193, 193t, 194t
- Azlocillin, in renal failure, 1054t, 1058t, 1067t
- Azotemia
due to diuretics, 398
prerenal, vs. acute renal failure, 3–4, 4b
- Azotemic renovascular disease, 647
- Aztreonam
for peritonitis, 928f
in renal failure, 1058t, 1066t
- B**
- B cells, 976, 977
- Backache, due to peritoneal dialysis, 933
- Baclofen, in renal failure, 1068t
- Bacteria, in dialysate fluid, 853–854, 854b
- Bacterial endotoxin–related pyrogenic reactions, to dialysis, 66
- Bacterial infections
glomerulonephritis due to, 142–145, 142t
with hemodialysis, 868, 902
- Bacteriuria, asymptomatic, 449
in pregnancy, 486
- Balloon angioplasty, for renovascular disease, 664–673
complications of, 660–661, 670–671, 671b, 671f
demographics of, 660, 661f
goals of, 660, 664
vs. medical therapy, 648, 652, 653–654
outcomes of, 666–670, 666f, 667t–669t, 670f
patient selection for, 671–673
restenosis after, 671, 671f
techniques of, 664–665
- Barnidipine, for hypertension, 610, 611t
- Bartter syndrome, 552–553, 552t
hypokalemia in, 360, 360t
- Basal energy expenditure, in acute renal failure, 82
- Basiliximab (Simulect), for renal transplantation, 980t, 988
- B-cell crossmatching, 978–979
- Belatacept, for renal transplantation, 977, 986
- Benazepril
with dialysis, 686t
for IgA nephropathy, 181t
for nephrotic syndrome, 283
pharmacology of, 602t
in renal failure, 606, 1070t
- Bendroflumethiazide, dosage of, 390t
- Bendroflumethiazide, for hypertension, 597t
- BENEDICT (Bergamo Nephrologic Diabetic Complications Trial), 613, 615t
- Benign familial hematuria (BFH), 504
- Benign prostatic hyperplasia (BPH), 471–472
- Benzathine benzylpenicillin, for poststreptococcal glomerulonephritis, 143
- Benzodiazepam, with dialysis, 684t
- Benzodiazepine(s), in end-stage renal disease
for anxiety disorders, 811
for pain management, 833t
- Benzodiazepine receptor agonists, for sleep apnea, in end-stage renal disease, 809
- Bepridil, with dialysis, 684t, 1060t
- Bergamo Nephrologic Diabetic Complications Trial (BENEDICT), 613, 615t
- Betaxolol
with dialysis, 685t
in renal failure, 1070t
- Bezafibrate, in renal failure, 1062t, 1071t
- BFH (benign familial hematuria), 504
- Biapenem, in renal failure, 1057t, 1065t
- Bias, lead-time, 741
- Bicarbonate (HCO_3^-)
in chronic kidney disease, 739, 743
for contrast-induced nephropathy, 42, 42t
for diabetic ketoacidosis, 372
gastrointestinal loss of, 375b, 375t
for lactic acidosis, 372–373
for metabolic acidosis due to renal failure, 374
in metabolic alkalosis, 381–384
in peritoneal dialysis fluids, 915, 916–917
for renal tubular acidosis, 376, 377
- Bicarbonate dialysis, 851–852
- Bicarbonate-buffered dialysate, 63, 68
- Bicarbonate/chloride ($\text{HCO}_3^-/\text{Cl}^-$) exchanger, in renal tubular acidosis, 376
- Bicitra (Shohl's Solution), for renal tubular acidosis, 377
- Biguanides, for transplant-associated hyperglycemia, 1014
- Bile acid sequestrants
for lipid management, 719t
for nephrotic syndrome, 286
- Biliary tract disease, posttransplantation, 1021
- Biocompatibility, of peritoneal dialysis fluids, 918
- Biofeedback system, for hemodialysis, 846, 847f
- Biofilm, on dialysate, 905
- Biomarkers, of acute kidney injury, 95, 95b
- Biopsy, renal. See Renal biopsy.
- Bipolar disorder, in end-stage renal disease, 802t, 812–813
- Bismuth subcitrate, colloidal, in renal failure, 1068t
- Bisoprolol
for hypertension, 597t
with dialysis, 685t
in renal failure, 1070t
- Bisphosphonates
for hypercalcemia, 415–416, 464
for multiple myeloma, 268, 464
for posttransplant osteoporosis, 1022–1023, 1022b
in renal failure, 1069t
- Bivalirudin, in renal failure, 1064t
- BK virus
allograft dysfunction due to, 999
posttransplantation, 1040–1041
- BK virus nephropathy (BKVN), 1040–1041
- Black patients, hypertension in, diuretics and β -blockers for, 594
- Bladder cancer, obstructive uropathy due to, 472
- Bladder dysfunction, obstructive uropathy due to, 473
- Bleeding. See also Hemorrhage.
with peritoneal dialysis, 933
after renal transplantation, 973
in uremia, 9, 759–761, 760t, 761b, 762t
- Bleomycin
in renal failure, 1068t
thrombotic microangiopathy due to, 302
- Blood circuit, for hemodialysis, 845–846, 846f
- Blood glucose control, for prevention of diabetic nephropathy, 323–324
- Blood group antigens, 977
- Blood leak detector, for hemodialysis, 845–846
- Blood loss
classification of, 6
during hemodialysis, 900–901
- Blood pressure (BP), high normal, 569–570, 570f, 571t
- Blood pressure control
for diabetic nephropathy, 326
in prevention, 324–325
for end-stage renal disease, 774–776, 775t
for prevention of progressive renal failure, 700–702, 700f
- Blood pressure measurement, 568–569
in children, 512
- Blood pressure monitoring, ambulatory, 568–569
- Blood pressure regulation, cholesterol and, 638
- Blood pump(s), for hemodialysis, 845
malfunction of, 888
- Blood pump flow rate (BPPF), for hemodialysis, 867
- Blood sampling, in hemodialysis, 886–888, 887b, 888b
- Blood transfusion, exchange, for poisoning, 1076
- Blood type, in renal transplantation, 957
- Blood urea nitrogen (BUN) concentration, hemodialysis and, 60, 880, 880f, 882–883
- Blood viscosity, n-3 fatty acids and, 116
- Bloodstream infection (BSI), with hemodialysis, 868
- BMD (bone mineral density)
after renal transplantation, 1021–1023, 1022b
and renal transplantation, 961
- Bohr effect, in metabolic alkalosis, 381
- Bone and mineral disease
in chronic kidney disease, 765–771
calciphylaxis as, 770–771
in childhood and adolescence, 524–525
high-turnover, 766
due to hyperparathyroidism, 765–766, 766f
due to hyperphosphatemia, 766–768, 767t
low-turnover, 766
renal osteodystrophy as, 765–766
after renal transplantation, 770
treatment of, 769–770
due to vitamin D deficiency, 768–769
hypophosphatemic nonrheumatic, 549t, 550
- Bone loss, due to thiazide diuretics, 594
- Bone marrow transplantation–associated thrombotic microangiopathy, 302–303, 307t
- Bone mineral density (BMD)
after renal transplantation, 1021–1023, 1022b
and renal transplantation, 961
- Bone morphogenetic protein, 7
for focal segmental glomerulosclerosis, 230t
for prevention of progressive renal failure, 709
- Bone protection, with lupus nephritis, 165b

- Boniva (ibandronate)
for hypercalcemia, 415–416
for posttransplant osteoporosis, 1022
- Bortezomib, for multiple myeloma, 267–268
- Bosentan
for focal segmental glomerulosclerosis, 230t
in renal failure, 1070t
- Bowel irrigation, for poisoning, 1074
- BP. *See* Blood pressure (BP).
- BPFR (blood pump flow rate), for hemodialysis, 867
- BPH (benign prostatic hyperplasia), 471–472
- Breast-feeding, and hypernatremic dehydration, 8
- Bretium, in renal failure, 1061t, 1069t
- British Hypertension Society, 570–571, 571t, 587–588, 588f
- Bromfenac, in renal failure, 1056t
- Bromocriptine, for erectile dysfunction, 787
- Bronchodilators, in renal failure, 1055t, 1060t, 1069f
- Bronchospasm, β -blockers with, 594
- BSI (bloodstream infection), with hemodialysis, 868
- B-type natriuretic peptide, 391
for congestive heart failure, 397
- Buffers, in peritoneal dialysis fluids, 917, 916t
- Buflomedil, in renal failure, 1062t, 1070t
- Bumetanide
for acute kidney injury, 37t, 38
dosage of, 390t
ceiling, 400–401, 401t
pharmacokinetics of, 391, 392t, 393
- BUN (blood urea nitrogen) concentration, hemodialysis and, 60, 880, 880f, 882–883
- Buprenorphine, for pain management in end-stage renal disease, 832t
- Bupropion (Wellbutrin, Zyban)
for posttransplant smoking cessation, 1015
in renal failure, 800t, 812
- Buspirone (Buspar), in renal failure, 805t, 1055t, 1064t
- Butorphanol, in renal failure, 1063t
- BX471, for focal segmental glomerulosclerosis, 230t
- ## C
- C3 nephritic factors (C3NeFs), in membranoproliferative glomerulonephritis, 249, 252, 253f
- C3a, dialysis reactions due to, 895, 902
- C4d, in kidney transplantation, 978
- C5a, dialysis reactions due to, 895, 902
- Ca²⁺. *See* Calcium.
- CABG (coronary artery bypass graft)
acute renal failure due to, 16t–17t
posttransplantation, 1016
- CAD (coronary artery disease)
chronic kidney disease and, 715–717, 716t, 778–779
with dialysis, 680–681
renal artery stenosis and, 651t, 654
- Calan. *See* Verapamil.
- Calcidiol, in hypercalcemia, 413, 413f
- Calcification, vascular, in chronic kidney disease, 768
- Calcijex. *See* Calcitriol.
- Calcimimetic agents, for bone disease, 769–770
- Calcineurin inhibitors (CIs)
for focal segmental glomerulosclerosis, 227, 231
for glomerular and tubulointerstitial disease, 107
for idiopathic membranous nephropathy, 242t, 243–244
for minimal change disease, 213, 214t
in children, 213, 214t, 500
posttransplant hypertension due to, 675–677
for renal transplantation, 980t–981t, 983, 987–988
nephrotoxicity of, 1001–1002, 1001t, 1003–1004
optimal dose of, 1004
withdrawal from, 989
- Calciphylaxis, 770–771
acral, 419
- Calcitonin
for hypercalcemia, 416
for posttransplant osteoporosis, 1023
- Calcitriol (Rocaltrol, Calcijex)
for bone disease, 769
in hypercalcemia, 413
for hyperphosphatemia, 420
for hypocalcemia, 417f, 418
after parathyroidectomy, 770
for posttransplant osteoporosis, 1022
- Calcium (Ca²⁺)
in chronic kidney disease, 767t
in hemodialysate fluid, 852, 853, 899–900
and hypertension, 576, 576t
in peritoneal dialysis fluids, 916, 916t
serum concentration of, 412
- Calcium acetate
for bone disease, 768
for hyperphosphatemia, 420
- Calcium carbonate
for bone disease, 768
for hyperphosphatemia, 420
for hypocalcemia, 418
for posttransplant osteoporosis, 1022
- Calcium channel blockers (CCBs)
for diabetic nephropathy, 325
with dialysis, 684, 684t
diuretic resistance due to, 400t
in end-stage renal disease, 616, 776
for hypertension, 610–617
in children, 514t
efficacy of, 610–612
guidelines for selection of, 621t
pharmacology of, 610, 611t
due to pheochromocytoma, 694
and prevention of cardiovascular morbidity and mortality, 612–613, 612t
and prevention of progression of chronic kidney disease, 613–615, 615t
due to primary aldosteronism, 692–693
after renal transplantation, 616, 677
for hypertensive urgencies, 628t, 629
and progressive renal failure, 702
for renal artery stenosis, 649–650, 649f, 650f, 653
safety of, 616–617
- Calcium chloride
for hyperkalemia, 361
for hypocalcemia, 418
- Calcium citrate, for hypocalcemia, 418
- Calcium disorder(s), 412–418
during hemodialysis, 903
hypercalcemia as, 412–416, 413f, 414f
hypocalcemia as, 416–418, 416f, 417f
- Calcium glubionate (Neo-Calglucon), for hypocalcemia, 418
- Calcium gluceptate, for hypocalcemia, 417–418, 417f
- Calcium gluconate
for hyperkalemia, 361–362
for hypocalcemia, 417, 417f
after parathyroidectomy, 770
- Calcium homeostasis, 412
abnormalities in, in nephrotic syndrome, 287
- Calcium intake
with chronic kidney disease, 742t, 743
with end-stage renal disease in childhood and adolescence, 523t, 524
after renal transplantation, 744–745
- Calcium oxalate stones
evaluation of, 431, 432f, 433f
prevention of, 431–433
risk factors for, 431b
- Calcium phosphate metabolism, in chronic kidney disease, 777–778
- Calcium phosphate stones
diagnosis of, 430–431
prevention of, 434
- Calcium resonium, for hyperkalemia, 364
- Calcium salts, for hyperkalemia, 8–9
- Calcium supplements, for hypocalcemia, 417, 417f
- Calcium-based phosphate binders, for bone disease, 767–768
- Calculus(i). *See also* Nephrolithiasis.

 progressive
 mechanisms underlying, 699–700, 700f
 prevention of, 699–710, 700f
 ACE inhibitors and angiotensin receptor
 blockers for, 700f, 702–706, 703t, 706f
 antihypertensive therapy in, 700–702, 700f
 calcium channel blockers for, 613–615, 615t
 control of hyperglycemia for, 708
 dietary interventions for, 699, 700f, 707
 future therapies for, 708–709
 lipid lowering for, 700f, 707–708
 monitoring for, 708
 pharmacologic inhibition of renin-angiotensin
 system in, 702–706, 703t, 706f
 proteinuria as therapeutic target in, 699, 700f, 706–709
 smoking cessation for, 700f, 708
 strategy for maximal renoprotection in, 709–710, 709t
 due to renal artery stenosis, 647, 651t, 653–654
 renal osteodystrophy in, 765–766
 sleep disorders in, 791–793
 thrombotic complications of, 761–762
 vascular calcification in, 768
 vitamin D deficiency in, 768–770, 778
 Chronic kidney insufficiency, diuretics for, 395
 Chronic obstructive pulmonary disease (COPD),
 β -blockers with, 594
 Chronic renal failure. *See* Chronic kidney disease (CKD).
 Churg-Strauss syndrome, 187
 Chyloperitoneum, due to peritoneal dialysis, 933
 Chymase, 604–605
 CI(s). *See* Calcineurin inhibitors (CIs).
 Cialis (tadalafil)
 for erectile dysfunction, 787–788
 in renal failure, 1071t
 Cibenzoline, in renal failure, 1061t, 1069t
 Cidofovir
 for polyomavirus nephropathy, 1000, 1041
 for posttransplant adenovirus, 1039
 for posttransplant cytomegalovirus, 1037
 in renal failure, 1060t, 1069t
 Cigarette smoking
 in end-stage renal disease, 773–774
 and hypertension, 636b, 636f, 638–639
 and posttransplant cardiovascular complications, 1014–1015
 and progressive renal failure, 708
 with renal artery stenosis, 654
 Cilazapril
 in renal failure, 1062t, 1070t
 renal protective effects of, 614, 615t
 Cimetidine, in renal failure, 1056t, 1064t
 CIN. *See* Contrast-induced nephropathy (CIN).
 Cinacalcet hydrochloride (Sensipar)
 for calciophylaxis, 771
 for hyperparathyroidism, 769–770
 posttransplantation, 1023
 for hyperphosphatemia, 420
 Cinoxacin, in renal failure, 1067t
 Ciprofibrate, in renal failure, 1071t
 Ciprofloxacin
 for exit-site infections, 929
 for peritonitis, 928f
 in renal failure, 1059t, 1067t
 for UTI, 450, 451

- Circulatory support, for edema, 403–404
- Cirrhosis
 diuretics for, 397–398
 and hyponatremia, 346–347
- Cisapride, in renal failure, 1056t
- Citalopram (Celexa), in renal failure, 798t, 812, 1063t
- Citrate
 with hemodialysis, 63, 65t
 with plasmapheresis, 127
 for prevention of stone formation, 470
 urinary, 433, 433f
- CKD. *See* Chronic kidney disease (CKD).
- Cl. *See* Clearance (Cl).

 half-life and, 1051
 residual native kidney, 883, 883t
- Clemastine, for pruritus in end-stage renal disease, 833t
- Clindamycin, in renal failure, 1058t
- Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE), 813
- Clinical research, computer and, 1085
- CLKT (combined liver-kidney transplantation), for hepatorenal syndrome, 49
- Clodronate, for hypercalcemia, 415
- Clofibrate
 for diabetes insipidus, 350, 350t
 for lipid management, 719t
 in renal failure, 1062t, 1071t
- Clomiphene citrate, for erectile dysfunction, 786
- Clomipramine (Anafranil), in renal failure, 799t
- Clonazepam (Klonopin)
 in renal failure, 805t
 for restless legs syndrome, 833t
- Clonidine
 with dialysis, 687, 687t, 1062t
 for hypertension in children, 514t
 for hypertensive urgencies, 628t, 629
 for renal artery stenosis, 653
 in renal failure, 1070t
- Clopidogrel
 posttransplantation
 for coronary heart disease, 1015–1016
 for peripheral arterial disease, 1017
 for vascular access thrombosis, 762
- Clopidogrel for High Atheroembolic Risk and Ischemia Stabilization, Management and Avoidance (CHARISMA) study, 1015
- Clopidogrel for Reduction of Events During Observation (CREDO) study, 1016
- Clopidogrel versus Aspirin in Patient at Risk of Ischaemic Events (CAPRIE) trial, 1017
- Clorazepate (Tranxene), in renal failure, 805t
- Cloxacillin, in renal failure, 1058t
- Clozapine (Clozaril), in end-stage renal disease, 803t, 813
- CMV (cytomegalovirus), posttransplantation, 1035–1037
- CNF (Finnish-type congenital nephrotic syndrome), 502
- Cobalamin metabolism inborn abnormal, thrombotic microangiopathy with, 305, 307t
- Cocoa consumption and hypertension, 576t, 577
- Codeine
 for pain management in end-stage renal disease, 832t
 in renal failure, 1054t, 1063t
- Coefficient of diffusion, 877
- Coffee consumption, and hypertension, 576t, 577
- Cognitive impairment, drugs for, in renal failure, 1071t
- COL4A4 gene, 504
- COL4A5 gene, 504
- Colchicine
 for AA amyloidosis, 263
 for familial Mediterranean fever, 553–554, 554t
 for posttransplant gout, 1024, 1025b
 in renal failure, 1072t
- Colesevelam, for lipid management, 719t
- Colestipol
 for lipid management, 719t
 for nephrotic syndrome, 286
- Colic, renal, 430
- Colistin, in renal failure, 1059t, 1067t
- Collagen vascular diseases, in pregnancy, 489
- Collapsing glomerulopathy (CG), 221t, 223, 225, 234
- Collecting duct diuretics, 389–391. *See also* Potassium (K⁺)-sparing diuretics.
 in combination, 402b
- Colloid fluids, for volume replacement, 5–6
- Colloidal bismuth subcitrate, in renal failure, 1068t
- Colon perforation, posttransplantation, 1021
- Colonoscopy, posttransplantation, 1021
- Combined liver-kidney transplantation (CLKT), for hepatorenal syndrome, 49
- Comorbidities, hemodialysis vascular access with, 862
- Comparison of Amlodipine vs. Enalapril to Limit Occurrences of Thrombosis (CAMELOT) trial, 612t, 613
- Complement cascade, in membranoproliferative glomerulonephritis, 249, 250f, 252–253, 253f

 Dopamine receptors, 14, 22
 Dopaminergic agent(s), for acute renal failure, 13–23
 dopamine as (*See* Dopamine)
 fenoldopam as, 22–23, 24t–27t
 DOPPS (Dialysis Outcomes and Practice Patterns Study), 616, 684
 Dose
 loading, 1049–1050, 1050t
 maintenance, 1050
 modified, 1051
 Dose adjustment, principles of, 1049–1052, 1050t
 Dosing rate, 1050
 Dosing recommendations, with renal failure, 1052–1053
 Dosing regimens, 1051–1052
 Double-filtration apheresis, 126–127
 Doxacurium, in renal failure, 1063t
 Doxazosin
 for benign prostatic hypertrophy, 472
 with dialysis, 688t
 for hypertension due to pheochromocytoma, 694, 694b
 in renal failure, 1061t
 Doxepin (Sinequan), in renal failure, 800t
 Doxercalciferol, for bone disease, 769
 Doxycycline
 for leptospirosis, 145
 in renal failure, 1059t
 D/P Cr (dialysate-to-plasma ratio of creatinine), 918, 919
 DRASTIC (Dutch Renal Artery Stenosis Intervention Cooperative) trial, 648, 668
 Dronabinol, for anorexia in end-stage renal disease, 834t
 Droperidol, in end-stage renal disease, 813
 Drug clearance
 and dose adjustment, 1050
 half-life and, 1051
 Drug concentration
 average, 1050
 initial, 1049
 Drug dosing
 Internet site on, 1086
 in renal failure, 1049–1072
 active metabolites in, 1052
 for analgesics, 1054t, 1055t, 1063t
 for anesthetics, 1054t, 1055t, 1063t–1064t
 for anthelmintics, 1064t
 for anti-anxiety agents, sedatives, and hypnotics, 1054t, 1055t–1056t, 1064t
 for anticholinergics and cholinergics, 1056t, 1064t
 for anticoagulants, antifibrinolytics, and antiplatelet agents, 1056t, 1064t
 for anticonvulsants, 1054t, 1056t, 1064t

 for hypoglycemic agents, 1062t, 1072t
 for hypouricemic agents, 1062t, 1072t
 for immunologic agents, 1063t
 loading dose in, 1049–1050, 1050t
 maintenance dose in, 1050
 principles of, 9, 1049–1052
 for psychotherapeutic agents, 1063t, 1072t
 recommendations on, 1052–1053
 regimens for, 1051–1052
 for steroids, 1063t
 for sympathomimetics, 1072t
 volume of distribution in, 1049–1050, 1054t–1055t
 Drug elimination, enhanced, for poisoning, 1074–1075
 Drug interactions, in treatment of posttransplant infections, 1034, 1035t
 Drug overdose, 1073–1079
 chelation for, 1076–1079
 dialysis for, 1075–1076, 1077b–1078b
 enhanced elimination for, 1074–1075
 enteric decontamination for, 1074
 immunopharmacologic treatment of, 1079
 indications for extracorporeal techniques in, 1075
 initial approach to, 1073–1074, 1074f
 plasma exchange and exchange blood transfusion for, 1076
 seizures due to, 1073
 sorbent hemoperfusion for, 1076, 1078b, 1078t
 Drug removal, dialysis for, 61, 62t
 Drug-associated thrombotic microangiopathy, 301–302, 307t
 Drug-eluting stents (DES), for posttransplant coronary heart disease, 1016
 Drug-induced acidosis, 373
 Drug-induced acute interstitial nephritis, 313, 314
 Drug-induced erectile dysfunction, in chronic kidney disease, 785, 786b
 Drug-induced renal tubular acidosis, 376t
 Drug-induced seizures, in end-stage renal disease, 809
 DSAs (donor-specific anti-HLA antibodies), 977, 978–979
 DSM-IV (*Diagnostic and Statistical Manual of Mental Disorders, 4th Edition*), 811
 Dt/V (ionic dialysance), 882
 Duloxetine (Cymbalta), in renal failure, 801t, 812
 Dutasteride, for benign prostatic hypertrophy, 472
 Dutch Renal Artery Stenosis Intervention Cooperative (DRASTIC) trial, 648, 668
 Dwell volumes, in peritoneal dialysis, 939
 Dynacirc (isradipine)
 cardiovascular effects of, 612, 612t
 pharmacology of, 610, 611t
 Dyphylline, in renal failure, 1060t, 1069t
 Dyslipidemia(s)
 atherogenic, 715, 717b, 718–720
 as cardiovascular risk factor
 in chronic kidney disease, 715–717, 716t
 in hypertension, 635–638, 636b, 636f, 637t
 in childhood and adolescence, 525
 with chronic kidney disease, 715–722, 776–777
 atherogenic, 715, 717b, 718–720
 not requiring dialysis, 721–722
 requiring dialysis, 722
 with diabetic nephropathy, 720–721
 during hemodialysis, 904
 high risk conditions for, 716–717, 718b
 low-density lipoprotein-lowering therapies for, 718, 719t
 in metabolic syndrome, 716, 717b, 720, 720t
 in nephrotic syndrome, 285–287, 720, 721f
 in progressive renal failure, 700f, 707–708
 with renal artery stenosis, 654, 656
 after renal transplantation, 722
 risk assessment for, 716, 716b, 717b
 target of therapy for, 715, 716t
 therapeutic lifestyle changes for, 716t, 718, 718b
 due to thiazide diuretics and β -blockers, 593
 Dysnatremias. *See also* Hyponatremia; Hyponatremia.
 during hemodialysis, 903
 Dysproteinemias, 461–466, 462t
 Dysuria, 449
- E
 E2F decoy, in glomerulonephritis and renal fibrosis, 560–561
 Early growth response gene 1 (*egr-1*), in glomerulosclerosis and interstitial fibrosis, 560
 Ebastine, in renal failure, 1064t
 EBCT (empty bed contact time), for hemodialysis, 853
 EBV (Epstein-Barr virus), posttransplantation, 1037 and malignancies, 1019
 ECF (extracellular fluid), potassium ions in, 353–354, 354f
 ECF (extracellular fluid) volume depletion, due to diuretics, 398
 Echinocandins, for posttransplant infections, 1042t
 Eclampsia
 management of, 484f, 630f, 632
 postpartum, 484
 EC-MPS (mycophenolate sodium, enteric-coated), for renal transplantation, 979f, 981t, 984, 1020
 Economics, of end-stage renal disease, 836–841
 for hemodialysis, 837–838, 838t, 839t
 Medicare spending in, 836, 837, 837f
 methodologies for evaluating, 836–837, 837t
 for peritoneal dialysis, 839
 for transplantation, 839–840, 840t, 841t
 for vascular access, 838–839
 Eculizumab, for membranoproliferative glomerulonephritis, 253f
 ED. *See* Erectile dysfunction (ED) in chronic kidney disease.
 EDD (extended daily dialysis), 58, 59, 61t, 78
 EDDf (extended daily dialysis with filtration), 78
 Edema
 cerebral, due to hyponatremia, 338–339, 339b
 cyclic, diuretic resistance due to, 400t
 diuretics for (*See* Diuretic[s])
 genital, due to peritoneal dialysis, 932
 idiopathic, 398
 leg, after renal transplantation, 974–975
 in nephrotic syndrome, 284–285, 395–396
 in pregnancy, 479
 pulmonary, hypertension with, 630f, 631, 631t
 Edmonton Symptom Assessment System, 829, 830f
 EFA (essential fatty acid) deficiency, 116–117
 Efalizumab, for renal transplantation, 986
 Effector mechanisms, in immune system, 977–978
 Effexor (venlafaxine), in renal failure, 801t, 1072t
 for anxiety disorders, 811
 for depression, 812
egr-1 (early growth response gene 1), in glomerulosclerosis and interstitial fibrosis, 560
 EHEC (enterohemorrhagic *E. coli*), hemolytic-uremic syndrome due to, 509, 510
 Eicosanoids, production of, 114–115, 115f
 Eicosapentaenoic acid (EPA), 113, 113f, 114–116, 115f
 EKR (equivalent continuous clearance), 884
 EKRjc (equivalent renal urea clearance), 67
 Elavil (amitriptyline), in renal failure, 799t
 for pain management, 833t
 Elderly
 anti-GBM antibody disease in, 201
 hyponatremia in, 347
 hypernatremic dehydration in, 8
 hypertension in, 572, 572f
 diuretics and β -blockers for, 594
 hypertensive emergencies in, 625
 Electroconvulsive therapy, for depression in end-stage renal disease, 812–813
 Electrohydraulic lithotripsy, 437
 Electrolyte(s)
 in acute renal failure, 84
 in continuous renal replacement therapy, 76
 in parenteral nutrition for acute renal failure, 88t
 in peritoneal dialysis fluids, 916, 916t
 Electrolyte disturbances, in acute renal failure, 8–9
 Elimination, enhanced, for poisoning, 1074–1075
 E-mail, security of, 1087
 Embolic protection devices, with renal artery stent, 664, 665
 Embolism
 air, during hemodialysis, 845, 899
 pulmonary, with idiopathic membranous nephropathy, 241
 Emedastine, in renal failure, 1064t
 Emetics, for poisoning, 1074
 Empty bed contact time (EBCT), for hemodialysis, 853

- Emtricitabine, in renal failure, 1069t
 ENaC(s) (epithelial Na⁺ channels), 354, 355
 ENaC (epithelial Na⁺ channel) blockers, for hypokalemia, 359
- Enalapril
 cardiovascular effects of, 612, 613
 with dialysis, 686t, 1062t
 for hypertension in children, 514t
 for IgA nephropathy, 181t
 pharmacology of, 602t
 for renal artery stenosis, 650, 650f
 in renal failure, 606, 1070t
 renal protective effects of, 614
 with renal transplantation, 616
- Enalaprilat
 for hypertensive urgencies, 627t
 for renal artery stenosis, 649
- Encapsulating peritoneal sclerosis, 924
- Encephalopathy, hypertensive, 624–625
 treatment of, 630, 630f, 631t
- Encryption, 1087
- Eндартectomy vs. Angioplasty in Patient with Symptomatic Severe Carotid Stenosis (EVA-3S) study, 1017
- EndNote, 1084
- Endocarditis, infective, glomerulonephritis due to, 140, 142t, 143–144
- Endocrine disorders
 in chronic kidney disease, erectile dysfunction due to, 784, 784b
 due to end-stage renal disease, in childhood and adolescence, 523–524
- End-of-life care, 828–835
 background of, 828
 integration of, 832–834, 834f
 for other symptoms, 829, 833t–834t
 for pain management, 829, 831b
 adjuvant medications in, 833t
 analgesic ladder of, 829, 831f, 832b, 832t
 assessment for, 831b
 opioids in, 829, 831b, 831f, 832b, 832t
 psychosocial issues with, 831b
 principles of good death in, 834, 834b
 symptom assessment for, 829, 830f
 symptom prevalence and impact for, 828–829
 symptoms of end of life in, 834, 835t
 withholding and withdrawing dialysis in, 828–832, 948–953, 949b
- Endopeptidase inhibitors, for edema, 403
- Endothelial dysfunction, in end-stage renal disease, 682
- Endothelin type A (ET_A) receptor antagonists, for prevention of progressive renal failure, 709
- Endotoxins, in dialysate, 902
- Endovascular stents, 664–673
 complications of, 660–661, 670–671, 671b, 671f
 demographics of, 660, 661f
 embolic protection devices with, 664, 665
 goals of, 660, 664
 outcomes of, 666–670, 666f, 667t–669t, 670f
 techniques of, 664–665
- End-stage renal disease (ESRD). *See also* Chronic kidney disease (CKD); Dialysis; Uremia.
 amyloidosis-associated, 263–264
 anorexia in, 834t
 antioxidant therapy for, 731–734, 732t, 733t
 cardiovascular complications of, 773–779
 anemia as, 777
 blood pressure control for, 774–776, 775t
 coronary artery disease as, 778–779
 dialysis for, 778
 dyslipidemia as, 776–777
 healthy lifestyle for, 773–774
 heart failure as, 779
 hyperparathyroidism as, 777–778
 risk factors for, 773, 774t
 sudden death as, 779
 treatment goals for, 773, 774t
 in childhood and adolescence, 522–531
 anemia due to, 525
 cardiovascular disease due to, 525
 dialysis for, 526–528
 endocrine disorders due to, 523–524
 growth retardation due to, 523–524
 hypertension due to, 525
 mortality due to, 526
- End-stage renal disease (ESRD) (*Continued*)
 neurodevelopmental outcome for, 525–526
 nutrition for, 522–523, 523t
 primary diagnoses for, 522, 523t
 psychosocial adjustment for, 526
 quality of life for, 526
 renal osteodystrophy due to, 524–525
 renal transplantation for, 522, 528–531, 529b, 529t
- cramps in, 833t
 diabetic patient with, 329–330
 economics of, 836–841
 for hemodialysis, 837–838, 838t, 839t
 Medicare spending in, 836, 837, 837f
 methodologies for evaluating, 836–837, 837t
 for peritoneal dialysis, 839
 for transplantation, 839–840, 840t, 841t
 for vascular access, 838–839
- hepatitis B virus in, 275–276
 HIV in, 277
 hyperhomocysteinemia in, 725–728, 726f–728f
 hypertension in, 680–689
 calcium channel blockers for, 616
 in childhood and adolescence, 525
 epidemiology of, 680–681, 681f
 monitoring of, 680
 pathophysiology of, 681–683, 682f
 treatment of, 683–689
 ACE inhibitors for, 686–687, 686t
 adrenergic blocking agents for, 687–688, 688t
 algorithm for, 688f, 689
 angiotensin II receptor blockers for, 687, 687t
 β-blockers for, 684–686, 685t
 calcium channel blockers for, 684, 684t
 centrally acting drugs for, 687, 687t
 diuretics for, 683–684
 goals of, 683
 nonpharmacologic, 683
 nonspecific vasodilators for, 688–689, 688t
- hypotension in, 834t
 lethargy and fatigue in, 834t
 in living kidney donor, 963–964
 due to lupus nephritis, 167
- neuropsychiatric disorder(s) in, 795–814
 adjustment disorders as, 810–811
 algorithm for treatment of, 796f, 814
 anxiety disorders as, 811
 delirium as, 797b, 810
 dementia as, 810
 depression and manic depression as, 811–813
 drugs used to treat, 798t–808t
 analgesics as, 808t
 anticonvulsants as, 806t–807t, 809
 antidepressants as, 798t–801t
 antimanic agents as, 802t
 antiparkinsonian agents as, 808t
 antipsychotics as, 802t–804t
 anxiolytics/hypnotics as, 804t–806t
 etiology of, 797b
 insomnia as, 809–810
 peripheral neuropathies as, 797
 schizophrenia/psychotic disorders as, 813
 seizures as, 797–809
 sexual disorders as, 813–814
- pain in, 828
 management of, 829, 831b
 adjuvant medications in, 833t
 analgesic ladder of, 829, 831f, 832b, 832t
 assessment for, 831b
 opioids in, 829, 831b, 831f, 832b, 832t
 psychosocial issues with, 831b
- palliative and supportive care in, 828–835

transplant-associated, 1013–1014
- Hyperhomocysteinemia, in chronic kidney disease, 725–728, 726f–728f
- Hyperkalemia, 361–366
in acute renal failure, 8–9
due to Addison's disease, 365
causes of, 361f
cyclosporine-induced, 365
during hemodialysis, 903
due to hyporeninemic hypoaldosteronism, 365
with low K⁺ concentration in cortical collecting duct, 355
pentamidine-induced, 365
in renal tubular acidosis, 377
due to renin system blockade, 606
due to spironolactone, 607
treatment of, 361–366
general considerations for, 361–365
in medical emergencies, 361–363, 362f
with no medical emergency, 362f, 364–365
trimethoprim-induced, 365
- Hyperlipidemia
as cardiovascular risk factor
in chronic kidney disease, 715–717, 716t
in hypertension, 635–638, 636b, 636f, 637t
- Hyperlipidemia (*Continued*)
in childhood and adolescence, 525
with chronic kidney disease, 715–722, 776–777
atherogenic, 715, 717b, 718–720
not requiring dialysis, 721–722
and primary nephrotic syndrome, 720, 721f
requiring dialysis, 722
in diabetic nephropathy, 720–721
due to diuretics, 399
high-risk conditions for, 716–717, 718b
low-density lipoprotein-lowering therapies for, 718, 719t
in metabolic syndrome, 716, 717b, 720, 720t
in nephrotic syndrome, 285–287, 720, 721f
with peritoneal dialysis, 934
posttransplantation, 722, 1011–1012, 1012t, 1013t
with renal artery stenosis, 654, 656
risk assessment for, 716, 716b, 717b
target of therapy for, 715, 716t
therapeutic lifestyle changes for, 716t, 718, 718b
due to thiazide diuretics and β -blockers, 593
- Hyperlipoproteinemia, in nephrotic syndrome, 285
- Hypermagnesemia, 422, 422f
- Hypernatremia, 347–351
in acute renal failure, 8
cerebral response to, 347
clinical presentation of, 349
defined, 347
in diabetes mellitus, 347–348
in elderly, 347
epidemiology of, 347
euvolemic, 348f, 349–350, 350t
during hemodialysis, 903
in hospitalized patients, 347–348, 347b
hypervolemic, 348f, 351
hypovolemic, 348f, 350
polyuria in, 347–348
prevention of, 347–348, 347b
treatment of, 348–351, 348f, 349b
for euvolemic disease, 348f, 349–350, 350t
for hypervolemic disease, 348f, 351
for hypovolemic disease, 348f, 350
- Hyperparathyroidism (HPT)
in chronic kidney disease, 765–766, 766f, 777–778
in childhood and adolescence, 524
erectile dysfunction due to, 784, 787
in nephrotic syndrome, 287
posttransplantation, 770, 1023–1024
primary, 412–414
secondary, 420
- Hyperphosphatemia, 419–420, 419f
in chronic kidney disease, 766–768, 767t, 778
in childhood and adolescence, 524
with hypocalcemia, 417
pseudo-, 419
- Hyperprolactinemia, in chronic kidney disease, erectile dysfunction due to, 784, 786–787
- Hypertension
accelerated, 624
treatment of, 629–630, 631t
ACE inhibitors and angiotensin receptor blockers for, 601–606
with dialysis, 686–688, 686t–688t
guidelines for selection of, 621t
history of, 601
and natural history of renal injury, 605
and nephropathy, 605–606
optimization of use of, 607–608
pharmacology of, 602–603, 602t, 603t
renal actions of, 604–605
with renal failure, 606
with renal transplantation, 677
due to activation of mineralocorticoid receptors, 693
acupuncture for, 578
with adrenergic crisis, 630f, 631t, 632
due to adrenocortical disorders, 691–693, 692f, 692t
aldosterone antagonists for, 607, 622
due to aldosteronism
glucocorticoid-remediable, 693
primary, 691–693, 692f, 692t
allograft dysfunction due to, 1001t
and autosomal dominant polycystic kidney disease, 541–542
 α -blockers for
in children, 514t
guidelines for selection of, 621t

Hypertension (*Continued*)

- αβ-blockers for, in children, 514t
- calcium channel blockers for, 610–617
 - with dialysis, 684, 684t
 - efficacy of, 610–612
 - in end-stage renal disease, 616
 - guidelines for selection of, 621t
 - pharmacology of, 610, 611t
 - and prevention of cardiovascular morbidity and mortality, 612–613, 612t
 - and prevention of progression of chronic kidney disease, 613–615, 615t
 - with renal transplantation, 616, 677
 - safety of, 616–617
- cardiovascular risk factor(s) in, 635–641, 636b
 - C-reactive protein as, 640–641, 640f
 - diabetes as, 636f, 636t, 639
 - dyslipidemias as, 635–638, 636b, 636f, 637t
 - emerging, 640–641, 640f, 641f
 - homocysteine as, 640, 640f
 - lipoprotein (a) as, 640, 640f
 - smoking as, 636f, 636t, 638–639
- cardiovascular risk in, 567, 568, 568t, 635–641
 - estimate of, 635, 636f
 - reduction of, 639–640
- due to cerebrovascular accident, 630, 630f, 631t, 632t
- in children, 511–513
 - causes of, 512, 512t
 - defined, 511–512
 - diagnosis of, 513
 - epidemiology of, 511–512
 - risk factors for, 512–513, 512b
 - screening for, 512–513, 512b
 - therapy for, 513, 514t, 515t
- complementary and alternative medicine for, 578
- with coronary ischemia, 631, 631t
- decisions for management of, 567–572
 - defined, 567–568
- due to 11-deoxycorticosterone excess, 691
- diabetes and, 571t, 636b, 636f, 639
- with dialysis, 680–689
 - epidemiology of, 680–681, 681f
 - monitoring of, 680
 - pathophysiology of, 681–683, 682f
 - treatment of, 683–689
 - ACE inhibitors for, 686, 686t
 - adrenergic blocking agents for, 687–688, 688t
 - algorithm for, 688f, 689
 - angiotensin II receptor blockers for, 687, 687t
 - β-blockers for, 684–686, 685t
 - calcium channel blockers for, 684, 684t
 - centrally acting drugs for, 687, 687t
 - diuretics for, 683–684
 - goals of, 683
 - nonpharmacologic, 683
 - nonspecific vasodilators for, 688–689, 688t
 - vasodilators for, 688–689, 688t
- dietary intervention(s) for, 569
 - alcohol restriction, 576t, 577
 - and cardiovascular risk reduction, 639–640
 - cocoa restriction, 576t, 577
 - coffee restriction, 576t, 577
 - DASH diet, 575, 576t, 578–579, 579t, 580
 - effects of, 576t
 - individual micro- and macronutrients in, 576–577, 576t
 - OMNI-Heart trial of, 575–576
 - with other nonpharmacologic interventions, 578–580
 - PREMIER study of, 578–579
 - recommendations, 579t, 580
 - sodium restriction, 569, 583–588
 - algorithm for, 587–588, 588f
 - assessment for, 586
 - in DASH diet, 585–586
 - definitions for, 583
 - dietary patterns and, 585
 - effect of, 576t, 577, 583–584
 - in established disease, 587, 587b
 - practical advice on, 587, 587b
 - as prevention, 586–587
 - public health strategies for, 584–585
 - TONE study of, 579–580
- direct renin inhibitor for, 603–604

Hypertension (*Continued*)

- with dissecting aortic aneurysm, 630f, 631–632, 631t
- diuretics and β-blockers for, 591–597
 - adverse effects of, 592–594
 - algorithm for, 596, 597f
 - in black patients, 594
 - with cardiovascular disease, 595
 - with chronic kidney disease, 595–596
 - with COPD and bronchospasm, 594
 - in developing countries, 596
 - with dialysis, 684–686, 685t
 - dosage of, 596, 597t
 - in elderly, 594
 - guidelines for selection of, 621t, 622
 - with heart failure, 595
 - with left ventricular hypertrophy, 595
 - randomized trials of, 591–592
 - with renal transplantation, 677
 - in specific patient groups, 594–596
- in elderly, 572, 572f
 - diuretics and β-blockers for, 594
- in end-stage renal disease, 680–689
 - in childhood and adolescence, 525
 - epidemiology of, 680–681, 681f
 - monitoring of, 680
 - pathophysiology of, 681–683, 682f
 - treatment of, 683–689
 - ACE inhibitors for, 686–687, 686t
 - adrenergic blocking agents for, 687–688, 688t
 - algorithm for, 688f, 689
 - angiotensin II receptor blockers for, 687, 687t
 - β-blockers for, 684–686, 685t
 - calcium channel blockers for, 684, 684t
 - centrally acting drugs for, 687, 687t
 - diuretics for, 683–684
 - goals of, 683
 - nonpharmacologic, 683
 - nonspecific vasodilators for, 688–689, 688t
- due to erythropoiesis-stimulating agents, 752
- exercise for, 576t, 577–578, 639–640
- goals for treatment of, 570–572, 571t
- guidelines for diagnosis and treatment of, 570–571, 571t
- guidelines for selecting drug treatment of, 620–622, 621f, 621t
 - due to hemolytic-uremic syndrome, 510
 - and IgA nephropathy, 179, 181t
 - individualization of pharmacologic therapy for, 620–622, 621f, 621t
 - inflammation and, 118f, 119–120
 - intradialytic, 898
 - isolated systolic, 571t
 - with left ventricular failure, 631, 631t
 - lifestyle interventions for, 569, 575–580
 - in living kidney donor, 965
 - malignant, 624
 - thrombotic microangiopathy in, 301
 - treatment of, 629–630, 631t
 - measurement of, 568–569
 - with myocardial infarction, 630f, 631, 631t
 - nonpharmacologic treatment of, 575–580
 - due to pheochromocytoma, 693–694, 694b
 - postoperative (perioperative), 630f, 631t, 632
 - pre-, 569–570, 570f, 571t
 - in pregnancy, 479–485
 - chronic, 480–481, 480t, 481f, 482t
 - classification of, 479, 480t
 - defined, 479
 - diuretics and β-blockers for, 595
 - gestational, 479, 480t
 - and postpartum contraception, 485
 - due to preeclampsia and eclampsia, 480t, 481–485, 482b, 483f, 484f
 - with preexisting renal disease, 488
 - transient, 480t
 - prevention of, lifestyle modifications for, 586–587
 - pulmonary, after arteriovenous shunt placement, 867
 - with pulmonary edema, 630f, 631, 631t
 - due to renal artery stenosis, 647, 651–653, 651t, 653f, 656f
 - with renal failure, 631t, 632–633
 - as renal risk factor, 567, 568t
 - after renal transplantation, 675–678
 - causes of, 675–677, 676b
 - clinical features of, 675

Hypertension (*Continued*)

- refractory, 678
- treatment of, 676f, 677
 - ACE inhibitors and angiotensin receptor blockers for, 677
 - calcium channel blockers for, 616, 677
 - diuretics for, 677
- renin in, 588
- renovascular, 647, 660–673
 - demographics of, 661
 - diagnostic considerations in, 663–664, 663f
 - renal angioplasty and stenting for, 664–673
 - complications of, 660–661, 670–671, 671b, 671f
 - demographics of, 660, 661f
 - embolic protection devices with, 664, 665
 - goals of, 660, 664
 - vs. medical therapy, 648, 652, 653–654
 - outcomes of, 666–670, 666f, 667t–669t, 670f
 - patient selection for, 671–673
 - restenosis after, 671, 671f
 - techniques of, 664–665
 - risks of progression of, 661–663, 662f
 - severe, 631t, 633
 - natural history of, 624–625
 - smoking cessation for, 576t, 578
 - stress reduction for, 578
 - subarachnoid hemorrhage due to, 630–631, 631t
 - tai chi for, 576t, 578
 - weight loss for, 576t, 577, 587, 639–640
- Hypertension Optimal Treatment (HOT) trial, 577, 613, 639
- Hypertensive crisis(es), 624–633
 - algorithm for treatment of, 630f
 - in children, 513, 515t
 - nature of, 624–625, 625b
 - in preeclampsia, 630f, 631t, 632
 - treatment of, 625–633
 - drugs for, 626–629, 627t–628t, 630t
 - general considerations in, 625–626
 - for specific conditions, 629–633, 631t, 632t
- Hypertensive emergencies, 624–633
 - in children, 513, 515t
 - nature of, 624–625, 625b
 - treatment of, 625–633
 - drugs for, 626–629, 627t–628t
 - general considerations in, 625–626
 - for specific conditions, 629–633, 631t, 632t
- Hypertensive encephalopathy, 624–625
 - treatment of, 630, 630f, 631t
- Hypertensive urgencies
 - drugs for, 629, 630f
 - nature of, 624, 625b
- Hypertonic saline
 - for hyponatremia, 341
 - for volume replacement, 6
- Hypertriglyceridemia
 - during hemodialysis, 904
 - posttransplantation, 1011, 1012
- Hyperuricemia
 - due to diuretics, 399
 - posttransplantation, 1024–1025, 1025b
 - due to thiazide diuretics, 593
- Hyperventilation
 - hypophosphatemia due to, 421
 - respiratory alkalosis due to, 385, 386, 386t
- Hyperviscosity syndrome, 466
- Hypnotics
 - in end-stage renal disease, 804t–806t
 - in renal failure, 1054t, 1055t–1056t, 1064t
- Hypoalbuminemia
 - during hemodialysis, 904
 - and malnutrition, 736–737, 738
 - in nephrotic syndrome, 281–284
- Hypoadosteronism
 - hyporeninemic
 - hyperkalemia due to, 364
 - renal tubular acidosis due to, 377
 - pseudo-
 - classic, 548
 - type 2, 553
- Hypocalcemia, 416–418, 416f, 417f
 - during hemodialysis, 903
 - in nephrotic syndrome, 287
- Hypocapnea, respiratory alkalosis due to, 385
- Hypoglycemic agents, in renal failure, 1062t, 1072t

- Hypokalemia, 356–361
 in apparent mineralocorticoid excess, 360t, 361
 in Bartter syndrome, 360, 360t
 causes of, 356b, 357f, 359–361, 360t
 diuretic-induced, 359, 360t, 398–399, 592
 in Gitelman's syndrome, 360, 360t
 in glucocorticoid-remediable aldosteronism, 360–361, 360t
 during hemodialysis, 903
 in Liddle syndrome, 360t, 361
 in primary hyperaldosteronism, 359–360, 360t
 treatment of, 356–361
 initial approach to, 356f
 K⁺ preparations for, 358–359, 359t
 K⁺-sparing diuretics for, 359
 magnitude of K⁺ deficit and, 358
 in medical emergencies, 356–357
 without medical emergency, 357–358, 357f, 358f
 risks of, 359
 route of K⁺ administration for, 358
 specific issues with K⁺ replacement therapy for, 358–359
- Hypokalemic periodic paralysis, 357–358
- Hypomagnesemia, 423, 423f, 550
 during hemodialysis, 904
 with hypocalcemia, 417
 posttransplantation, 1026
- Hypomagnesemic tetany, 550
- Hyponatremia, 338–347
 asymptomatic euvolemic, 345–346, 346t
 cerebral adaptations to, 338
 in children, 339
 due to diuretics, 339, 399
 euvolemic, 345–346, 346t
 during hemodialysis, 903
 hospital-acquired, in premenopausal women, 339
 hypertonic, 337
 hypervolemic, 346–347, 347b
 hypotonic, 338
 hypovolemic, 346, 347b
 hypoxia and, 338–339
 neurological complication(s) of, 338–339
 cerebral edema as, 338–339, 339b
 osmotic demyelination as, 338, 339, 339b
 risk factors for, 338, 339b
 polydipsia and, 339
 symptomatic
 acute, 340–342, 340f, 341b
 chronic, 340f, 342–345, 343t
 translocational, 337
 treatment of, 339–347
 for acute symptomatic disease, 340–342, 340f, 341b
 for asymptomatic euvolemic disease, 345–346, 346t
 for chronic symptomatic disease, 340f, 342–345, 343t
 for hypervolemic disease, 346–347, 347b
 for hypovolemic disease, 346, 347b
- Hypoparathyroidism, hypocalcemia due to, 418
- Hypophosphatemia, 420–422, 420f, 421t
 in alcoholic ketoacidosis, 372
 in diabetic ketoacidosis, 371–372
 during hemodialysis, 903–904
 posttransplantation, 1026
- Hypophosphatemic nonrachitic bone disease, 549t, 550
- Hypophosphatemic osteomalacia, adult sporadic, 549t
- Hypophosphatemic rickets
 autosomal dominant, 549t, 550
 hereditary, with hypercalciuria, 549t, 550
 primary or X-linked, 548–550, 549t
- Hypopnea, 791
- Hyporeninemic hypoaldosteronism
 hyperkalemia due to, 364
 renal tubular acidosis due to, 377
- Hypotension

 for systemic vasculitis, 191
- Immunoglobulin(s) (Igs), 977
 intravenous (*See* Intravenous immunoglobulin [IVIg])
 pooled human, for IgA nephropathy, 178
 for thrombotic microangiopathy, 306t
- Immunoglobulin A (IgA), decreasing production of, 174
- Immunoglobulin A (IgA) deposition
 alteration of immune and inflammatory events that follow, 174–182
 prevention and removal of, 174
- Immunoglobulin A (IgA) nephritis, crescentic, rapidly progressive renal failure due to, 174
- Immunoglobulin A (IgA) nephropathy (IgAN), 172–184, 506–507
 alteration of immune and inflammatory events that follow IgA deposition in, 174–182
 in children, 506–507
 clinical features of, 172, 506
- Immunoglobulin A (*Continued*)
 disease mechanisms in, 172–173
 hypertension in, 179, 181t
 nephrotic syndrome in, 178
 predicting risk of progression of, 179
 slowly progressive, 178–179
 after transplantation, 182
 treatment of, 173–182, 506–507
 ACE inhibitors for, 179, 181t
 angiotensin receptor antagonists for, 179, 181t, 507
 antiplatelet agents for, 179, 180t, 507
 approaches to, 173–174
 azathioprine for, 175, 177t, 507
 corticosteroids for, 174–175, 176t, 507
 cyclophosphamide for, 175, 177t
 cyclosporine for, 175, 177t
 decreasing IgA production in, 174
 endpoints for, 173
 fish oil for, 179, 182t, 507
 future directions for, 184
 HMG-CoA reductase inhibitors for, 182
 leflunomide for, 175, 177t
 mizoribine for, 178
 mycophenolate mofetil for, 175–178, 178t
 with nephrotic syndrome, 178
 phenytoin for, 174
 plasmapheresis for, 132
 pooled human immunoglobulin for, 178
 prevention and removal of IgA deposits in, 174
 recommendations on, 183, 183f
 with slowly progressive disease, 178–179
 study design on, 173–174
 tonsillectomy for, 174, 507
- Immunoglobulin light-chain metabolism, and renal lesions, 461–462, 462t
- Immunologic agents, in renal failure, 1063t
- Immunology, transplant, 976–978
 alloimmunity in
 cellular, 977
 humoral, 977
 clinical application of, 978–979
 components of immune system in, 976–977
 crossmatch methods in, 978–979
 detection of anti-HLA antibodies in, 978
 effector mechanisms in, 977–978
 recognition of alloantigen in, 977
 tissue-typing techniques in, 978
- Immunomodulatory effects, of continuous renal replacement therapy, 76–77
- Immunopharmacology, for poisoning, 1079
- Immunosuppressive medication(s), 979–989, 980t–981t
 for acute interstitial nephritis, 314–318, 317f, 318t
 for acute kidney injury, 96
 adjuvant agents as, 981t, 984–985, 988
 for anti-GBM antibody disease, 199, 199t, 200, 201–202, 201t
 antimetabolites as, 981t, 984–985
 calcineurin inhibitors as, 980t–981t, 983, 987–988
 withdrawal from, 989
 in childhood and adolescence, 530
 cost of, 840
 drug interactions of, 985, 986b, 1034, 1035t
 for focal segmental glomerulosclerosis, 227–229, 233
 for glomerular and tubulointerstitial disease, 105–109
 glucocorticoids as, 981t, 985
 withdrawal from, 989
 for idiopathic membranous nephropathy, 241–245, 243b, 244b
 for IgA nephropathy, 174–178, 507
 in induction treatment, 979–983, 980t–981t, 988–989
 intravenous immunoglobulins as, 985–986
 for lupus nephritis, 157–168
 mechanisms of action of, 979f, 980t–981t
 monoclonal lymphocyte-depleting antibodies as, 980t, 982
 monoclonal nondepleting antibodies as, 983
 new, 986–987
 polyclonal lymphocyte-depleting antibodies as, 979–982, 980t
 posttransplant hypertension due to, 675–677
 protocols for, 987, 987t
 and sensitization, 989–990
 for systemic vasculitis, 189–193, 191t, 193t, 194t
 target of rapamycin inhibitors as, 984–985
 for thrombotic microangiopathy, 306t

- Immunotactoid glomerulopathy, 258t, 268–269
 Impotence, due to diuretics, 399
 Imuran. *See* Azathioprine.
 In vitro models, of acute kidney injury, 93
 In vivo models, of acute kidney injury, 92–93
 Incompetent patient, withholding or withdrawal of dialysis for, 948–950, 949b
 Incremental Decrease in End Points Through Aggressive Lipid Lowering (IDEAL) trial, 637t
 Indapamide
 dosage of, 390t
 pharmacokinetics of, 392t
 Individualized therapy, for hypertension, 620–622, 621f, 621t
 Indobufen, in renal failure, 1065t
 Indomethacin (Indocin)
 in end-stage renal disease, 808t
 for nephrotic syndrome, 283
 Induction treatment, for renal transplantation, 979–983, 980t–981t, 988–989
 Indwelling catheters, 473
 and UTIs, 449
 Infant(s), ureteral stones in, 442
 Infantile nephropathic cystinosis, 551
 Infection(s)
 due to dialysate fluid, 853–854, 854b
 exit-site
 with hemodialysis vascular access, 868
 with peritoneal dialysis, 928–929, 929t
 due to hemodialysis vascular access, 860, 866, 868
 in nephrotic syndrome, 288
 with peritoneal dialysis, 924–929
 exit-site and tunnel, 928–929, 929t
 peritonitis as, 924–928, 925f–928f
 posttransplantation, 1034–1044
 bacterial urinary tract, 1041–1043
 in childhood and adolescence, 530
 drug interactions in treatment of, 1034, 1035t
 epidemiology of, 1034
 fungal, 1041, 1042t
 with human immunodeficiency virus, 1043–1044
 with *Pneumocystis jiroveci*, 1041
 timeline for, 1034, 1036f
 with tuberculosis and nontuberculous mycobacteria, 1043
 viral, 1035–1041
 wound, 972–973
 renal transplantation with
 in living donor, 963b, 965
 in recipient, 958b, 960
 urinary tract (*See* Urinary tract infection[s] [UTIs])
 Infection-associated glomerulonephritis, 140–149
 bacterial, 142–145, 142t
 diagnosis and management of, 141, 148–149, 149f
 fungal, 146
 future directions for, 147–148
 parasitic, 146–147
 pathogenesis of, 141
 prognosis for, 141, 147–148
 recent developments in, 140–142, 142t
 ricketsial, 146
 viral, 145–146
 Infection-related acute interstitial nephritis, 313–314
 Infective endocarditis, glomerulonephritis due to, 140, 142t, 143–144
 Inferior vena cava, renal cancer involving, 458
 Inflammation
 acute, 112
 in acute kidney injury, 93–94
 chronic, 112
 defined, 112
 fatty acids and, 113–117, 113f–115f
 and hypertension, 118f, 119–120
 and malnutrition, 736–737
 tissue phenomena in, 112
 vitamins, 117–118
 Inflammatory reactions, defined, 112
 Inflammatory response, dietary modulation of, 112–120
 Inflammatory state, obesity as, 118–119, 118f
 Infliximab
 for focal segmental glomerulosclerosis, 230t
 for systemic vasculitis, 190, 191
 Influenza, posttransplantation, 1038–1039
 Information sites, online, 1089t
 Informed consent, for dialysis, 948, 949b
 Infrarenal aortic clamping, acute renal failure due to, 16t–17t
 Inherited renal disease
 aminoacidurias as, 547–548
 autosomal dominant polycystic kidney disease as, 539–544
 defined, 539
 epidemiology of, 539
 extrarenal manifestations of, 539–541, 540t
 kidney pain in, 542, 543t
 management of complications of, 540t
 renal manifestations of, 540t, 541–542
 slowing of progression of, 544
 Bartter syndrome as, 552–553, 552t
 chloride shunt (Gordon's) syndrome as, 553
 Fabry's disease as, 554–555, 554t
 familial Mediterranean fever as, 553–554, 554t
 Fanconi syndrome as, 550–552, 551t
 gene therapy for, 557–562
 glycosurias as, 548
 Liddle syndrome as, 553
 magnesiumurias as, 550
 phosphaturias as, 548–550, 549t
 pseudohypoaldosteronism as, 548
 Initiating Dialysis Early and Late (IDEAL) Study, 877
 Innate immune system, 977
 Inorganic phosphates, for hypercalcemia, 416
 Inotropic agents, for edema, 403–404
 INSIGHT (Intervention as a Goal in Hypertension Treatment) trial, 612, 612t
 Insomnia, in end-stage renal disease, 809–810
 Instantaneous cross-dialyzer clearance (K_d), 878
 Insulin
 for diabetic ketoacidosis, 371
 for hyperkalemia, 361–362
 in parenteral nutrition for acute renal failure, 88t
 Insulin resistance
 in acute renal failure, 82, 83
 and malnutrition, 737
 due to thiazide diuretics and β -blockers, 593
 Insulin-like growth factor, in renal failure, 1055t
 Intercompartmental mass transfer coefficient (K_c), 880–881
 Interferon (IFN) therapy, for renal cell carcinoma, 458
 Interferon- α (IFN- α)
 for familial Mediterranean fever, 554t
 for HBV-associated renal disease, 273, 274–275, 274t
 for HCV-associated membranoproliferative glomerulonephritis, 152–153, 153t, 154, 154t
 for posttransplant hepatitis C, 1040
 thrombotic microangiopathy due to, 302
 Interferon- γ (IFN- γ), for focal segmental glomerulosclerosis, 230t
 Interleukin-2 (IL-2), for renal cell carcinoma, 458–459, 560
 Interleukin-7 (IL-7), for renal cell carcinoma, 560
 Intermittent centrifugation, for plasmapheresis, 126
 Intermittent hemodiafiltration (IHF), 59
 Intermittent hemodialysis (IHD)
 for acute kidney injury, 60–61
 advantages and disadvantages of, 58
 anticoagulants with, 63, 64t–65t
 complications of, 66–67
 continuous vs., 59, 76–78
 defined, 58
 for drug/toxin removal, 61, 62t
 vs. hybrid therapies, 59, 61t
 metabolic impact of, 84b
 prescription for, 60–61
 sorbent system, 58–59
 Intermittent ultrafiltration, 59
 Internal jugular catheter, for hemodialysis, 62
 International Verapamil-Trandolapril Study (INVEST), 595, 612t, 613
 Internet, 1083–1087
 defined, 1083
 government organizations on, 1090t
 information sites on, 1089t
 integrating word processor and, 1083–1084
 Physician Quality Reporting Initiative on, 1087, 1088f
 renal organizations on, 1089t
 security of, 1087
 tools for nephrologists on, 1085–1087
 Interstitial fibrosis (IF), gene therapy for, 560–561
 Interstitial fibrosis/tubular atrophy (IF/TA), allograft dysfunction due to, 1000–1003, 1001t, 1002b
 Interstitial nephritis, acute. *See* Acute interstitial nephritis (AIN).
 Intervention as a Goal in Hypertension Treatment (INSIGHT) trial, 612, 612t
 Intra-access pressure (IAP), 864–866, 865b
 Intracavernosal injection therapy, for erectile dysfunction, 788
 Intracellular fluid (ICF), potassium ions in, 353–354, 354f
 Intracorporeal lithotripsy, 437–438
 Intracranial aneurysms (ICAs), and autosomal dominant polycystic kidney disease, 540–541
 Intracranial hemorrhage, due to hypertension, 630–631, 631t
 Intradialytic hypertension, 898
 Intradialytic hypotension (IDH), 896–898
 Intratubular obstruction, in acute kidney injury, 94
 Intravenous immunoglobulin (IVIG)
 for BK virus nephropathy, 1041
 for glomerular and tubulointerstitial disease, 109
 for lupus nephritis, 164b
 posttransplantation
 for cytomegalovirus, 1037
 for respiratory syncytial virus, 1039
 for renal transplantation, 985–986
 for systemic vasculitis, 190
 Intrinsic clearance, of dialyzer, 878
 INVEST (International Verapamil-Trandolapril Study), 595, 612t, 613
 Ionic dialysance (Dt/V), 882
 Irbesartan
 cardiovascular effects of, 613
 for diabetic nephropathy, 326, 327, 328f
 with dialysis, 687t, 1061t
 high-dose, 607
 for IgA nephropathy, 181t
 pharmacology of, 603, 603t
 renal actions of, 604
 renoprotective effect of, 605, 614, 615t, 704
 Irbesartan Diabetic Nephropathy Trial (IDNT), 326, 327, 328, 612t, 613, 704
 Iron deficiency
 in chronic kidney disease, 752–753, 753f, 753t, 758–759
 functional, 758
 Iron dextran
 for chronic kidney disease, 752, 753t, 758
 dialysis reactions due to, 896
 Iron sucrose, for chronic kidney disease, 752, 753t, 758
 Ischemic heart disease, renal transplantation with, 959
 Ischemic nephropathy, 647, 660
 Isoniazid, in renal failure, 1060t, 1068t
 Isoptin. *See* Verapamil.
 Isotonic saline, for hyponatremia, 346
 Isotretinoin, for focal segmental glomerulosclerosis, 230t
 Isradipine
 with dialysis, 684t, 1061t
 in renal failure, 1069t
 Isradipine (DynaCirc)
 cardiovascular effects of, 612, 612t
 pharmacology of, 610, 611t
ITGB4 gene, 224t
 Itraconazole
 for posttransplant infections, 1042t
 in renal failure, 1059t
 IVIG. *See* Intravenous immunoglobulin.
- J**
 Janus kinase 3 inhibitor, for renal transplantation, 987
 Jaw, osteonecrosis of, due to bisphosphonates, 416
 JC virus, allograft dysfunction due to, 999
 Joint National Commission Report 7 (JNC-7), on hypertension, 570, 571, 571t
 Joulie solution
 for phosphaturic syndromes and Fanconi syndrome, 551t
 for X-linked hypophosphatemic rickets, 548–550
 Jugular vein catheter, for hemodialysis, 62, 859

- K**
 K^+ . *See* Potassium.
 K (dialyzer clearance rate), 876
 Kaposi's sarcoma, posttransplantation, 1020, 1038
 Kaposi's sarcoma-associated herpesvirus (KSHV), post-transplantation, 1038
 Kayexalate
 for hyperkalemia, 364
 for poisoning, 1074
 K_c (intercompartmental mass transfer coefficient), 880–881
 KCl. *See* Potassium chloride.
 K_d (instantaneous cross-dialyzer clearance), 878
 K/DOQI. *See* Kidney Disease Outcome Quality Initiative.
 Ketanserin, in renal failure, 1062t
 Ketoacidosis
 alcoholic, 372
 diabetic, 371–372
 Ketoconazole, in renal failure, 1059t
 Ketoprofen, in renal failure, 1065t
 Ketorolac, in renal failure, 1065t
 Ketotifen, for pruritus in end-stage renal disease, 833t
 Kidney
 horseshoe, stone in, 441
 medullary sponge, stone in, 441
 solitary, stone in, 441
 transplanted, stone in, 441
 Kidney after liver transplantation, for hepatorenal syndrome, 49
 Kidney biopsy. *See* Renal biopsy.
 Kidney disease, chronic. *See* Chronic kidney disease (CKD).
 Kidney Disease Outcome Quality Initiative (K/DOQI)
 on anemia
 screening for, 749
 treatment of, 751, 756, 757, 758
 on bone and mineral disorders, 765, 766
 on peritoneal dialysis, 937, 938
 Kidney Disease Quality of Life Questionnaire, 819
 Kidney donor, living. *See* Living kidney donor.
 Kidney failure
 acute (*See* Acute renal failure [ARF])
 chronic (*See* Chronic kidney disease [CKD])
 Kidney injury, acute. *See* Acute kidney injury (AKI).
 Kidney pain, in autosomal dominant polycystic kidney disease, 542, 543t
 Kidney size, in pregnancy, 487t
 Kidney stone disease. *See* Nephrolithiasis.
 Kidney transplantation. *See* Renal transplantation.
 Klonopin (clonazepam)
 in renal failure, 805t
 for restless legs syndrome, 833t
 K_o (mass transfer coefficient), 878
 K_oA (mass transfer area coefficient), 878
 K-Phos
 for hypophosphatemia, 421–422, 421t
 for phosphaturic syndromes and Fanconi syndrome, 551t
 Kramer, Peter, 73
 KSHV (Kaposi's sarcoma-associated herpesvirus), post-transplantation, 1038
 Kt/V. *See* Fractional clearance of urea.
- L**
 Labetalol
 with dialysis, 685, 685t, 1061t
 for hypertension
 with acute ischemic stroke, 632t
 in children, 514t, 515t
 due to pheochromocytoma, 694
 in pregnancy, 482t
 for hypertensive emergencies, 626, 628t
 for hypertensive urgencies, 629
 for renal artery stenosis, 653
 Lacidipine, for hypertension, 610, 611t
 Lactate, in peritoneal dialysis fluids, 915, 916–917, 916t
 Lactate-based dialysate, 63, 68
 Lactated Ringer's solution, for volume replacement, 5
 Lactic acidosis
 with contrast agents, 44
 D-, 373
 L-, 372–373
 due to metformin, 9
 LAMB2 gene, 224t
 Lamictal (lamotrigine), in renal failure, 802t
 Lamifiban, in renal failure, 1064t
 Lamivudine (3TC)
 for HBV-associated renal disease, 273–274, 274t, 275t
 for posttransplant hepatitis B, 1039–1040
 in renal failure, 1060t, 1069t
 Lamotrigine (Lamictal), in renal failure, 802t
 Lanreotide, in renal failure, 1072t
 Lansoprazole
 for posttransplant peptic ulcer disease, 1021
 in renal failure, 1060t
 Lanthanum carbonate (Fosrenol)
 for bone disease, 768
 for hyperphosphatemia, 420
 Laser lithotripsy, 438, 470
 LCDD (light-chain deposition disease), 258t, 264–265
 monoclonal, 264, 461–462, 462t, 463–464
 LDL. *See* Low-density lipoprotein (LDL).
 L-dopa, 13
 LEA29Y, for renal transplantation, 977, 986
 Leachable substances, dialysis reactions due to, 894–895, 896
 Lead-time bias, 741
 Lean body mass, in peritoneal dialysis, 936, 937b, 940
 Leflunomide (Arava)
 for BK virus nephropathy, 1040–1041
 for IgA nephropathy, 175, 177t
 in renal failure, 1056t
 for renal transplantation, 986
 for systemic vasculitis, 191
 Left internal jugular catheter, for hemodialysis, 62
 Left ventricular failure, hypertension with, 631, 631t
 Left ventricular hypertrophy (LVH)
 anemia and, in chronic renal disease, 750, 777
 and autosomal dominant polycystic kidney disease, 542
 hypertension with
 as cardiovascular risk factor, 636f
 diuretics and β -blockers for, 595
 Leg edema, after renal transplantation, 974–975
 Legal basis, for withholding or withdrawal of dialysis, 950–951
 Leishmaniasis, visceral, glomerulonephritis due to, 147
 Lenalidomide
 for AL amyloidosis, 261t, 263, 264
 for multiple myeloma, 267
 Lentivirus-based vectors, for gene therapy, 558
 Leprosy, glomerulonephritis due to, 144–145
 Leptospirosis, glomerulonephritis due to, 145
 Lercanidipine
 for hypertension, 610, 611t
 in renal failure, 1069t
 Lethargy, in end-stage renal disease, 834t
 Leukocyte activation, in hemodialysis, 902
 Leukoencephalopathy, reversible posterior, 625
 Leukotrienes (LTs), 115, 115f
 Levamisole, for minimal change disease, 215
 in children, 215, 500
 Levetiracetam, in renal failure, 1056t, 1064t
 Levitra (vardenafil), for erectile dysfunction, 787–788
 Levocabastine, in renal failure, 1056t, 1065t
 Levodopa, for restless legs syndrome, 822t
 Levofloxacin, in renal failure, 1059t, 1067t
 Lexapro (escitalopram), in renal failure, 798t
 LHCDD (light and heavy chain deposition disease), 264, 461
 Liddle syndrome, 553
 hypokalemia in, 360t, 361
 metabolic alkalosis in, 385
 Lidocaine, for pruritus in end-stage renal disease, 833t
 Life Options Rehabilitation Council, 819
 Lifestyle modifications
 for dyslipidemia, 716t, 718, 718b
 for end-stage renal disease, 773–774, 775t
 for hypertension, 569, 575–580, 586–587
 Light and heavy chain deposition disease (LHCDD), 264, 461
 Light-chain deposition disease (LCDD), 258t, 264–265
 monoclonal, 264, 461–462, 462t, 463–464
 Light-chain metabolism, and renal lesions, 461–462, 462t

 Linezolid, in renal failure, 1058t
 Linoleic acid, 113, 113f, 115f
 α -Linolenic acid, 113, 113f, 115f
 Lipid(s), in parenteral nutrition for acute renal failure, 87–89, 88t
 Lipid mediators, production of, 114–115, 115f
 Lipid metabolism, in acute renal failure, 84
 LIPID (Long-term Intervention with Pravastatin in Ischemic Disease) study, 635–636
 Lipid-lowering agents, 715, 717, 718, 718b, 719t
 for lupus nephritis, 164b–165b
 posttransplantation, 1011–1012, 1013t
 for prevention of progressive renal failure, 700f, 707–708
 in renal failure, 1055t, 1062t, 1071t
 Lipoid nephrosis. *See* Minimal change disease (MCD).
 Lipoprotein
 high-density, as cardiovascular risk factor in hypertension, 636b, 636f, 637–638
 low-density
 as cardiovascular risk factor
 in chronic kidney disease, 715–720, 716t, 775t
 in hypertension, 635–638, 636b, 636f, 637t
 with renal artery stenosis, 654, 656
 very low density, in chronic kidney disease, 720, 722
 Lipoprotein (a) (Lp[a]), as cardiovascular risk factor, in hypertension, 640, 640f
 Lisinopril
 with dialysis, 686t, 1062t
 and nephropathy, 605, 606
 pharmacology of, 602, 602t
 in renal failure, 606, 1070t
 renal protective effects of, 614, 615t
 with renal transplantation, 616
 List management, 1084
 Lithium (Eskalith, Lithobid, Lithonate)
 hemodialysis for intoxication with, 62t
 for hyponatremia, 345
 in renal failure, 802t, 812, 1063t
 Lithotripsy, 437–439
 efficacy of, 438–439
 electrohydraulic, 437
 extracorporeal shock wave, 430, 437
 antibiotics and, 442
 for cystine stones, 548
 efficacy of, 438–439
 indications for, 471
 for renal calculi, 440, 441, 441f
 technique of, 470–471
 for ureteral calculi, 441–442
 Intracorporeal, 437–438
 laser, 438, 470
 pneumatic, 438
 ultrasonic, 437–438
 Liver disease, polycystic, 539–540
 Liver transplantation
 acute renal failure due to
 dopamine for, 16t–17t, 20
 fenoldopam for, 22, 24t–25t
 for hepatorenal syndrome, 48–49, 48t, 52, 53
 orthotopic, for hereditary amyloidosis, 263
 Living kidney donor
 choice of kidney from, 971
 contraindications to, 964, 964b
 evaluation of, 961–966
 anatomic, 963b
 for cancer, 963b, 965
 for cardiopulmonary disease, 966
 cardiovascular, 962b, 965, 966
 for hypertension, 965
 imaging for, 971
 for infection, 963b, 965
 medical, 961, 962b–963b, 964–966
 metabolic-focused, 963b
 for nephrolithiasis, 965
 for obesity, 965
 psychosocial, 961, 962b
 renal-focused, 963b, 965–966
 for renovascular disease, 965–966
 for venous thromboembolism, 965
 quality of life of, 966
 relationship of, 961, 962b, 964f
 risks to, 961–964
 survival benefit of, 957, 958f
 Lixivaptan
 for hyponatremia, 346, 346t
 mechanism of action of, 391

- LMWH (low molecular weight heparin)
with hemodialysis, 64t, 1056t
in renal failure, 1050, 1056t, 1064t
- L α 2, glomerulonephritis due to, 147
- Loading dose, 1049–1050, 1050t
- Lomefloxacin, in renal failure, 1059t, 1067t
- Long-term dialysis, 61, 62t
- Long-term Intervention with Pravastatin in Ischemic Disease (LIPID) study, 635–636
- Loop diuretics
in acute kidney injury
ceiling dosage of, 400–401, 401t
for established disease, 37, 37t, 395
pharmacology and dose recommendations for, 38–39
for prevention, 36, 36t
adverse effects of, 398–399, 398t
for chronic kidney insufficiency, 395
for cirrhosis, 401t
in combination, 401–402, 402b
for congestive heart failure, 397, 401t
dosage of, 390t
ceiling, 400–401, 401t
high-dose, 400–401, 401t
for hypercalcemia, 414f, 415
for hyponatremia, 346
intravenous, 400–401, 401t
mechanism of action of, 389, 389f
for nephrotic syndrome, 284–285, 396
pharmacokinetics of, 391, 392–393, 392t, 393f
- Loracarbef, in renal failure, 1066t
- Loratadine, in renal failure, 1056t
- Lorazepam (Ativan), in renal failure, 805t
- Lorcainide, in renal failure, 1061t
- Lornoxicam, in renal failure, 1056t
- Losartan
for diabetic nephropathy, 325, 327
with dialysis, 687, 687t, 1061t
for end-stage renal disease, 776
for hypertension
with dialysis, 687, 687t
after renal transplantation, 616, 677
for nephrotic syndrome, 283
pharmacology of, 603, 603t
for posttransplant gout, 1025
renal protective effects of, 614–615, 615t
- Lotrifen, in renal failure, 1064t
- Lovastatin
for cardiovascular risk reduction in hypertension, 635
for lipid management, 719t
for posttransplant hyperlipidemia, 1011, 1013t
in renal failure, 1071t
- Low molecular weight heparin (LMWH)
with hemodialysis, 64t, 1056t
in renal failure, 1050, 1056t, 1064t
- Low-density lipoprotein (LDL)
as cardiovascular risk factor
in chronic kidney disease, 715–720, 716t, 775t
in hypertension, 635–638, 636b, 636f, 637t
with renal artery stenosis, 654, 656
- Low-density lipoprotein cholesterol (LDL-C), after renal transplantation, 1011–1012, 1012t
- Low-density lipoprotein (LDL)-lowering therapies, 715, 717, 718, 718b, 719t
- Lowe syndrome, 551
- Low-protein diet, for chronic kidney disease, 739–742, 740t, 742t
- Low-turnover bone disease, in chronic kidney disease, 766
- Lp(a) (lipoprotein [a]), as cardiovascular risk factor, in hypertension, 640, 640f
- LTs (leukotrienes), 115, 115f
- Ludimil (maprotiline), in renal failure, 801t
- Luminal (phenobarbital), in renal failure, 807t, 1056t
- Lunesta (eszopiclone), in renal failure, 806t
- Lung hemorrhage, in anti-GBM antibody disease, 197, 198, 201, 202
- Lupus erythematosus, systemic, 157, 163–167
in pregnancy, 489
thrombotic microangiopathy in, 301
- Lupus membranous nephropathy, 163, 167b
- Lupus nephritis, 157–168
animal studies on, 158, 158b
background of, 157
bone protection with, 165b
- Lupus nephritis (*Continued*)
end-stage renal failure due to, 167
future issues with, 167–168
human studies on, 158–162, 159b–160b
in pregnancy, 489
prognosis for, 162, 163b
proliferative, 163, 166b
relapse of, 163
thrombotic diathesis with, 165b
treatment of
angiotensin antagonists for, 164b
antihypertensives for, 164b
azathioprine for, 159b, 160b, 161–162, 164b, 166b
corticosteroids for, 158–161, 159b, 164b, 166b, 167b
cyclophosphamide for, 159b, 160b, 161, 163, 164b–167b
cyclosporine for, 164b, 167b
experimental therapies for, 167, 168t
hydroxychloroquine for, 164b
intravenous immunoglobulins for, 164b
lipid-lowering drugs for, 164b–165b
methotrexate for, 164b
mycophenolate mofetil for, 160b, 162, 164b, 166b
options for, 162–163, 164b–167b
plasmapheresis for, 129–131, 131t, 160b, 162, 164b
rituximab for, 164b
specific recommendations for, 162–167, 164b–167b
tacrolimus for, 164b
- Luteinizing hormone, in chronic kidney disease, 784
- Luvox (fluvoxamine), in renal failure, 798t
- LVH. *See* Left ventricular hypertrophy.
- Lymphatic obstruction, diuretic resistance due to, 400t
- Lymphocyte, after renal transplantation, 974
- Lymphocyte immune globulin, for renal transplantation, 979–982, 980t, 988
- Lymphoproliferative disease, posttransplant, 1018–1019
in childhood and adolescence, 530
Epstein-Barr virus and, 1037
- Lyrca (pregabalin), in renal failure, 807t, 1056t, 1064t
- Lysozyme amyloidosis, 259t
- Lysuride hydrogen maleate, for erectile dysfunction, 787
- M**
- Macroglobulinemia, Waldenström's, 462t, 465–466
- Macrolide antibiotics, in renal failure, 1054t, 1058t, 1066t
- Macronutrients, and hypertension, 575–577
- Macrophages, adipocytes and, 118
- Magnesium
in hemodialysis fluid, 853
and hypertension, 576, 576t
in peritoneal dialysis fluids, 916t
- Magnesium carbonate, for bone disease, 768
- Magnesium deficiency, 550
- Magnesium disorder(s), 422–423
during hemodialysis, 904
hypermagnesemia as, 422, 422f
hypomagnesemia as, 423, 423f, 550
- Magnesium homeostasis, 422
- Magnesium oxide (Mag-Ox 400, Slow-Mag, Uro-Mag)
for Gitelman's syndrome, 553
for magnesurias, 550
for posttransplant hypomagnesemia, 1026
- Magnesium pyrrolidine carboxylate, for Gitelman's syndrome, 553
- Magnesium sulfate
for hypomagnesemia, 423
for hypomagnesemic tetany, 550
for preclampsia, 483
- Magnesurias, 550
- Mag-Ox 400 (magnesium oxide)
for Gitelman's syndrome, 553
for magnesurias, 550
for posttransplant hypomagnesemia, 1026
- Maintenance dose, 1050
modified, 1051
- Major histocompatibility complex (MHC) antigens, 976, 977
- Malaria, glomerulonephritis due to, 146–147
- Malignancy, humoral hypercalcemia of, 413, 415
- Malignant disease, posttransplantation, 1018–1020
- Malignant hypertension, 624
thrombotic microangiopathy in, 301
treatment of, 629–630, 631t
- Malnutrition
in peritoneal dialysis, 940–941, 943
in renal disease, 736–737, 737f
- Manic depression, in end-stage renal disease, 802t, 812–813
- Manidipine, for hypertension, 610, 611t
- Mannitol
in acute kidney injury
for established disease, 36–37, 37t
pharmacology and dose recommendations for, 38
for prevention, 35–36, 36t, 394
for contrast-induced nephropathy, 43
dosage of, 390t
mechanism of action of, 391
in renal failure, 1071t
- MAP (mean arterial pressure), in renal artery stenosis, 649f, 650f
- MapPoint, 1085
- Maprotiline (Ludimil), in renal failure, 801t
- MARS (molecular adsorbents recirculation system), for hepatorenal syndrome, 48t, 51–52
- Mass transfer area coefficient (K_{tA}), 878
- Mass transfer coefficient (K_{tO}), 878
- MC (mixed cryoglobulinemia), 151–154
- MCD. *See* Minimal change disease (MCD).
- MCP (membrane cofactor protein)
in hemolytic-uremic syndrome, 510
in thrombotic microangiopathy, 299f, 303, 304, 307t, 308
- MDRD study. *See* Modification of Diet in Renal Disease (MDRD) study.
- Mean arterial pressure (MAP), in renal artery stenosis, 649f, 650f
- Measuring Effects on Intima-Media Thickness: An Evaluation of Rosuvastatin (METEOR) study, 1016
- Mechanical ventilation
respiratory alkalosis due to, 386, 386t
volume status with, 5
- Medicare spending, for end-stage renal disease, 836, 837, 837f
- Medicated urethral system for erection (MUSE), 788
- Medullary sponge kidney, stone in, 441
- Mefloquine, in renal failure, 1059t
- Mefruside, dosage of, 390t
- MEFV gene, 553
- Megestrol, for anorexia in end-stage renal disease, 834t
- Meglitinides, for transplant-associated hyperglycemia, 1014
- MELD (Model for End-stage Liver Disease) score, 48, 52
- Melphalan
for AL amyloidosis, 260t, 262–263, 264
for light-chain deposition disease, 265
for multiple myeloma, 267
- Memantine, in renal failure, 1071t
- Membrane cofactor protein (MCP)
in hemolytic-uremic syndrome, 510
in thrombotic microangiopathy, 299f, 303, 304, 307t, 308
- Membrane filtration, for plasmapheresis, 126, 127f
- Membranoproliferative glomerulonephritis (MPGN)
in children, 508
hepatitis B–associated, 273, 274t, 275
hepatitis C–associated, 140, 151–155, 249
clinical features, pathology, and pathophysiology of, 151–152
treatment of, 152–155, 153t, 154t
idiopathic, 249–254
in children, 508–509
classification of, 249
complement cascade in, 249, 250f, 252–253, 253f
genetic predisposition to, 250
glomerular basement membrane in, 250f, 252–253
pathogenesis of, 249–251, 250f, 508
prognosis for, 250
treatment of, 251–254
antiplatelet agents and anticoagulants for, 251
corticosteroids for, 251, 508
cytotoxic agents for, 251
indications for, 251
kidney transplantation for, 252
plasma exchange for, 251–252, 508
targets in complement cascade for, 252–253, 253f
useful links on, 254

- Membranous nephropathy (MN)
 HBV-associated, 273, 274t, 275
 idiopathic, 239–246
 clinical trials and specific recommendations on, 240–245
 general strategy for, 240–241
 natural history of, 239
 prognostic indicators for, 239–240
 with renal insufficiency, 244–245, 244b
 without renal insufficiency, 244t, 241–244, 242t
- Men, UTIs in, 450, 451–452
- Meperidine
 for pain management in end-stage renal disease, 832t
 in renal failure, 1055t, 1063t
- Meprobamate, in renal failure, 1055t
- α -Mercaptopropionylglycine (α -MPG, tiopronin), for cystine stones, 470, 548
- Meropenem, in renal failure, 1057t, 1065t
- Metabolic acidosis
 in acute renal failure, 9
 clinical examples of, 370–378
 compensation for, 368, 370t
 defined, 368
 diagnosis of, 368, 369f
 high anion gap, 368, 370–374
 alcoholic ketoacidosis as, 372
 causes of, 370, 370b
 diabetic ketoacidosis as, 371–372
 diagnosis of, 369f, 370–371, 371f
 D-lactic acidosis as, 373
 drug-induced, 373
 L-lactic acidosis as, 372–373
 due to renal failure, 374
 toxin-induced, 373–374
 and malnutrition, 737
 normal anion gap (hyperchloremic), 368, 374–378
 of chronic renal failure, 374
 diagnosis of, 369f
 differential diagnosis of, 374, 375b
 distinguishing features of, 375t
 pathogenesis of, 374
 renal tubular acidosis as, 375–378, 375b, 376b, 378b
 renal response to, 368–370
 sleep disorders with, 792

 online calculations of, 1085, 1086
 on protein restriction, 707, 739–741

- Moexipril
with dialysis, 686t
pharmacology of, 602t
in renal failure, 1070t
- Molecular adsorbents recirculation system (MARS), for hepatorenal syndrome, 48t, 51–52
- Monitoring, for prevention of progressive renal failure, 708
- Monobactams, in renal failure, 1058t, 1066t
- Monoclonal immunoglobulin deposition diseases (MIDD), 264, 461, 462t, 463–464
- Monoclonal light-chain deposition disease, 264, 461–462, 462t, 463–464
- Monoclonal lymphocyte-depleting antibodies, for renal transplantation, 980t, 982
- Monoclonal nondepleting antibodies, for renal transplantation, 983
- Monocyte activation, in hemodialysis, 902
- Monoglobulin immunoglobulin-associated kidney disease, 257, 258t
- AL amyloidosis as, 257, 259–263
clinical features of, 259t
pathophysiology of, 461
treatment of, 259–263, 260t–261t, 462–463, 462t
light-chain deposition disease as, 258t, 264–265
myeloma cast nephropathy as (See Cast nephropathy)
- Morphine, for pain management in end-stage renal disease, 829, 832t
- Motrin (ibuprofen), in end-stage renal disease, 808t
- Mouse models
of acute kidney injury, 92–93
of lupus nephritis, 158, 158b
- Moxalactam, in renal failure, 1058t, 1066t
- Moxonidine, in renal failure, 1070t
- MP (microscopic polyangiitis), 187, 188, 192
- MPA (mycophenolic acid), 315
- α -MPG (α -mercaptopropionylglycine), for cystine stones, 470, 548
- MPGN. See Membranoproliferative glomerulonephritis.
- MRSA (methicillin-resistant *Staphylococcus aureus*), peritonitis due to, 925, 926, 927
- mtDNA, in podocytopathies, 224t
- Mucocutaneous candidiasis, glomerulonephritis due to, 146
- Multicenter Isradipine Diuretic Atherosclerosis Study (MIDAS), 593, 612, 612t
- Multiple myeloma, 461–465
AL-type amyloidosis in, 461, 462–463, 462t
cast nephropathy due to (See Cast nephropathy)
chemotherapy for, 266t, 267–268
diagnosis, clinical features, and kidney histology of, 265
hypercalcemia in, 464
kidney disease in, 265, 461–465, 462t
kidney transplantation in, 268
monoclonal light-chain deposition disease in, 461–462, 462t, 463–464
renal failure with, 464
plasmapheresis for, 133–134, 134t
- Murine models, of lupus nephritis, 158, 158b
- Muromonab-CD3 (Orthoclone, OKT3)
for allograft rejection, 997–998, 998t
for renal transplantation, 979f, 980t, 982, 989
- Muscle cramps
in end-stage renal disease, 833t
due to hemodialysis, 899–900
- MUSE (medicated urethral system for erection), 788
- Mycobacterial infections
glomerulonephritis due to, 144–145
posttransplantation, 1043
- Mycophenolate mofetil (MMF, CellCept)
for acute interstitial nephritis, 315–316, 317, 317f, 318t
for focal segmental glomerulosclerosis, 227–228, 231f
in children, 501
for glomerular and tubulointerstitial disease, 108
for idiopathic membranous nephropathy, 243b, 244, 244b
for IgA nephropathy, 175–178, 178t
for interstitial fibrosis and tubular atrophy in allograft, 1002–1003
for lupus nephritis, 160b, 162, 164b, 166b
for minimal change disease, 213–215, 217
in children, 213–215, 500
in renal failure, 1063t
- Mycophenolate mofetil (MMF, CellCept) (Continued)
for renal transplantation, 979f, 981t, 984, 988, 989
diarrhea due to, 1020
gout due to, 1025b
for systemic vasculitis, 190–191, 191t, 193t, 194t
- Mycophenolate sodium, enteric-coated (EC-MPS, Myfortic), for renal transplantation, 979f, 981t, 984, 1020
- Mycophenolic acid (MPA), 315
- Myeloma, multiple, 461–465
AL-type amyloidosis in, 461, 462–463, 462t
cast nephropathy due to (See Cast nephropathy)
chemotherapy for, 266t, 267–268
diagnosis, clinical features, and kidney histology of, 265
hypercalcemia in, 464
kidney disease in, 265, 461–465, 462t
kidney transplantation in, 268
monoclonal light-chain deposition disease in, 461–462, 462t, 463–464
renal failure with, 464
plasmapheresis for, 133–134, 134t
- Myeloma cast nephropathy. See Cast nephropathy.
- Myeloperoxidase-bound immunosorbent columns, for systemic vasculitis, 191
- Myfortic (mycophenolate sodium, enteric-coated), for renal transplantation, 979f, 981t, 984, 1020
- Myocardial infarction (MI), hypertension with, 630f, 631, 631t
diuretics and β -blockers for, 595
- Myoglobinuria, in acute renal failure, 7–8
- N**
- n-3 fatty acids, 112
biologic properties and effects of, 113–116, 113f–115f
dietary supplementation with, 117
- n-6 fatty acid deficiency, 116–117
- Na⁺. See Sodium (Na⁺).
- Nabumetone, in renal failure, 1056t
- N-acetylcysteine (NAC), for contrast-induced nephropathy, 42–43, 42t
- N-acetyl-procainamide (NAPA), in renal failure, 1069t
- Nadolol
with dialysis, 685, 685t, 1061t
for IgA nephropathy, 181t
in renal failure, 1070t
- Nafcillin, in renal failure, 1058t
- NaHCO₃. See Sodium bicarbonate.
- Naked DNA, for gene therapy, 558
- Nalidixic acid, in renal failure, 1068t
- Nalmefene, in renal failure, 1054t, 1055t, 1063t
- Naloxone, for poisoning, 1073
- NAPA (N-acetyl-procainamide), in renal failure, 1069t
- Nateglinide, for transplant-associated hyperglycemia, 1014
- National Cholesterol Education Program (NCEP), 715
- National Cooperative Dialysis Study (NCDS), 66–67

in autosomal dominant polycystic kidney disease, 542, 543t
bilateral, 440
in calyceal diverticula, 440–441
clinical and laboratory manifestations of, 429
clinical and metabolic evaluation of, 430–431, 431b, 432b, 432f, 433f
due to cystinuria, 470, 547–548
cystoscopic stone removal for, 430
diagnosis of, 429–430
differential diagnosis of, 429–430
epidemiology of, 429
follow-up for, 434
with horseshoe kidney, 441
imaging of, 429
in infants, 442
lithotripsy for, 437–439
extracorporeal shock wave, 430
in living kidney donor, 965
medical treatment of, 430, 470
with medullary sponge kidney, 441
with obesity, 442
obstructive uropathy due to, 469–471
percutaneous nephrostolithotomy for, 430
during pregnancy, 442
prevention of recurrence of, 431–434, 470
recommendations for, 440–442, 440b, 441f, 442f
risk factors for, 430–431, 431b
with solitary kidney, 441
spontaneous stone passage in, 470
with staghorn calculi, 434, 441
stone composition in, 430, 470
surgical modalities for, 439–440
in transplanted kidney, 441
ureteral stent for, 430
- Nephrolithotomy
anatomic, 439
percutaneous, 430, 439, 471
recommendations for, 440, 441, 441f
- Nephron, aldosterone-sensitive distal, 389, 402

- Nephron.org, 1085–1086
- Nephropathy
BK virus, 1040–1041
chronic allograft, 1000–1003, 1001t, 1002b
contrast-induced (See Contrast-induced nephropathy [CIN])
diabetic (See Diabetic nephropathy [DN])
IgA (See Immunoglobulin A (IgA) nephropathy [IgAN])
ischemic, 647, 660
membranous (See Membranous nephropathy [MN])
myeloma cast (See Cast nephropathy)
polyomavirus, posttransplantation, 1040–1041
allograft dysfunction due to, 999–1000
renin system blockade and, 605–606
- Nephrosis, lipid. See Minimal change disease (MCD).
- Nephrotic syndrome (NS), 281–288
abnormalities of calcium homeostasis in, 287
in children, 498–503, 499t, 502b
congenital, 501–503, 502b
defined, 281, 395
diuretics for, 284–285, 396, 401t

- Nephrotic syndrome (NS) (*Continued*)
 edema in, 284–285, 395–396
 Fanconi syndrome with, 552
 hypercoagulability and thromboembolism in, 287–288
 hyperlipidemia in, 285–287, 720, 721f
 hypoalbuminemia/proteinemia in, 281–284
 idiopathic (*See* Minimal change disease [MCD])
 due to idiopathic membranous nephropathy (*See* Idiopathic membranous nephropathy)
 in IgA nephropathy, 178
 increased susceptibility to infection in, 288
 Nephrotomy, radical paravascular, 439
 Nephrotoxicity, of contrast media, 43–44
 Nesiritide
 for congestive heart failure, 397
 dosage of, 390t
 Net present value (NPV), 1084
 Neuraminidase inhibitors, for posttransplant influenza, 1039
 Neuraminidase-associated thrombotic microangiopathy, 298, 307t
 Neuroblastoma, 459
 Neurodevelopmental outcome, of end-stage renal disease in childhood and adolescence, 525–526
 Neurogenic alterations, in chronic kidney disease, erectile dysfunction due to, 784, 784b, 785f
 Neuroleptics, in end-stage renal disease, 802t–804t, 813
 Neurological complications, of hemodialysis, 899–900
 Neurontin. *See* Gabapentin.
 Neuropathies, in chronic kidney disease, sleep disorders with, 792
 Neuropsychiatric disorder(s), in end-stage renal disease, 795–814
 adjustment disorders as, 810–811
 algorithm for treatment of, 796f, 814
 anxiety disorders as, 811
 delirium as, 797b, 810
 dementia as, 810
 depression and manic depression as, 811–813
 drugs used to treat, 798t–808t
 analgesics, 808t
 anticonvulsants, 806t–807t, 809
 antidepressants, 798t–801t
 antimanic agents, 802t
 antiparkinsonian agents, 808t
 antipsychotics, 802t–804t
 anxiolytics/hypnotics, 804t–806t
 etiology of, 797b
 insomnia as, 809–810
 peripheral neuropathies, 797
 schizophrenia/psychotic disorders, 813
 seizures, 797–809
 sexual disorders, 813–814
 Neutral phosphate, for X-linked hypophosphatemic rickets, 548–550
 Neutra-Phos
 for hypophosphatemia, 421–422, 421t
 for phosphaturic syndromes and Fanconi syndrome, 551t
 New-onset diabetes mellitus (NODM), transplant-associated, 1013–1014
 NF-kB (nuclear factor kB)
 in glomerulonephritis and renal fibrosis, 560–561
 in graft rejection, 559
 NH₄⁺ (ammonium), in metabolic acidosis, 369–370, 374
 NHE (sodium/hydrogen ion exchanger), 354, 354f
 Niacin (Niaspan), for cardiovascular risk reduction, in hypertension, 637–638
 Niaspan (nicotinic acid), for lipid management, 719t
 Nicardipine (Cardene)
 for hypertension
 with acute ischemic stroke, 632t
 cardiovascular effects of, 613
 with dialysis, 684t
 pharmacology of, 610, 611t
 for hypertensive urgencies, 628t, 629
 Nicotinamide, for Hartnup disease, 547
 Nicotine replacement therapy, for posttransplant smoking cessation, 1015
 Nicotinic acid (Niaspan), for lipid management, 719t
 NICS-EH (National Intervention Cooperative Study in Elderly Hypertensives), 613
 Nifedipine (Adalat, Procardia)
 cardiovascular effects of, 612, 612t
 with dialysis, 684t, 1061t
 for hypertension
 in children, 514t, 515t
 due to pheochromocytoma, 694
 in pregnancy, 482t
 due to primary aldosteronism, 693
 for hypertensive urgencies, 629
 for IgA nephropathy, 181t
 pharmacology of, 610, 611t
 and progressive renal failure, 702
 renal protective effects of, 614, 615t
 safety of, 616
 Nightly intermittent peritoneal dialysis (NIPD), 920
 Nil disease. *See* Minimal change disease (MCD).
 Nimodipine (Nimotop), for hypertension, 610, 611t
 Nisoldipine (Sular)
 cardiovascular effects of, 612, 612t
 with dialysis, 684t
 pharmacology of, 610, 611t
 renal protective effects of, 614, 615t
 Nitrendipine
 cardiovascular effects of, 612t, 613
 pharmacology of, 610, 611t, 612
 Nitric oxide (NO)
 in erection, 784, 785f
 in uremic bleeding, 9
 Nitrofurantoin
 in renal failure, 1068t
 for UTI, 450
 Nitroglycerin, for hypertensive emergencies, 626, 627t
 Nitroimidazoles, in renal failure, 1058t
 Nitroprusside
 with dialysis, 688t, 689
 for hypertension with acute ischemic stroke, 632t
 for hypertensive emergencies, 626, 627t
 in children, 514t
 Nizatidine, in renal failure, 1056t, 1065t
 NKCC2, in Bartter syndrome, 552
 NLM (National Library of Medicine), 1086, 10084
 NO (nitric oxide)
 in erection, 784, 785f
 in uremic bleeding, 9
 Nocturnal penile tumescence (NPT), 783
 NODM (new-onset diabetes mellitus), transplant-associated, 1013–1014
 Nondihydropyridines, 610
 Nonsteroidal anti-inflammatory drugs (NSAIDs)
 for diabetes insipidus, 350, 350t
 diuretic resistance due to, 400t
 for nephrotic syndrome, 283
 for pain management in end-stage renal disease, 832t
 Nonviral vectors, for gene therapy, 558
 Nordic Diltiazem (NORDIL) study, 612t, 613
 Norepinephrine
 for acute renal failure, 26–27, 28t–29t
 for hepatorenal syndrome, 49t, 50–51
 Norfloxacin
 for hepatorenal syndrome, 54
 in renal failure, 1054t, 1059t, 1067t
 Normal Hematocrit Cardiac Trial, 752
 Normal saline, for hypercalcemia, 414–415, 414f
 Normoglycemia, for end-stage renal disease, 774, 775t
 Norpramin (desipramine), in renal failure, 799t
 for pain management, 833t
 Nortriptyline (Aventyl, Pamelor), in renal failure, 800t, 812
 Norvasc. *See* Amlodipine.
 NPHS1 gene, 223, 224t, 502
 NPHS2 gene, 223, 224t, 232
 NPT (nocturnal penile tumescence), 783
 NPV (net present value), 1084
 NS. *See* Nephrotic syndrome (NS).
 NSAIDs. *See* Nonsteroidal anti-inflammatory drugs (NSAIDs).
 Nuclear factor kB (NF-kB)
 in glomerulonephritis and renal fibrosis, 560–561
 in graft rejection, 559
 Nucleoside/nucleotide analogues, for HBV-associated renal disease, 273–274, 275t
 Nutrient administration, for acute renal failure, 85f, 86–89
 Nutrition, for end-stage renal disease in childhood and adolescence, 522–523, 523t
 Nutritional assessment, in renal diseases, 737–739, 738b
 Nutritional issues, in renal transplant patients, 744–745
 Nutritional management. *See also* Diet.

patient selection for, 671–673
restenosis after, 671, 671f
techniques of, 664–665
- Renal artery, distal embolic protection devices in, 664, 665
- Renal artery angioplasty. *See* Renal artery revascularization.
- Renal artery disease. *See* Renal artery stenosis (RAS).
- Renal artery revascularization, 664–673
complications of, 660–661, 670–671, 671b, 671f
demographics of, 660, 661f
goals of, 660, 664
outcomes of, 666–670, 666f, 667t–669t, 670f
techniques of, 664–665
- Renal artery stenosis (RAS), 647–657, 660–673
aortic aneurysm due to, 651t
atherosclerotic, 647, 650, 651t
angioplasty and stenting for, 664, 668–670, 668t, 669t, 670f
and cardiovascular disease, 650–651, 651t
cerebrovascular disease due to, 651t
chronic kidney disease due to, 647, 651t, 653–654
clinical syndromes of, 660, 661b
comorbidities with, 650–651, 654–655
congestive heart failure due to, 651t
and coronary artery disease, 651t, 654
defined, 647
- Renal artery stenosis (RAS) (*Continued*)
demographics of, 661
and diabetes, 651t, 654
diagnostic considerations in, 663–664, 663f
dyslipidemia with, 654, 656
end-stage renal disease due to, 647
due to fibromuscular dysplasia, 647–648, 666, 666f, 667t
hypertension due to, 647, 651–653, 651t, 653f, 656f
natural history of, 647–648
peripheral vascular disease due to, 651t
risks of progression of, 661–663, 662f
and smoking, 654
transplant, 675–678, 974
treatment of, 651–655
ACE inhibitors and angiotensin receptor blockers
for, 652, 653f, 655, 655f, 656f
pathophysiologic basis for, 648–650, 649f, 650f
algorithm for, 656f, 672
antiplatelet agents for, 654–655, 656, 656f
 β -blockers for, 653
calcium channel blockers for, 649–650, 649f, 650f, 653
central agents for, 653
diuretics for, 652–653
medical vs. surgical, 648, 652, 653–654
outcomes and goals of, 651–655, 660, 664
pathophysiologic basis for, 648–650, 649f, 650f
recommendations for, 655–657, 655f, 656f
renal angioplasty and stenting for, 664–673
complications of, 660–661, 670–671, 671b, 671f
demographics of, 660, 661f
embolic protection devices with, 664, 665
goals of, 660, 664
vs. medical therapy, 648, 652, 653–654
outcomes of, 666–670, 666f, 667t–669t, 670f
patient selection for, 671–673
restenosis after, 671, 671f
techniques of, 664–665
- Renal biopsy
of allograft, 996, 997b
for HBV-associated renal disease, 273
for HIV-associated renal disease, 276
during pregnancy, 490
- Renal blood flow (RBF)
dopamine and, 14–15, 15t
in pregnancy, 487t
in renal artery stenosis, 648, 650
- Renal calculi, 440–441, 441f. *See also* Nephrolithiasis.
- Renal cell carcinoma, 455–459
bilateral, 455
diagnostic evaluation of, 456, 457f
epidemiology of, 455
future directions for, 459
gene therapy for, 560
metastatic, 455, 457, 458–459
pathologic classification of, 456, 456t
presentation of, 455
recurrence of, 458
risk factors for, 455
staging of, 457, 458t
thiazide diuretics and, 594
treatment of, 457–459
- Renal colic, 430
- Renal cyst, 456
- Renal failure
acute (*See* Acute renal failure [ARF])
chronic (*See* Chronic kidney disease [CKD])
drug dosing in, 1049–1072
active metabolites in, 1052
for analgesics, 1054t, 1055t, 1063t
for anesthetics, 1054t, 1055t, 1063t–1064t
for antihelmintics, 1064t
for anti-anxiety agents, sedatives, and hypnotics, 1054t, 1055t–1056t, 1064t
for anticholinergics and cholinergics, 1056t, 1064t
for anticoagulants, antifibrinolytics, and antiplatelet agents, 1056t, 1064t
for anticonvulsants, 1054t, 1056t, 1064t
for antifungals, 1054t, 1059t, 1068t
for antihistamines, 1054t, 1056t, 1064t–1065t
for anti-inflammatory agents, 1054t, 1056t–1057t, 1065t
for antimetabolites, 1059t, 1068t
for antimicrobials/antibacterials, 1054t, 1057t–1059t, 1065t–1068t

- Renal failure (*Continued*)
 for antineoplastics and antimetabolites, 1060t, 1068t
 for antiparasitics, 1068t
 for antispasticity agents, 1068t
 for antituberculous agents, 1060t, 1068t
 for antiulcer agents, 1068t
 for antiviral agents, 1060t, 1068t–1069t
 for bisphosphonates, 1069t
 for bronchodilators, 1055t, 1060t, 1069t
 for cardiovascular agents, 1055t, 1060t–1062t, 1069t–1071t
 for cognitive impairment, 1071t
 with dialysis, 1052, 1055t–1063t
 for diuretics, 1071t
 for erectile dysfunction, 1071t
 half-life in, 1050–1051
 for hormonal agents, 1055t, 1062t, 1072t
 for hypoglycemic agents, 1062t, 1072t
 for hypouricemic agents, 1062t, 1072t
 for immunologic agents, 1063t
 loading dose in, 1049–1050, 1050t
 maintenance dose in, 1050
 principles of, 1049–1052
 for psychotherapeutic agents, 1063t, 1072t
 recommendations on, 1052–1053
 regimens for, 1051–1052
 for steroids, 1063t
 for sympathomimetics, 1072t
 volume of distribution in, 1049–1050, 1054t–1055t
 hypertension with, 631t, 632–633
 with multiple myeloma, 464
 plasmapheresis for, 133–134, 134t
 progressive (*See Progressive renal failure*)
 renin system blockade with, 606
 Renal fibrosis, gene therapy for, 560–561
 Renal function
 dopamine and, 14–15, 15t
 with renal artery stenosis, 653–654
 therapeutic ablation of, for nephrotic syndrome, 284
 Renal hemodynamics
 dopamine and, 14–15, 15t
 in pregnancy, 487t
 Renal hypertension. *See Renovascular hypertension.*
 Renal insufficiency
 drug dosing with, 1063t–1072t
 in pregnancy, 488
 Renal limited vasculitis, 187
 Renal mass, diagnostic evaluation of, 456, 457f
 Renal organizations, online, 1089t
 Renal osteodystrophy, 765–766
 in childhood and adolescence, 524–525
 Renal replacement therapy (RRT). *See also Dialysis.*
 for acute renal failure, 9–10
 for cast nephropathy, 465
 in childhood and adolescence, 526–528
 continuous, 73–79
 clinical aspects of, 76–78
 evolution of, 73–75, 74f, 75f
 vs. intermittent hemodialysis, 59
 metabolic impact of, 84, 84b
 for contrast-induced nephropathy, 43
 costs of, 837–841, 838t–841t
 for diabetic nephropathy, 329–330
 drug dosage with, 9
 for hemolytic-uremic syndrome, 510
 hepatitis B virus in, 275–276
 for hepatorenal syndrome, 48t, 51
 HIV and, 277–278
 metabolic impact of, 84, 84b
 prolonged intermittent daily, 78
 Renal revascularization, 664–673
 complications of, 660–661, 670–671, 671b, 671f
 demographics of, 660, 661f
 goals of, 660, 664
 outcomes of, 666–670, 666f, 667t–669t, 670f
 techniques of, 664–665
 Renal transplantation
 for AL amyloidosis, 463
 allograft dysfunction after (*See Renal allograft dysfunction*)
 anti-GBM antibody disease after, 200–201, 202
 in Alport's syndrome, 198
 bilateral native nephrectomy for, 970
 cadaver donors for, 970–971, 994
 Renal transplantation (*Continued*)
 for cast nephropathy, 465
 in childhood and adolescence, 528–531, 972
 bone disease after, 524–525
 donor for, 528, 529t
 failure of, 530–531
 immunosuppressive therapy for, 530
 infections after, 530
 preparation for, 528–530, 529b
 prognostic risk factors for, 529t
 complication(s) of, 972–975
 acute vascular necrosis, 1024
 bleeding, 975
 cancer, 1018–1020
 cerebrovascular disease, 1016–1017
 coronary heart disease, 1009–1016
 diagnosis of, 1011
 epidemiology of, 1009
 medical and interventional treatment of, 1015–1016
 risk factor management for, 1010–1015, 1010b, 1012t, 1013t
 erythrocytosis, 1018–1019
 gastrointestinal, 1020–1021
 gout, 1024–1025, 1025b
 hyperparathyroidism, 1023–1024
 hypomagnesemia, 1026
 hypophosphatemia, 1026
 infectious, 1034–1044
 bacterial urinary tract, 1041–1043
 drug interactions in treatment of, 1034, 1035t
 epidemiology of, 1034
 fungal, 1041, 1042t
 with human immunodeficiency virus, 1043–1044
 with *Pneumocystis jiroveci*, 1041
 timeline for, 1034, 1036f
 with tuberculosis and nontuberculous mycobacteria, 1043
 viral, 1035–1041
 leg edema, 976–977
 lymphocele, 976
 obstruction of collecting system, 975–976
 osteoporosis, 1021–1023, 1022b
 peripheral arterial disease, 1017–1018
 transplant renal artery stenosis, 976
 urine leak, 975
 vascular thrombosis, 975
 vesicoureteral reflux, 976
 wound, 972–975
 cost of, 839–840, 840t, 841t
 with diabetes, 1005
 for diabetic nephropathy, 330
 for diffuse mesangial sclerosis, 502
 dopamine for, 20
 dual-kidney, 972
 dyslipidemia after, 722
 for fibrillary glomerulonephritis or immunotactoid glomerulopathy, 269
 for focal segmental glomerulosclerosis, in children, 501
 gene therapy with, 559–560
 hemodialysis vascular access prior to, 862
 for hemolytic-uremic syndrome, 510, 511
 Henoch-Schönlein purpura after, 183
 hepatitis B virus in, 276
 with human immunodeficiency virus, 278, 960, 1043–1044
 hyperparathyroidism after, 770
 hypertension after, 675–678
 causes of, 675–677, 676b
 clinical features of, 675
 refractory, 678
 treatment of, 676f, 677
 ACE inhibitors and angiotensin receptor blockers for, 677
 calcium channel blockers for, 616, 677
 diuretics for, 677
 IgA nephropathy after, 182
 immunology of, 976–978
 alloimmunity in
 cellular, 977
 humoral, 977
 clinical application of, 978–979
 components of immune system in, 976–977
 Renal transplantation (*Continued*)
 crossmatch methods in, 978–979
 detection of anti-HLA antibodies in, 978
 effector mechanisms in, 977–978
 recognition of alloantigen in, 977
 tissue-typing techniques in, 978
 immunosuppressive medication(s) for, 979–989, 980t–981t
 adjuvant agents, 981t, 984–985, 988
 antimetabolites, 981t, 984–985
 calcineurin inhibitors, 980t–981t, 983, 987–988
 withdrawal from, 989
 drug interactions of, 985, 986b
 glucocorticoids, 981t, 985
 withdrawal from, 989
 in induction treatment, 979–983, 980t–981t, 988–989
 intravenous immunoglobulins, 985–986
 mechanisms of action of, 979f, 980t–981t
 monoclonal lymphocyte-depleting antibodies, 980t, 982
 monoclonal nondepleting antibodies, 983
 new, 986–987
 polyclonal lymphocyte-depleting antibodies, 979–982, 980t
 protocols for, 987, 987t
 and sensitization, 989–990
 target of rapamycin inhibitors, 984–985
 improvement in erectile dysfunction after, 788–789
 living donor for
 choice of kidney from, 971
 contraindications to, 964, 964b
 evaluation of, 961–966
 anatomic, 963b
 for cancer, 963b, 965
 for cardiopulmonary disease, 966
 cardiovascular, 962b, 965, 966
 for hypertension, 965
 imaging for, 971
 for infection, 963b, 965
 medical, 961, 962b–963b, 964–966
 metabolic-focused, 963b
 for nephrolithiasis, 965
 for obesity, 965
 psychosocial, 961, 962b
 renal-focused, 963b, 965–966
 for renovascular disease, 965–966
 for venous thromboembolism, 965
 quality of life of, 966
 relationship of, 961, 962b, 964f
 risks to, 961–964
 survival benefit of, 957, 958f
 mannitol for, 36
 for membranoproliferative glomerulonephritis, 252
 for monoclonal light-chain deposition disease, 463–464
 in multiple myeloma, 268
 nephrolithiasis after, 441
 nutritional issues after, 744–745
 plasmapheresis for, 134–135, 135t
 pregnancy with, 490–493, 492t
 procedure for, 971–972
 and quality of life, 819
 recipient evaluation for, 957–961, 958b, 970
 age in, 957, 959f
 for blood type and histocompatibility, 957
 for bone density, 961
 for cancer, 958b, 959–960
 for cardiovascular disease, 958b, 959
 cystoscopy or cystography in, 970
 for failed allografts, 961
 for infection, 958b, 960
 for obesity, 960
 psychosocial, 958b, 961
 pulmonary function tests in, 961
 for recurrent disease, 958b, 960–961
 re-evaluation while on waiting list in, 961
 recurrent and de novo renal disease after, 1004–1005
 subsequent, 972
 systemic vasculitis after, 193, 193t, 194t
 for thrombotic microangiopathy
 with genetic abnormalities in complement regulatory proteins, 304
 for Shiga toxin-associated, 298

- Renal tubular acidosis (RTA), 375–378
 differential diagnosis of, 375b
 distal, 376–378
 classic, 375t, 376–377, 376b
 generalized, 375t, 377–378, 378b
 proximal, 375–376, 375t
- Renal tubule assist device (RAD), for acute kidney injury, 96
- Renal vein thrombosis (RVT), in nephrotic syndrome, 288
- Renal-focused evaluation, of living kidney donor, 963b, 965–966
- Renin, in hypertension, 588
- Renin-angiotensin system (RAS), pharmacologic inhibition of, for prevention of progressive renal failure, 702–706, 703t, 706f
- Renin-angiotensin system (RAS) blockade
 for diabetic nephropathy, 327–329, 327f, 328f
 prevention of, 325
 historical background of, 601
 for hypertension, 601–608
 and natural history of renal injury, 605
 and nephropathy, 605–606
 optimization of, 607–608
 pharmacology of, 602–604, 602t, 603t
 renal actions of, 604–605
 with renal failure, 606
- Renin-angiotensin-aldosterone system (RAAS)
 in autosomal dominant polycystic kidney disease, 541, 542
 in end-stage renal disease, 682–683
- Renin-angiotensin-aldosterone system (RAAS) antagonists, for chronic renal disease, 733, 733t, 776
- Renoprotection, in chronic kidney disease, 699–710
 ACE inhibitors and angiotensin receptor blockers for, 702–706, 703t, 706f
 antihypertensive therapy for, 700–702
 calcium channel blockers for, 702
 dietary interventions for, 707
 future therapies in, 708–709
 glycemic control for, 708
 lipid lowering for, 707–708
 monitoring in, 708
 smoking cessation for, 708
 strategy for maximal, 709–710, 709t
- Renovascular disease, 647, 660–673
 azotemic, 647
 demographics of, 661
 diagnostic considerations in, 663–664, 663f
 in living kidney donor, 965–966
 renal angioplasty and stenting for, 664–673
 complications of, 660–661, 670–671, 671b, 671f
 demographics of, 660, 661f
 embolic protection devices with, 664, 665
 goals of, 660, 664
 vs. medical therapy, 648, 652, 653–654
 outcomes of, 666–670, 666f, 667t–669t, 670f
 patient selection for, 671–673
 restenosis after, 671, 671f
 techniques of, 664–665
 risks of progression of, 661–663, 662f
- Renovascular hypertension, 647, 660–673
 demographics of, 661
 diagnostic considerations in, 663–664, 663f
 renal angioplasty and stenting for, 664–673
 complications of, 660–661, 670–671, 671b, 671f
 demographics of, 660, 661f
 embolic protection devices with, 664, 665
 goals of, 660, 664
 vs. medical therapy, 648, 652, 653–654
 outcomes of, 666–670, 666f, 667t–669t, 670f
 patient selection for, 671–673
 restenosis after, 671, 671f
 techniques of, 664–665
 risks of progression of, 661–663, 662f
- Repaglinide
 in renal failure, 1062t, 1072t
 for transplant-associated hyperglycemia, 1014
- Replacement fluids, with plasmapheresis, 128
- Requip (ropinirole), in renal failure, 808t
- Rescue treatments, for thrombotic microangiopathy, 308
 with ADAMTS-13 deficiency, 300
 Shiga toxin–associated, 296–298
- Research, computer and, 1085
- Residual native kidney clearance, 883, 883t
- Residual syndrome, 877
- Resolvins, 116
- Respiratory acidosis, 378–379
 causes of, 378
 compensation for, 368, 370t
 diagnosis of, 378–379, 379b
 treatment of, 379
- Respiratory alkalosis, 385–386, 386t
 compensation for, 368, 370t
 hypophosphatemia due to, 421
- Respiratory compensation, for metabolic disturbances, 368, 370t
- Respiratory effects, of metabolic alkalosis, 381
- Respiratory syncytial virus (RSV), posttransplantation, 1038–1039
- Respiratory viruses, posttransplantation, 1038–1039
- Restless legs syndrome (RLS), 809, 822t, 833t
 in dialysis patients, 900
- Restoril (temazepam), in renal failure, 806t
- Resuscitation fluid
 monitoring and administration of, 6–7
 selection of, 5–6
- Retroviral vectors, for gene therapy, 557–558
- Reuse syndrome, 895
- Revascularization, for renal artery stenosis, 664–673
 complications of, 660–661, 670–671, 671b, 671f
 demographics of, 660, 661f
 goals of, 660, 664
 outcomes of, 666–670, 666f, 667t–669t, 670f
 techniques of, 664–665
- Reverse osmosis (RO) system, for hemodialysis, 846f, 853
- Reversible posterior leukoencephalopathy, 625
- rhEPO (recombinant human erythropoietin), 757–758, 760t
- Ribavirin
 for HCV-associated membranoproliferative glomerulonephritis, 152, 153, 153t, 154, 154t
 posttransplantation
 for adenovirus, 1039
 for hepatitis C, 1040
 in renal failure, 1060t, 1069t
- Rickets
 hypophosphatemic
 autosomal dominant, 549t, 550
 hereditary, with hypercalciuria, 549t, 550
 X-linked (vitamin D–dependent, familial), 548–550, 549t
 oncogenic, with phosphaturia, 549t
- Rickettsial infections, glomerulonephritis due to, 146
- Rifampin, for exit-site infections, 929
- RIFLE criteria, for acute renal failure, 3, 4f
- Right internal jugular catheter, for hemodialysis, 62
- Rilmendine, in renal failure, 1071t
- Rimantadine, in renal failure, 1069t
- Ringer, Sidney, 5
- Risedronate, for hypercalcemia, 414, 415
- Risk adjuster model, for renal transplantation costs, 839–840, 840t
- Risperidone (Risperdal)
 in end-stage renal disease, 803t, 813
 in renal failure, 1072t
- Rituximab (Rituxan)
 for glomerular and tubulointerstitial disease, 108
 for idiopathic membranous nephropathy, 243b, 244
 for lupus nephritis, 164b
 for membranoproliferative glomerulonephritis, 253f
 HCV-associated, 154–155
 for minimal change disease, 215
 for posttransplant malignancies, 1019
 for renal transplantation, 980t, 982
 for systemic vasculitis, 190
 for thrombotic microangiopathy with ADAMTS-13 deficiency, 300
- RLS (restless legs syndrome), 809, 822t, 833t
 in dialysis patients, 900
- RNA interference (RNAi), 558–559
- RO (reverse osmosis) system, for hemodialysis, 846f, 853
- Rocaltrol. *See* Calcitriol.
- Rocky Mountain spotted fever, glomerulonephritis due to, 146
- Rodent models, of acute kidney injury, 92–93
- ROMK, in Bartter syndrome, 552
- Ropinirole (Requip), in renal failure, 808t
- ROS (reactive oxygen species), 731
- Rosiglitazone
 in renal failure, 1062t
 for transplant-associated hyperglycemia, 1014
- Rosuvastatin
 for lipid management, 719t
 for posttransplant cerebrovascular disease, 1016
- Roxatidine, in renal failure, 1054t, 1065t
- Roxithromycin, in renal failure, 1058t, 1066t
- Rozerem (ramelteon), in renal failure, 806t
- RPGN (rapidly progressive glomerulonephritis)
 due to anti-GBM disease (*See* Antiglomerular basement membrane [anti-GBM] antibody disease)
 plasmapheresis for, 129, 130t
 due to systemic vasculitis (*See* Systemic vasculitis)
- RRT. *See* Renal replacement therapy.
- RSS (Really Simple Syndication), 1086
- RSV (respiratory syncytial virus), posttransplantation, 1038–1039
- RTA. *See* Renal tubular acidosis (RTA).
- Rufloxacin, in renal failure, 1059t, 1067t
- RVT (renal vein thrombosis), in nephrotic syndrome, 288
- S**
- 4S (Scandinavian Simvastatin Survival Study), 635, 636
- SAFE study, 6
- Salicylate(s)
 metabolic acidosis due to, 373
 in renal failure, 1054t, 1055t
- Salicylate intoxication, 1074–1075
 hemodialysis for, 62t
 respiratory alkalosis due to, 386, 386t
- Saline diuresis, for hyperphosphatemia, 419
- Saline-resistant metabolic alkalosis, 383t, 384–385, 384t
- Saline-responsive metabolic alkalosis, 382–384, 383t
- Salmonella*, glomerulonephritis due to, 144
- Salt intake, 583
- Salt reduction
 for end-stage renal disease, 774–775
 for hypertension, 569, 583–588
 algorithm for, 587–588, 588f
 assessment for, 586
 in DASH diet, 585–586
 definitions for, 583
 dietary patterns and, 585
 effect of, 576t, 577, 583–584
 in established disease, 587, 587b
 practical advice on, 587, 587b
 as prevention, 586–587
 public health strategies for, 584–585
 TONE study of, 579–580
 for nephrotic syndrome, 284
- Salt retention, in end-stage renal disease, 681–682
- Salt sensitivity, and inflammation, in hypertension, 119–120
- Salt substitutes, 585
- Sandimmune. *See* Cyclosporine.
- Sarafem (fluoxetine), in renal failure, 798t, 812
- Saralasin
 pharmacology of, 602–603
 renal actions of, 604
- Satavaptan
 for hyponatremia, 346t
 mechanism of action of, 391
- SC (sieving coefficient), 1076
- Scandinavian Simvastatin Survival Study (4S), 635, 636
- SCC (squamous cell carcinoma), posttransplantation, 1019–1020
- Schistosomiasis, glomerulonephritis due to, 147
- Schizophrenia, in end-stage renal disease, 802t–804t, 813
- Schloendorff v Society of New York Hospital*, 950
- Scleroderma, thrombotic microangiopathy in, 301
- Scribner, Belding, 947
- Scrub typhus, glomerulonephritis due to, 146
- SCT. *See* Stem-cell transplantation (SCT).
- SCUF (slow continuous ultrafiltration), 75f
- Secondary Prevention with Antioxidants of Cardiovascular disease in End-stage renal disease (SPACE) trial, 732
- Sedatives, in renal failure, 1054t, 1055t–1056t, 1064t
- Seizures
 in end-stage renal disease, 797–809, 806t–807t
 due to poisoning, 1073

- Selective serotonin reuptake inhibitors (SSRIs), in renal failure, 798t–799t
 for anxiety disorders, 811
 for depression, 812
- Selegiline, in renal failure, 1072t
- Selenium, in acute renal failure, 84
- Self-tolerance, 105
- Sematilide, in renal failure, 1061t, 1070t
- Senile systemic amyloidosis, 257, 259t
- Sensipar. *See* Cinacalcet hydrochloride.
- Sepsis, acute renal failure due to
 fenoldopam for, 23, 24t–27t
 vasopressor agent(s) for, 23–30
 epinephrine, 27–28
 norepinephrine, 26–27, 28t–29t
 phenylephrine, 28–29
 vasopressin, 29–30
- Septic shock, acute renal failure due to, vasopressor agent(s) for, 23–30
 epinephrine, 27–28
 norepinephrine, 26–27, 28t–29t
 phenylephrine, 28–29
 vasopressin, 29–30
- Serax (oxazepam)
 for intradialytic muscle cramps, 900
 in renal failure, 806t, 1054t, 1055t
- Seroquel (quetiapine)
 in end-stage renal disease, 803t, 813
 in renal failure, 1072t
- Sertindole
 in end-stage renal disease, 813
 in renal failure, 1063t
- Sertraline (Zoloft), in renal failure, 799t, 1063t
 for depression, 812
 for hypotension, 834t
- Serum sickness, plasmapheresis for, 135
- Sevelamer (Renagel)
 for bone disease, 768
 for hyperphosphatemia, 420
- Sexual dysfunction
 in end-stage renal disease, 813–814
 erectile (*See* Erectile dysfunction [ED])
 due to thiazide diuretics, 593–594
- SHEP (Systolic Hypertension in the Elderly Program) trial, 592, 593
- SHIFTS program, 1086–1087
- Shiga toxin, 295
- Shiga toxin binding agent (Synsorb Pk), 296
- Shiga toxin–associated hemolytic-uremic syndrome (Stx-HUS), 295–298
- Shiga toxin–associated thrombotic microangiopathy, 295–298, 307t, 309
- Shiga-like toxin, 295, 509
- Shigella dysenteriae*, 295
- Shock wave lithotripsy (SWL), extracorporeal, 430, 437
 antibiotics and, 442
 efficacy of, 438–439
 indications for, 471
 for renal calculi, 440, 441, 441f
 technique of, 470–471
 for ureteral calculi, 441–442
- Shohl's Solution (Bicitra), for renal tubular acidosis, 377
- Short hairpin RNAs (shRNAs), for gene therapy, 559
- Shunt nephritis, 144
- SIADH (syndrome of inappropriate secretion of antidiuretic hormone), 345, 346
- Sieving coefficient (SC), 1076
- Sildenafil (Viagra)
 for erectile dysfunction, 787–788814
 in renal failure, 1071t
- Simulect (basiliximab), for renal transplantation, 980t, 988
- Simvastatin
 for cardiovascular risk reduction in hypertension, 635, 636, 637t
 for lipid management, 719t
 for posttransplant hyperlipidemia, 1011, 1013t
- Sinemet (carbidopa/levodopa)
 in renal failure, 808t
 for restless legs syndrome, 833t
- Sinequan (doxepin), in renal failure, 800t
- Single-pool urea kinetics, 879–880
- siRNAs (small interfering RNAs), for gene therapy, 558–559, 561
- Sirolimus (Rapamune, SRL)
 drug interactions with, 985, 986b
 for focal segmental glomerulosclerosis, 228–229
 for glomerular and tubulointerstitial disease, 107–108
 for interstitial fibrosis and tubular atrophy in allograft, 1002, 1003
 posttransplant hypertension due to, 675–676
 for renal transplantation, 979f, 981t, 984–985, 988, 989
- Skim milk, for hypophosphatemia, 421t
- Skin cancer, posttransplantation, 1018, 1019–1020
- SLE (systemic lupus erythematosus), 157, 163–167
 in pregnancy, 489
 thrombotic microangiopathy in, 301
- SLED (slow low-efficiency dialysis), 58, 59, 61t
- SLEDD (sustained low efficiency daily dialysis), 75f, 78
- Sleep apnea, 681, 791–793, 809
- Sleep disorders, in chronic kidney disease
 insomnia as, 809–810
 periodic leg movements as, 809
 restless legs syndrome as, 809
 sleep apnea as, 791–793, 809
- Slow continuous dialysis, 58, 59
- Slow continuous ultrafiltration (SCUF), 75f
- Slow low-efficiency dialysis (SLED), 58, 59, 61t
- Slow-blood-flow method, for blood sampling in hemodialysis, 887–888, 888b
- Slow-Mag (magnesium oxide)
 for Gitelman's syndrome, 553
 for magnesuria, 550
 for posttransplant hypomagnesemia, 1026
- Small interfering RNAs (siRNAs), for gene therapy, 558–559, 561
- Small solute clearance, in peritoneal dialysis, 935–938
 clinical studies of, 937
 principles of quantification for, 935–937, 936b, 936f, 937b
 randomized controlled trials of, 937–938, 937t, 938f
- Smoking
 in end-stage renal disease, 773–774
 and hypertension, 636b, 636f, 638–639
 and posttransplant cardiovascular complications, 1014–1015
 and progressive renal failure, 708
 with renal artery stenosis, 654
- Smoking cessation
 and blood pressure, 638–639
 for end-stage renal disease, 774, 775t
 for hypertension, 576t, 578
 posttransplantation, 1014–1015
 for prevention of progressive renal failure, 700f, 708
 for renal artery stenosis, 654
- SNS (sympathetic nervous system)
 in end-stage renal disease, 683
 in erection, 784, 785f
- Sodium (Na⁺)
 faster reabsorption of, 355
 in hemodialysis fluid, 851, 897
 and inflammation, in hypertension, 119–120
 in peritoneal dialysis fluids, 916, 916t
 slower reabsorption of, 355
 total body, 337
- Sodium bicarbonate (NaHCO₃)
 for Fanconi syndrome, 551
 for hyperkalemia, 363
 for hypokalemia, 358
 in metabolic alkalosis, 383
- Sodium (Na⁺) channel(s), epithelial, 354, 355
- Sodium (Na⁺) channel blockers
 mechanism of action of, 389
 for metabolic alkalosis, 385
- Sodium chloride (NaCl)
 for pseudohypoaldosteronism, 548
 for volume replacement, 5
- Sodium citrate, for renal tubular acidosis, 377
- Sodium concentration, plasma, 337–338
- Sodium dialysance, 882
- Sodium (Na⁺) disturbances, during hemodialysis, 903
- Sodium excretion, dopamine as, 13–14, 15t
- Sodium ferric gluconate, for chronic kidney disease, 752, 753t, 758
- Sodium intake, 583
 with chronic kidney disease, 742t, 743
- Sodium modeling, for hemodialysis, 851, 900
- Sodium nitroprusside
 with dialysis, 688t, 689
 for hypertension with acute ischemic stroke, 632t
 for hypertensive emergencies, 626, 627t
 in children, 514t
- Sodium phosphate, for hypophosphatemia, 421t
- Sodium profiling, 897
- Sodium ramping, 897
- Sodium restriction
 for end-stage renal disease, 774–775
 for hypertension, 569, 583–588
 algorithm for, 587–588, 588f
 assessment for, 586
 in DASH diet, 585–586
 definitions for, 583
 dietary patterns and, 585
 effect of, 576t, 577, 583–584
 in established disease, 587, 587b
 practical advice on, 587, 587b
 as prevention, 586–587
 public health strategies for, 584–585
 TONE study of, 579–580
 for nephrotic syndrome, 284
 for prevention of progressive renal failure, 707
- Sodium sieving, 916, 940
- Sodium thiosulfate (STS), for calciphylaxis, 771
- Sodium-gradient hemodialysis, 851
- Sodium/hydrogen ion (Na⁺/H⁺) exchanger (NHE), 354, 354f
- Sodium-potassium adenosine triphosphatase (Na⁺/K⁺-ATPase), 353–354, 354f
- Sodium-potassium adenosine triphosphatase (Na⁺/K⁺-ATPase) inhibitor, in end-stage renal disease, 682
- Software, 1083
- Solid organ transplantation–associated thrombotic microangiopathy, 302–303, 307t
- Solu-Medrol. *See* Methylprednisolone.
- Solute accumulation, in hemodialysis adequacy, 876–877
- Solute disequilibrium, in hemodialysis, 880–882, 880f
- Solute distribution volume, 883–884
- Solute removal, in continuous renal replacement therapy, 76
- Solute sequestration, in hemodialysis, 880–882, 880f
- Somatostatin C, for autosomal dominant polycystic kidney disease, 544
- Sonata (zaleplon)
 for insomnia in end-stage renal disease, 810
 in renal failure, 806t
- Sorafenib, for renal cell carcinoma, 459
- Sorbent hemoperfusion, for poisoning, 1076, 1078b, 1078t
- Sorbent system intermittent hemodialysis, 58–59
- Sotalol
 with dialysis, 685, 685t, 1061t
 in renal failure, 1070t
- SPA (standard peritoneal permeability analysis), 918–919, 918t, 929–930
- SPACE (Secondary Prevention with Antioxidants of Cardiovascular disease in End-stage renal disease) trial, 732
- SPARCL (Stroke Prevention by Aggressive Reduction in Cholesterol Levels) study, 1016
- Sparfloxacin, in renal failure, 1059t, 1067t
- Spectinomycin, in renal failure, 1057t
- S-phosphorus, in end-stage renal disease, 775t
- Spirapril
 with dialysis, 686t
 in renal failure, 1071t
- Spirochetes, glomerulonephritis due to, 145
- Spirolactone
 adverse effects of, 607
 for ascites, 397–398
 in combination, 402–403, 402b
 dosage of, 390t
 historical background of, 607
 for hypertension, 597t, 607, 622
 in children, 514t
 due to primary aldosteronism, 691–692, 692f, 692t, 693
 for idiopathic edema, 398
 mechanism of action of, 389, 607
 for metabolic alkalosis, 385
 for nephrotic syndrome, 283–284
 pharmacokinetics of, 392t, 393
 pharmacology of, 607

- Spirolactone (*Continued*)
 for posttransplant coronary heart disease, 1016
 for prevention of progressive renal failure, 709
- Spitzer-Weinstein syndrome, 553
- Splenectomy, for thrombotic microangiopathy with ADAMTS-13 deficiency, 300
- Spreadsheets, 1084
- Squamous cell carcinoma (SCC), posttransplantation, 1019–1020
- SRL. *See* Sirolimus.
- SSRIs (selective serotonin reuptake inhibitors), in renal failure, 798t–799t
 for anxiety disorders, 811
 for depression, 812
- Staghorn calculi, 434, 441
- Standard peritoneal permeability analysis (SPA), 918–919, 918t, 929–930
- Staphylococcal infection, glomerulonephritis due to, 140, 142t, 143–144
- Staphylococcal septicemia, glomerulonephritis due to, 142t, 144
- Staphylococcus aureus*
 exit-site infections due to, 929
 glomerulonephritis due to, 142t, 143, 144
 peritonitis due to, 925, 926, 926f, 927–928
- Staphylococcus saprophyticus*, UTIs due to, 449, 450
- Statins. *See* 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors.
- Stavudine, in renal failure, 1069t
- Steal syndrome, dialysis-associated, 898–899
- Steinstrasse, 439, 471
- Stem-cell transplantation (SCT)
 for acute kidney injury, 96
 for AL amyloidosis, 260t, 262–263, 264, 462–463
 for cast nephropathy, 464–465
 for monoclonal light-chain deposition disease, 463
 for systemic vasculitis, 191–192
- Stenosis, of hemodialysis vascular access, 863–866, 863t, 865b
- Stenotrophomonas*, peritonitis due to, 926
- Stenting, for renovascular disease, 664–673
 complications of, 660–661, 670–671, 671b, 671f
 demographics of, 660, 661f
 embolic protection devices with, 664, 665
 goals of, 660, 664
 vs. medical therapy, 648, 653–654
 outcomes of, 666–670, 666f, 667t–669t, 670f
 techniques of, 664–665
- Steroids. *See* Corticosteroids.
- Stone disease. *See* Nephrolithiasis.
- STOP-2 trial, 612, 612t
- Stop-dialysate-flow method, for blood sampling in hemodialysis, 888, 888b
- Streptococcal infection, glomerulonephritis due to, 140, 141, 142–143, 142t
 in children, 507–508
- Streptococcus faecalis*, glomerulonephritis due to, 143
- Streptococcus pneumoniae*, neuraminidase-associated thrombotic microangiopathy due to, 298
- Streptococcus viridans*, glomerulonephritis due to, 142t, 143
- Streptogramins, in renal failure, 1059t
- Streptokinase, for thrombotic microangiopathy, 306t
- Stress reduction, for hypertension, 576t, 578
- Stroke
 hypertension due to, 630, 630f, 631t, 632t
 due to renal artery stenosis, 651t
- Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) study, 1016
- Struvite stones
 diagnosis of, 431
 prevention of, 434
 treatment of, 470
- STS (sodium thiosulfate), for calciphylaxis, 771
- Stx-HUS (Shiga toxin-associated hemolytic-uremic syndrome), 295–298
- Subarachnoid hemorrhage, due to hypertension, 630–631, 631t
- Subclavian catheter, for hemodialysis, 62, 860
- Subjective Global Assessment, 739
- Sudden death
 in dialysis patients, 779
 of hemodialysis patients, 898
- Sular. *See* Nisoldipine.
- Sulbactam, in renal failure, 1063t, 1072t
- Sulfamethoxazole, in renal failure, 1059t, 1067t
- Sulfamethoxazole/trimethoprim, for peritonitis, 928f
- Sulfisoxazole, in renal failure, 1067t
- Sulfonamides, in renal failure, 1059t, 1067t
- Sulindac, in renal failure, 1057t
- Sulodexide
 for focal segmental glomerulosclerosis, 230t
 for membranoproliferative glomerulonephritis, 253f
 for prevention of progressive renal failure, 709
- Sulotroban, in renal failure, 1064t
- Sulpiride, in renal failure, 1072t
- Sunitinib, for renal cell carcinoma, 459
- Superoxide anion, 731
- Supersaturation, relative, in nephrolithiasis, 431
- Supportive care, for end-stage renal disease, 828–835
 background of, 828
 integration of, 832–834, 834f
 for other symptoms, 829, 833t–834t
 for pain management, 829, 831b
 adjuvant medications in, 833t
 analgesic ladder of, 829, 831f, 832b, 832t
 assessment for, 831b
 opioids in, 829, 831b, 831f, 832b, 832t
 psychosocial issues with, 831b
 principles of good death in, 834, 834b
 symptom assessment for, 829, 830f
 symptom prevalence and impact for, 828–829
 symptoms of end of life in, 834, 835t
 withholding and withdrawing dialysis in, 828–832, 948–953, 949b
- Surrogate decision maker, withholding or withdrawal of dialysis with, 948–950, 949b
- Sustained low efficiency daily dialysis (SLEDD), 75f, 78
- SV40 virus, allograft dysfunction due to, 999
- Swiss LithoClast, 438
- SWL. *See* Shock wave lithotripsy, extracorporeal.
- Symmetrel (amantadine), in renal failure, 808t, 1060t, 1069t
- Sympathetic nervous system (SNS)
 in end-stage renal disease, 683
 in erection, 784, 785f

- Systemic immune disorders, acute interstitial nephritis in, 314
- Systemic lupus erythematosus (SLE), 157, 163–167
 in pregnancy, 489
 thrombotic microangiopathy in, 301
- Systemic vasculitis, 187–194
 defined, 187
 diagnosis of, 187–188
 treatment of, 188–194
 azathioprine for, 190, 191t, 193, 193t, 194t
 clinical trials on, 188–192
 cotrimoxazole for, 189, 192, 193t, 194t
 cyclophosphamide for, 189, 190, 191t, 192, 193, 193t, 194t
 cyclosporine for, 190, 191
 deoxyspergualin for, 191
 future directions in, 193
 induction, 188–190, 193t, 194t
 infliximab for, 190, 191
 intravenous immunoglobulin for, 190
 maintenance, 190–192, 191t, 193t, 194t
 methotrexate for, 189, 191, 191t, 192–193
 methylprednisolone for, 189, 191t, 192, 193t, 194t
 mycophenolate mofetil for, 190–191, 191t, 193t, 194t
 outcome of, 192
 plasma exchange for, 129, 130t, 188–189, 192, 194t
 prednisolone for, 191t, 192, 193, 193t, 194t
 rituximab for, 190
 specific recommendations on, 192–193
 after transplantation, 193, 193t, 194t
- SYST-EUR study, 612t, 613
- Systolic Hypertension in the Elderly Program (SHEP) trial, 592, 593
- Systolic pressure, 569
- T**
- T cell(s), 976–977
 in acute kidney injury, 93–94
 and immunosuppressive agents, 108–109
- TA (tubular atrophy), allograft dysfunction due to, 1000–1003, 1001t, 1002b
- Tacrolimus, extended-release (Prograf XL), for renal transplantation, 987
- Tacrolimus (Prograf, FK506)
 for allograft rejection, 999
 drug interactions with, 985, 986b, 1035t
 for focal segmental glomerulosclerosis, 227
 in children, 501
 for glomerular and tubulointerstitial disease, 107
 for idiopathic membranous nephropathy, 243–244, 243b
 for lupus nephritis, 164b
 posttransplant hypertension due to, 675–677
 for renal transplantation, 979f, 981t, 983, 987–988
 nephrotoxicity of, 1003
 optimal dose of, 1004
- Tadalafil (Cialis)
 for erectile dysfunction, 787–788
 in renal failure, 1071t
- Tai chi, for hypertension, 576t, 578
- Tamsulosin, for benign prostatic hypertrophy, 472
- Target of rapamycin (TOR) inhibitors, for renal transplantation, 981t, 984–985
- Tazobactam, in renal failure, 1063t, 1072t
- TB (tuberculosis)
 glomerulonephritis due to, 145
 posttransplantation, 1043
 and renal transplantation, 960
- 3TC (lamivudine)
 for HBV-associated renal disease, 273–274, 274t, 275t
 for posttransplant hepatitis B, 1039–1040
 in renal failure, 1060t, 1069t

- Venovenous high-flux dialysis, continuous, 75f
- Venovenous pumped techniques, 73–74
- Ventricular hypertrophy, left. *See* Left ventricular hypertrophy (LVH).
- Ventriculoatrial shunts, glomerulonephritis due to, 144
- Verapamil (Calan, Covera, Isoptin, Verelan)
 for diabetic nephropathy, 325
 with dialysis, 684t
 for hypertension
 cardiovascular effects of, 612–613, 612t
 pharmacology of, 610, 611t
 renal protective effects of, 613, 614, 615t
 with renal transplantation, 616
 safety of, 617
- Verapamil in Hypertension and Atherosclerosis Study (VHAS), 612, 612t
- Verotoxin, 295, 509
- Versed (midazolam), in renal failure, 805t
- Very low density lipoprotein (VLDL), in chronic kidney disease, 720, 722
- Vesicoureteral reflux (VUR)
 in children, 515–516
 after renal transplantation, 974
 and UTIs, 449
- Veterans Administration High-density Lipoprotein Cholesterol Intervention Trial (VA-HIT), 637
- VHAS (Verapamil in Hypertension and Atherosclerosis Study), 612, 612t
- Viagra (sildenafil)
 for erectile dysfunction, 787–788, 814
 in renal failure, 1071t
- Vidarabine, in renal failure, 1060t, 1069t
- Vigabatrin, in renal failure, 1064t
- Vincristine, for thrombotic microangiopathy, 306t, 308
- Viral hepatitis, glomerulonephritis due to, 145
- Viral infection(s)
 allograft dysfunction due to, 145–146
 glomerulonephritis due to, 145–146
 posttransplantation, 1035–1041
 with BK virus, 1040–1041
 with cytomegalovirus, 1035–1037
 with Epstein-Barr virus, 1037
 hepatitis B, 1039–1040
 hepatitis C, 1040
 with herpes simplex viruses 1 and 2, 1037–1038
 with human herpesvirus 8, 1038
 with human herpesviruses 6 and 7, 1038
 respiratory, 1038–1039
 with varicella-zoster virus, 1037–1038
- Viral vectors, for gene therapy, 557–558
- Virtual private network, 1085
- Visceral abscess, glomerulonephritis due to, 144
- Visceral leishmaniasis, glomerulonephritis due to, 147
- Vitamin(s)
 during hemodialysis, 904
 and inflammation, 117–118
 in parenteral nutrition for acute renal failure, 88t
- Vitamin A
 for chronic kidney disease, 744
 and inflammation, 118
- Vitamin B₆
 for hyperhomocysteinemia, 726–728, 727f, 728f
 and inflammation, 117–118
- Vitamin B₁₂, for hyperhomocysteinemia, 726–727, 727f, 728f
- Vitamin C
 in acute renal failure, 84
 for chronic kidney disease, 731, 744
- Vitamin D
 for chronic kidney disease, 744
 for hypocalcemia, 418
 for nephrotic syndrome, 287
 for posttransplant hyperparathyroidism, 1023
 for renal osteodystrophy in childhood and adolescence, 524
- Vitamin D deficiency, in chronic kidney disease, 768–770, 778
- Vitamin D intoxication, 413, 413f
- Vitamin D sterols, for bone disease, 767t, 769
- Vitamin D₂, for hypocalcemia, 418
- Vitamin D₃
 in calcium homeostasis, 412
 for hypocalcemia, 418
- Vitamin D–dependent rickets, 548–550, 549t
- Vitamin E
 for chronic kidney disease, 731, 732, 732t
 and inflammation, 118
 for thrombotic microangiopathy, 306t, 308
- Vitamin requirements
 in acute renal failure, 84
 in chronic kidney disease, 743–744
- Vitamin supplementation
 during hemodialysis, 904
 for hyperhomocysteinemia, 726–728, 727f
- VLDL (very low density lipoprotein), in chronic kidney disease, 720, 722
- Voiding, 473
- Voiding cystourethrogram (VCUG), 515–516
- Volume depletion
 assessment of, 4–5, 7, 7f
 classification of, 6
 compensated, 6
 due to diuretics, 398
 with electrolyte disturbances, 8–9
 volume replacement for, 4–8
- Volume expander
 monitoring and administration of, 6–7
 selection of, 5–6
- Volume expansion, for acute renal failure, 4–8
- Volume of distribution (V_d), 1049–1050, 1054t–1055t
- Volume of urea distribution, 876
 causes of discrepancies in, 885, 886b
- Volume overload, sleep disorders due to, 792
- Volume replacement, 4–8
 assessing need for, 4–5, 7, 7f
 with electrolyte disturbances, 8–9
 monitoring and administration of, 6–7
 with myoglobinuria, 7–8
 selection of fluid for, 5–6
- Volume status
 assessment of, 4–5, 7, 7f
 in peritoneal dialysis, 939–940, 943
- Vomiting, metabolic alkalosis due to, 382
- von Willebrand's factor (vWF), plasmapheresis for removal of, 125, 133
- von Willebrand's factor (vWF)-cleaving protease deficiency
 congenital, 305, 307t, 309
 immune-mediated, 298–300, 307t, 309
- Voriconazole, for posttransplant infections, 1042t
- VUR (vesicoureteral reflux)
 in children, 515–516
 after renal transplantation, 974
 and UTIs, 449
- vWF (von Willebrand's factor), plasmapheresis for removal of, 125, 133
- vWF (von Willebrand's factor)-cleaving protease deficiency
 congenital, 305, 307t, 309
 immune-mediated, 298–300, 307t, 309
- VZV (varicella-zoster virus), posttransplantation, 1037–1038
- W**
- Waldenström's macroglobulinemia, 462t, 465–466
- Warfarin
 for IgA nephropathy, 179, 180t, 507
 for membranoproliferative glomerulonephritis, 251
- Warfarin (*Continued*)
 in renal failure, 1050, 1056t
 for vascular access thrombosis, 762
- Water intake. *See* Fluid intake.
- Water softeners, for hemodialysis, 853
- Water treatment system (WTS), for hemodialysis, 846f, 852–853, 904–905
- Websites, 1085–1087, 1089t, 1090t
- Wegener's granulomatosis (WG), 187
 treatment of
 clinical trials on, 188
 induction, 188, 189, 190
 maintenance, 190, 191, 192
 outcome of, 192
 specific recommendations for, 192
- Weight loss
 for end-stage renal disease, 774, 775t
 for hypertension, 576t, 577, 587, 639–640
 for obstructive sleep apnea, 793
 for prevention of progressive renal failure, 707
- Wellbutrin (bupropion)
 for posttransplant smoking cessation, 1015
 in renal failure, 800t, 812
- West of Scotland Coronary Prevention Study (WOSCOPS), 635
- WG. *See* Wegener's granulomatosis.
- Whole bowel irrigation, for poisoning, 1074
- Wikikidney.org, 1086
- Wilms' tumor, 459
- Wilson's disease, 552
- Wood alcohol, acidosis due to, 374
- Word processor, integrating Internet with, 1083–1084
- WOSCOPS (West of Scotland Coronary Prevention Study), 635
- Wound care, for calciphylaxis, 771
- Wound infection, after renal transplantation, 972–973
- WT1 gene, 224t, 502
- WTS (water treatment system), for hemodialysis, 846f, 852–853, 904–905
- Wuchereria bancrofti*, glomerulonephritis due to, 147
- X**
- Xanax (alprazolam), in renal failure, 804t
- Xanthine oxidase inhibitor, for posttransplant gout, 1025
- Ximoprofen, in renal failure, 1065t
- X-linked hypophosphatemic rickets, 548–550, 549t
- Z**
- Zalcitabine, in renal failure, 1069t
- Zaleplon (Sonata)
 for insomnia in end-stage renal disease, 810
 in renal failure, 806t
- Zanamivir
 for posttransplant influenza, 1039
 in renal failure, 1069t
- Zemplar (paricalcitol)
 for bone disease, 769
 for hyperphosphatemia, 420
- Zenapax (daclizumab), for renal transplantation, 980t, 983
- Zidovudine, in renal failure, 1060t, 1069t
- Zileuton, in renal failure, 1060t
- Ziprasidone (Geodon), in end-stage renal disease, 804t, 813
- Zoledronic acid (Zometa)
 for hypercalcemia, 415
 for posttransplant osteoporosis, 1022, 1023
- Zoloft (sertraline), in renal failure, 799t, 1063t
 for depression, 812
 for hypotension, 834t
- Zolpidem (Ambien), in renal failure, 806t
- Zopiclone, in renal failure, 1056t
- Zyban (bupropion)
 for posttransplant smoking cessation, 1015
 in renal failure, 800t, 812
- Zyprexa (olanzapine)
 in end-stage renal disease, 803t, 813
 in renal failure, 1063t
