Loss of functioning renal parenchyma due to progressive renal failure is commonly associated with metabolic acidosis, which is typically hyperchloremic when the glomerular filtration rate is 20 to 50 mL/min but may convert to the classic high AG acidosis of uremia with more advanced renal failure, that is, when the glomerular filtration rate is less than 15 mL/min. The major defect in acidification with advanced renal failure is that ammoniogenesis is reduced in proportion to the loss of functional renal mass. In addition, medullary NH_4^+ accumulation and trapping in the medullary collecting duct are impaired. Because of adaptive increases in K^+ secretion by the collecting duct and colon, the acidosis of chronic renal insufficiency is typically normokalemic.⁶

Box 31-2 Differential Diagnosis of Hyperchloremic Metabolic Acidosis

Gastrointestinal Bicarbonate Loss Diarrhea External pancreatic or small bowel drainage Uterosigmoidostomy, jejunal loop Drugs Calcium chloride (acidifying agent) Magnesium sulfate (diarrhea) Cholestyramine (bile acid diarrhea)	Drug-induced hyperkalemia Potassium-sparing diuretics (amiloride, triamterene, spironolactone) Trimethoprim Pentamidine ACE inhibitors and ARBs NSAIDs Cyclosporine, tacrolimus Normokalemia Early renal insufficiency

FE_{HCO₃⁻}, fractional excretion of bicarbonate; RTA, renal tubular acidosis; TTKG, transtubular potassium gradient.

Renal Tubular Acidosis**Proximal Renal Tubular Acidosis**

Diagnostic Points The majority of cases of proximal RTA fit into the category of generalized proximal tubular dysfunction with glycosuria, generalized aminoaciduria, hypercitraturia, and phosphaturia. The generalized failure of proxi-

mal tubular function is referred to as Fanconi syndrome. The diagnosis is confirmed by demonstrating an inappropriately high rate of bicarbonate excretion in the face of a slow or normal plasma bicarbonate (>10%–15%). Causes of acquired proximal RTA include the dysproteinemias, heavy metal intoxication, vitamin D deficiency or resistance, cancer chemotherapeutic drugs (such as ifosfamide), and

genetically transmitted systemic diseases (Wilson's disease, hereditary fructose intolerance).²

Treatment The treatment of proximal RTA is directed toward amelioration of, or improvement in, the fluid, electrolyte, and acid-base abnormalities. In patients with proximal RTA, large amounts of exogenous bicarbonate are required to correct the $[\text{HCO}_3^-]$ to normal. Moreover, because bicarbonate absorption in the proximal tubule is impaired, the increase in distal bicarbonate delivery results in enhanced renal potassium wasting and hypokalemia. Therefore, large alkali loads are not advised; rather, smaller amounts of alkali therapy may be provided as Shohl's Solution (one to two tablespoons three times daily) or sodium bicarbonate tablets (650 mg, one to two tablets three times daily or 5–10 mEq/kg/day). If there is a compelling necessity to correct the plasma bicarbonate (growing children with proximal RTA), hydrochlorothiazide may be added to enhance proximal bicarbonate absorption. Most children and some adults will require potassium supplementation (K-Shohl's Solution or Polycitra, or -Lyte), particularly if larger doses of alkali are provided.

Classic Distal Renal Tubular Acidosis

Pathophysiology and Diagnostic Points The typical findings in classic distal RTA include hypokalemia, hyperchloremic acidosis, an abnormally low excretion of urinary NH_4^+ (positive UAG or low urinary osmolal gap), and, in contradistinction to proximal RTA, an inappropriately high urine pH in the face of systemic metabolic acidosis. Recently, the genetic bases of inherited forms of classic distal RTA have been elucidated. A number of patients in families with autosomal recessive distal RTA have been shown to have point mutations in the gene that encodes the basolateral $\text{HCO}_3^-/\text{Cl}^-$ exchanger (or band 3 protein) in A-type intercalated cells of the collecting duct. Other families with inherited sensorineural deafness and classic distal RTA have been shown to have defects in the H^+ -ATPase (Box 31-3). Finally, an inherited form not associated with hearing impairment has been associated with an abnormality of a unique subunit of the H^+ -ATPase. Under a number of different circumstances, including acute acid infusion, patients with classic hypokalemic distal RTA are unable to acidify their urine to a pH less than 5.5. Most patients with acquired distal RTA and many with inherited forms of distal RTA (except those with the $\text{HCO}_3^-/\text{Cl}^-$ exchanger defect)

uniformly display a lower urinary P_{CO_2} than normal subjects. These abnormalities suggest that one or both of the transporters in the collecting duct involved in bicarbonate absorption (H^+ -ATPase or H^+/K^+ -ATPase) are defective. In contrast, patients with the inherited HCO_3^-/Cl^- exchanger abnormality have been reported to have higher than normal urinary P_{CO_2} . This finding suggests that the HCO_3^-/Cl^- exchanger may be mistargeted to the apical membrane in these patients. With the exception of the gradient lesion (insertion of a leak pathway) that accompanies amphotericin B intoxication, most patients with distal RTA studied with dynamic tests of urinary acidification, such as urinary P_{CO_2} , have been shown to have a defect in H^+ secretion or a pump defect rather than the "gradient" or "leak" defect as proposed initially.²

Hypokalemia and hypercalciuria often accompany this disorder, but proximal tubule reabsorptive function is preserved. Thus, hypocitraturia is common, and the combination of hypercalciuria and hypocitraturia enhance urinary stone formation and nephrocalcinosis. Nephrocalcinosis is a marker of classic distal RTA because it does not occur with proximal RTA or the generalized dysfunction of the nephron associated with hyperkalemia. Nephrocalcinosis aggravates further the decrease in net acid excretion by impairing the transfer of NH_4^+ from Henle's loop to the collecting duct.

Most patients with distal RTA have distal RTA in association with a systemic illness, which is referred to as secondary distal RTA.

Treatment Correction of chronic metabolic acidosis can usually be achieved in patients with classic distal RTA by administration of alkali in an amount sufficient to neutralize the production of metabolic acids derived from the diet. In adult patients with distal RTA, this is usually equal to no more than 1 mEq/kg/day or 10 to 30 mL with water after meals and at bedtime, as Shohl's Solution or sodium bicarbonate tablets. Preparations include (1) Shohl's Solution (Bictra) (sodium citrate 500 mg and citric acid 334 mg/5 mL) and (2) sodium bicarbonate tablets (325 and 650 mg contain 3.8 and 7.6 mEq, respectively). In patients with distal RTA, correction of acidosis with alkali therapy reduces urinary potassium excretion, and hypokalemia and sodium depletion may resolve without additional therapy. Frank wasting of potassium may occur in a minority of patients in association with secondary hyperaldosteronism despite correction of the acidosis by the alkali therapy. A major benefit of correction of the acidosis is that the renal failure should not progress, especially when nephrocalcinosis accompanies distal RTA. The frequency of nephrolithiasis, when present, is usually markedly reduced by alkali therapy.²

Generalized Distal Nephron Dysfunction (Type 4 Renal Tubular Acidosis)

Pathophysiology and Diagnostic Points Although hyperchloremic metabolic acidosis and hyperkalemia occur with regularity in advanced renal insufficiency, patients with type 4 RTA have hyperkalemia that is disproportionate to the decrease in the glomerular filtration rate. In such patients, a generalized dysfunction of potassium and acid secretion by the collecting tubule is present. In this group of disorders, urinary NH_4^+ excretion is depressed and renal function often compromised at the time of diagnosis. Patients with renal insufficiency and hyperkalemia (>5.0 mEq/L) have hyperkalemia that is disproportionate to the decrease in the glomerular filtration rate. The causes of type 4 RTA are listed in Box 31-4.

The transtubular potassium gradient = $(U_K/P_K)/(U/P)_{osm}$, where U represents urine values and P represents plasma values. The transtubular potassium gradient is abnormally low in patients with this disorder, indicating that the collecting tubule is not responding appropriately to the prevailing hyperkalemia. Impaired NH_4^+ production and excretion, in part due to hyperkalemia, leads to impaired net acid excretion and systemic metabolic acidosis. This form of generalized distal tubule dysfunction with hyperkalemia is acquired with diabetic nephropathy, obstructive uropathy, sickle cell nephropathy, tubulointerstitial diseases, and transplant rejection (see Box 31-4).²

A number of patients have been reported with hyperkalemia, hyperchloremic metabolic acidosis, hypertension, undetectable plasma renin activity, and low aldosterone levels (type 2 pseudohypoaldosteronism). These patients generally have not exhibited glomerular or tubulointerstitial disease. The acidosis in such patients is mild and can be accounted for by the magnitude of hyperkalemia. Renal potassium secretion is resistant to mineralocorticoid administration. Renin and aldosterone levels both increase if volume expansion is corrected by diuretics or salt restriction. This autosomal dominant disorder is the result of an increase in expression and function of the sodium chloride cotransporter (NCCT) in the distal convoluted tubule. Specifically, the interacting proteins WNK1 and WNK4 normally responsible for regulating apical membrane localization of NCCT are defective. The hyperkalemia that follows depresses, in turn, NH_4^+ production and excretion and may result in hyperchloremic metabolic acidosis, especially in the face of even mild renal insufficiency. The result of this defect is constitutive activation of NCCT causing volume expansion, shunting of voltage, and a decrease in delivery of Na^+ and Cl^- to the cortical collecting tubule, causing decreased K^+ secretion.

In addition to this specific genetic abnormality, voltage defects may be acquired. For example, impaired operation of the sodium channel can also occur as a result of drugs that interfere with sodium channel function such as amiloride, triamterene, pentamidine, and trimethoprim, as a result of conditions that alter sodium absorption indirectly such as aldosterone resistance, or as a result of cyclosporine or tacrolimus administration. Nonsteroidal anti-inflammatory drugs and the angiotensin-converting enzyme inhibitors may also produce hyperkalemia and metabolic acidosis, particularly in patients with preexisting renal insufficiency or volume depletion or in the elderly. Therefore, drugs should always be considered as a possible cause of hyperkalemia and metabolic acidosis in such patients.²

Treatment A decrease in serum potassium enhances renal ammoniogenesis and NH_4^+ excretion, increasing net acid excretion and thus improving or correcting the metabolic acidosis. Treatment of patients with mild chronic hyperkalemia and metabolic acidosis with chronic renal insufficiency is not always necessary, and the decision to treat is often based on the severity of the hyperkalemia and acidosis, when present. Patients with combined glucocorticoid and mineralocorticoid deficiency should receive both adrenal steroids in replacement doses. Patients with hyporeninemic hypoaldosteronism may respond to a cation-exchange resin (sodium polystyrene sulfonate 15 g orally once daily *without sorbitol*), alkali therapy (Shohl's Solution, one to two tablespoons twice daily), or a loop diuretic (furosemide 40–80 mg/day) to induce renal potassium and salt excretion. with 9 α -fludrocortisone (0.1–0.3 mg/day) can theoretically improve net acid excretion. However, mineralocorticoid administration is contraindicated in the face of coexisting hypertension or congestive heart failure. Volume depletion should be avoided unless the patient is volume overexpanded or hypertensive. Pseudohypoaldosteronism in children (type I) should be treated with avid dietary sodium chloride intake, whereas pseudohypoaldosteronism in adults (type II) responds to thiazide diuretics and dietary salt restriction. Because bicarbonate is not avidly absorbed in the distal nephron, administration of bicarbonate in sufficient quantity to induce bicarbonaturia may reverse the voltage defect induced by amiloride, pentamidine, or trimethoprim by enhancing K⁺ and H⁺ secretion by the collecting duct.²

RESPIRATORY ACIDOSIS**Diagnostic Points**

Respiratory acidosis can be due to severe pulmonary disease, respiratory muscle fatigue, or abnormalities in ventilatory control and is recognized by an increase in PaCO₂ and a decrease in pH (Box 31-5). In acute respiratory acidosis, there is an immediate compensatory increase (due to cellular buffering mechanisms) in [HCO₃⁻], which increases by 1 mmol/L for every

10-mm Hg increase in PaCO₂. In chronic respiratory acidosis (>24 hours), renal adaptation increases the [HCO₃⁻] by 4 mmol/L for every 10-mm Hg increase in PaCO₂. The serum [HCO₃⁻] usually does not increase to more than 38 mmol/L.^{4,8}

The clinical features vary according to the severity and duration of the respiratory acidosis, the underlying disease, and whether there is accompanying hypoxemia. A rapid increase in PaCO₂ may cause anxiety, dyspnea, confusion, psychosis, and hallucinations and may progress to coma. Lesser degrees of dysfunction in chronic hypercapnia include sleep disturbances, loss of memory, daytime somnolence, personality changes, impairment of coordination, and motor disturbances such as tremor, myoclonic jerks, and asterixis. Headaches and other signs that mimic increased intracranial pressure, such as papilledema, abnormal reflexes, and focal muscle weakness, are due to vasoconstriction secondary to loss of the vasodilator effects of CO₂.

Depression of the respiratory center by a variety of drugs, injury, or disease can produce respiratory acidosis. This may occur acutely with general anesthetics, sedatives, and head trauma or chronically with sedatives, alcohol, intracranial tumors, and the syndromes of sleep-disordered breathing (e.g., primary alveolar and obesity hypoventilation syndromes). Abnormalities or disease in the motor neurons, neuromuscular junction, and skeletal muscle can cause hypoventilation via respiratory muscle fatigue. Mechanical ventilation, when not

properly adjusted or supervised, may result in respiratory acidosis, particularly if CO₂ production suddenly increases (because of fever, agitation, sepsis, or overfeeding) or alveolar ventilation decreases because of worsening pulmonary function. High levels of positive end-expiratory pressure in the presence of reduced cardiac output may cause hypercapnia as a result of large increases in alveolar dead space. Permissive hypercapnia is used to decrease barotrauma compared with conventional mechanical ventilation. It seems prudent to keep the pH in the range of 7.2 to 7.3 by administration of sodium bicarbonate.^{4,8}

Acute hypercapnia follows sudden occlusion of the upper airway or generalized bronchospasm as in severe asthma, anaphylaxis, inhalational burn, or toxin injury. Chronic hypercapnia and respiratory acidosis occur in end-stage obstructive lung disease. Restrictive disorders involving both the chest wall and the lungs can cause respiratory acidosis because the high metabolic cost of respiration causes ventilatory muscle fatigue. Advanced stages of intrapulmonary and extrapulmonary restrictive defects present as chronic respiratory acidosis.

The diagnosis of respiratory acidosis requires the measurement of PaCO₂ and arterial pH. A detailed history and physical examination often indicate the cause.

Treatment

The management of respiratory acidosis depends on its severity and rate of onset. Acute respiratory acidosis can be life threatening, and measures to reverse the underlying cause should be undertaken simultaneously with restoration of adequate alveolar ventilation. This may necessitate tracheal intubation and assisted mechanical ventilation. Oxygen administration should be titrated carefully in patients with severe obstructive pulmonary disease and chronic CO₂ retention who are breathing spontaneously. When oxygen is used injudiciously, these patients may experience progression of the respiratory acidosis. Aggressive and rapid correction of hypercapnia should be avoided because the decreasing PaCO₂ may provoke the same complications noted with acute respiratory alkalosis (i.e., cardiac arrhythmias, reduced cerebral perfusion, and seizures). The PaCO₂ should be lowered gradually in chronic

respiratory acidosis, aiming to restore the PaCO₂ to baseline levels and to provide sufficient Cl⁻ and K⁺ to enhance the renal excretion of HCO₃⁻.

Chronic respiratory acidosis is frequently difficult to correct, but measures aimed at improving lung function such as cessation of smoking, use of oxygen, bronchodilators, glucocorticoids, diuretics, and physiotherapy can help some patients and forestall further deterioration in most. The use of respiratory stimulants may be useful in selected patients, particularly if hypercapnia is out of proportion to the abnormality in lung function.

METABOLIC ALKALOSIS

The pathogenesis of metabolic alkalosis involves both the generation and maintenance of this disorder.¹ The generation of metabolic alkalosis refers to the addition of new HCO_3^- to the blood as a result of either loss of acid or gain of alkali. New HCO_3^- may be generated by either renal or extrarenal mechanisms. Because the kidneys have an enormous capacity to excrete HCO_3^- , even vigorous HCO_3^- generation may not be sufficient to produce sustained metabolic alkalosis. To maintain a metabolic alkalosis, the capacity of the kidney to correct the alkalosis must be impaired, or, equivalently, the capacity to reclaim HCO_3^- must be enhanced. After correcting the underlying cause, the treatment of metabolic alkalosis is directed toward removing those factors responsible for maintaining the alkalosis.

Clinical Consequences of Metabolic Alkalosis

Metabolic alkalosis is generally considered a benign condition by most physicians. However, there is evidence to suggest that under certain circumstances, metabolic alkalosis can contribute significantly to mortality. In fact, a direct relationship has been shown between increasing blood pH and hospital mortality in patients with a pH of greater than 7.48.^{2,3} The demonstration that high arterial blood pH correlates with mortality does not establish a cause-and-effect relationship. It is certainly plausible that conditions associated with high mortality cause metabolic and respiratory alkalosis, making alkalosis merely a marker of a poor prognosis. However, there are a number of reasons to believe that high blood pH can contribute to the poor prognosis. This is based on

some of the known pathophysiological effects of a high blood pH (Box 32-1).

First, increases in blood pH (alkalemia) cause respiratory depression. This effect of metabolic pH changes on respiration is mediated via both central and peripheral chemoreceptors. Although the effects of metabolic alkalosis on respiration are well appreciated, the effects of alkalosis to decrease tissue oxygen delivery are less well appreciated. Alkalosis can decrease oxygen delivery by two possible mechanisms. First, by the Bohr effect, alkalosis leads to a shift in the oxygen dissociation curve of hemoglobin, which decreases the ability of hemoglobin to release oxygen in peripheral tissues. Thus, even in the absence of changes in blood flow, alkalosis can lead to marked decreases in oxygen delivery to tissues.

In addition to the Bohr effect, alkalosis is a potent vasoconstrictor. Numerous studies have shown that increases in pH associated with decreases in PCO_2 (respiratory alkalosis) lead to vasoconstriction and decreased perfusion of the brain, heart, and peripheral circulation. Respiratory alkalosis is used clinically to decrease cerebral blood flow in patients with cerebral edema. Although it is unclear from studies in humans and whole animals whether pH changes due to metabolic alkalosis have the same effect, *in vitro* studies show that pH is the critical determinant of vascular smooth muscle tone irrespective of whether pH is altered by changes in PCO_2 or HCO_3^- concentration.^{4,5}

Alkalosis-induced vasoconstriction together with the Bohr effect may cause clinical tissue hypoxia in certain settings. For example, hyperventilation has been shown to precipitate chest pain, ST segment increase, and spasm on coronary angiography in patients with Prinzmetal's angina.⁶ Similarly, hyperventilation has been shown to cause angina in the presence or absence of coronary artery disease.⁷ Alkalosis has also been

Box 32-1 Systemic Effects of Metabolic Alkalosis

 - B. Central: Confusion, lethargy, seizures

reported to induce cardiac arrhythmias that are unresponsive to antiarrhythmics and respond only to correction of the alkalosis. Unfortunately, this is only substantiated by a number of case reports, and it is difficult to prove an increased incidence.

In summary, evidence suggests that alkalemia can decrease oxygen delivery to tissues, and this may become a key factor in some critically ill patients. Alkalemia constricts vascular smooth muscle *in vitro* and appears to decrease tissue perfusion *in vivo*. This, along with inhibition of oxygen release from hemoglobin, leads to decreased tissue oxygen delivery, which is demonstrable clinically with regard to the heart where coronary artery spasm, angina, arrhythmias, and congestive heart failure may be precipitated. Most likely, oxygen delivery to the brain is also compromised in ill patients with alkalosis, but it is frequently clinically difficult to distinguish brain hypoxia from other causes of encephalopathy. Given these considerations, alkalosis should be aggressively corrected in critically ill patients in whom perfusion of the heart and brain is essential.

Treatment

Metabolic alkalosis is best approached according to the mechanism of maintenance because correction of the maintenance mechanism leads to correction of the metabolic alkalosis. Reduced effective arterial blood volume is the mechanism responsible for the maintenance of metabolic alkalosis in the majority of patients. In those settings where effective blood volume can be restored with saline, the metabolic alkalosis is easily corrected.⁸

A number of conditions are poorly responsive to the administration of NaCl. These conditions are generally maintained by a combination of increased mineralocorticoid levels along with high distal Na⁺ delivery and hypokalemia. The distinction between these entities relies on assessment of the effective arterial volume. Effective arterial volume is assessed by physical examination (postural changes in blood pressure and pulse), the blood urea nitrogen-to-creatinine ratio, serum uric acid concentration, and urinary electrolytes. Although the urine Na⁺ concentration is useful in most patients to assess effective arterial volume, the urinary Cl⁻ is actually more helpful in this situation.

The advantage of urinary Cl⁻ is because many patients with metabolic alkalosis may have intermittent bicarbonaturia. HCO₃⁻ functions as a nonreabsorbable anion and carries a varying combination of Na⁺ and K⁺ into the urine causing urinary Na⁺ to be increased even though the patient may be volume contracted. In this setting, urinary Cl⁻ remains low and thus is more reflective of the volume contracted state. A urinary Cl⁻ less than 15 mEq/L is suggestive of metabolic alkalosis maintained by a low effective arterial volume, whereas a urinary Cl⁻ greater than 20 mEq/L is suggestive of metabolic alkalosis maintained by other mechanisms (Table 32-1).

Approach to the Patient with Decreased Effective Arterial Volume: Saline Responsive

Gastrointestinal Acid Loss

Loss of acid as occurs with vomiting or nasogastric suction is a common cause of metabolic alkalosis maintained by volume contraction. The loss of gastric acid generates a metabolic alkalosis, whereas the loss of NaCl in the gastric fluid leads to volume contraction. During active vomiting, the plasma HCO₃⁻ concentration tends to be higher than the threshold for reabsorption in the proximal nephron. The resultant bicarbonaturia leads to increased excretion of NaHCO₃ and KHCO₃, resulting in further total body Na⁺ depletion and development of K⁺ depletion. During this active phase, urinary electrolytes show a urine Cl⁻ less than 15 mEq/L, in the presence of a high urine Na⁺, a high urine K⁺, and a urine pH of 7 to 8. When the patient stops vomiting, an equilibrium is established such that bicarbonaturia disappears but a metabolic alkalosis is maintained by the volume contraction, K⁺ depletion, and decreased glomerular filtration rate. Of these factors, the effective arterial volume contraction is clearly the main factor in maintenance of metabolic alkalosis. At this time, urine Na⁺ and Cl⁻ are both low. Administration of NaCl results in bicarbonaturia and the metabolic alkalosis is corrected.

The amount of saline required to correct the alkalotic state should be determined by an ongoing assessment of the volume status of the patient. This assessment should include frequent monitoring for the presence of orthostatic changes in blood pressure and pulse, examination of the neck veins to assess jugular venous pressure, and determination of skin turgor. In addition to a decrease in the serum bicarbonate concentration, laboratory data indicating the effectiveness of therapy include a decrease in the blood urea nitrogen-to-creatinine ratio and evidence of less hemoconcentration as reflected by a decrease in albumin concentration and hematocrit.

K⁺ can be given orally or intravenously as KCl salt. The safest way to administer KCl is orally. KCl can be given in doses of 100 to 150 mEq/day. Liquid KCl is bitter tasting and like the tablet can be irritating to the gastric mucosa. The microencapsulated or wax-matrix forms of KCl are better tolerated. Intravenous administration of K may be necessary if the patient cannot take oral medications or if the K deficit is large and is resulting in cardiac arrhythmias, respiratory paralysis, or rhabdomyolysis. Intravenous KCl should be given at a

Table 32-1 Classification of Metabolic Alkalosis According to Mechanism, Cause, and Response to Administration of Saline

Effective Arterial Volume	Low	Low	High
Urine Cl concentration (mEq/L)	<15	>15	>15
Response to saline	Corrects (saline responsive)	No correction (saline resistant)	No correction (saline resistant)
Maintenance	Low effective arterial volume	Low effective arterial volume + high distal Na ⁺ delivery and mineralocorticoid effect	High distal Na ⁺ delivery and mineralocorticoid effect
	I. Gastrointestinal acid loss	I. Primary increase in distal delivery of Na ⁺	Primary increase in mineralocorticoid or mineralocorticoid-like effect
	A. Vomiting/nasogastric suction	A. Active diuretic use (loop and thiazide)	
	B. Congenital chloridorrhea	B. Mg ²⁺ deficiency	
	C. Villous adenoma	C. Bartter syndrome	
		D. Gitelman's syndrome	
	II. Posthypercapnic alkalosis		
	III. Diuretics		
	IV. Nonreabsorbable anions		

maximum rate of 20 mEq/hr and maximum concentration of 40 mEq/L.

Diuretics

Thiazide and loop diuretics are another common cause of a metabolic alkalosis. These diuretics lead to a metabolic alkalosis that is generated in the distal nephron by the combination of high aldosterone levels and enhanced distal delivery of Na⁺. If diuretics are stopped and the patient is maintained on a low-salt diet, the alkalosis will be maintained despite the fact that distal delivery is no longer increased. In this setting, patients tend to be volume contracted and K⁺ deficient. Once again, it is the contraction of the effective arterial volume that is the major factor leading to the maintenance of metabolic alkalosis. Saline infusion in this setting corrects the metabolic alkalosis.

Posthypercapnic Alkalosis

Another saline-responsive metabolic alkalosis is posthypercapnic alkalosis. When a patient becomes hypercapnic, the kidney retains NaHCO₃. The retention of NaHCO₃ leads to increased urinary excretion of NaCl in an attempt to maintain extracellular fluid volume unchanged. When the Pco₂ is then returned to normal, the kidney will attempt to correct the metabolic alkalosis by excreting NaHCO₃. However, if the patient is on a low-salt diet, as these patients frequently are for prevention of right-sided heart failure, the NaHCO₃ diuresis will lead to volume contraction, causing the bicarbonaturia to abate. The patient will be left with a metabolic alkalosis, once again maintained by decreased effective arterial volume. Administration of saline corrects the metabolic alkalosis.

In certain patients, it may be difficult to correct the factors responsible for maintenance of metabolic alkalosis. This most frequently occurs in patients whose metabolic alkalosis is

maintained by decreased effective arterial volume, but whose cardiovascular system cannot tolerate administration of NaCl. In these situations, one must ask how important it is to correct the metabolic alkalosis. Based on the previous discussion, patients in whom one would want to aggressively correct metabolic alkalosis would include (1) those with chronic lung disease in whom intubation is imminent or extubation is difficult and metabolic alkalosis needs to be corrected to improve the drive to respiration; (2) those with myocardial ischemia with evolving myocardial infarction, those who are having chest pain post-infarction, or those with unstable angina; and (3) ill patients with cerebral dysfunction in whom cerebral hypoperfusion is a possible contributing factor.

If metabolic alkalosis needs to be treated aggressively and cannot be treated by correcting the cause of the generation or maintenance, a number of options still exist. First, ammonium chloride can be given.⁹ This is generally a safe way to administer acid if given orally. However, if given intravenously, especially in patients with liver disease, ammonium chloride administration may cause ammonia toxicity. Arginine hydrochloride has been used in the past to lower the plasma [HCO₃⁻] but has been removed from the market because of life-threatening hyperkalemia.

The most commonly used approach to correcting alkalosis in these difficult patients is administration of carbonic anhydrase inhibitors such as acetazolamide. Carbonic anhydrase catalyzes the dehydration of luminal carbonic acid (produced when filtered HCO₃⁻ reacts with secreted H⁺) to water and CO₂ and the hydration of cellular CO₂ to carbonic acid, allowing the formation of H⁺ for secretion into the luminal fluid. The uncatalyzed dehydration of carbonic acid occurs very slowly. By inhibiting the activity of this enzyme, carbonic anhydrase inhibitors inhibit renal acidification and thus cause the kidney to at least partially correct the metabolic alkalosis.¹⁰

The magnitude of the bicarbonaturia induced is directly related to the serum HCO_3^- concentration. As the HCO_3^- concentration decreases, the clinical effectiveness of the drug declines in a parallel fashion. As a result, only rarely does the plasma HCO_3^- concentration return to normal.

Acetazolamide is frequently used in patients with chronic respiratory acidosis who develop a metabolic alkalosis. Normally, in patients with chronic respiratory acidosis, the capacity of the kidney to reabsorb bicarbonate increases, resulting in an increase in plasma HCO_3^- concentration. Use of loop diuretics in such patients, as in the treatment of cor pulmonale, can result in further increases in the serum HCO_3^- concentration. In this setting, the induction of a metabolic alkalosis can depress ventilation, aggravating both the hypoxemia and hypercapnia. Normally the metabolic alkalosis can be treated by discontinuing the diuretic and administering NaCl. In the patient who is significantly edematous, however, this approach may not be practical. In this circumstance, acetazolamide can be used to inhibit HCO_3^- reabsorption and thus lower serum HCO_3^- concentration.

A potential problem that is associated with use of carbonic anhydrase inhibitors in patients with lung disease is a worsening of hypercapnia. Carbonic anhydrase is normally present within red blood cells and is involved in CO_2 movement into red cells in peripheral tissues and movement from red cells into the alveoli in the lungs. Thus, carbonic anhydrase inhibition can prevent red-cell uptake of CO_2 in peripheral tissues and can prevent CO_2 release in the lung. The latter can lead to an increase in the Pco_2 of the arterial blood, whereas the former leads to an even further increase in Pco_2 in peripheral tissues. Generally, patients with normal lungs can respond to this by increasing respiration and preventing the increase in the Pco_2 of the arterial blood. However, patients with lung disease cannot respond adequately and further increases in arterial Pco_2 as well as even larger increases in unmeasured tissue Pco_2 may be dangerous to the patient.

A safe approach to the aggressive treatment of metabolic alkalosis that has gained support is the use of hydrochloric acid (HCl) infusions.^{11,12} In general, HCl can be safely administered as a 0.15 to 0.25 normal solution in normal saline or 5% dextrose in water given through a central line. Due to the sclerosing properties of HCl, it is imperative that the position of the central line in the superior vena cava be

verified by chest radiograph before initiating infusion. Infusion rates should be no more than 0.2 mmol/kg of body weight per hour. One should use a bicarbonate space of 50% of ideal body weight when calculating the amount of HCl to be given. As an example, to decrease the plasma bicarbonate from 50 to 40 mmol/L in a 70-kg patient, the amount of HCl required is 350 mmol ($10 \times 70 \times 0.5$). If the physician wishes, the HCl can be added to an amino acid solution in total parenteral nutrition and given centrally.¹³ In addition, there is also a report in which HCl was given in an amino acid solution with intralipid through a peripheral vein.¹⁴

Approach to the Patient with Decreased Effective Arterial Volume: Saline Resistant

In some forms of metabolic alkalosis, the alkalosis is maintained by a decreased effective arterial volume, but because other maintenance factors are also present, the alkalosis is not completely saline responsive. In these patients, saline infusions may improve the metabolic alkalosis but will not completely correct it. In general, these patients may have a low effective arterial volume but typically do not have a low urine Cl^- . One cause of this syndrome is continued use of thiazide or loop diuretics. Diuretic-induced volume contraction contributes to maintenance, but an additional factor, the combination of high distal Na^+ delivery without suppressed mineralocorticoid levels, also contributes to maintenance. Other conditions, such as magnesium deficiency, Gitelman's syndrome, and Bartter syndrome, are similar to this in that NaCl absorption in Henle's loop or distal convoluted tubule is inhibited. Once again, volume contraction contributes to maintenance of metabolic alkalosis, but the alkalosis is also maintained by high distal Na^+ delivery with high mineralocorticoid levels. The treatments of these conditions are summarized in Table 32-2.

Approach to the Patient with Increased Effective Arterial Volume: Saline Resistant

The last type of metabolic alkalosis is not maintained by a decreased effective arterial volume, but rather maintained by high

Table 32-2 Treatment of Various Saline-Resistant Causes of Metabolic Alkalosis

↓EABV		↑EABV	
Cause	Treatment	Cause	Treatment
Thiazide and loop diuretics	Discontinue drug, replete EABV	Renin-secreting tumor	Remove tumor
Mg^{2+} deficiency	Replete Mg^{2+} deficit	Primary hyperaldosteronism	Remove tumor, spironolactone for BAH
Gitelman's syndrome	Amiloride, triamterene, or spironolactone, K^+ supplements, Mg^{2+} supplements	Glucocorticoid-suppressible hyperaldosteronism	Dexamethasone
Bartter syndrome	Amiloride, triamterene, or spironolactone, K^+ supplements, Mg^{2+} supplements in some	Liddle syndrome	Amiloride or triamterene

BAH, bilateral adrenal hyperplasia; EABV, effective arterial blood volume.

mineralocorticoid levels (in the presence of maintained distal delivery of Na^+) and K^+ deficiency. The most common cause of this saline-resistant alkalosis is a primary increase in mineralocorticoid levels not related to volume contraction. The mechanism of the generation of the alkalosis described previously, enhanced Na^+ delivery with high mineralocorticoid activity, is also responsible for maintenance of the metabolic alkalosis in this setting. In addition, K^+ deficiency, which also occurs in this setting, exacerbates the tendency to alkalosis.

The preferred treatment of metabolic alkalosis in patients with volume expansion and primary mineralocorticoid excess is to remove the underlying cause of the persistent mineralocorticoid activity (see Table 32-2). When this is not possible, therapy is directed at blocking the actions of the mineralocorticoid at the level of the kidney. The potassium-sparing diuretics are effective agents in blocking the actions of mineralocorticoids in the kidney and are commonly used in the treatment of these disorders. Mineralocorticoid receptor blockers such as spironolactone are effective in these patients, with the exception of Liddle syndrome, in which the defect is distal to the receptor. Spironolactone inhibits Na^+ reabsorption by blocking the binding of aldosterone to its cytoplasmic receptor thereby inhibiting aldosterone-induced Na^+ reabsorption. The decrease in luminal electronegativity impairs distal acidification as a result of the decrease in the electrical driving force for H^+ secretion into the tubular lumen. Spironolactone can further limit distal H^+ secretion because this drug not only inhibits aldosterone-stimulated Na^+ reabsorption but also blocks the direct stimulatory effect of aldosterone on the H^+ secretory pump.

Na^+ channel blockers such as amiloride and triamterene are also effective in these patients. These drugs directly inhibit the luminal membrane Na^+ channel, decreasing the luminal electronegativity of the collecting duct and secondarily impairing renal K^+ and H^+ losses. The net result is inhibition of renal Na^+ retention, K^+ loss, and increases in renal net acid excretion, resulting in prevention of hypertension and hypokalemic alkalosis.

Liddle syndrome is characterized by hypokalemic metabolic alkalosis and volume expansion but is not due to mineralocorticoid excess. Rather, this disorder results from overactivity of the Na^+ channel in the distal nephron. Predictably, use of spironolactone to block the mineralocorticoid receptor is without effect in this disorder. By contrast, the electrolyte abnormalities and hypertension are normalized by use of the sodium channel blockers triamterene and amiloride.

RESPIRATORY ALKALOSIS

Primary respiratory alkalosis results from hypocapnia and is defined by a Paco_2 of less than 35 mm Hg in the setting of alkalemia. Primary respiratory alkalosis needs to be differentiated from secondary hypocapnia, which is a compensatory mechanism in the setting of primary metabolic acidosis.

Cause

An increase in alveolar ventilation relative to CO_2 production gives rise to respiratory alkalosis. Because changes in CO_2 production are negligible, almost all cases of hypocapnia result from increased CO_2 elimination, which is the equivalent of increased alveolar hyperventilation.

In the majority of cases, primary hypocapnia reflects pulmonary hyperventilation due to increased ventilatory drive. The latter might result from signals arising from the lung, the peripheral chemoreceptors (carotid and aortic), the brainstem chemoreceptors, or influences originating in other centers of the brain. The response to CO_2 of the brainstem chemoreceptors can be augmented by systemic diseases (e.g., sepsis, liver disease), pharmacological agents, anxiety, volition, and other influences. Hypoxemia is a major stimulus to pulmonary ventilation, but Pao_2 values less than 60 mm Hg are required to elicit this effect consistently.

Primary hypocapnia is probably the most frequent acid-base disturbance encountered. In critically ill patients, its presence might be a grave prognostic sign, especially if Pco_2 levels are less than 20 to 25 mm Hg.¹⁵ Furthermore, respiratory alkalosis is the most common acid-base abnormality in patients hospitalized in intensive care units, occurring either as the simple disorder or as a component of mixed disturbances.

Hepatic failure is a common and important cause of primary hypocapnia.¹⁶ The severity of hypocapnia correlates with the level of blood ammonia and has prognostic significance. Systemic infections arising from gram-positive and gram-negative bacteria are also a major cause of respiratory alkalosis. Direct stimulation of central chemoreceptors by bacterial toxins from gram-negative organisms accounts, at least in part, for the hyperventilation observed in some patients with sepsis. Thus, unexplained respiratory alkalosis in a hospitalized patient calls for evaluation for the presence of gram-negative sepsis. The presence of respiratory alkalosis can be an important clue to the presence of salicylate intoxication. High progesterone levels (pregnancy) can also cause respiratory alkalosis.

Clinical Manifestation of Respiratory Alkalosis

Although there is overlap in the clinical manifestations of metabolic and respiratory alkalosis, this section discusses those features specific to respiratory alkalosis. Mild respiratory alkalosis causes lightheadedness, palpitations, and paresthesias of the extremities and the circumoral area.¹⁷ Acute hypocapnia decreases cerebral blood flow and produces decreased acidity in all body fluids as well as hypocalcemia, hypokalemia, and a pH-induced shift of oxyhemoglobin dissociation curve; all these alterations have been implicated as determinants of the clinical manifestations of this acid-base disorder.^{18,19} The acute hypocapnia-induced reduction in cerebral blood flow might reach values less than 50% of normal, resulting in an increased lactate output by the brain due to cerebral hypoxia. A decrease in intracranial pressure, which is generally not harmful, and electroencephalographic changes consisting of generalized slowing and high-voltage waves are also present in acute respiratory alkalosis. The effects of acute hypocapnia on the cerebral circulation have been used in the treatment of brain edema resulting from neurosurgical procedures, head trauma, meningitis, and encephalitis. Unfortunately, the hypocapnia-induced reduction in intracranial pressure is short lasting, and blood flow returns to normal in sustained hypocapnia.

Hypocapnia leads to alkalemia, which causes binding of free calcium to albumin in the blood. Thus, patients with acute respiratory alkalosis might present clinically in a similar

way as patients with hypocalcemia. Chvostek's and Trousseau's signs are well-known clinical tests that can be occasionally elicited in patients with acute respiratory alkalosis.

The cardiovascular manifestations of respiratory alkalosis might be also very prominent. A major reduction in cardiac output accompanied by arteriolar vasoconstriction, tissue hypoperfusion, and a large increment in plasma lactate is frequently attributed to severe acute hypocapnia. This syndrome is typically observed in surgical patients under general anesthesia or those having depression of the central nervous system and receiving mechanical respiratory assistance; in all likelihood, it reflects the effects of passive hyperventilation. Normal volunteers with active hyperventilation do not develop clinical manifestations of coronary insufficiency or cardiac arrhythmias. Patients with ischemic heart disease might occasionally develop cardiac arrhythmias, ischemic electrocardiographic changes, and even angina pectoris during acute hypocapnia. None of the previously described hemodynamic effects seems to be present in uncomplicated chronic hypocapnia.

Treatment

Primary respiratory alkalosis is treated by correcting the underlying cause (Box 32-2). A patient with anxiety-hyperventilation syndrome should be treated by providing reassurance. Rebreathing into a paper bag or any other closed system will cause the PCO_2 to increase with each breath taken and lead to a partial correction of hypocapnia and improvement of symptoms. In the rare case in which there is no response to conservative management, sedatives can be used.

In mechanically ventilated patients the PCO_2 can be increased by either increasing the inspired CO_2 tension or by increasing the dead space of the ventilator circuit. Correction of respiratory alkalosis may prove helpful in correcting arrhythmias in patients with underlying coronary disease. By contrast, one needs to be cautious in increasing the PCO_2 in patients with brain injury because cerebral perfusion may increase and cause further worsening of intracranial pressure.

Respiratory alkalosis frequently develops as a complication of hypoxia. Administration of oxygen or return to lower altitudes can reverse the respiratory alkalosis that develops in this setting.

Box 32-2 Treatment of Respiratory Alkalosis

- I. Treatment begins with correcting underlying cause
- II. Hypoxemia
 - A. Supplemental oxygen
 - B. Return to lower altitude
- III. Mechanical ventilation
 - A. Increase dead space in ventilatory circuit
 - B. Sedation and/or use of paralytic agent
- IV. Psychogenic hyperventilation
 - A. Rebreathe into closed system (paper bag)
 - B. Antianxiety medications where indicated
- V. Salicylate toxicity
 - A. Urinary alkalinization
 - B. Hemodialysis with severe clinical toxicity or level >80 mg/dL

Aspirin (acetylsalicylic acid) has a direct stimulatory effect on the respiratory center. In the overdose setting, increased ventilation decreases the PCO_2 and results in respiratory alkalosis. In addition to conservative management, the initial goal of therapy is to correct systemic acidemia and to alkalinize the urine pH. By increasing systemic pH, the ionized fraction of salicylic acid will increase, and, as a result, there will be less accumulation of the drug in the central nervous system. Similarly, an alkaline urine pH will favor increased urinary excretion because the ionized fraction of the drug is poorly reabsorbed by the tubule. At serum concentrations of more than 80 mg/dL or in the setting of severe clinical toxicity, hemodialysis can be used to accelerate the removal of the drug from the body.

“Flooding of the heart” was described by the ancient Egyptians, and cures were often heroic.¹ The term diuretic is derived from the Greek *diouretikos* (“promoting urine”), and diuretics have been employed for hundreds of years. Paracelsus recognized the diuretic properties of mercury.¹ The modern era of diuretics began with the synthesis of thiazides and loop diuretics, which were developed empirically. Although few new diuretics have become available during the past 10 years, our understanding of diuretic-sensitive transport pathways has exploded, and progress in rational therapeutic approaches to edematous conditions has continued. This chapter reviews uses of diuretic drugs to treat edematous conditions. Where data from controlled trials support particular approaches or where consensus recommendations on therapy are available, they are emphasized. Otherwise, the authors provide their personal recommendation. The reader is referred elsewhere for a discussion of diuretic treatment of hypertension and nonedematous disorders (Chapters 29, 30, 35, and 51).

SITES, MECHANISMS OF ACTION, AND RECOMMENDED DIURETIC DOSES

The sites and mechanisms of action of the most commonly used diuretics are shown in Figure 33-1. Recommended doses are summarized in Table 33-1. The subject has been reviewed.^{2,3}

Most diuretic drugs in clinical use act primarily on the renal tubules to inhibit Na^+ reabsorption and increase fractional Na^+ excretion. Active NaCl reabsorption is driven by the Na^+/K^+ -ATPase pump, which is expressed at the basolateral membrane (the blood side) of epithelial cells along the nephron, keeping the intracellular Na^+ concentration low. Each nephron segment possesses unique apical mechanisms that permit Na^+ to move across the luminal membrane; these specific transport pathways at the luminal membrane form the molecular bases of most diuretic action. Together, active Na^+ extrusion from the basolateral membrane and passive Na^+ entry across the luminal membrane permit vectorial Na^+ absorption.⁴

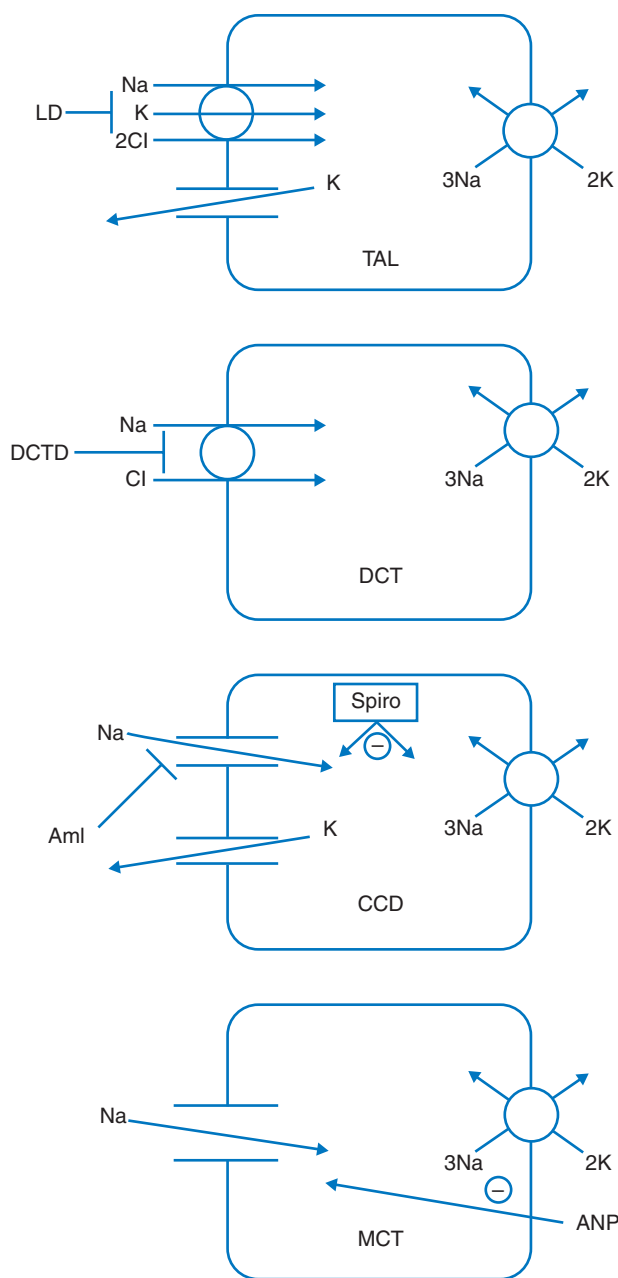

Figure 33-1 Principal cellular sites and mechanisms of action of the most commonly used classes of diuretics. Aml, amiloride; ANP, atrial natriuretic peptide; CCD, cortical collecting duct; DCT, distal convoluted tubule; DCTD, distal convoluted tubule diuretics; LD, loop diuretics; MCT, medullary collecting tubule; Spiro, spironolactone; TAL, thick ascending limb.

Proximal Tubule Diuretics

An important pathway by which Na^+ crosses the luminal membrane of proximal tubule cells involves electroneutral exchange of Na^+ for H^+ . Protons then titrate filtered bicarbonate, forming carbonic acid, which dehydrates to CO_2 and H_2O , a reaction catalyzed by carbonic anhydrase.^{5,6} Carbonic anhydrase inhibitors interfere with enzyme activity both inside the

cell and within the brush border. The net result is impaired Na^+ , HCO_3^- , Cl^- , and water reabsorption by the proximal tubule and increased renal Na^+ , Cl^- , HCO_3^- , and water excretion (for more details, see Ellison and Wilcox²). The use of carbonic anhydrase inhibitors is limited by the development of tolerance and unwanted adverse effects.^{2,7-12}

Loop Diuretics

Approximately 25% of the filtered NaCl is reabsorbed along Henle's loop. An electroneutral $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ transport pathway generates net NaCl reabsorption because much of the absorbed K^+ is recycled via a luminal K^+ channel. Loop diuretics such as furosemide, bumetanide, and torsemide inhibit the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ pathway directly (see Fig. 33-1).^{2,13,14} Loop diuretics are potent (high-ceiling) drugs that promote the excretion of Na^+ and Cl^- . Although they inhibit K^+ reabsorption along the thick ascending limb, their effects on K^+ excretion reflect predominantly an increase in K^+ secretion along the distal nephron. Loop diuretics increase Mg^{2+} and Ca^{2+} excretion.¹⁵⁻¹⁷ Loop diuretics also impair the ability of the kidney to concentrate and dilute urine and have important hemodynamic effects, both within the kidney and systemically. They increase secretion of vasodilatory prostaglandins¹⁸ and, when administered intravenously, often decrease cardiac preload owing to venodilation. Loop diuretics block the tubuloglomerular feedback mechanism.¹⁹ In normal subjects, they increase renal blood flow but have little effect on glomerular filtration rate (GFR).²⁰

Distal Convoluted Tubule Diuretics

Distal convoluted tubule (DCT) diuretics (thiazides and thiazide-like drugs) bind to the Na^+/Cl^- transporter expressed at the apical membrane of cells along the distal tubule (see Fig. 33-1).²¹ DCT diuretics impair urinary diluting capacity, but have no effect on urinary concentrating ability. Most DCT diuretics become less effective when the GFR decreases to less than 30 to 40 mL/min. DCT diuretics increase Mg^{2+} excretion but, in contrast to loop diuretics, decrease Ca^{2+} excretion.²²

Potassium-Sparing Distal Diuretics

Sodium reabsorption along the aldosterone-sensitive distal nephron (ASDN) (comprising the late DCT, the connecting tubule, and the cortical collecting duct), which amounts to only 3% to 5% of the filtered NaCl load, is primarily electrogenic (current generating), unlike transport along more proximal segments. Two groups of diuretics act predominantly in the ASDN. Sodium channel blockers (see Fig. 33-1), such as triamterene and amiloride,^{3,23} act from the lumen to inhibit Na^+ movement through Na^+ channels in cells of the ASDN. Because these drugs impair Na^+ movement along the ASDN, the lumen-negative transepithelial voltage decreases, thereby inhibiting K^+ secretion. This accounts for their potassium-sparing action. The second class is represented by spironolactone and eplerenone, competitive antagonists of mineralocorticoid receptors. Aldosterone stimulates Na^+ reabsorption and K^+ secretion along the ASDN and increases the lumen-negative transepithelial voltage. By inhibiting the action of aldosterone, these drugs cause mild natriuresis and K^+ retention. Spironolactone has troubling estrogenic side effects.²⁴

Table 33-1 Commonly Prescribed Classes of Diuretic and Recommended Dose Range

Class of Diuretic	Available Dose Sizes	Daily Dose Range (Starting Dose to Maximum Recommended* Dose)
Carbonic Anhydrase Inhibitors		
Acetazolamine	125, 250, 500 mg	125–375 mg
Loop Diuretics		
Furosemide	20, 40, 500 mg; 1 mg/mL (pediatric); 10 mg/mL (injection)	20–500 mg
Bumetanide	1, 5; 1 mg/5 mL (liquid); 0.5 mg/mL (injection)	0.5–10 mg
Torsemide	5, 10, 20, 100 mg; 5 mg/mL (injection)	5–200 mg
Ethacrynic acid	50 mg; 50 mg (powder for injection)	25–400 mg
Distal Convoluted Tubule Diuretics		
Bendrofluazide	2.5, 5 mg	2.5–10 mg
Chlorothiazide	250, 500 mg	250–2000 mg
Cyclopentiazide	25, 50 mg	25–100 mg
Hydrochlorothiazide	12.5, 25, 50 mg	12.5–200 mg
Hydroflumethiazide	50 mg	25–200 mg
Indapamide	1.25, 2.5 mg	1.25–5 mg
Methychlorothiazide	2.5, 5 mg	2.5–10 mg
Polythiazide	1, 2, 4 mg	0.5–4 mg
Chlorthalidone	15, 25, 50, 100 mg	15–200 mg
Mefruside	25 mg	12.5–100 mg
Metolazone	2.5, 5, 10 mg	2.5–10 mg (up to 150 mg has been used in renal failure)
Distal Potassium-Sparing Diuretics		
Na⁺ Channel Blockers		
Amiloride	5 mg	5–20 mg
Triamterene	50, 100 mg	50–250 mg
Mineralocorticoid Antagonists		
Spironolactone	25, 50, 100 mg	50–400 mg
Eplerenone	25, 50, 100 mg	50–200 mg
Aquaretics		
Conivaptan (IV)	20-mg load, then 20–40 mg/day	20 mg/4 mL
Natriuretic Peptides		
Nesiritide (IV)	1.5 mg powder	2 µg/kg bolus, then 0.01–0.03 µg/kg/min
Osmotic Diuretics		
Mannitol (IV)	5, 10, 15, 20, 25%	25–200 g

*The maximum safe dose of most diuretics is rarely indicated or advantageous.

Eplerenone is a more selective aldosterone antagonist without these adverse effects.²⁵

Natriuretic Peptides

Atrial natriuretic peptide (ANP) and B-type natriuretic peptide act at many sites in the kidney and elsewhere to decrease left atrial pressure and blood pressure and increase renal salt excretion. As shown in Figure 33-1, a major site of ANP action in the kidney is along the medullary collecting tubule. Natriuretic peptides are metabolized by endopeptidases. Drugs that inhibit neutral endopeptidase increase plasma ANP concentrations. In hypertensive patients, this decreases blood pressure, increases the GFR and renal Na^+ excretion, and decreases the plasma renin activity.²⁶ Nesiritide is a recombinant B-type natriuretic peptide that is approved for use in patients with decompensated heart failure.²⁷

Osmotic Diuretics

Osmotic diuretics, such as mannitol, do not interfere directly with specific transport proteins but rather act as osmotic particles in tubule fluid. This inhibits both fluid and NaCl reabsorption (for more details, please see Ellison and Wilcox,² Better and colleagues,²⁸ and Warren and Blantz²⁹). Thus, these drugs increase the excretion not only of fluid but also of Na^+ , K^+ , Cl^- , bicarbonate, and other solutes. The urinary osmolality during osmotic diuresis approaches that of plasma, regardless of the state of hydration. Osmotic diuretics increase renal blood flow and wash out the medullary solute gradient, effects that contribute to the diuretic-induced impairment in urinary concentrating capacity.

Aquaretics

Arginine vasopressin receptor antagonists (aquaretics) are new therapeutic agents to treat euvolemic and hypervolemic hyponatremia. Unlike the other diuretics discussed previously, these drugs enhance the excretion of electrolyte-free water by blocking arginine vasopressin binding to vasopressin receptors. In the kidney, vasopressin type 2 receptors (V_2 receptors) at the basolateral membrane of collecting duct cells transduce an increase in apical water permeability, thereby increasing water reabsorption; conversely, blocking this receptor increases water excretion when vasopressin is present. Conivaptan is the first aquaretic approved for clinical use in the United States. It is a combined V_2 and V_{1a} antagonist that is available only as an intravenous preparation. In a controlled trial of patients with euvolemic and hypervolemic hyponatremia, it caused a dose-dependent increase in serum sodium concentration (S_{Na}),³⁰ whereas in patients with heart failure, it increased urine volume and decreased the pulmonary capillary wedge pressure.³¹ It is currently approved to treat both euvolemic and hypervolemic hyponatremia, but its route of administration means that its use is restricted to hospitalized patients. Although its nonselective properties make hypotension a potential side effect, owing to the blockade of vascular V_1 receptors, this has not been prominent in clinical studies to date.

Orally active vasopressin receptor antagonists cause free water diuresis without appreciable natriuresis in water-deprived human subjects.³² They increase urine volume, free

water clearance, and S_{Na} in hyponatremic patients with syndrome of inappropriate secretion of antidiuretic hormone (SIADH).³³ One such agent, lixivaptan, is an oral vasopressin receptor antagonist that is selective for aquaretic (V_2) receptors and increases S_{Na} in patients with syndrome of inappropriate secretion of antidiuretic hormone, congestive heart failure (CHF), or cirrhosis.³⁴ Tolvaptan is another agent that has been subjected to controlled trials. When given to patients with heart failure, it increases the urine volume, decreases the body weight, and decreases edema at 7 days³⁵ and maintains the S_{Na} within the normal range for as long as 25 days.³⁶ In the second study of hospitalized patients with an ejection fraction less than 40%, it decreased the body weight on the first day. Although it did not modify CHF outcomes at 2 months, it corrected hyponatremia and appeared beneficial in subgroups of patients with azotemia or those with clinical signs of congestion at baseline. A recent study in patients with New York Heart Association class II to III CHF has shown that 30 mg tolvaptan produces a diuresis similar to that with 80 mg furosemide, but, unlike furosemide, does not increase renal Na^+ and K^+ excretion and does not decrease renal blood flow.³⁷ A recent large controlled international trial of tolvaptan in hospitalized patients with worsening heart failure failed to detect a decrease in long-term mortality or heart failure–related mortality over 9 months.³⁸ A third oral V_2 receptor antagonist, satavaptan, was effective in controlling S_{Na} for as long as 12 months in an open-label study.³⁹ Thus, arginine vasopressin antagonists appear to be an effective means to treat acute or chronic conditions associated with dilutional hyponatremia.

New Agents

Aminophylline is an adenosine receptor antagonist that inhibits NaCl reabsorption in the proximal tubule and diluting segments and causes a modest increase in GFR.⁴⁰ Highly selective adenosine type 1 receptor antagonists are natriuretic⁴¹ and antihypertensive, and potentiate furosemide-induced natriuresis in normal humans⁴² and in patients with diuretic-resistant CHF. Adenosine type 1 receptor antagonists disrupt glomerulotubular balance and tubuloglomerular feedback, thereby decreasing proximal reabsorption and maintaining the GFR.⁴¹

PHARMACOKINETICS

Most diuretics in clinical use have their predominant site of action on the luminal membrane of the nephron. Therefore, to be effective, they must be absorbed across the gastrointestinal tract, reach the systemic circulation in active form, and be concentrated in tubular fluid; the final process usually requires secretion across the proximal tubule.⁴³

Most diuretics are well absorbed. The bioavailability of furosemide is 50% to 69%,² whereas the bioavailability of bumetanide and torsemide is approximately 90% (Table 33-2). Loop diuretics circulate bound to albumin (95%–99%). Therefore, loop diuretics do not enter kidney tubules by glomerular filtration and instead undergo secretion along the proximal tubule. Carbonic anhydrase inhibitors, loop diuretics, and thiazides are weak organic anions (OA^-) that are taken up across the basolateral membrane of the proximal tubule by an organic anion transporter (OAT) (Fig. 33-2).⁴⁴ Four OAT genes are

Table 33-2 Pharmacokinetics of Diuretic Drugs

Diuretic	Oral Bioavailability (%)	ELIMINATION HALF-LIFE (HR)			
		Normal	CKD	Cirrhosis	Heart Failure

expressed in the kidney.⁴⁴ OAT-1 and OAT-3 have been shown to have high affinity for loop, thiazide, and carbonic anhydrase diuretics^{45,46}; genetic disruption of OAT-1 leads to furosemide resistance in mice, indicating that OAT-1 plays an important

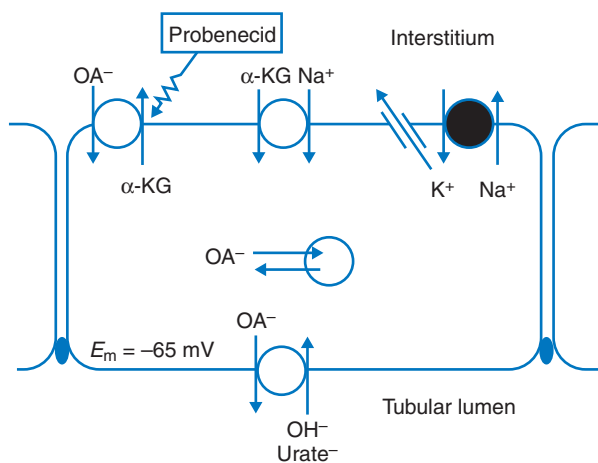

Figure 33-2 Cell model for secretion of organic anions (OA^-) by proximal tubule cells. For description, see text. Carbonic anhydrase, loop, and thiazide diuretics can all be transported by the organic anion transporter (OAT) in exchange for α -ketoglutarate (α -KG). E_m , membrane potential.

role in diuretic secretion by the proximal tubule.⁴⁴ OA transport across the basolateral cell membrane is a tertiary active system in which OAs are exchanged for intracellular α -ketoglutarate. The intracellular levels of α -ketoglutarate are kept high by a parallel cotransporter of Na^+ / α -ketoglutarate. This uses the favorable electrochemical gradient for Na^+ created by the operation of the basolateral Na^+/K^+ -ATPase and a negative membrane potential created by a basolateral K^+ conductance.

The luminal brush border secretory pathway for OA^- and diuretics is less well defined. Two mechanisms have been identified. One is a voltage-driven OAT⁻ that derives energy from the negative membrane potential.⁴⁷ This process can transport loop diuretics and thiazides in addition to *p*-aminohippurate and urate.⁴⁷ There is also an OA:urate/hydroxyl anion countertransport mechanism that could provide an exit route for diuretics from the proximal tubule cells.⁴⁴

Several factors alter secretion of loop diuretics, thereby affecting their actions. Other OAs can compete with diuretics for transport by OAT. These include β -lactam and sulfonamide antibiotics, nonsteroidal anti-inflammatory drugs,⁴⁸ antiviral agents such as adefovir, *p*-aminohippurate, methotrexate, uric acid, and a number of endogenous organic anions.⁴⁹ In contrast, uptake of loop diuretics into the proximal tubule cells is stimulated by alkalosis⁵⁰ and by albumin across the range found in plasma.^{51,52} Therefore, chronic kidney disease impairs loop diuretic secretion because of the

accumulation of OAs and urate, the development of acidosis, and often a decrease in serum albumin concentration.⁵³

Approximately one half of an intravenous dose of furosemide is eliminated unchanged by the kidney, whereas one half is eliminated as the inactive glucuronide. In contrast, bumetanide and torsemide are not subjected to major glucuronidation, but instead are metabolized by a cytochrome P-450 process in the liver to inactive metabolites.^{43,54} Thiazide diuretics are mostly excreted in active form. As noted, proximal tubule cells possess mechanisms to bioinactivate furosemide specifically.^{55–57} Studies in experimental animals have shown that, after peritubular uptake into the early segment of the proximal tubule, furosemide is metabolized by uridine diphosphate-glucuronyl transferase to the inactive glucuronide, which is secreted into the proximal lumen.⁵⁸ In experimental animals, this uptake process is inhibited by serum albumin,⁵³ in contrast to the stimulation by albumin of the uptake process that transports active furosemide into the tubular lumen. Therefore, a decrease in serum albumin concentration may decrease the secretion of active furosemide and increase the renal uptake and metabolism to the inactive glucuronide. These studies in animals have yet to be confirmed by clinical investigation.

The relationship between the log of the plasma or urinary loop diuretic concentration and the fractional sodium excretion is normally sigmoidal (Fig. 33-3). This is analogous to a dose-response curve. Inhibition of proximal secretion with probenecid decreases diuretic secretion into the urine and natriuresis, but does not perturb the relationship between natriuresis and diuretic excretion. This is consistent with the effect of probenecid to inhibit diuretic secretion rather than blocking the diuretic action on the nephron.⁴⁹ A similar interaction occurs with indomethacin,⁴⁸ although the main effect of nonsteroidal anti-inflammatory drugs is to decrease the responsiveness of

the tubule to furosemide.⁴⁸ This is predominantly the result of decreased generation of prostaglandin E₂ because the natriuretic response to furosemide can be restored in indomethacin-treated rats by microperfusion of prostaglandin E₂ into the nephron.⁵⁹ A reduced dietary salt intake and repeated administration of furosemide during salt restriction cause a shift in the natriuresis-drug concentration curve to the right and thereby diminish the natriuretic responsiveness to a unit delivery of diuretic to the tubule lumen.⁶⁰

There are some pharmacokinetic differences between loop diuretics. Bumetanide is more extensively metabolized than furosemide, which accounts for its shorter half-life.⁴³ Torsemide is less extensively metabolized and more bioavailable than other loop diuretics and has a rather longer half-life.^{54,61–63} The more lipid-soluble drugs (e.g., bendroflumethiazide and polythiazide) are more potent, have a more prolonged action, and are more extensively metabolized.⁶⁴ DCT diuretics are handled at the kidney similarly to loop diuretics.⁶⁴

Of the distal potassium-sparing agents, triamterene is well absorbed. It is rapidly hydroxylated to metabolites that retain some diuretic activity.^{65,66} The drug and its metabolite are excreted by the kidney, with a half-life of approximately 3 to 5 hours, which is delayed in renal failure.⁶⁷ Amiloride is incompletely absorbed. It is secreted in active form into tubular fluid.⁶⁸ It has a longer duration of action, approximately 18 hours. Spironolactone is an aldosterone antagonist. It is metabolized to active compounds (canrenones).^{69,70} It is readily absorbed and bound to plasma proteins. Although spironolactone itself has a relatively short half-life, the half-life of pharmacologically active metabolites is approximately 20 hours, meaning that effects of spironolactone on serum potassium can persist for several days after discontinuation. Spironolactone takes as long as 48 hours to become fully effective.

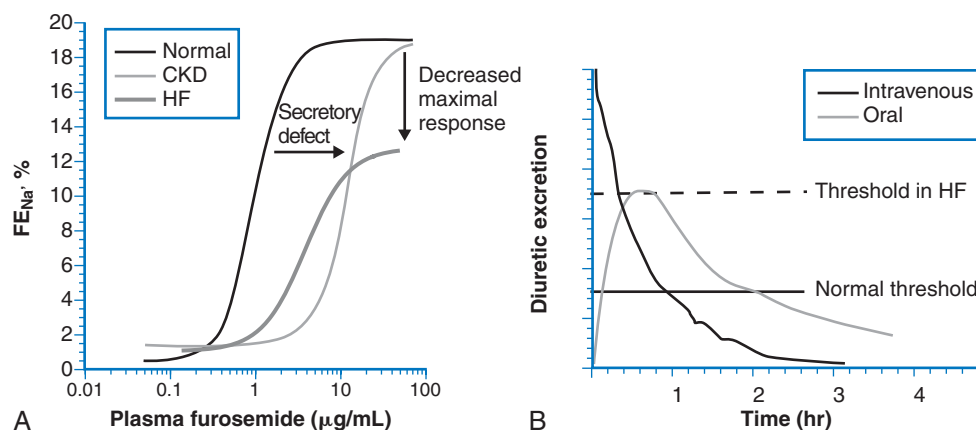

Figure 33-3 Dose-response curve for loop diuretics. **A**, The fractional Na⁺ excretion (FE_{Na}) as a function of plasma loop diuretic concentration. Compared with normal subjects, patients with chronic kidney disease (CKD) show a rightward shift in the curve owing to impaired diuretic secretion. The maximal response is preserved when expressed as FE_{Na} (but not when expressed as absolute Na⁺ excretion). Patients with congestive heart failure (CHF) demonstrate a rightward and downward shift, even when expressed as FE_{Na}, and thus are relatively diuretic resistant. **B**, Comparison of the response to intravenous and oral doses of loop diuretics. In a normal individual (Normal), an oral dose may be as effective as an intravenous dose because the time above the natriuretic threshold (indicated by the Normal threshold line) is approximately equal. If the natriuretic threshold increases (as indicated by the Heart Failure threshold line), then the oral dose may not provide a high enough serum level to elicit natriuresis.

Nesiritide (B-type natriuretic peptide) is approved only for intravenous use. It exhibits biphasic disposition from the plasma. The mean terminal half-life is approximately 18 minutes. The mean initial half-life is approximately 2 minutes.

CLINICAL USE OF DIURETICS

A general approach to diuretic treatment of edema and diuretic resistance is presented in Figure 33-4. Use of diuretics to treat specific disorders is discussed in the following.

Acute Renal Failure

Acute renal failure is frequently associated with a decrease in urine output. Obstruction of kidney tubules by casts and sloughed cells can contribute to renal dysfunction. Patients who develop oliguria in the setting of acute renal failure have mortality rates that are higher than those in whom oliguria does not develop. For all these reasons, diuretic drugs have been used commonly in attempts to prevent or treat acute renal failure⁷¹ (see also Chapter 3). However, a review of 11 randomized trials found no benefit of loop

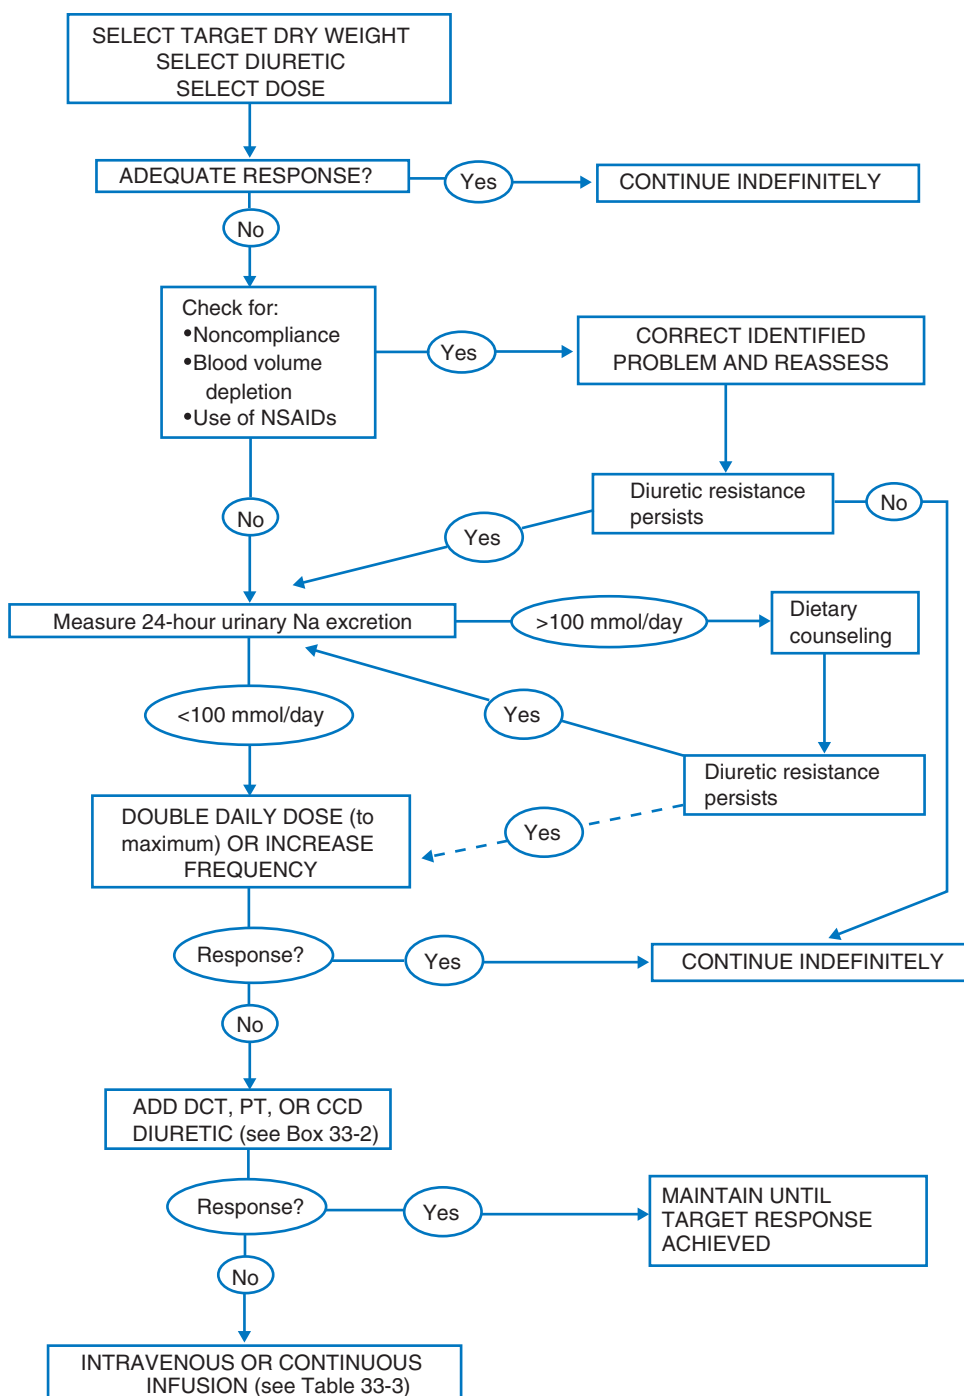

Figure 33-4 Algorithm for treating patients with ascites. TIPS, transjugular intrahepatic portosystemic shunting. Based in part on recommendations of Runyon.¹³⁶

diuretics or mannitol for the prevention or treatment of acute renal failure.⁷¹

Prevention

Several studies have examined the ability of diuretics, including mannitol, to prevent renal failure in high-risk situations. Mannitol decreases the risk of acute renal failure after renal transplantation.⁷² Mannitol is also commonly used as prophylaxis for patients undergoing vascular surgery, although data in support of its efficacy are mixed.⁷³ Mannitol may also be effective as part of a regimen of forced alkaline diuresis in the setting of crush injuries and rhabdomyolysis,⁷⁴ although controlled studies are not available. In a subset of patients with diabetic kidney disease, mannitol was found to decrease the likelihood of acute renal failure after cardiac catheterization, but the number of patients studied was small.⁷⁵ Conversely, in several situations, mannitol provides no prophylactic benefit. In a well-controlled study of radiocontrast-induced acute renal failure, both mannitol and furosemide were inferior to 0.45% NaCl as prophylaxis.⁷⁶ Furthermore, mannitol itself may induce acute renal failure.⁷⁷ In reviewing data concerning mannitol and acute renal failure, Conger⁷³ concluded that mannitol has an established role only in preventing primary transplant dysfunction. Most clinicians would also use mannitol (initial dose of 12.5 g followed by 50–100 g/24–48 hr) to prevent myoglobinuric acute renal failure.

Furosemide does not appear to have a role in prophylaxis for radiocontrast-induced acute renal failure.⁷⁶ Lassnigg and colleagues⁷⁸ reported that neither dopamine nor furosemide was superior to saline to prevent renal failure after cardiac surgery. Thus, loop diuretics are not indicated for prophylaxis for acute renal failure.

Treatment

High doses of loop diuretics (2–15 mg/kg) can increase urine output in some patients with oliguric acute renal failure.^{79,80} This may be a useful effect because increasing water and electrolyte excretion makes controlling extracellular fluid (ECF) volume easier. Although initial reports showed that patients whose urine output increases after diuretic administration have lower mortality than those whose output does not increase, the effect is not causal. Shilliday and colleagues⁸¹ randomized 92 patients with acute renal failure to either loop diuretics or placebo. All patients received dopamine and mannitol. The results showed that loop diuretics significantly increased urine output, but did not affect the requirement for dialysis or the time until renal recovery. These data suggest that a positive response to diuretics identifies a less severely affected subgroup of patients. A cohort study of patients in intensive care units with acute renal failure showed a positive association between diuretic use and mortality, raising the possibility that these drugs may have adverse effects in this clinical setting.⁸² A subsequent randomized, controlled study of dialysis-dependent patients with acute renal failure did not show a significant effect of diuretics on mortality.⁸³ These conflicting results and the continuing use of diuretics in this clinical setting have led to calls for larger multicenter randomized trials.⁸⁴

High-dose loop diuretic infusion in the setting of acute renal failure is not necessarily benign. In one study, deafness occurred in 3.4% of patients treated with high doses of furosemide (3 g/day in addition to an initial bolus).⁸⁵ Renal failure

impairs metabolic clearance of loop diuretics, especially furosemide. Thus, renal failure is a risk factor for loop diuretic-induced ototoxicity.

To summarize, several studies indicate that loop diuretics can increase urine output in the setting of oliguric acute renal failure. Continuous infusion may be especially effective in this regard. Despite increasing urine output, there is no evidence that loop diuretics (or mannitol) improve prognosis, lessen the need for dialysis, or speed recovery from acute renal failure. Some investigators recommend a trial of loop diuretics for patients with oliguric acute renal failure to attempt to increase urine output. If diuresis does not ensue or if excessive doses are required, diuretic treatment should be stopped. One protocol is to give 40 mg furosemide, 1 mg bumetanide, or 25 mg torsemide IV and to double the dose every hour if there is no response to a total daily dose of 1 g furosemide or equivalent.⁷¹ Bumetanide or torsemide are hepatically metabolized and therefore may be preferred to furosemide, which is metabolized by the kidney and accumulates to a greater degree in patients with renal insufficiency.

In experimental animals, ANP speeds recovery from a renal insult.⁸⁶ Unfortunately, this effect was not replicated in a trial of acute renal failure in humans,⁸⁷ although a subgroup analysis suggested a beneficial effect in oliguric patients. At this time, ANP cannot be recommended to treat patients with acute renal failure.

Chronic Renal Insufficiency

This has been reviewed recently.^{88,89} Sodium and water retention occurs very commonly in the setting of chronic kidney disease. Dietary NaCl restriction is important to control hypertension and edema, but diuretic therapy is often necessary. Loop diuretics are preferred because DCT diuretics alone are usually ineffective when the GFR is less than 30 mL/min and distal potassium-sparing diuretics can cause serious hyperkalemia and acidosis in patients with renal insufficiency.

The ability of loop diuretics to increase fractional Na⁺ excretion (FE_{Na}) is preserved as the GFR decreases (see Fig. 33-3).^{62,90,91} This indicates that the absolute increase in renal Na⁺ excretion elicited by a ceiling dose of loop diuretic decreases in proportion to the decrease in the GFR. In addition, the dose of drug required to achieve a given increment in NaCl excretion in chronic kidney disease increases because accumulated organic acids compete with diuretics for proximal tubule secretion, as shown in Figure 33-3. When the GFR is 15 mL/min, only one fifth to one tenth as much loop diuretic is secreted as in a normal individual.⁶²

Patients with chronic renal insufficiency, however, usually do remain responsive to loop diuretics, even when the GFR is as low as 10 to 15 mL/min, providing they are prescribed at a higher dose. DCT diuretics, conversely, are relatively ineffective for patients whose GFRs are less than 30 mL/min when they are administered by themselves. However, these drugs remain effective in renal failure when added to a regimen that includes a loop diuretic, as discussed later,⁹¹ but at the cost of a sharp further increase in the serum creatinine and blood urea nitrogen concentrations and a high incidence of hypokalemia and electrolyte disorders.⁹² For refractory patients, a loop diuretic infusion (e.g., bumetanide, 1 mg/hr for 12 hours) produces a greater natriuresis and less myalgia than two bolus injections.⁹³

Nephrotic Syndrome

Nephrotic syndrome is a combination of proteinuria of 3.5 g/24 hr or more, hypoalbuminemia, and edema. Hypoalbuminemia may contribute to edema by reducing plasma oncotic pressure and permitting a shift of fluid out of the capillaries and into the interstitium. In this case, one would anticipate that the plasma volume would be lower than normal.⁹⁴ Although this mechanism may be of central importance for patients with minimal change nephropathy or severe hypoalbuminemia,⁹⁵ many nephrotic patients do not show evidence of plasma volume depletion. This has led to an alternative “overflow hypothesis,” which posits that primary renal salt retention underlies the edema of nephrotic syndrome.^{96,97} Evidence in support of this hypothesis includes observations that the sympathetic nervous system and the renin-angiotensin-aldosterone axis are often not strongly stimulated in nephrotic patients, as would be expected if they had a decreased blood volume,^{98,99} that many such patients are hypertensive, and that natriuresis during treatment often begins before plasma oncotic pressure increases. Yet, primary renal salt retention alone causes hypertension but not edema because escape occurs.¹⁰⁰ Thus, it seems likely that fluid shift out of the vascular tree is a necessary component of nephrotic edema.⁹⁴ In many patients, and especially in diabetic nephrosis, primary renal salt retention plays an important role.

Regardless of the mechanism, diuretics are important for treating nephrotic edema. As with other causes of edema, dietary salt restriction plays a central role in treatment. Because most nephrotic patients are significantly diuretic resistant,⁶² DCT diuretics are generally not used as first-line agents. Loop diuretics, such as furosemide 40 to 60 mg/day, can be administered orally and increased to a maximum of 240 mg/day as single or divided doses.

Intravenous albumin has been used to treat nephrotic edema for more than 50 years. Early work showed that some nephrotic patients achieve natriuresis with albumin alone, presumably because plasma volume increases.¹⁰¹ After loop diuretics were introduced into clinical practice, albumin was no longer used by itself because diuretic drugs were found to be more effective. Nevertheless, despite concerns about efficacy, safety, and expense, the combination of albumin and loop diuretics is commonly used to treat nephrotic edema, especially in pediatric patients. Controlled studies in adults suggest that albumin may potentiate diuresis or natriuresis when combined with a loop diuretic, but only modestly.^{102–104} Studies in children, in whom the diagnosis is often minimal change nephropathy, suggest that combined loop diuretics and albumin infusion effectively reduce ECF volume.^{105,106} This effect is transient, unless remission is achieved, and complications are common. Several concepts for rational albumin use can be advanced. First, the therapeutic approach should be based on a careful assessment of the vascular volume. Many adult patients or those with diabetes or focal and segmental glomerulosclerosis have ECF volume expansion. In this setting, albumin use should be discouraged.^{102,106,107} In contrast, for patients who appear to be volume depleted, especially patients with minimal change disease and profound hypoalbuminemia, albumin may be indicated. For children, albumin is generally administered as a 25% solution (1 g/kg body weight for 1–4 hours) together with furosemide 1.5 mg/kg. Such treatment has been reported to induce a 0.4-kg weight loss per infusion and can be repeated five or more times.^{105,108}

Hypoalbuminemia decreases the binding of furosemide to plasma proteins and thereby increases its volume of distribution.¹⁰⁹ Although one study reported that premixing furosemide with 6 g albumin in the syringe before intravenous injection enhanced the diuresis of patients with the nephrotic syndrome,¹¹⁰ this has not been confirmed.^{102,103,111} Indeed, two studies have shown that patients with a serum albumin of 2 g/100 dL can deliver normal quantities of furosemide into the urine.^{109,112} Although diuretic resistance in nephrotic patients can result from impairments in diuretic delivery into tubular fluid, patients with nephrotic syndrome usually demonstrate normal diuretic clearance,¹¹³ suggesting that other mechanisms predominate. Diuretics may bind to albumin in the tubule lumen. Kirchner and colleagues¹¹⁴ showed that albumin in tubule fluid blunts the ability of loop diuretics to inhibit Na⁺ and Cl⁻ transport. In animal models, inhibiting diuretic binding restores a normal response, but a study in human nephrotic syndrome suggests that this is not a predominant mechanism. Thus, binding inhibitors should not be considered therapeutic options.¹¹³

Heart Failure

Heart failure affects 5 million people in the United States. General aspects of heart failure diagnosis and treatment are beyond the scope of this chapter (see Consensus Recommendations for the Management of Chronic Heart Failure¹¹⁵). The following discussion focuses on the role of diuretics in treating heart failure. Systolic dysfunction (left ventricular ejection fraction $\leq 40\%$) is the best understood form of heart failure. When left ventricular function is impaired, cardiac output decreases. This leads to a decrease in mean arterial pressure and activation of neurohumoral systems, including the renin-angiotensin-aldosterone axis, which, together with other factors, lead to salt and fluid retention, with resulting symptoms of dyspnea, exercise intolerance, and edema.¹¹⁶

Diuretic drugs have been used to treat CHF for more than 500 years. It is clear that, except in mild cases, most patients with CHF require diuretic treatment to control symptoms of fluid overload. It is not possible to conduct placebo-controlled trials to determine whether diuretics reduce mortality. However, a meta-analysis of trials in CHF concluded that diuretics decreased the odds ratio for death to 0.25 and for hospitalization to 0.31.¹¹⁷ Results of the recent Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial in hypertensive subjects show that randomization to a thiazide diuretic decreases the risk of hospitalization or dying of heart failure compared with an angiotensin-converting enzyme inhibitor (ACEI) or a calcium channel blocker.¹¹⁸ Early attempts to withdraw diuretics and treat CHF ACEIs alone frequently led to recrudescence of volume overload.¹¹⁹ However, because diuretics have not been shown to affect mortality except in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial, they should not be employed as monotherapy for patients with systolic dysfunction. Instead, they should be used for symptomatic control as supplementary but essential agents. They should always be combined with moderate restriction of dietary Na⁺ (approximately 2 g Na⁺/day).

The goal of diuretic treatment of CHF is to eliminate symptoms and signs of fluid retention.^{115,120,121} Azotemia or symptomatic hypotension should prompt a slowing or temporary cessation of diuretic treatment. Once the patient has stabilized, additional attempts to control ECF volume expansion

sion should be made. The dry weight can be estimated as the weight at which symptoms of orthopnea and paroxysmal nocturnal dyspnea disappear, the jugular venous pressure returns to normal, and edema disappears. Once this weight is determined, diuretic therapy is adjusted to achieve this weight. The GFR should be expected to decrease modestly (10%–20%) as the patient achieves dry weight.

Either thiazides⁶² or loop diuretics can be used for mild CHF.¹²² The efficacy and safety of loop and DCT diuretics appear to be similar.^{123–125} A lower incidence of postural hypotension has been reported when treating elderly patients with loop rather than DCT diuretics,¹²⁶ but other studies suggest that DCT diuretics are tolerated better.¹²⁵

A dose of 25 to 50 mg/day of hydrochlorothiazide can be used to treat patients with mild heart failure. For patients with more severe disease and normal renal function, a typical regimen is 20 mg furosemide twice daily.⁶² Because the dose-response curve for loop diuretics is steep, it is important to ensure that the chosen dose exceeds the diuretic threshold. This is established by doubling the diuretic dose until a clear natriuretic response ensues or a safe maximal dose is obtained. Most ambulatory patients can detect such an effect within 4 hours and can identify the effective dose in this manner. Thereafter, furosemide can be administered two times or more daily to ensure adequate contraction of the ECF volume. There is sufficient postdiuretic salt retention after a short-acting loop diuretic that it is difficult to achieve a negative salt balance if the diuretic is given once daily unless dietary salt is very severely restricted.⁶⁰ Therefore, patients unable to restrict dietary salt intake require more frequent dosing. Indeed, during high salt intake, furosemide may fail to contract the ECF volume because postdiuretic NaCl retention overcomes initial natriuresis.⁶⁰

Patients with uncompensated congestive heart failure may develop diuretic resistance owing to impaired diuretic absorption across the gastrointestinal tract (see Fig. 33-3). Brater¹²⁷ showed that absorption of furosemide and bumetanide is slowed in CHF, leading to a 50% decrease in peak urinary diuretic concentrations. In contrast, the bioavailability (which is the percentage of total dose absorbed in active form) is unchanged.¹²⁸ Inasmuch as loop diuretics must achieve a critical threshold concentration to inhibit salt transport effectively, slowed gastrointestinal absorption may lead to diuretic resistance. This provides some rationale for intravenous diuretic therapy in patients resistant to oral agents. Absorption generally improves with clearance of edema.¹²⁹ Bowel wall edema, impaired gastrointestinal motility, and altered bowel wall perfusion may all contribute to delayed diuretic absorption.

Nesiritide is a recombinant human B-type natriuretic peptide that was approved by the U.S. Food and Drug Administration for the treatment of acute decompensated CHF.¹³⁰ Studies of natriuretic peptide receptor A–deficient mice implicate this system in the natriuretic response to blood volume expansion¹³¹ and provide a rationale for B-type natriuretic peptide in the treatment of decompensated CHF. Nesiritide given short term to patients with decompensated CHF can decrease the pulmonary capillary wedge pressure.²⁷ However, subsequent studies have shown that nesiritide is not a diuretic in patients with chronic heart failure and, when compared with placebo, may increase the risk of death and worsening renal function.^{132–134} Until more data are available, nesiritide cannot be recommended as a primary therapy for decompensated CHF.

Cirrhosis and Ascites

Ascites, which commonly accompanies hepatic cirrhosis, results primarily from three mutually reinforcing processes. First, systemic and splanchnic vasodilation reduce the effective arterial pressure (predominantly determined by the mean arterial pressure), leading to renal salt retention. Second, fluid transudes from the plasma to the interstitium owing to hypoalbuminemia and vasodilation. Third, increased blood volume and portal resistance lead to portal hypertension. Together, these processes lead to ECF volume expansion, with a predominance of fluid in the peritoneal cavity (ascites).^{116,135}

Nonhepatic causes of ascites may be responsible in as many as 20% of cases (such as peritoneal carcinomatosis). These do not respond to diuretic treatment. An algorithm for treating cirrhotic ascites is shown in Figure 33-4. The first component is abstinence from alcohol, which decreases portal pressure in some patients.¹³⁶ The second factor is to restrict the dietary Na⁺ intake to 2 g/day (86 mEq/day). A more severe Na⁺ restriction will promote a more rapid decrease in ECF volume, but is considerably less palatable. Restricting water intake is usually not necessary, unless the serum Na⁺ level is less than 120 mmol/L. Bed rest is not generally recommended.

For patients with tense ascites, large-volume (4–6 L) paracentesis is usually indicated. This treatment is usually tolerated well, improves well-being, and leads to rapid resolution of ascites,¹³⁷ although the prognosis is not affected. The use of colloid during or after paracentesis remains a subject of debate.^{138–140} Many investigators suggest that a single paracentesis of 4 to 6 L can be tolerated without administering albumin, if edema is present. If there is no edema and if paracentesis is repeated, then albumin (25–50 g) can be administered.¹³⁶ Following paracentesis, diuretics must be continued to decrease reaccumulation of edema.¹⁴¹

Although large-volume paracentesis has assumed an important role in treating patients with tense ascites, approximately 90% of patients with ascites can be controlled with diuretics and salt restriction.¹⁴² Thus, practice guidelines approved by the American Association for the Study of Liver Disease emphasize the primary role of diuretics to treat cirrhotic ascites. Spironolactone has traditionally been the drug of choice. Concerns about hyperkalemia, slow onset of action, half-life, and side effects have prompted investigation of other agents for these patients. Amiloride does not induce painful gynecomastia, as does spironolactone, but is less effective.¹⁴³ In randomized, controlled trials, spironolactone was also shown to be more effective than furosemide when given alone and had a lower incidence of side effects.^{144,145} When ascites is mild, spironolactone may be administered at 25 to 50 mg/day or eplerenone at 50 to 100 mg/day. There is no pharmacokinetic justification for the common practice of administering spironolactone more than once daily.¹⁴⁶ When ascites is more pronounced, spironolactone or eplerenone is usually initiated together with furosemide. A regimen of spironolactone and furosemide, in a ratio of 100 mg to 40 mg, has been found empirically to lead to the highest ratio of efficacy to side effects.¹³⁶ The rapid onset of furosemide action initiates diuresis before the peak effect of spironolactone action (at approximately 2 weeks¹⁴⁴). Spironolactone attenuates furosemide-induced hypokalemia and alkalosis, which can precipitate encephalopathy. Furosemide attenuates

spironolactone-induced hyperkalemia. Doses can be increased to a maximum of 400 mg spironolactone/160 mg furosemide. Furosemide can be withheld initially from hypokalemic patients. Conversely, spironolactone must be used carefully for patients with intrinsic renal disease, especially diabetic nephropathy. Eplerenone, a more selective aldosterone antagonist, is more expensive, equally effective, but does not have estrogenic side effects.

Treatment is documented by daily weight loss. For patients who have peripheral edema, there is no ceiling for daily weight loss. For patients without edema, daily weight losses should not exceed 0.5 kg.¹⁴⁷ Severe hyponatremia (<120 mmol/L), prerenal azotemia (creatinine > 2.0 mg/dL), or encephalopathy should prompt cessation of diuretics.

Patients who are refractory to diuretic treatment or who require repeated paracenteses should be considered for transjugular intrahepatic portosystemic shunting.¹⁴⁸ A recent systematic meta-analysis concluded that transjugular intrahepatic portosystemic shunting is more effective at removing ascites compared with paracentesis without a significant difference in mortality, gastrointestinal bleeding, infection, and acute renal failure. However, transjugular intrahepatic portosystemic shunting patients develop hepatic encephalopathy significantly more often than patients treated with paracentesis.¹⁴⁹ Definitive therapy of cirrhotic ascites often involves liver transplantation.

Idiopathic Edema

Idiopathic edema is diagnosed by excluding other systemic and local (venous, lymphatic, and neural) causes.¹⁵⁰ The classic features of idiopathic edema include periodic swelling of the legs, hands, and face and abdominal bloating, occurring almost exclusively in women. Idiopathic edema is frequently associated with eating disorders. When present in obese individuals, it often disappears or improves if weight is lost. Many patients with idiopathic edema are already taking diuretics when first evaluated. Diuretic abuse may be a component of the disorder.^{151,152} It is not clear whether diuretics should be used as treatment. A low-salt diet should be prescribed, and adherence to the prescribed regimen can be confirmed by measuring renal sodium excretion. If diuretics are used, they may be given at night, when they may be more effective. Spironolactone is a good choice because its action is prolonged, making rebound edema less of a problem and because it prevents the effects of secondary hyperaldosteronism. Potassium-sparing diuretics such as amiloride will also help to address the hypokalemia that frequently accompanies idiopathic edema. Unfortunately, diuretics usually fail to control the edema.¹⁵⁰

TOXICITY AND USE IN SPECIAL CIRCUMSTANCES

The main metabolic adverse effects of diuretics are listed in Box 33-1; these and other adverse side effects are discussed elsewhere in more detail.² Toxic effects can be divided into metabolic effects, which are often dose related, and idiosyncratic effects, which are dose independent. The latter usually manifest as allergic sulfonamide-like skin reactions that can occasionally develop into severe and life-threatening Stevens-Johnson syndrome.^{153–155}

Box 33-1 Adverse and Clinically Useful Metabolic Effects of Diuretics

DCT Diuretics	Loop Diuretics	Potassium-sparing Distal Diuretics
Hypokalemia	Hypokalemia	Hyperkalemia
Hyponatremia	Hyperglycemia	Metabolic acidosis
Hyperglycemia	Hyperlipidemia	Hypomagnesuria
Hyperlipidemia	Metabolic alkalosis	
Metabolic alkalosis	Hypercalciuria	
Hypocalciuria and hypercalcemia	Hypocalciuria	
Hypermagnesuria	Hypermagnesuria	
Hyperuricemia		

DCT, distal convoluted tubule.

Azotemia and Extracellular Fluid Volume Depletion

Diuretics are frequently administered to treat edema, which can result in a decrease in the effective arterial blood volume. Overzealous diuretic use or intercurrent complicating illnesses can lead to excessive contraction of the intravascular volume, orthostatic hypotension, renal dysfunction, and sympathetic overactivity. Although patients with CHF usually require diuretic therapy, the combination of diuretics and ACEIs is especially likely to cause renal dysfunction. High diuretic doses or extreme dietary NaCl restriction may predispose to renal dysfunction during therapy with diuretics and ACEIs for CHF.^{156,157} It is important to attempt to continue ACEIs because they are shown to decrease mortality. Functional renal failure in such patients often responds to a decrease in diuretic dose or a liberalization in dietary NaCl intake. Other patients at increased risk for relative contraction of the intravascular volume during loop diuretic therapy include the elderly,¹⁵⁸ patients with pre-existing renal insufficiency,¹⁵⁹ patients with right-sided heart failure or pericardial disease, and patients taking nonsteroidal anti-inflammatory drugs.

Hypokalemia

Hypokalemia occurs commonly during therapy with both loop and DCT diuretics. A decline in serum K⁺ concentration is common in patients given DCT diuretics, but most patients do not become frankly hypokalemic.¹⁶⁰ The clinical significance of diuretic-induced hypokalemia continues to be debated.^{161–167} Hypokalemia may be more common during treatment with long-acting DCT diuretics, such as chlorthalidone, than with shorter acting DCT diuretics, such as hydrochlorothiazide, or with the very short acting loop diuretics.¹⁶⁸ DCT diuretics also increase renal Mg²⁺ excretion and can lead to hypomagnesemia, which contributes to the hypokalemia observed under these conditions.^{169,170} Some studies suggest that maintenance magnesium therapy can prevent or attenuate the development of hypokalemia,¹⁷¹ but this has not been supported universally. Hypokalemia also occurs commonly during therapy with loop diuretics, although the magnitude is smaller than that induced by DCT diuretics (loop diuretics 0.3 mmol/L compared with DCT diuretics 0.5–0.9

mmol/L^{168,172}). During prolonged therapy with loop diuretics, the degree of potassium wasting correlates best with volume contraction and serum aldosterone levels.¹⁷³

Hyponatremia

Diuretics have been reported to contribute to more than one half of all hospitalizations for serious hyponatremia. Potentially life-threatening hyponatremia is relatively common during treatment with DCT diuretics.¹⁷⁴ Several factors contribute. DCT diuretics inhibit solute transport in the diluting segment of the kidney, can reduce the GFR, contract the ECF volume, and lead to hypokalemia.¹⁷⁵ Hyponatremia is less common with loop diuretics because these drugs block the concentrating mechanism. In fact, loop diuretics can be used to treat hyponatremia, when combined with hypertonic saline, for the SIADH.^{176,177} The combination of loop diuretics and ACEIs can correct hyponatremia in the setting of heart failure.¹⁷⁸

Glucose Intolerance

Glucose intolerance is a dose-related complication of DCT diuretic use.^{179,180} The pathogenesis remains unclear, but several contributory factors have been suggested.¹⁸¹ First, diuretic-induced hypokalemia may decrease insulin secretion by the pancreas via effects on the membrane voltage of pancreatic beta cells. Prevention of hypokalemia by oral potassium supplementation normalizes the insulin response to hyperglycemia.¹⁸² Hypokalemia interferes with insulin-mediated glucose uptake by muscle, but most patients demonstrate relatively normal insulin sensitivity.¹⁸³ Recently, it has been suggested that DCT diuretics directly activate calcium- or adenosine triphosphate-activated potassium channels on pancreatic beta cells that inhibit insulin secretion.¹⁸⁴ In a large randomized study, fasting glucose was not significantly different after 4 years of treatment with chlorthalidone versus amlodipine.¹⁸⁵

Hyperlipidemia

DCT diuretics increase levels of total cholesterol, total triglyceride, and low-density lipoprotein cholesterol and reduce high-density lipoprotein.¹⁸³ Definitive information about the mechanisms by which DCT diuretics alter lipid metabolism is not available, but many of the mechanisms that affect glucose homeostasis have been suggested to contribute. Hyperlipidemia, like hyperglycemia, is a dose-related side effect and one that wanes with time.¹⁸⁶ In some clinical studies, the effect of low-dose DCT diuretic treatment on serum low-density lipoprotein was not significantly different from that of placebo,¹⁸⁷ whereas in others, total cholesterol was higher during diuretic treatment (1.6 mg/dL higher, $P = .009$, in the group treated with chlorthalidone than amlodipine).¹⁸⁵ Hypertension treatment with DCT diuretics has now been shown clearly to reduce the risk of stroke, coronary heart disease, CHF, and cardiovascular mortality.¹⁸⁸

Metabolic Alkalosis

Diuretics cause metabolic alkalosis via several mechanisms. They increase the excretion of bicarbonate-free acidic urine and stimulate the renin-angiotensin-aldosterone pathway. Al-

dosterone stimulates H⁺ secretion by the medullary collecting tubule¹⁸⁹ and increases the magnitude of the transepithelial voltage in the ASDN. Hypokalemia contributes to metabolic alkalosis by increasing ammonium production,¹⁹⁰ stimulating bicarbonate reabsorption by proximal tubules,^{191,192} and increasing the activity of the H⁺/K⁺-ATPase in the distal nephron.¹⁹³ Finally, contraction of the ECF volume stimulates Na⁺/H⁺ exchange in the proximal tubule and may decrease the filtered load of bicarbonate. All these factors may contribute to the metabolic alkalosis observed during chronic loop diuretic treatment.

Hyperuricemia and Gout

Thiazide and loop diuretics increase the plasma uric acid concentration because they reduce the ECF volume and increase the proximal tubule fluid reabsorption. They also compete with the urate secretory mechanism. Thus, they can aggravate or precipitate gout.

Ototoxicity

Ototoxicity is the most common toxic effect of loop diuretics unrelated to their effects on the kidney. Deafness, although usually temporary, can be permanent.^{194,195} All loop diuretics can cause ototoxicity.^{194,195} The mechanism involves inhibition of the secretory isoform of the Na⁺/K⁺/2Cl⁻ in the stria vascularis.^{196–199} Ototoxicity appears to be related to the peak serum concentration of loop diuretics and therefore tends to occur during rapid drug infusion of high doses. For this reason, this complication is most common in patients with uremia.²⁰⁰ Furosemide infusion should be limited to 240 mg/hr.²⁰¹ The incidence is higher in patients with renal failure and cirrhosis and in those receiving aminoglycosides or cisplatin, as well as in infants.²⁰⁰

Impotence

Impotence is a common side effect of thiazide diuretics²⁰² and responds to sildenafil.²⁰³

DIURETIC RESISTANCE

General Causes

Resistance to a diuretic implies an inadequate reduction in ECF volume during treatment with moderate to high diuretic doses. The evaluation and management of diuretic resistance are summarized in Table 33-3 and Figure 33-4.

The first step is to ensure that the patient has renal edema. This must be differentiated from lymphatic or venous obstruction, from idiopathic edema, or from a complication of therapy, such as with a calcium entry blocker that redistributes fluid from the plasma to the interstitial compartment.

The second step is to assess compliance. Therapy with a loop diuretic or thiazide is almost invariably accompanied by a decrease in serum K⁺ concentration and an increase in plasma bicarbonate and urate concentrations. Therefore, failure to detect these changes from pretreatment values suggests noncompliance. Noncompliance with the diuretic prescription often results from adverse effects, including impotence. However, the most common cause of resistance to diuretics is

Table 33-3 Identification and Management of General Causes of Diuretic Resistance

Cause or Example	Identification	Management
Nonrenal Edema		
Lymphatic or venous obstruction	Diagnose from clinical history and examination	Institute appropriate nondiuretic therapy
Cyclic edema	Ask about periodicity (women)	Institute appropriate therapy
CCB therapy	Obtain drug history	Reduce dose of CCB, substitute another agent, or add an ACEI
Noncompliance		
With diuretic prescription	Check for decrease in S_K , increase in plasma HCO_3^- and urate levels with loop or thiazide therapy; urinary diuretic screen	Counsel patient and ask direct questions concerning adverse effects and problems with impotence
With diet	Measure 24-hr Na^+ excretion, corrected for creatinine excretion. Goal (mmol Na^+ /24 hr) is: mild hypertension or edema, <100; severe hypertension or edema, <80	Obtain dietary consultation; repeat 24-hr urine to ensure that problem is corrected
Pharmacokinetic Alterations		
Incomplete or delayed absorption	Measure plasma levels	Change to more bioavailable drug, increase dose or administer intravenously
Decreased renal function	Quantify GFR	Increase dose in proportion to decrease in GFR
Pharmacodynamic Alterations		
Edematous states	Clinical examination	Increase diuretic dose
Activation of RAA axis	Measure PRA	Consider ACEI, AT_1 antagonist, or spironolactone
Intranephronal adaptation to primary diuretic		Consider concurrent use of second diuretic
Adverse Drug Interactions		
NSAIDs	Obtain drug history	Decrease dose or discontinue NSAIDs

ACEI, angiotensin-converting enzyme inhibitor; AT_1 , angiotensin I receptor blocker; CCB, calcium entry blockers; GFR, glomerular filtration rate; NSAIDs, nonsteroidal anti-inflammatory drugs; PRA, plasma renin activity; RAA, renin-angiotensin axis; S_K , serum potassium concentration.

failure to comply with restriction of NaCl intake. For patients with mild edema, a diet with no added salt, using a KCl substitute, and abstinence from salted or canned foods is usually sufficient to reduce Na^+ intake to a target of 100 mmol/24 hr (2.3 g Na^+ /24 hr). For patients with diuretic resistance or severe edema, the help of a dietitian is necessary to reduce daily Na^+ intake to levels of 80 mmol or less. Dietary Na^+ compliance can be assessed by a 24-hour urine collection for Na^+ excretion (with concurrent estimation of creatinine to judge the adequacy of the collection), providing the patient is stable and has not just started or stopped diuretic therapy.

The third step is to search for pharmacokinetic or pharmacodynamic limitations of diuretic action. Diuretic absorption in patients with severe edema may be incomplete or delayed because of edema or poor blood flow to the intestines. A decrease in the GFR limits the fraction of diuretic eliminated in active form via the tubular lumen. Doses of loop diuretics should be increased in proportion to the decrease in GFR. Patients with severe edema typically exhibit diuretic resistance because of

salt-retaining mechanisms in nephron segments whose reabsorptive processes are not blocked by the diuretic. There may be pronounced activation of the renin-angiotensin-aldosterone axis that can be assessed by measurement of plasma renin activity and that is caused by the combined actions of the underlying disease state and the diuretic. Intranephronal adaptations occur during diuretic therapy that enhance reabsorption at other sites. This can be addressed rationally by adding a second diuretic, as described in the following. Finally, nonsteroidal anti-inflammatory drugs can limit both the natriuretic and antihypertensive action of diuretics.

Therapeutic Approaches

High-Dose and Intravenous Diuretic Therapy

High doses of loop diuretics are frequently used to treat severe volume overload, especially when treatment is urgent. Ceiling doses of furosemide, bumetanide, and torsemide have been

estimated (Table 33-4). When given as a bolus, ceiling doses of furosemide range from 80 mg IV in hepatic cirrhosis to 500 mg IV in severe acute renal failure. The ceiling dose is that which provides maximal inhibition of the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ co-transporter, thereby reaching the plateau of the loop diuretic dose-response curve. Administering doses above the ceiling may increase 24-hour NaCl excretion because the time during which the urinary diuretic concentration is above the natriuretic threshold is prolonged. However, the effects of higher doses are marginal. It is better to increase the frequency of administration rather than administer extremely large doses.

High doses of loop diuretics given intravenously lead to capacitance vessel vasodilation that may be useful in patients with CHF who experience symptomatic relief before significant volume and NaCl losses have occurred. In one study,²⁰⁴ patients with ECF volume expansion after an acute myocardial infarction experienced a decrease in left ventricular filling pressure and an improvement in dyspnea within 5 to 15 minutes of receiving 0.5 to 1.0 mg/kg of intravenous furosemide. The early decrease in left ventricular filling pressure resulted from increased venous capacitance rather than diuresis. Pretreatment of animals with indomethacin greatly attenuates furosemide-induced venodilation, suggesting that prostaglandin secretion contributes importantly to the effects of loop diuretics on vascular tone.²⁰⁵

Although venodilation and improvements in cardiac hemodynamics frequently result from intravenous loop diuretic therapy in acute left ventricular failure, other reports indicate that the hemodynamic response may be more complex. Loop diuretics stimulate renin secretion both by activating the macula densa mechanism and by reducing ECF volume. In two series, 1.0- to 1.5-mg/kg furosemide boluses, administered to patients with chronic CHF, resulted in transient deterioration in hemodynamics (during the first hour), with a decrease in stroke volume index, an increase in left ventricular filling pressure, and exacerbation of CHF symptoms.^{206,207} These changes were attributed to activation of the renin-angiotensin system because ACEIs attenuated the pressor response. Johnston and colleagues²⁰⁸ reported that low-dose intravenous furosemide increased venous capacitance but that higher doses did not,

perhaps because angiotensin II generation overwhelms the prostaglandin-mediated vasodilatory effects. Nevertheless, intravenous loop diuretics remain the primary therapy for patients in acute pulmonary edema because symptoms usually do improve before natriuresis, suggesting that, even when cardiac output decreases, most patients experience a rapid decrease in left ventricular filling pressure. Further symptomatic improvement occurs later with natriuresis.

The major limitation of high doses of loop diuretics is drug toxicity. Fluid and electrolyte complications result directly from the diuresis and natriuresis. For diuretic-resistant patients, ototoxicity may occur during high-dose therapy,²⁰⁹ especially when administered as a bolus.²¹⁰ Furosemide toxicity is minimized by administering the diuretic less than 10 mg/min.^{209,211} Myalgias may occur after high doses of bumetanide. Continuous infusion of diuretics avoids high peak levels and the concomitant toxicity (see “Continuous Diuretic Infusion”) in diuretic-resistant patients.

Another complication of high-dose furosemide treatment can be thiamine deficiency.²¹² Chronic furosemide administration has been reported to lead to thiamine deficiency in animals and, in some reports, in humans. In one study,²¹³ patients with CHF who had received 80 mg/day furosemide for at least 3 months were randomized to receive intravenous thiamine or placebo. Intravenous thiamine improved hemodynamics, natriuresis, and indices of thiamine status. This work must be confirmed before thiamine can be recommended routinely for patients using prolonged high-dose loop diuretic treatment, but it raises the possibility that loop diuretics may predispose to nutritional deficiencies.

Combined Diuretic Therapy

Diuretic resistance can often be treated with two classes of diuretic used simultaneously. Controlled trials²¹⁴ suggest little or no benefit from giving two agents of the same class (e.g., ethacrynic acid and furosemide). In contrast, adding a proximal tubule diuretic or a DCT diuretic to a loop diuretic is often dramatically effective. DCT diuretics added to loop diuretics are synergistic (the combination is more effective than

Table 33-4 Ceiling Daily Doses of Loop Diuretics

	FUROSEMIDE		BUMETANIDE		TORSEMIDE	
	IV	PO	IV	PO	IV	PO
Chronic kidney disease						
GFR 20–50 mL/min	80–160	160	4–8	4–8	50	50
GFR <20 mL/min	200	240	8–10	8–10	8–10	100
Severe acute renal failure	500	NA	12	NA	200	NA
Nephrotic syndrome	120	240	3	3	20–50	20–50
Cirrhosis	40–80	80–160	1	1–2	10–20	20
Congestive heart failure	40–80	80–160	1–2	1–2	10–20	20

Ceiling dose indicates the dose that produces the maximal increase in fractional Na^+ excretion (FE_{Na}). Larger doses may increase net daily natriuresis by increasing the duration of natriuresis without increasing the maximal rate. All doses are in milligrams.

GFR, glomerular filtration rate; NA, not available.

Based on Brater DC: Diuretic therapy. *N Engl J Med* 1998;339:387–395.

Box 33-2 Combination Diuretic Therapy

To a ceiling dose of a loop diuretic (Table 33-1) add:

- Distal convoluted tubule diuretics
 - Metolazone 2.5–10 mg/day PO*
 - Hydrochlorothiazide (or equivalent) 25–100 mg/day PO
 - Chlorothiazide 500–1000 mg IV
- Proximal tubule diuretics
 - Acetazolamide 250–375 mg/day or up to 500 mg IV
- Collecting duct diuretics
 - Spironolactone 100–200 mg/day
 - Eplerenone 100–200 mg/day
 - Amiloride 5–10 mg/day

*Metolazone is generally best given for a limited period of time (3–5 days) or should be reduced in frequency to three times per week once extracellular fluid volume has decreased to the target level. Only in patients who remain volume expanded should full doses be continued indefinitely, based on the target weight.

the sum of the effects of each drug alone) (see Box 33-2 for regimens).^{2,91,215–219}

DCT diuretics do not alter the pharmacokinetics or the bioavailability of loop diuretics. The addition of a DCT diuretic to a loop diuretic enhances NaCl excretion via several mechanisms (for a review, see Ellison⁴). The most important mechanism is probably by inhibiting NaCl transport along the distal tubule, where tubular Na⁺ and Cl⁻ uptake is stimulated by the loop diuretic. During prolonged use of loop diuretics for resistant edema, distal nephron cells become hypertrophic and hyperplastic,²²⁰ and there is an increase in the density of Na⁺/K⁺-ATPase pump sites,^{221,222} in the density of Na⁺/Cl⁻ cotransporters,²²³ and in the intrinsic capacity to reabsorb Na⁺ and Cl⁻.²²⁴ Thus, when microperfused with a standard NaCl load, distal tubules from animals treated long term with loop diuretics reabsorb Na⁺ and Cl⁻ as much as three times more rapidly than those of control animals.²²⁵ Because DCT diuretics can inhibit apical Na⁺/Cl⁻ cotransport by the distal tubule even under these stimulated conditions, the effects of these diuretics will be greatly magnified in patients in whom high doses of loop diuretics have led to hypertrophy and hyperplasia. Loon and coworkers²¹⁹ showed that the natriuretic effect of chlorothiazide in humans was enhanced after treatment with furosemide for 1 month. These data suggest that daily oral furosemide treatment, even in modest doses, may be sufficient to induce adaptive changes along the distal nephron and that these may be treated with combination drug therapy.

When a second class of diuretic is added, the dose of loop diuretic should not be altered because the shape of the loop diuretic dose-response curve is not affected by addition of other classes of diuretic. Thus, the loop diuretic should be given in an effective or ceiling dose (see Table 33-4). The choice of DCT diuretic is arbitrary. Many clinicians choose metolazone because its half-life is longer than some classic thiazide diuretics and because metolazone has been reported to remain effective even when the GFR is low. Yet, direct comparisons between metolazone and classic thiazides have shown little difference in natriuretic potency when combined

with loop diuretics in patients with nephrotic edema, heart failure, or azotemia.^{91,226,227}

DCT diuretics may be added in full doses (see Box 33-2) when a rapid and robust response is needed, but this is likely to lead to complications and an extremely close follow-up is mandatory. We advocate hospitalizing patients when initiating aggressive combination therapy because fluid and electrolyte depletion, sometimes massive, occurs commonly during combination diuretic therapy. Serious side effects are noted in as many as two thirds of published reports describing combination therapy.²²⁸ One reasonable approach is to establish a therapeutic target weight and achieve control of the expanded ECF volume by adding escalating daily doses of a DCT diuretic. When the target weight is attained, the DCT diuretic can be prescribed three times weekly and the dose adjusted based on the patient's weight.

Another approach to combination therapy may be a short fixed course. Comparison was made of adding a thiazide-type diuretic to furosemide for either a fixed 3-day period or adjusting the dose to achieve targeted volume losses during 5 to 7 days. Both regimens were equally effective in decreasing ECF volume and symptoms. Surprisingly, natriuresis and diuresis continued even after the thiazide-type diuretic was discontinued during the fixed regimen.²²⁶ For outpatients requiring combined therapy, one approach is to add a modest dose of a DCT diuretic, such as 2.5 to 5.0 mg/day of metolazone, for 3 days only. Higher doses or longer time periods are effective but probably too dangerous for routine outpatient use. Because DCT diuretics are absorbed more slowly than loop diuretics (peak levels at 1.5–4.0 hours for DCT diuretics compared with 0.5–2.0 hours for loop diuretics), it is rational to administer the DCT diuretic 0.5 to 1 hour before the loop diuretic.

Drugs that act on the ASDN, such as amiloride, spironolactone, and eplerenone, can be added to a regimen of loop diuretics, but their effects are generally less dramatic than those of DCT diuretics.²²⁹ The combination of spironolactone and loop diuretics has not been shown to be synergistic, but can prevent hypokalemia while maintaining renal Na⁺ excretion. Potassium-sparing distal diuretics are used commonly to treat patients with cirrhosis of the liver in whom hypokalemia must be avoided because it predisposes to hepatic encephalopathy. A combination of furosemide and spironolactone or eplerenone is now considered the preferred regimen for cirrhotic ascites.¹³⁶ Potassium-sparing distal diuretics also reduce Mg²⁺ excretion, making hypomagnesemia less likely than when combined with loop diuretics.

It is now clear that blockade of mineralocorticoid receptors can improve mortality of patients with systolic dysfunction.²³⁰ Although this effect has been attributed to direct cardiac or vascular effects, renal effects also contribute. Barr and colleagues²³¹ randomized 42 patients with New York Heart Association class II to III CHF to either 50 to 100 mg/day spironolactone or placebo added to a regimen of loop diuretics and ACEIs. Spironolactone increased Na⁺ excretion, increased the urinary Na⁺-to-K⁺ ratio, increased the serum Mg²⁺ concentration, and decreased ventricular arrhythmias. Others have reported similar results.^{232,233} Nevertheless, hyperkalemia is a concern when adding spironolactone to ACEI therapy, especially in those patients with renal insufficiency.²³⁴ In one study, potentially life-threatening hyperkalemia during spironolactone treatment was found to be predicted by renal insufficiency, diabetes, older age, dehydration, and concomitant

use of other medications that may cause hyperkalemia.²³⁵ Similar effects likely accompany eplerenone therapy.

Combination diuretic therapy is often indicated for hospitalized patients in an intensive care unit who need urgent diuresis because of diuretic resistance in the setting of obligate fluid and solute loads. Two intravenous drugs are available to supplement loop diuretics: chlorothiazide (500–1000 mg once or twice daily) and acetazolamide (250–375 mg as many as four times daily). Chlorothiazide has relatively potent carbonic anhydrase-inhibiting capacity in the proximal tubule and also blocks the thiazide-sensitive Na^+/Cl^- cotransporter in the DCT. It has a longer half-life than some other thiazides. Both chlorothiazide and acetazolamide can act synergistically with loop diuretics. Acetazolamide is especially useful when metabolic alkalosis complicates the treatment of edema because this may make it difficult to correct hypokalemia or to wean a patient from a ventilator.²³⁶ The use of acetazolamide can correct alkalosis without the need to administer saline but often requires replacement of K^+ losses with additional KCl. In other situations, combination diuretic therapy may be targeted at the underlying disease process. Theophylline is a mild diuretic acting at adenosine type 1 receptors in the proximal tubule,^{30,31} but acts synergistically with loop diuretics and may be useful when bronchospasm and edema are present together. For patients with left ventricular dysfunction, afterload reduction may enhance diuresis.

Continuous Diuretic Infusion

Continuous diuretic infusion can be considered for hospitalized patients who are resistant to diuretic therapy.²³⁷ There are several potential advantages. First, it prevents the postdiuretic NaCl retention that complicates intermittent administration. Second, constant infusion yields greater acute natriuresis than bolus therapy. In one study of patients with chronic kidney disease, a continuous infusion of bumetanide was 32% more efficient than a bolus of the same dose.²³⁸ In another study of patients with severe CHF, 60 to 80 mg/day furosemide was more effective when given as a continuous infusion after a loading dose (30–40 mg) than when given as bolus doses three times daily. Bumetanide has a short half-life, torsemide has a longer half-life, and furosemide is intermediate. Therefore, the ratio of the efficiency of continuous infusion to bolus is greatest for bumetanide and least for torsemide. Indeed, bolus torsemide is an alternative approach to continuous bumetanide infusion. Third, poorly documented observations suggest that some patients who are resistant to large doses of diuretics given by bolus may respond to continuous infusion.^{239,240} These studies have failed to compare equivalent doses or to randomize the treatments, but Van Meyel and colleagues²⁴⁰ showed natriuresis during constant infusion in patients who had failed to respond to 250 mg furosemide given as a bolus. Fractional Na^+ excretion varied in a linear manner with total daily furosemide dose between 480 and 3840 mg/day. Fourth, the diuretic response can be more easily titrated and is smoother with continuous diuretic infusion. Magovern and Magovern²⁴¹ reported successful diuresis of hemodynamically compromised patients after cardiac surgery by continuous furosemide infusion. Infusing loop diuretics continuously may decrease the sympathetic discharge and activation of the renin-angiotensin system and may moderate the abrupt solute and fluid losses that occur after a large intravenous bolus. Finally, drug toxicity from loop diuretics, such as ototoxicity (observed with all loop diuretics) and myopathies (with bumetanide), appears to be less common

when the drugs are administered as continuous infusions. Total daily furosemide doses exceeding 2 g have been well tolerated when administered over 24 hours, but these high infusion rates may lead to toxic serum concentrations if continued for prolonged periods in patients with renal failure. Torsemide, which has a relatively greater clearance by hepatic metabolism, may be preferred for prolonged high-dose therapy.

Additional Measures in Specific Circumstances

Endopeptidase Inhibitors and Atrial Peptides

ANP and other biologically active peptides are degraded by neutral endopeptidases. Therefore, drugs that inhibit these enzymes increase plasma ANP levels and cause natriuresis. Indeed, neutral endopeptidase inhibitors given to hypertensive subjects do increase plasma ANP concentrations, lower blood pressure,²⁴² and, when given to normotensive subjects, increase glomerular filtration and Na^+ excretion and decrease the plasma renin activity.²⁶ Therefore, such therapy might potentiate diuretic-induced Na^+ and fluid loss. This hypothesis was tested in a dog model of acute CHF. Furosemide alone caused natriuresis, but decreased the GFR and activated the renin-angiotensin axis. During low-dose ANP infusion, the furosemide-induced natriuresis was potentiated, the GFR was stabilized and the renin-angiotensin-aldosterone axis was maintained.²⁴³ Therefore, endopeptidase inhibition or ANP infusion might be effective in treating loop diuretic resistance, but this requires validation in human subjects. As discussed previously, brain natriuretic peptide has recently been approved for use in decompensated CHF.²⁷ However, follow-up studies have been quite discouraging.^{132–135}

Aquaretics

As noted previously, oral vasopressin receptor antagonists have been developed but are not yet available in the United States. An intravenous nonselective vasopressin antagonist, however, is available to treat euvolemic and hypervolemic hyponatremia. These agents may become useful in promoting free-water excretion and normalizing S_{Na} in patients with diuretic-induced hyponatremia. However, they will have to be used with care because in these circumstances, the hyponatremia can represent renal free-water retention, which is a final line of volume defense during forced diuretic-induced natriuresis.

Circulatory Support and Inotropic Agents

Dopamine, dobutamine, and milrinone are used commonly to increase urinary Na and water excretion. Their use to prevent acute renal failure was described earlier in this chapter. Acute dopamine infusion increases renal plasma flow, urinary sodium excretion, the GFR, and the functional status of patients with moderate to severe CHF. Beregovich and coworkers²⁴⁴ showed that cardiac output and Na^+ excretion increase progressively as dopamine infusion is increased from 1 to 5 and 10 mg/kg/min in patients with classes III and IV CHF. However, stroke volume and urinary flow rate peak at 5 mg/kg/min, and several patients develop sinus tachycardia or striking increases in systemic vascular resistance at doses of 5 mg/kg/min or more. Although acute effects of dopamine infusion on renal sodium excretion and cardiac hemodynamics are often dramatic, natriuretic effects typically wane after 12 to 24 hours.²⁴⁵

Dobutamine is a dopamine derivative that is a potent inotrope without significant effects on mesenteric or systemic vascular tone or blood pressure. Both dopamine and dobutamine have been reported to improve cardiac output, renal perfusion, and, in some situations, Na^+ excretion. Hilberman and colleagues²⁴⁶ compared the effects of dopamine and dobutamine in 12 patients who had undergone open heart surgery and developed depressed left ventricular performance postoperatively. The drugs were administered in random order in doses that increased cardiac output equally (dopamine 5.0 ± 1.8 and dobutamine 3.5 ± 1.8 mg/kg/min). Although they had similar effects on renal plasma flow, renal vascular resistance, and glomerular filtration rate, dopamine increased urinary flow rate by 2.8-fold and Na^+ excretion by 4.6-fold more than dobutamine. Because dopamine can increase Na^+ and water excretion during treatment with dobutamine in patients with CHF, it appears to have unique natriuretic properties. These studies provide a rationale for combining low doses (2–5 mg/kg/min) of dopamine and dobutamine in critically ill patients.

Two other studies limit the enthusiasm for dopamine when added to a loop diuretic to treat CHF. In one study of six patients with chronic stable CHF, neither dopamine nor dobutamine was more effective than placebo in increasing urine volume.²⁴⁷ In a randomized, crossover study,²⁴⁸ dopamine (1–3 mg/kg/min) did not increase urinary solute and water excretion when added to a maximally effective dose of furosemide given to patients with stable heart failure, but did lead to potentially serious tachyarrhythmias in several patients. Although this study does not provide evidence supporting the use of low-dose dopamine in patients with CHF, the patients studied were stable and did respond to furosemide alone. Whether dopamine might elicit diuresis in patients who become refractory to furosemide alone was not addressed. According to the most recent guidelines of the Heart Failure Society of America, intravenous inotropes (dobutamine or milrinone) may be considered to relieve symptoms and improve end-organ function in patients with advanced heart failure characterized by left ventricular dilation, reduced left ventricular ejection fraction, and diminished peripheral perfusion or end-organ dysfunction (low output syndrome), particularly if these patients have marginal systolic blood pressure (<90 mm Hg), have symptomatic hypotension despite adequate filling pressure, or are unresponsive to or intolerant of intravenous vasodilators. These agents may be considered in similar patients with evidence of fluid overload if they respond poorly to intravenous diuretics or manifest diminished or worsening renal function. The same group does not make a recommendation with respect to dopamine.

Another situation in which dopamine is often employed is in critically ill patients with mild to moderate renal dysfunction. In two uncontrolled studies of critically ill patients, dopamine (1.5–2.5 mg/kg/min) increased urine output by 42% to 50% in patients with baseline urinary outputs less than 0.5 to 1 mL/kg/hr.^{249,250} In a controlled, crossover study of critically ill patients comparing dopamine (200 mg/min) with dobutamine (175 mg/min) or placebo, dopamine increased urine output significantly without affecting creatinine clearance, whereas dobutamine increased creatinine clearance significantly without affecting urine output.²⁵¹ Taken together, these data suggest that dopamine may increase renal Na^+ and water excretion in some patients with mild to moderate renal dysfunction.

In summary, dopamine and dobutamine are effective inotropes that increase cardiac output and can improve renal

perfusion and Na^+ and water excretion when administered to patients with systolic dysfunction. In contrast, data supporting a role for low (renal)-dose dopamine to protect against acute renal failure, to treat stable CHF, or to treat diuretic resistance are lacking.

Ultrafiltration

Most patients who appear to be resistant to diuretics respond to one of the approaches outlined (see Table 33-4 and Fig. 33-4). Side effects of diuretic therapy such as prerenal azotemia and metabolic alkalosis, rather than diuretic resistance, usually limit the ability to reduce ECF volume further. When pharmacologic therapy fails, plasma ultrafiltration, with or without accompanying hemodialysis, may be used to remove ECF. Agostoni and colleagues²⁵² randomized patients with CHF to equal volume removal by ultrafiltration or furosemide. The ECF volume remained contracted after ultrafiltration but rebounded to baseline after the intravenous diuretic treatment was discontinued. The ECF volume rebound after loop diuretic use was associated with a brisk increase in plasma renin and angiotensin II levels. ECF volume contraction induced by diuretics or ultrafiltration stimulates renin secretion via effects on vascular fullness, but loop diuretics additionally stimulate renin secretion directly via the macula densa. This loop diuretic-induced counterregulatory hormonal response may contribute to more rapid fluid reaccumulation. Recently, ultrafiltration was compared with intravenous diuretics in a randomized study of patients hospitalized with heart failure. The results showed that net fluid losses were greater in the ultrafiltration group and at 90 days, and fewer ultrafiltration patients had been hospitalized.²⁵³ These results suggest a role for ultrafiltration in selected patients with heart failure.

General Approach to Patients with Diuretic Resistance

A general approach to diuretic resistance is given in Figures 33-4 and 33-5 and Table 33-3. It is important to establish a target response. This can be defined by a set weight, by clearance of peripheral edema, or by improvement in respiratory or other symptoms. Some patients require modest edema to maintain renal perfusion and general well-being, but recent recommendations for treating heart failure recommended keeping patients quite dry.

Noncompliance with dietary prescription can be determined by measuring the sodium excretion rate over 24 hours. If excretion exceeds 100 mmol ($43 \text{ mmol Na}^+ = 1 \text{ g Na}^+$; $100 \text{ mmol} = 2.3 \text{ g}$), then excessive dietary NaCl intake is likely contributing to the apparent resistance.

If diuretic resistance persists despite effective NaCl restriction, the dose of loop diuretic should be doubled until a response is obtained or until the ceiling dose (see Table 33-5) is attained. A distinct increase in urinary output should be noted within 4 hours of an oral diuretic dose if a clinical response has been attained. If the response is still inadequate, poor gastrointestinal absorption should be considered and a drug with a higher and more consistent bioavailability, such as torsemide, should be selected or the diuretic should be given intravenously.

If the response remains inadequate, combination diuretic therapy should be considered (see Box 33-1). This is best initiated under observation in hospital. The most potent combina-

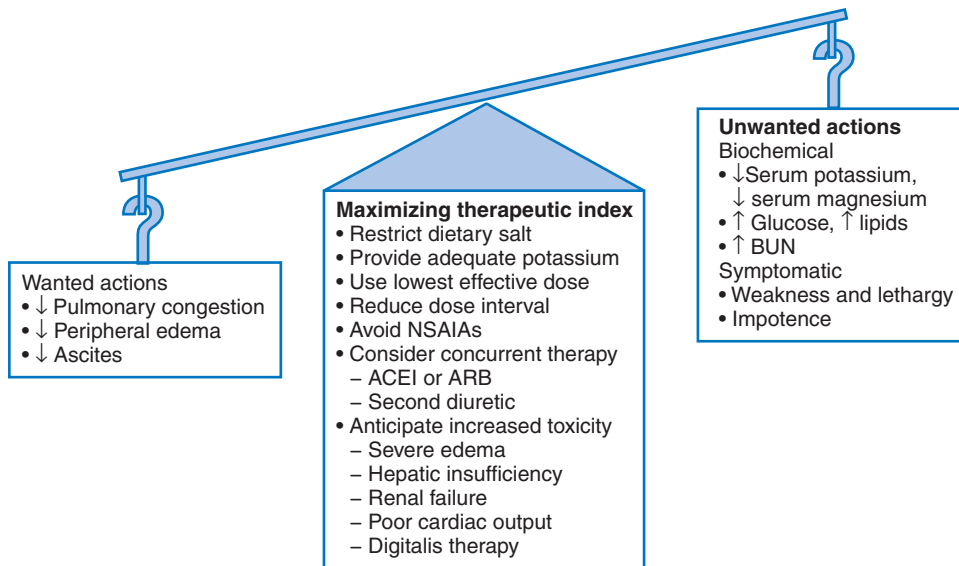

Figure 33-5 Balancing the desirable and undesirable actions of diuretics. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BUN, blood urea nitrogen; NSAIDs, nonsteroidal anti-inflammatory agents.

tion is metolazone or a thiazide added to a loop diuretic, but this approach carries a significant risk of hypokalemia, azotemia, and severe volume depletion. For patients whose serum potassium concentration or blood pressure is low, adding a collecting duct diuretic, such as spironolactone, eplerenone, and amiloride, is preferable. These patients must be followed for the potential development of hyperkalemia, especially those who are on concomitant ACEI therapy.

For those patients who remain unresponsive, more aggressive therapy in the hospital is indicated with intravenous loop diuretic infusions that can be combined, if necessary, with intravenous or oral DCT diuretics or carbonic anhydrase inhibitors. While the role of ultrafiltration remains unclear, it should be considered in selected unresponsive patients with intractable congestive cardiac failure.

CALCIUM DISORDERS

Homeostasis

The adult human body contains approximately 1200 g of calcium, of which more than 99% is within bone. The remaining 1% is distributed in three different plasma fractions: approximately 50% is bound to serum albumin, 10% is complexed to various serum anions (phosphate, bicarbonate, citrate, lactate), and 40% is free and ionized. Ionized calcium is the physiologically active form. Its concentration is tightly regulated by the endocrine system. Normal total serum calcium concentration (S_{Ca}) ranges from 8.5 to 10.5 mg/dL (2.1–2.5 mmol/L), whereas ionized S_{Ca} is approximately 5 mg/dL (1.2 mmol/L). A decrease in serum albumin lowers the total S_{Ca} , although the ionized fraction remains normal. A correction for hypoalbuminemia may be made by adding 0.8 mg/dL to the total S_{Ca} for every 1-g/dL drop in serum albumin concentration less than 4 g/dL. Conversely, falsely elevated S_{Ca} may result from hemoconcentration and may be found in rare patients with multiple myeloma who produce calcium-binding paraproteins.¹ In contrast to changes in serum albumin, which affect only total S_{Ca} , changes in pH affect the ionized but not total S_{Ca} . Acidosis increases ionized calcium by decreasing its binding to albumin, whereas alkalosis has the opposite effect. A direct measurement of ionized S_{Ca} is preferred in patients who have combined changes in pH and serum albumin.

The S_{Ca} normally reflects a balance between the entry of calcium into the extracellular fluid (ECF) from the gastrointestinal tract, skeleton, and kidneys and its removal by renal excretion and deposition into the skeleton. The precise regulation of

S_{Ca} is largely controlled by parathyroid hormone (PTH) and the highly-active-vitamin D_3 metabolite 1,25-dihydroxycholecalciferol (1,25[OH] $_2$ D $_3$, also called cholecalcitriol). Dietary calcium is absorbed in the proximal intestine via both active and passive processes. Absorption is enhanced by calcitriol, the principal hormonal regulator of intestinal absorption. In the kidneys, 99% of the filtered load of calcium is reabsorbed. Approximately 90% of reabsorption occurs passively in the proximal tubule and Henle's loop; the remaining 10% occurs in the distal tubule under the regulation of PTH. A decrease in free S_{Ca} stimulates the release of PTH, which increases renal calcium reabsorption. PTH also mediates the hydroxylation of calciferol (dihydroxyvitamin D_3) to calcitriol. The effects of S_{Ca} on PTH secretion are mediated via a calcium-sensing receptor. This cell-surface receptor is coupled with guanine-nucleotide regulatory G proteins and is expressed in the parathyroid, kidney, brain, and other organs.²

Hypercalcemia

Pathophysiology, Clinical Features, and Cause

Hypercalcemia is usually caused by an increase in ionized S_{Ca} . Hypercalcemia develops when the rate of entry of calcium into the ECF exceeds its excretion into urine or deposition in bone. An increase in influx can result from increased absorption from either intestine or bone, or both. However, multiple sites can be involved. For example, hypervitaminosis D increases both intestinal calcium absorption and bone resorption. Primary hyperparathyroidism (PHP) increases reabsorption from bone and renal tubules and increases renal synthesis of

calcitriol. The major causes of hypercalcemia are PHP and malignancy: PHP accounts for more than 90% of cases in ambulatory patients, whereas in hospitalized patients, cancer accounts for approximately 65% of cases.³

Clinical presentation of hypercalcemia depends on the magnitude and rapidity of the elevation in S_{Ca} . Mild hypercalcemia (10.6–2 mg/dL) accompanying PHP is generally asymptomatic.⁴ More severe hypercalcemia is frequently associated with neurological, gastrointestinal, and renal manifestations. Neurological symptoms may range from subtle changes in concentration to depression, confusion, increased somnolence, and even coma. Gastrointestinal symptoms are often prominent, with constipation, anorexia, nausea, and vomiting. The most important renal manifestations are nephrolithiasis, renal tubular dysfunction (particularly decreased concentrating ability⁵), and acute and chronic renal insufficiency. Nephrolithiasis has been reported in 20% of patients with PHP, whereas 4% to 5% of stone formers have PHP.⁶ Increased calcitriol production may contribute to both hypercalciuria and stone formation.

Rarely, familial hypocalciuric hypercalcemia (FHH), also known as familial benign hypercalcemia, is easily confused with milder cases of the more common PHP. FHH is generally asymptomatic and does not require treatment. However, it is important to identify patients with FHH to avoid unnecessary parathyroidectomy for presumable PHP. Because most cases of FHH are associated with loss-of-function mutations in a single gene (*CASR* or calcium-sensing receptor), genetic testing can assist in the diagnosis of FHH.

Diagnosis

PHP and malignancy account for 80% to 90% of cases. Long-standing asymptomatic hypercalcemia suggests FHH. An elevated serum intact PTH concentration (measured by immunoradiometric assay) indicates the presence of PHP or a patient taking lithium.⁷ If the plasma PTH level is below normal, a neoplastic disorder should be strongly considered (Fig. 34-1). The diagnosis of humoral hypercalcemia of malignancy can be confirmed by demonstrating an elevated serum PTH-related protein. The serum levels of the vitamin D metabolites calcitriol and 25-hydroxycholecalciferol (caldiol) should be measured if there is no obvious malignancy and neither PTH nor PTH-related protein levels are elevated. An elevated serum caldiol is indicative of vitamin D intoxication due to the ingestion of either vitamin D or caldiol itself. Conversely, increased levels of calcitriol may be induced by direct intake of this metabolite, extrarenal production in granulomatous diseases or lymphoma, or increased renal production by PTH.

Treatment

Overview

The definitive treatment of hypercalcemia depends on the treatment of the underlying disease, for example, parathyroidectomy for PHP and chemotherapy for a malignancy. The initial treatment can be instituted without a specific diagnosis. General measures include rapid mobilization and hydration. Volume depletion, by limiting renal calcium excretion, perpetuates a vicious circle and worsens acute hypercalcemia. Medications that worsen hypercalcemia, such as thiazide diuretics, should be discontinued. Volume expansion with isotonic saline usually decreases S_{Ca} by enhancing renal calcium excretion. Only after volume repletion should loop diuretics be used to enhance sodium and calcium excretion

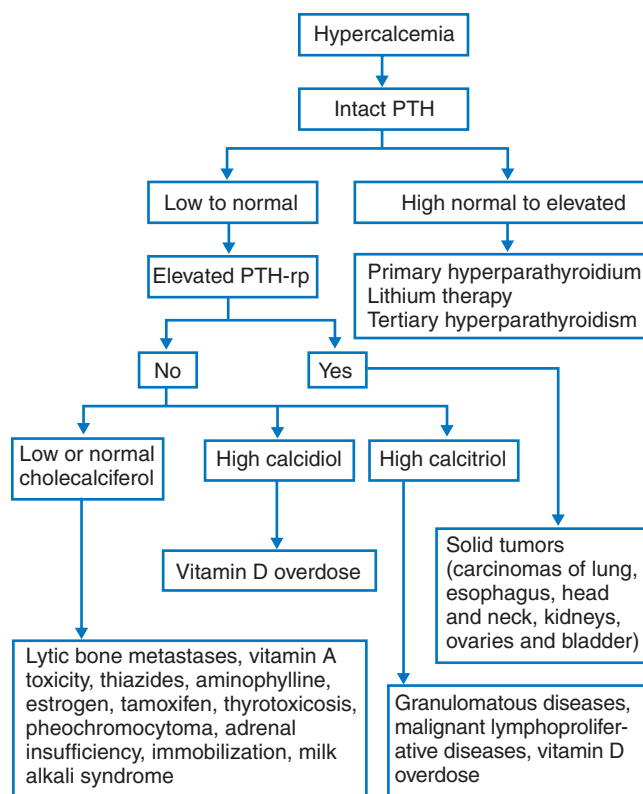

Figure 34-1 Diagnostic approach to hypercalcemia. PTH, parathyroid hormone; PTH-rp, PTH-related protein.

(Fig. 34-2). In patients with renal failure, dialysis effectively removes calcium from the ECF. Careful monitoring of cardiac function and serum electrolytes is necessary with both saline diuresis and dialysis treatment. Hypercalcemia can be divided into mild ($S_{Ca} < 12$ mg/dL), moderate (S_{Ca} 12–14 mg/dL), and severe ($S_{Ca} > 14$ mg/dL).⁸

Mild Hypercalcemia

Most cases of mild hypercalcemia are caused by PHP. All patients with PHP and symptomatic hypercalcemia who are surgical candidates should be referred to an experienced parathyroid surgeon for parathyroidectomy. Few would disagree that the best management for the patient with obvious symptoms or associated conditions of the disease or profound hypercalcemia (>12 mg/dL) is parathyroidectomy.⁹ Patients with FHH require no therapy.

There is a debate surrounding the issue of the best management of asymptomatic patients or those with mild symptoms and no associated conditions of PHP. To address this issue, in 1990, the National Institutes of Health together with the National Institute of Diabetes and Digestive and Kidney Diseases defined a set of guidelines for operative interventions in these patients. These include markedly elevated serum calcium (>12 mg/dL); history of an episode of life-threatening hypercalcemia; decreased creatinine clearance by 30% compared with age-matched normal subjects; markedly elevated 24-hour urine calcium (>400 mg/day); nephrolithiasis; age older than 50; osteitis fibrosa cystica; bone mass more than 2 SD below controls matched for age, gender, and ethnic

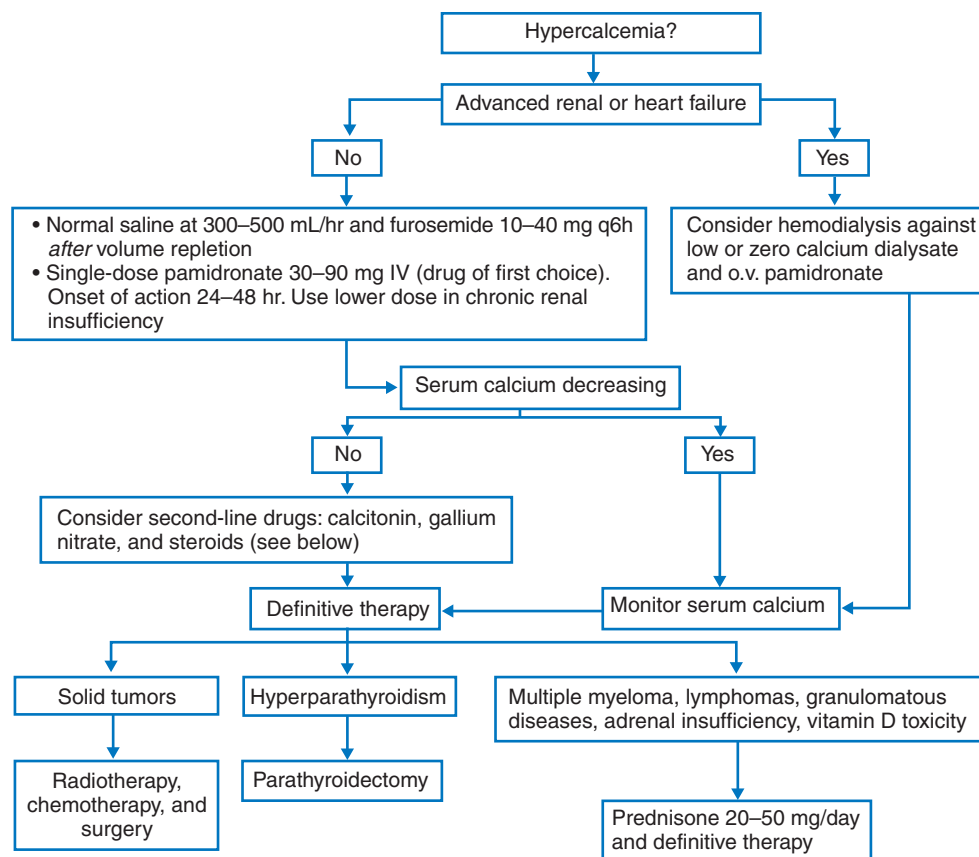

Figure 34-2 Treatment of hypercalcemia. IV, intravenous.

group; and neuromuscular symptoms (i.e., documented proximal weakness, atrophy, hyperreflexia, and gait disturbance).⁹ However, management of patients with asymptomatic PHP remains controversial.¹⁰ Immediate intervention is not necessary. Surgery may be beneficial in patients with vertebral osteopenia, in whom parathyroidectomy may lead to a dramatic improvement (as much as 20%) in bone density.¹¹ Consideration of parathyroidectomy should also be given to patients with PHP who are vitamin D deficient because the loss of inhibition by calcitriol on the PTH gene worsens the PHP.¹² Replacement of vitamin D in face of hypercalcemia and/or hypercalciuria can be risky. Estrogen-progestin therapy is beneficial in postmenopausal women with PHP because it decreases bone resorption and decreases S_{Ca} by 0.5 to 1.0 mg/dL and increases bone density modestly.¹³ Estrogen-progestin therapy decreases urinary calcium and hydroxyproline excretion and serum alkaline phosphatase, indicating decreased bone resorption, without changes in PTH.¹⁴

Diuretics should not be used to treat patients with mild PHP. Loop diuretics increase calcium excretion in the urine but may induce volume depletion. Thiazide diuretics are contraindicated because they decrease urinary calcium excretion and increase S_{Ca} . Oral inorganic phosphates can effectively lower S_{Ca} , but the resultant ectopic calcification is harmful to kidneys, blood vessels, and soft tissues. Thus, inorganic phosphates are reserved for patients who are not candidates for or who have failed alternate therapies and those who are moderately hypophosphatemic. The use of β -adrenergic blockers such as propranolol, H_2 receptor antagonists such as cimetidine, and

progesterin has been unsuccessful in decreasing S_{Ca} in patients with PHP.

Bisphosphonates are potent inhibitors of bone but are rarely required for mild hypercalcemia. However, risedronate, a newer bisphosphonate that can be given orally, inhibits bone resorption and decreases fasting S_{Ca} in patients with PHP.¹⁵ It may become the drug of choice for patients with PHP, particularly those with osteoporosis. However, long-term benefit has not been documented (see “Severe Hypercalcemia”). Drugs under development include those that activate the calcium-sensing receptor in the parathyroid gland, thereby inhibiting PTH secretion,¹⁶ calcitriol analogues that inhibit PTH secretion directly but do not stimulate gastrointestinal calcium or phosphate absorption,¹⁷ and drugs that block the PTH receptor.¹⁸

Moderate Hypercalcemia

Moderate hypercalcemia (S_{Ca} 12–14 mg/dL) should be treated aggressively if there are signs or symptoms. The severity of the symptoms correlates with the rate of increase in S_{Ca} . In patients with few or mild symptoms, treatment of the underlying cause should be instituted while embarking on hydration and mobilization. When neurological symptoms are the sole manifestation of hypercalcemia, other causes of an altered mental status must be excluded.¹⁹

The rationale for the use of normal saline for initial treatment is that volume depletion impairs glomerular filtration and increases sodium and calcium reabsorption in the proximal tubule. Normal saline should be administered to replenish

volume and decrease proximal tubule calcium reabsorption. Occasional patients may become hypernatremic and require hypotonic fluids because of the relative resistance to antidiuretic hormone in hypercalcemia combined with impairment of thirst if they are confused. If congestive heart failure develops or a more rapid decrease in S_{Ca} is desired, small doses of a loop diuretic may be added (e.g., furosemide 10–20 mg every 6 hours). Diuretic-induced ECF depletion should be avoided as this worsens hypercalcemia. Higher doses of loop diuretics may be required in patients with renal insufficiency. The combination of intravenous normal saline and loop diuretics should decrease S_{Ca} rapidly, by approximately 1 to 3 mg/dL, within 1 to 2 days. If the symptoms persist or hypercalcemia worsens, the treatment plan for severe hypercalcemia should be instituted.

Severe Hypercalcemia

When S_{Ca} exceeds 14 mg/dL, therapy should be initiated regardless of whether the patient has signs or symptoms of hypercalcemia, except in terminally ill patients. Therapy involves a combination of volume replenishment, enhanced renal calcium excretion, reduced bone resorption, and management of the underlying disease.

Patients with an elevated PTH should be referred for prompt parathyroidectomy after S_{Ca} has been decreased sufficiently for safe surgery. Excessive preoperative correction of hypercalcemia leads to postoperative hypocalcemia due to a decrease in osteoclastic bone resorption and marked influx of calcium into unmineralized osteoid.

Malignancy is usually responsible for severe hypercalcemia. Specific treatment of tumors with radiation or chemotherapy should not be delayed. Mobilization and oral sodium chloride and water, although still helpful, are unlikely alone to correct hypercalcemia. The first step is replacement of ECF volume with 0.9% saline at 300 to 500 mL/hr, decreased after volume deficit has been partially corrected. At least 3 to 4 L should be given in the first 24 hours to achieve a positive fluid balance of at least 2 L. Caution is required in patients who are elderly and those with compromised cardiac or renal function. Saline infusion increases the delivery of sodium chloride, fluid, and calcium to Henle's loop. Therefore, a loop diuretic is used to block transport at this site. Furosemide (40–160 mg/day in divided doses) is given after the ECF volume has been replenished. Thiazide diuretics are contraindicated because they decrease renal calcium excretion. The patient's hemodynamic and electrolyte status (potassium, phosphate, and magnesium replenishment are usually required) must be monitored closely, often in an intensive care unit.

Concomitant measures to reduce osteoclastic bone resorption should be initiated because there is usually a marked enhancement of osteoclast-mediated bone resorption in patients with hypercalcemia. Bisphosphonates are analogues of pyrophosphate that are resistant to phosphatases. These bone-seeking compounds bind to hydroxyapatite and prevent its dissolution. They have a very long half-life. Because they are poorly absorbed (1%–5% of an oral dose), they should be given with water on an empty stomach at least 30 minutes before food.²⁰ Approximately 80% of the absorbed bisphosphonate is cleared by the kidney. The remaining 20% is taken up by bone, and this is enhanced by high bone turnover. Although the plasma half-life is only 1 hour, bisphosphonates may persist in bone for the patient's lifetime.²⁰ Intravenous

administration of bisphosphonate should be given as 500 mL over at least 4 hours to dilute the precipitated calcium bisphosphonate that likely accounts for much of the nephrotoxicity.²¹ In patients with renal insufficiency, therapy should be initiated with lower doses diluted in larger volumes of fluid with additional doses given if renal function remains stable.

Etidronate is given intravenously (7.5 mg/kg/day in saline over 4 hours) for at least three consecutive days. Prolonging treatment to 5 days increases the response rate from 60% to 100% of patients. Therapy should be interrupted if S_{Ca} decreases rapidly (2–3 mg/dL in the first 2–3 days) or normalizes to avoid hypocalcemia. Normocalcemia may persist for 1 to 7 weeks. Some patients can be maintained on oral etidronate (20 mg/kg/day). Prolonged administration has been associated with osteomalacia²² and hyperphosphatemia due to increased tubular reabsorption of phosphate. The dose of etidronate should be decreased by 50% in patients with renal insufficiency because some is excreted in the urine.

As pamidronate is more potent and long-lasting than etidronate, it is the bisphosphonate of choice.²² A single injection of pamidronate is more effective in ameliorating hypercalcemia than a 3-day regimen of intravenous etidronate.²³ The intravenous dose of pamidronate depends on the degree of hypercalcemia: 30 mg if S_{Ca} is less than 12 mg/dL (3 mmol/L), 60 mg if S_{Ca} is 12 to 13.5 mg/dL (3.0–3.4 mmol/L), and 90 mg if S_{Ca} is higher. It is usually given in isotonic saline as a single intravenous infusion over 4 to 24 hours.²⁴ The dose should not be repeated in less than 7 days. Pamidronate is well tolerated, although a few patients develop fever. It is excreted by the kidney. Although not approved for use in patients with renal failure, pamidronate seems to be safe and effective for the treatment of patients on dialysis who have severe hypercalcemia induced by the combination of calcium carbonate and calcitriol,²⁵ provided that the dose does not exceed 30 mg. Pamidronate produces sustained normocalcemia for 15 days. In patients with cancer, the duration of hypocalcemic effect correlates inversely with serum PTH-related protein concentrations, with values more than 12 pmol/L usually indicating a short-lived response.²⁶

Clodronate (4–6 mg/kg/day infused over 2–4 hours) is widely used in Europe but is not available in the United States.

Alendronate, although very potent when administered intravenously, is approved only for oral therapy of osteoporosis.

Zoledronic acid (Zometa) has been recently approved by U.S. Food and Drug Administration for the treatment of the hypercalcemia of malignancy. A single 4- to 8-mg dose of zoledronic acid is more effective than 90 mg pamidronate. The duration of normocalcemia is 32 to 43 days. In addition, a 4-mg dose of zoledronic acid offers the convenience of a 15-minute infusion time compared with 2 to 24 hours for pamidronate. Zoledronic acid also decreases the skeleton-related events in patients with metastatic breast cancer, multiple myeloma, Paget's disease, and bone metastasis from prostate and lung cancers.²⁷

Risedronate, a potent third-generation oral bisphosphonate, is being evaluated for treatment of hypercalcemia. It decreases S_{Ca} in mild PHP, but its long-term utility remains to be determined.

Ibandronate (Boniva) is approved by U.S. Food and Drug Administration as once per month oral treatment for osteoporosis. Its intravenous administration as a bolus within a few

minutes for the treatment of hypercalcemia of malignancy and skeleton-related events of solid tumors has been approved in Europe without an increased risk of nephrotoxicity compared with other intravenous forms of bisphosphonates (i.e., zoledronic acid and pamidronate).^{28,29}

Osteochemonecrosis of jaws is a well-described side effect of bisphosphonates. The oral preparations (i.e., alendronate and risedronate) are considered low risk of osteonecrosis. Nephrotoxicity is a rare but important reported side effect of zoledronic acid, which should be avoided in patients with any degree of renal failure. Other bisphosphonates need dose adjustments for creatinine clearance less than 30 mL/min.³⁰

Plicamycin (mithramycin) inhibits osteoclastic RNA synthesis and decreases osteoclastic bone resorption. It is given intravenously (15–25 µg/kg) over 3 to 6 hours and repeated in 1 to 2 days if required. S_{Ca} begins to decrease within 12 hours, usually reaching a nadir by 48 hours. The hypocalcemic effect lasts for several days. Repeated doses can be given at 3- to 7-day intervals. Use of mithramycin is limited by its toxicity, particularly in patients with liver, bone marrow, or kidney disease. It is rarely used.

Calcitonin inhibits osteoclastic bone resorption and enhances renal calcium excretion. The most potent form of the drug is salmon calcitonin, which is given intramuscularly or subcutaneously (4–8 U/kg every 6–12 hours). It is safe and nontoxic and acts rapidly within 4 to 6 hours. Unfortunately, calcitonin is effective in only 60% to 70% of patients, most of whom then develop tachyphylaxis rapidly.²² It is additive with bisphosphonates.

Gallium nitrate inhibits bone resorption by binding to bone, decreasing hydroxyapatite crystal solubility, and decreasing S_{Ca} . Because it also inhibits PTH secretion, it may be particularly effective in the treatment of hyperparathyroidism. It is administered intravenously over 5 days at a dose of 200 mg/m²/day in 1 L of saline over 24 hours. Like bisphosphonates, there is a latent period of 6 to 8 days before a nadir in S_{Ca} is seen, with the effect lasting approximately 1 week. However, adverse effects are more frequent and more severe, with nephrotoxicity being common as well as hypophosphatemia and anemia. The drug should be avoided in patients with renal insufficiency or those receiving concomitant nephrotoxic agents.

Glucocorticoids decrease S_{Ca} by inhibiting cytokine release, by direct cytolytic effects on select tumor cells, by inhibiting intestinal calcium absorption, and by increasing renal calcium excretion. They are effective in hypercalcemia due to myeloma, other hematologic malignancies, sarcoidosis, and vitamin D intoxication. Other tumors rarely respond. The initial oral dose of prednisone is 20 to 50 mg twice daily. The S_{Ca} may take 5 to 10 days to decrease, after which the dose should be gradually decreased. Toxicity limits the usefulness of glucocorticoids for long-term therapy.

Hemodialysis, with little or no calcium in the dialysis fluid, and peritoneal dialysis, albeit slower, are both very effective modes of therapy for hypercalcemia. Dialysis is particularly useful in patients with renal insufficiency or congestive heart failure who cannot safely be given intravenous saline.

Inorganic phosphates, although effective, are not recommended for therapy of hypercalcemia because of the precipitation of calcium phosphate crystals in blood vessels and soft tissues.

Future therapies for cancer-induced hypercalcemia include noncalcemic analogues of calcitriol (e.g., 22-oxacalcitriol)

that reduce the release of PTH-related protein. A calcimimetic agent, such as norcalcin, that binds to the calcium-sensing receptor and suppresses the release of PTH is being evaluated for PHP.

Hypocalcemia

Clinical Features, Pathophysiology, and Cause

The symptoms and signs of acute hypocalcemia include latent tetany, tetany, papilledema, and seizures. By comparison, ectodermal and dental changes, cataracts, basal ganglia calcification, and extrapyramidal disorders are features of chronic hypocalcemia.³¹ Hypocalcemia can cause emotional instability, anxiety, depression, confusional states, hallucinations, and frank psychosis. Hypocalcemia characteristically causes prolongation of the QT interval on the electrocardiogram. Because the ST segment rather than the T wave is affected, the interval to the onset of the T wave (QoTc interval) may be a more sensitive indicator of hypocalcemia.³² Hypocalcemia impairs the response to digitalis. Ventricular arrhythmias and congestive heart failure can occur. Chronic hypocalcemia, particularly when associated with hypophosphatemia and vitamin D deficiency, causes growth plate abnormalities in children (rickets) and defects in the mineralization of new bone. Severe symptomatic hypocalcemia requires immediate intervention.

Falsely low S_{Ca} due to hypoalbuminemia should first be excluded by measuring ionized S_{Ca} . The most common causes of hypocalcemia in hospital include magnesium deficiency, pancreatitis, sepsis, acute and chronic renal failure, hypoparathyroidism, vitamin D deficiency, and complexing of calcium with infused phosphate, citrate, or albumin³³ (Fig. 34-3).

Treatment

Rationale and Overview

Treatment of hypocalcemia varies with its severity, the rapidity with which it develops, and the underlying cause. At one end of the spectrum, an asymptomatic patient with mild hypocalcemia (7.5–8.5 mg/dL, 1.9–2.1 mmol/L) may

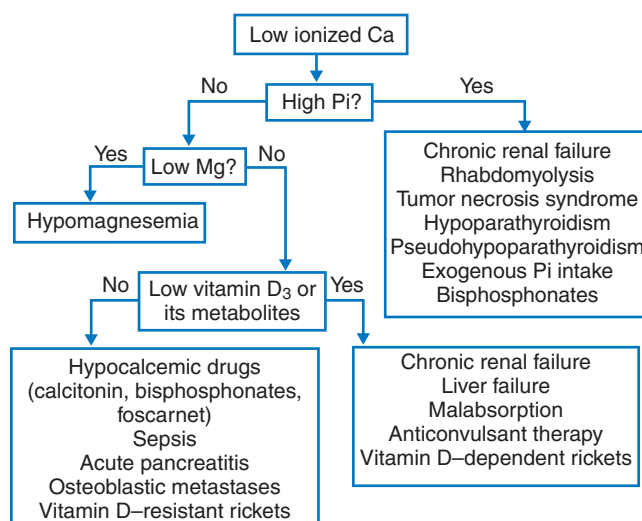

Figure 34-3 Diagnostic approach to hypocalcemia.

warrant cautious observation and require only oral calcium supplements (500–1000 mg elemental calcium every 6 hours ingested between meals). In contrast, a patient with tetany, a sign of severe hypocalcemia, must be treated aggressively with intravenous calcium. Patients with S_{Ca} less than 7.5 mg/dL, or any symptoms, require parenteral therapy (Fig. 34-4). Administration of calcium alone is only effective transiently. PTH is not available for clinical use; therefore, patients with PTH deficiency are treated with calcium and vitamin D.

Investigation into the underlying cause for hypocalcemia should include the serum phosphate (high in renal failure and tumor lysis and low in hypomagnesemia, osteoblastic metastatic disease, and vitamin D–deficient states such as osteomalacia), creatinine, and alkaline phosphatase (high in renal osteodystrophy, osteoblastic metastatic disease, and osteomalacia).

Hypocalcemia is often associated with other electrolyte and acid-base disorders. Hypomagnesemia should be treated as needed (see “Hypomagnesemia”). When metabolic acidosis is present, S_{Ca} must be corrected before acidosis because the treatment of acidosis decreases the ionized S_{Ca} , thereby precipitating problems such as tetany or cardiac arrest. Moreover, sodium bicarbonate and calcium salts must be administered in different intravenous lines to avoid precipitation of calcium carbonate. Because the administration of calcium potentiates digoxin toxicity, such patients should be monitored closely.

Hyperphosphatemia may accompany hypocalcemia in patients with hypoparathyroidism, renal disease, rhabdomyolysis, or tumor lysis. To avoid precipitation of calcium and phosphate, calcium supplementation must be given with phosphorus binders. By decreasing the fraction of calcium

bound to phosphate, a decrease in the serum phosphate improves ionized S_{Ca} . When hypocalcemia persists, it is best to delay calcium supplementation until the serum phosphate is less than 6 mg/dL.

Acute Hypocalcemia

Patients with symptomatic hypocalcemia should be treated immediately. Many patients have symptoms when ionized S_{Ca} is less than 2.8 mg/dL or total S_{Ca} is less than 7 mg/dL. In general, the intravenous infusion of 15 mg/kg of elemental calcium over 4 to 6 hours will increase total S_{Ca} by approximately 2 to 3 mg/dL.³⁰ Thus, a 70-kg patient with S_{Ca} of 6 mg/dL will require approximately 1 g of elemental calcium to increase S_{Ca} to 8 mg/dL. Several forms of calcium can be used for intravenous administration.

Calcium gluconate (10% in 10-mL ampoules containing 94 mg of elemental calcium) is given in emergency situations as one ampoule over 4 minutes followed by a calcium gluconate drip, if necessary. Solutions concentrated to greater than 200 mg (two ampoules) of calcium per 100 mL should be avoided because calcium is irritating to veins. Ten ampoules (100 mL) may be combined with 1000 mL of 5% dextrose and infused at 50 mL/hr (45 mg of elemental calcium per hour), titrating the rate as needed. For a symptomatic 70-kg patient, calcium may be infused more rapidly until symptoms subside, then the infusion is decreased to 50 mL/hr to achieve a low-normal calcium level within 8 to 18 hours. If necessary, all 10 ampoules may be infused over 4 to 6 hours.³⁴

Calcium gluceptate (10%) is similar to calcium gluconate but provides 90 mg of elemental calcium in a 5-mL ampoule, which is useful in patients who cannot tolerate large volumes

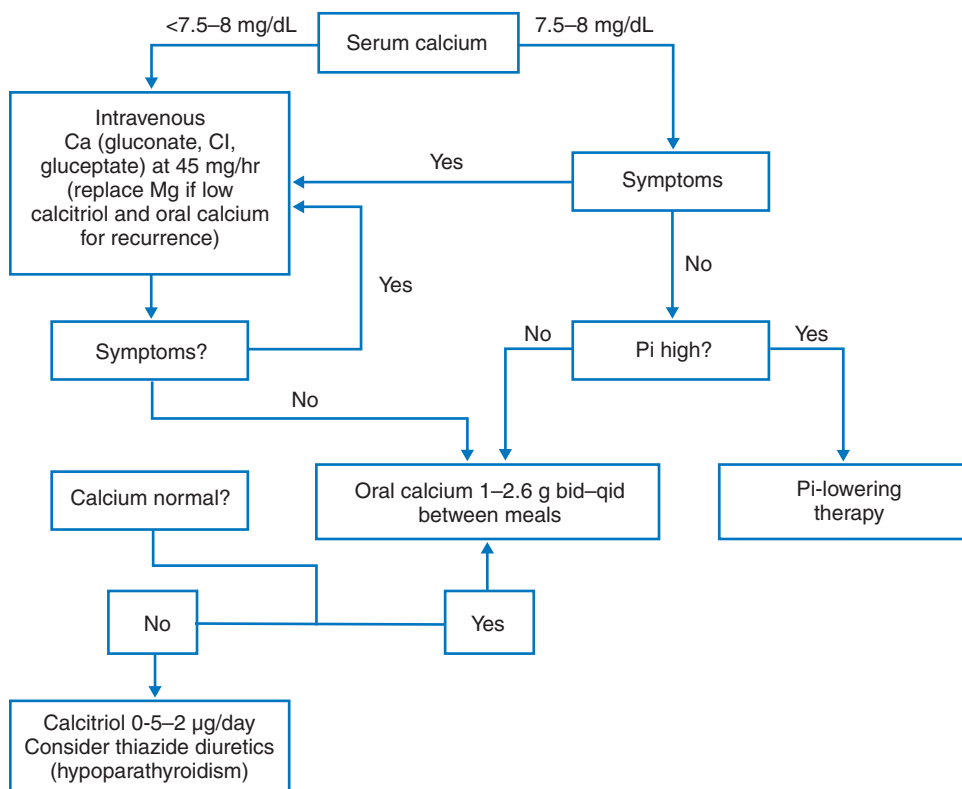

Figure 34-4 Treatment of hypocalcemia. S_{Ca} , serum calcium concentration.

of fluid. Ten ampoules (50 mL) may be added to 450 mL of 5% dextrose as 1.8 mg/mL. A dose of 45 mg of calcium (half an ampoule) can be infused in 25 mL of fluid.

Calcium chloride (10%) provides more calcium per ampoule (272 mg per 10-mL ampoule) and is more bioavailable than either calcium gluconate or calcium gluceptate. Although this results in a more rapid elevation in S_{Ca} , which may be preferable in emergency situations, it is more irritating to veins, thus rendering it less desirable for prolonged infusion.

Calcium glubionate (Neo-Calglucon) is an oral liquid that provides 23 mg of calcium per milliliter or 115 mg per teaspoon (5 mL). It is readily absorbed in the gastrointestinal tract and is well tolerated. It is an excellent supplement for hypocalcemic neonates and infants and for adults who lack intravenous access.

Patients with hypocalcemia following elective parathyroidectomy for renal osteodystrophy may require emergency vitamin D therapy. When the excessive PTH stimulation is withdrawn suddenly, calcium and phosphate accumulate rapidly in healing bone lesions and osteoclastic bone resorption is decreased. These effects cause a dramatic decrease in S_{Ca} (hungry bone syndrome). The failed kidneys cannot increase calcitriol, so that intestinal calcium absorption remains low. Intravenous calcium is often required initially and is replaced with oral calcium supplements and calcitriol. Calcitriol is the vitamin D metabolite with the greatest potency and most rapid onset of action. It is available in oral (Rocaltrol) and intravenous (Calcijex) preparations. Initially, large intravenous doses are generally required ($\sim 1\text{--}2\ \mu\text{g}/\text{day}$), decreasing to maintenance oral daily doses or three times weekly intravenous doses at dialysis of 0.2 to 1.0 μg .³³

Chronic Hypocalcemia

This requires treatment with oral calcium supplementation and, if necessary, vitamin D to enhance intestinal calcium absorption. Calcium is available with carbonate, gluconate, lactate, acetate, citrate, glubionate, and phosphate, although absorption varies with the preparation and timing of ingestion. Treatment is usually started at a dose of 1000 to 2600 mg two to four times daily between meals, adjusted according to S_{Ca} . Calcium carbonate is available in tablets containing 500 to 750 mg of calcium. Calcium citrate is well absorbed but should not be used in patients taking aluminum-containing medications because it enhances aluminum absorption. Calcium glubionate is well absorbed but expensive. Calcium phosphate should be avoided because it exacerbates hyperphosphatemia and metastatic calcification.³⁵

Patients with hypoparathyroidism may develop hypercalciuria with treatment because they lack the normal stimulatory effect of PTH on renal tubular calcium reabsorption and therefore excrete excessive calcium. This may cause nephrolithiasis, nephrocalcinosis, or chronic renal insufficiency. Therefore, the dose of calcium should be adjusted to maintain S_{Ca} slightly below normal range and calcium excretion should be measured periodically. A few patients with hypoparathyroidism can be treated with a thiazide diuretic.

In disorders associated with insufficient vitamin D (e.g., hypoparathyroidism, osteomalacia, chronic renal failure), calcitriol acts rapidly because it requires no further metabolism to function. Administration of 0.5 to 1.0 $\mu\text{g}/\text{day}$ is usually sufficient, although in extreme cases, such as immediately after parathyroidectomy, more may be required (2–3 μg). Calcitriol

is more expensive than the parent vitamin D compounds vitamin D₂ (ergocalciferol) and vitamin D₃ (cholecalciferol), which are adequate for nutritional deficiency at doses of approximately 400 U/day or for malabsorption at higher doses (50,000–100,000 U/day). However, their action may be delayed for several weeks because they require conversion to calcitriol. They are ineffective for diseases in which 25- or 1 α -hydroxylation is impaired, such as liver and renal failure, hypoparathyroidism, and vitamin D-dependent rickets type 1. In contrast to the rapid elimination of calcitriol and calcidiol (within days), vitamins D₂ and D₃ may continue to function for several weeks after dosing, potentially resulting in hypervitaminosis D.³⁵

PHOSPHATE DISORDERS

Homeostasis

Phosphate is the most abundant intracellular anion: approximately 80% is contained within bone mineral, 19% in cells, and approximately 1% in the ECF. Plasma phosphate concentrations are 2.5 to 4.5 mg/dL (0.81–1.45 mmol/L) in adults and 4.0 to 7.0 mg/dL (1.3–2.3 mmol/L) in children. Thus, changes in serum phosphate concentration (S_{Pi}) may not reflect total body content. The majority ($\sim 70\%$) of S_{Pi} is organic and present mainly in phospholipids, and the remainder is inorganic. Approximately 15% of inorganic phosphate is bound to protein and is therefore not available for ultrafiltration by the kidneys. The remainder exists mainly in the monohydrogen (HPO_4^{2-}) and dihydrogen (H_2PO_4^-) forms in a ratio of 4:1 at a physiologic pH of 7.4. Small amounts are complexed to sodium, magnesium, and calcium.

S_{Pi} is not as tightly regulated as S_{Ca} . It varies with dietary intake, age (higher in infants and children, decreasing with adolescence), time of day (peak at 4 AM and nadir 6–7 hours later), and hormonal status (higher in postmenopausal women). Phosphate is prevalent in meats, dairy products, and grains. Some 65% of ingested phosphate (800–1600 mg/day) is absorbed in the small intestine, both passively and by calcitriol-mediated active transport. Normally, phosphate transport occurs primarily through unregulated paracellular diffusive pathways. However, when luminal phosphate concentrations are low, absorption is by active sodium-dependent transport via a Na^+/P cotransporter that is secondarily active and uses the favorable sodium gradient from the basolateral Na^+/K^+ -ATPase.³⁶ Phosphate egress is passive. Calcitriol enhances phosphate absorption, whereas PTH stimulates intestinal phosphate absorption indirectly by increasing the synthesis of calcitriol. Other factors that increase intestinal phosphate absorption include low phosphate intake, acidosis, bile salts, lactose, prolactin, thyroid hormone, and the acute effect of glucocorticoids. Calcium, magnesium, and aluminum decrease phosphate absorption by binding to phosphate. Hypophosphatemia stimulates production of calcitriol, which subsequently enhances phosphate and calcium absorption. Hyperphosphatemia increases PTH secretion and decreases calcitriol production.

Renal phosphate excretion generally equals phosphate absorption. Some 85% of phosphate reabsorption occurs in the proximal tubule, where the brush-border membrane phosphate transporter is secondarily active via the Na^+/P cotransporter.³⁷

Growth hormone, insulin-like growth factor I, insulin, epidermal growth factor, thyroid hormone, and calcitriol stimulate renal phosphate reabsorption. PTH, PTH-related protein, calcitonin, atrial natriuretic factor, transforming growth factors α and β , and glucocorticoids inhibit phosphate absorption.²¹ Intravascular volume expansion and high-phosphate diets enhance phosphate excretion.

S_{P_i} can be decreased acutely by stimulating cellular uptake with intravenous glucose or insulin, ingestion of carbohydrate-rich meals, acute respiratory alkalosis, epinephrine, and rapid cell proliferation (e.g., neoplasia).³⁸ Conversely, S_{P_i} is increased by metabolic acidosis and intravenous infusion of calcium.

Hyperphosphatemia

Clinical Features, Pathophysiology, and Cause

Hyperphosphatemia ($S_{P_i} > 4.5$ mg/dL in adults, >7 mg/dL in children) is most commonly caused by decreased renal phosphate excretion due to renal failure (i.e., glomerular filtration rate < 20 – 25 mL/min). Hyperphosphatemia due to defective renal phosphate clearance also occurs with hypoparathyroidism, pseudohypoparathyroidism, increased growth hormone or insulin-like growth factor I, bisphosphonate therapy, and a variety of rare inherited diseases.¹⁹ Acidosis redistributes cellular phosphate to the plasma. Hyperphosphatemia can also occur during increased release of intracellular phosphate in acute tumor lysis or rhabdomyolysis coupled with acute renal failure³⁹ (Fig. 34-5).

In advanced renal failure, hyperphosphatemia is a universal finding. As the glomerular filtration rate decreases, fractional tubular phosphate excretion increases progressively, under the influence of PTH, to 60% to 90%. This maintains S_{P_i} until the glomerular filtration rate decreases to less than 25 mL/min. The ensuing hyperphosphatemia and loss of functioning kidney mass suppress the production of calcitriol, thus decreasing intestinal absorption of calcium. The ensuing

decrease in S_{Ca} and increase in S_{P_i} decrease calcitriol and increase PTH secretion, which may aggravate hyperphosphatemia by release of calcium and phosphate from bone. The eventual parathyroid hyperplasia and excessive PTH action cause high-turnover bone disease.³⁹

The rapid turnover of malignant tumors stimulated by chemotherapy releases intracellular potassium, uric acid, and phosphate. Uric acid precipitation in the renal tubules can cause acute renal failure, which may worsen the hyperphosphatemia and hyperkalemia. Increasing the urine pH with intravenous alkaline sodium bicarbonate solubilizes the uric acid but may enhance calcium phosphate precipitation, which can cause nephrocalcinosis or nephrolithiasis.

Pseudohyperphosphatemia due to hyperglobulinemia, hyperlipidemia, hemolysis, and hyperbilirubinemia can be assessed by serum analysis after deproteinization.

The manifestations of acute severe hyperphosphatemia are related mainly to accompanying hypocalcemia and tetany caused by precipitation of calcium phosphate. In addition, hyperphosphatemia inhibits the activity of 1α -hydroxylase in the kidney. The resulting decrease in calcitriol aggravates hypocalcemia further by impairing intestinal calcium absorption, inducing skeletal resistance to PTH. Profound hypocalcemia and tetany are occasionally observed during the early phase of the tumor lysis syndrome and rhabdomyolysis. When the (calcium \times phosphate) product exceeds approximately 65, patients may develop metastatic calcification in the skin, cornea, blood vessels, myocardium, heart valves, and other organs.³⁹ Patients on maintenance dialysis may also develop premature coronary artery calcification.⁴⁰ An extreme case of metastatic calcification, acral calciphylaxis, is rapid occlusion of small-sized arteries with necrosis and gangrene of the digits. Parathyroidectomy is recommended if PTH levels are extremely elevated.³⁹ Hyperphosphatemia is critical in the development of secondary hyperparathyroidism and renal osteodystrophy in chronic renal failure.

Treatment

Correction of the cause is the primary aim. Acute hyperphosphatemia in patients who do not have renal failure is treated by saline diuresis. Proximally acting diuretics, such as acetazolamide, are the most phosphaturic. Correction of acidosis or treatment of hyperglycemia with insulin promotes cellular phosphate uptake.

In patients with impaired renal function, S_{P_i} may be decreased by dietary phosphate restriction. Because phosphate is ubiquitous, severe dietary restriction is impractical. The average American diet contains 800 to 1600 mg of phosphate; restriction to 1000 to 1250 mg does not cause protein-calorie malnutrition.³⁹ In patients with end-stage renal disease or severe acute renal failure, S_{P_i} may be decreased by dialysis. Although dialysis membranes are permeant to phosphate, there is only a slow phosphate efflux from the large intracellular phosphate stores. Hemodialysis removes only approximately 2 to 3 g of phosphate per week. Nocturnal hemodialysis improves control of S_{P_i} .⁴¹ Peritoneal dialysis is more effective in eliminating phosphate but is still unable to match the dietary phosphate intake of most patients.

Phosphate binders form insoluble nonabsorbable compounds with phosphate in the intestines that are lost in stool. They must be ingested immediately before, during, or after the meal. Calcium, aluminum, and magnesium all bind phosphate,

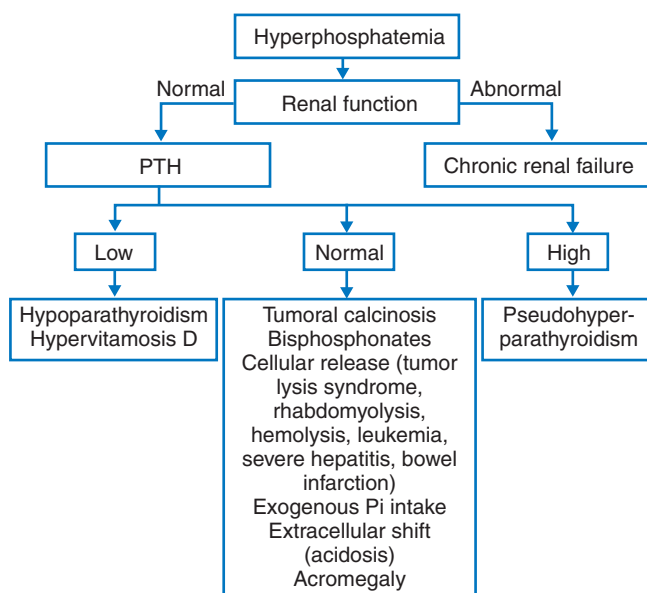

Figure 34-5 Diagnostic approach to hyperphosphatemia. PTH, parathyroid hormone.

although magnesium is relatively weak and is avoided in renal insufficiency. Oral calcium carbonate and the more potent calcium acetate are preferred to calcium citrate because the latter enhances intestinal aluminum absorption. Calcium carbonate is available in 500- and 1000-mg tablets. The initial dose is 1 g with each meal three times daily. If S_{P_i} does not decrease, the dose is gradually increased to 8 to 12 g/day. Persistent hyperphosphatemia may be due to incomplete dissolution of the tablets in the gastrointestinal tract, excessive phosphate intake, or noncompliance. Hypercalcemia is more likely if a vitamin D preparation is also given or if there is decreased bone turnover due to osteomalacia or adynamic bone disease.⁴² Absorption of calcium promotes coronary arterial calcification, which is associated with coronary atherosclerosis.⁴¹ If hypercalcemia develops or if the (calcium phosphate) product exceeds 65, the therapy should be replaced by noncalcium-based phosphate binders (Sevelamer or Fosrenol). Decreasing the dialysate calcium to 2.5 mg/L or less is useful when large doses of calcium are required.^{36,39} However, extended treatment with a low-calcium dialysate increases the risk of severe hyperparathyroidism. Aluminum hydroxide can cause aluminum intoxication, with vitamin D-resistant osteomalacia, a refractory microcytic anemia, bone and muscle pain, and dementia. It is no longer recommended.

Sevelamer (Renagel) is a nonabsorbable agent that contains neither calcium nor aluminum. It is a cationic polymer that binds phosphate through ion exchange. It is as effective as calcium carbonate or calcium acetate but does not affect S_{Ca} .⁴³ It lowers total cholesterol concentration by 15%. Gastrointestinal adverse effects may limit its use in some patients. At present, it is reserved for patients with hypercalcemia because of its considerable cost. The usual recommended dose is 800 to 1600 mg with meals three times per day.

Lanthanum carbonate (Fosrenol) is a first-line calcium-free phosphate binder that helps lower serum phosphate levels. The initial recommended dose is 750 to 1500 mg of Fosrenol tablets with each meal. It is in a chewable form only, which is good for dialysis patients trying to watch their fluid intake. The active ingredient in Fosrenol is two to three times more potent than sevelamer hydrochloride on a gram-for-gram basis. Lanthanum carbonate showed a safety profile that is similar to the overall profile of the standard therapy with calcium carbonate during 3 years of treatment.^{44,45}

Treatment of secondary hyperparathyroidism begins with a decrease in S_{P_i} while maintaining the (calcium \times phosphate) product less than 65. Thereafter, pulse oral or intravenous calcitriol two to three times per week can reduce PTH secretion. To prevent adynamic bone disease, most investigators recommend that intact PTH should be maintained in a mildly elevated range (<250 pg/mL).⁴⁶ Mild hyperparathyroidism (intact PTH 250–400 pg/mL) should be treated first with better control of S_{P_i} . If PTH continues to increase, calcitriol (intravenous Calcijex or oral Rocaltrol) is initiated at a dose of 1 μg three times weekly. For PTH greater than 600 to 700 pg/mL, an increase in calcitriol dose to 2 μg or more three times weekly is required. Calcitriol may cause hypercalcemia and may exacerbate hyperphosphatemia. Paricalcitol (Zemlar) in an active form of vitamin D for the treatment of secondary hyperparathyroidism in chronic kidney disease. The oral form is approved for stage 3 and 4 chronic kidney disease, and the intravenous form for patients on renal replacement therapy. The starting dose is 0.04 to 0.1 $\mu\text{g}/\text{kg}$. Paricalcitol, a selective new vitamin D analogue that is as effective in decreasing PTH, is equal to calcitriol but

with one tenth of the risk of inducing hypercalcemia, hyperphosphatemia, and elevated CaXP product to more than 65. The selectivity of paricalcitol makes this agent the analogue of choice in patients with chronic kidney disease.

Another recently approved novel agent for the treatment of secondary hyperparathyroidism in dialysis patients is Sensipar (cinacalcet hydrochloride), a calcimimetic agent. The major physiologic action of cinacalcet is that increases the sensitivity of the calcium-sensing receptor to activation by extracellular calcium. The result is a safe direct inhibition of PTH synthesis and secretion. In addition, cinacalcet has a mild effect in patients with chronic kidney disease in decreasing S_{Ca} and S_{P_i} . The starting dose is 30 mg once daily, which should be titrated up not more than every 2 to 4 weeks to 60, 90, 120, and 180 mg to achieve normal serum calcium and target PTH.⁴⁷ Cinacalcet should be used in combination with paricalcitol. S_{Ca} may also be decreased by decreasing dialysate calcium concentrations. Patients with refractory secondary hyperparathyroidism or those who develop severe hypercalcemia require parathyroidectomy.⁴⁸

Hypophosphatemia

Clinical Features, Pathophysiology, and Cause

Moderate hypophosphatemia (S_{P_i} 1–2.5 mg/dL, 0.32–0.81 mmol/L) is usually asymptomatic. Severe hypophosphatemia ($S_{\text{P}_i} < 1$ mg/dL or 0.32 mmol/L) indicates total body phosphate depletion and is potentially fatal. Numerous cellular mechanisms require phosphate (e.g. 2,3-diphosphoglycerate and adenosine triphosphate).^{36,39} Clinical features include erythrocyte, leukocyte, and platelet dysfunction; myopathy; confusion; ataxia; seizures and coma; respiratory insufficiency; osteomalacia; metabolic acidosis; cardiac arrhythmias; and cardiomyopathy. Hypophosphatemia may result from decreased intestinal phosphate absorption, increased renal phosphate losses, and a shift of phosphate to intracellular compartments (Fig. 34-6).

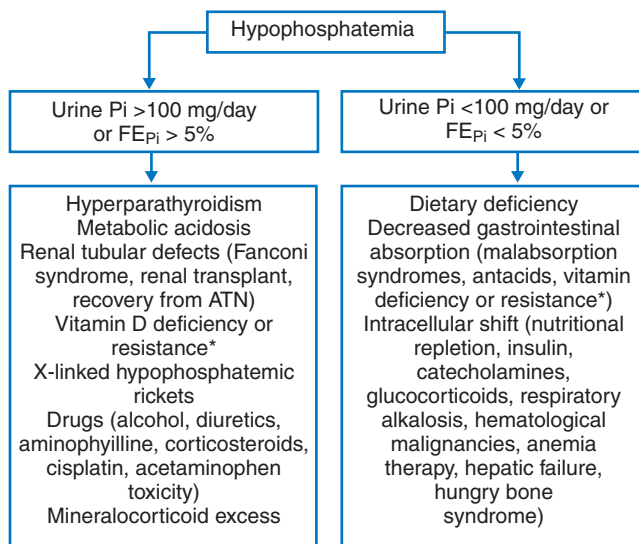

Figure 34-6 Diagnostic approach to hypophosphatemia. *More than one mechanism involved. ATN, acute tubular necrosis; FE_{P_i} , fractional excretion of phosphate.

Alcoholism and Alcohol Withdrawal

As many as 10% of chronic alcoholics are hypophosphatemic.^{36,39} The causes include insufficient phosphate intake, use of phosphate-binding antacids for gastrointestinal disorders, emesis, hypomagnesemia, diarrhea, and excessive alcohol-induced renal phosphate excretion, as well as intracellular shifts due to hyperventilation or glucose infusion in patients with alcoholic cirrhosis or in acute abstinence.³⁶

Nutritional Repletion

This may result in severe hypophosphatemia due to cellular phosphate uptake and utilization in anabolic tissue if sufficient amounts of phosphate are not provided. Phosphate requirements often exceed those provided in either enteral or parenteral feeds.^{36,39}

Diabetes Mellitus

Patients with decompensated diabetes associated with ketoacidosis excrete excessive phosphate due to osmotic diuresis. The plasma level is usually maintained because of large shifts of phosphate from cells into plasma. Administration of insulin, fluids, and correction of ketoacidosis causes S_{P_i} to decrease sharply. Patients with very low S_{P_i} usually require phosphate supplementation during correction of hyperglycemia and acidosis.³⁶

Acute Respiratory Alkalosis

Acute hyperventilation can reduce S_{P_i} to very low levels as phosphate enters muscle. Such a decrease in S_{P_i} is not observed in acute metabolic alkalosis. Paradoxically, chronic hyperventilation causes hyperphosphatemia.⁴⁸

Treatment

Rationale and Overview

The appropriate management of hypophosphatemia usually requires phosphate supplementation and diagnosis of the cause to prevent recurrence. Phosphate replacement can cause diarrhea (with oral supplements), hyperphosphatemia, and

hypocalcemia.^{36,39} Therefore, replacement should be used cautiously. Diarrhea is uncommon in patients with severe phosphate deficiency, especially when daily doses of phosphate are less than 1 g and given four times daily. Hypophosphatemia should be seen as a marker of an underlying disorder for which evaluation and therapy may be necessary. Hypophosphatemia should be anticipated in patients receiving enteral or parenteral nutrition, malnourished patients receiving glucose-containing intravenous fluids, and alcoholics.

Oral replacement is preferred in asymptomatic patients, even those with very low phosphate levels (Table 34-1). Correction of any associated hypokalemia and hypomagnesemia decreases phosphaturia (Fig. 34-7). Milk provides 1 g/L (33 mmol/L) of inorganic phosphate. It is usually better tolerated than phosphate tablets.^{36,39}

Mild Hypophosphatemia Mild hypophosphatemia ($S_{P_i} > 2$ mg/dL), especially when ascribed to intracellular shifts, usually resolves without pharmacologic intervention.

Moderate Hypophosphatemia Moderate hypophosphatemia ($S_{P_i} > 1$ mg/dL in adults, >2 mg/dL in children) responds to oral supplementation. Patients receiving total parenteral nutrition should receive at least 1000 mg/day (32 mmol) of phosphate. Lactose and lipids are poorly tolerated in malnourished patients with lactose or fat intolerance. Therefore, skim milk is preferable. With each 8-oz serving (containing ~235 mg of phosphate), most people can replenish their stores with four to eight glasses per day for 7 to 10 days.^{36,39}

Severe Hypophosphatemia In general, S_{P_i} less than 0.5 mg/dL reflects a phosphate deficit of more than 3 g; in the presence of symptoms, this deficit is more than 10 g.³⁶ In asymptomatic patients, severe hypophosphatemia is treated with oral supplements of phosphate (6–10 g) over several days. Oral supplements are available as monobasic, dibasic, and acid sodium and potassium salts. Neutral potassium and sodium

Table 34-1 Phosphate Preparations

	Phosphate	Sodium	Potassium
Oral Preparations			
Skim milk	1 g/L	28 mEq/L	38 mEq/L
Neutra-Phos	250 mg/packet	7.1 mEq/packet	7.1 mEq/packet
Phospho-Soda	150 mg/mL	4.8 mEq/mL	0
Neutra-Phos K	250 mg/capsule	0	14.25 mEq/capsule
K-Phos Original	150 mg/capsule	0	3.65 mEq/capsule
K-Phos Neutral	250 mg/tablet	13 mEq/tablet	1.1 mEq/tablet
Intravenous Preparations			
Neutral sodium potassium phosphate	1.1 mmol/mL	0.2 mEq/mL	0.02 mEq/mL
Neutral sodium phosphate	0.09 mmol/mL	0.2 mEq/mL	0
Sodium phosphate	3.0 mmol/mL	4.0 mEq/mL	0

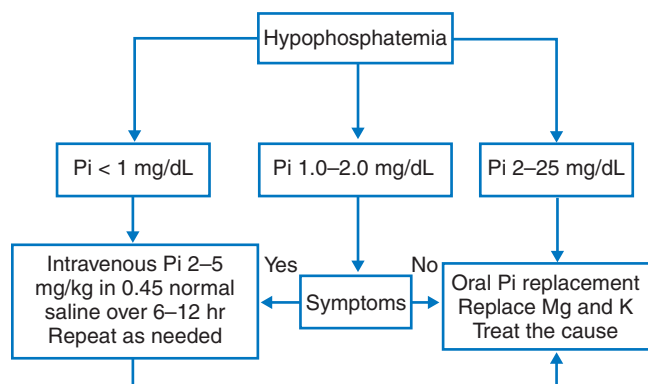

Figure 34-7 Treatment of hypophosphatemia.

preparations (Neutraphos, K-Phos Neutral) provide 250 mg of phosphate per tablet (see Table 34-1) but also contain large amounts of sodium. Phosphate enemas are also available (Fleet Enema) for patients intolerant of oral supplements. Because of the high sodium content, laxative effect, and erratic absorption, enemas are not primary therapy. In symptomatic patients, intravenous supplementation is usually required to increase S_{Pi} to more than 1.0 to 1.5 mg/dL, at which point oral supplements may be given. The usual starting dose is 2 mg/kg IV infused in half-normal saline over 6 hours or 5 mg/kg over 12 hours, checking S_{Pi} frequently and discontinuing the infusion when necessary. In symptomatic, severely hypophosphatemic patients, 1 g of phosphate in 1 L of fluid may be infused over 8 to 12 hours.^{36,39} Intravenous phosphate can precipitate with calcium and produce hypocalcemia, renal failure, and serious arrhythmias. Intravenous phosphate supplements are also available in combination with sodium or potassium.

MAGNESIUM DISORDERS

The normal body content of magnesium is approximately 1000 mmol or 22.66 g, of which 50% to 60% is contained in bone; extracellular magnesium accounts for only 1%. The normal serum magnesium concentration is 1.7 to 2.2 mg/dL (0.75–0.95 mmol/L). Approximately 55% is ionized and 15% complexed to bicarbonate, citrate, and phosphate; the remaining 30% is protein bound and thus is not available for ultrafiltration by the kidneys.

Magnesium is essential for the function of important enzymes, including those involved in the transfer of phosphate groups, all reactions that require ATP, and every step in the replication and transcription of DNA and translation of mRNA. Magnesium is also required for cellular energy metabolism and has an important role in membrane stabilization, nerve conduction, ion transport, and calcium channel activity.

Homeostasis

Maintenance of normal magnesium levels depends on gastrointestinal absorption and renal excretion. Daily magnesium intake is 300 to 350 mg. Absorption is by saturable and passive systems. Absorption is reduced by phosphate in the diet and enhanced by calcitriol.

Daily renal excretion of magnesium averages 100 mg. The thick ascending limb of Henle's loop reabsorbs 60% to

70%. Reabsorption in the thick ascending limb and distal tubule (~10%) is closely regulated by the serum magnesium concentration. Reabsorption in the thick ascending limb is regulated by the calcium/magnesium-sensing receptor, located on the basolateral membrane of the thick ascending limb.⁴⁹

Hypermagnesemia

Clinical Features, Pathophysiology, and Cause

Patients with renal insufficiency are susceptible to hypermagnesemia. Most cases are caused by magnesium ingestion. Hypermagnesemia due to cellular release complicates tumor lysis syndrome, rhabdomyolysis, acidosis, and catecholamine excess. Mild hypermagnesemia complicates FHH, Addison's disease, hyperparathyroidism, and lithium therapy.⁵⁰ Hypermagnesemia causes mild hypotension, nausea, flushing, and loss of deep tendon reflexes, somnolence, weakness, lethargy, and ultimately apnea due to muscular paralysis. Cardiac manifestations include prolongation of PR, QRS, and QT intervals, bradycardia, complete heart block, and even cardiac arrest.

Treatment

Patients with mild hypermagnesemia and normal renal function require only discontinuation of magnesium supplementation (Fig. 34-8). For those with severe symptoms of hypermagnesemia, intravenous calcium (100–200 mg) is the initial treatment. Glucose and insulin can shift magnesium intracellularly. Patients with a serum magnesium concentration in excess of 8 to 9 mg/dL should have cardiac monitoring and be considered for ventilatory support. Hemodialysis against a low-magnesium dialysate is more effective than peritoneal dialysis in rapidly decreasing the serum magnesium concentration in patients with renal failure.⁵¹

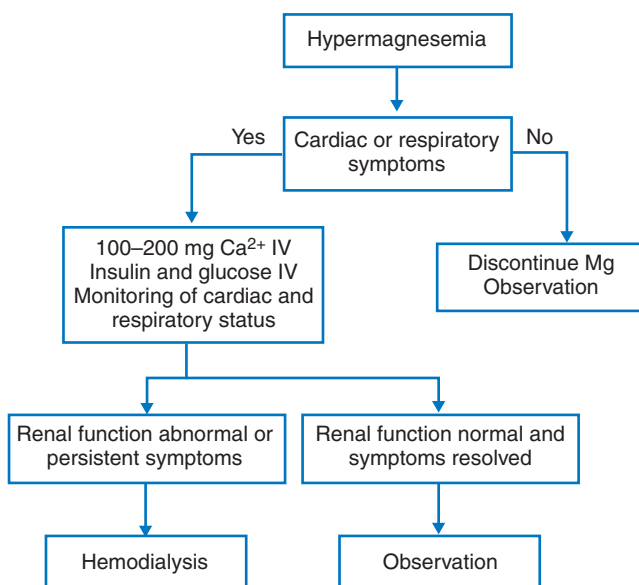

Figure 34-8 Treatment of hypermagnesemia.

Hypomagnesemia

Clinical Features, Pathophysiology, and Cause

Hypomagnesemia occurs in 12% of hospitalized patients.⁵¹ Gastrointestinal depletion occurs during acute or chronic diarrhea or during malabsorption. Thiazide and loop diuretics inhibit tubular magnesium reabsorption, although hypomagnesemia is usually mild because of increased proximal tubular magnesium reabsorption induced by the volume depletion. Diabetes mellitus is the most common cause of hypomagnesemia, probably secondary to glycosuria and osmotic diuresis (Fig. 34-9).

The possibility of cellular magnesium depletion despite a maintained serum magnesium concentration should be considered as a possible cause of refractory hypokalemia or unexplained hypocalcemia. This is detected by demonstrating a low renal magnesium excretion (<24 mg/day) or a low fractional excretion of magnesium (<2%).

Magnesium deficiency causes neuromuscular irritability, with tremor, tetany, asterixis, myoclonus, seizures, muscular weakness, prolongation of PR and QT intervals, ventricular and supraventricular arrhythmias, and diminished response to digoxin. Accompanying hypokalemia or hypocalcemia can be refractory to therapy unless magnesium deficiency is corrected.

Treatment

Mild hypomagnesemia can be treated with oral replacement (Fig. 34-10) using a sustained-release preparation such as Slow Mag, containing magnesium chloride, or Mag-Tab SR, containing magnesium lactate (2.5–3.5 mmol or 60–84 mg of magnesium per tablet). Patients with severe magnesium deficiency require six to eight tablets daily, whereas those with mild asymptomatic disease require only two to four tablets daily. Patients with renal magnesium wasting due to loop diuretics benefit from a magnesium-sparing diuretic such as amiloride (5–10 mg/day). Amiloride is also used for the persistent renal magnesium wasting associated with Bartter or

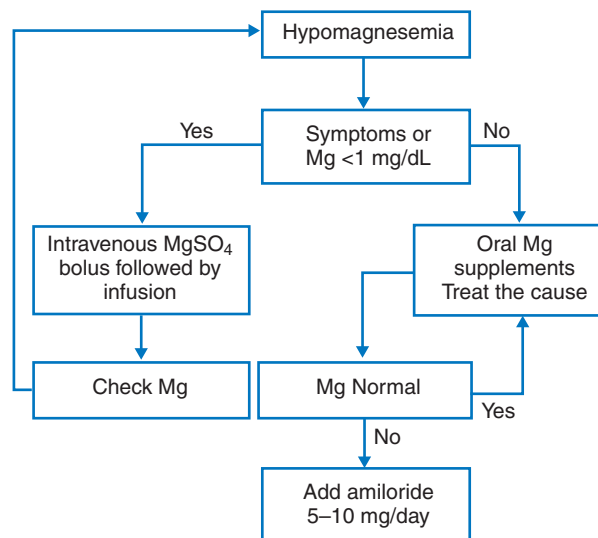

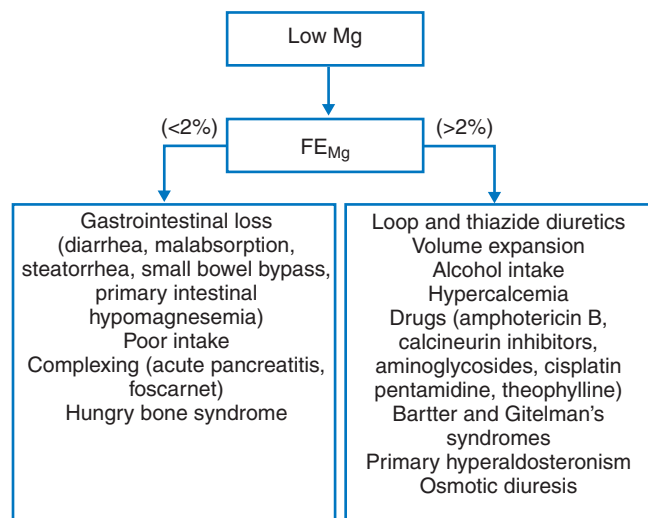

Figure 34-10 Treatment of hypomagnesemia.

Gitelman’s syndrome or cisplatin nephrotoxicity. Adults with malabsorption may require daily magnesium supplementation of as much as 50 mmol (~1 g); children with malabsorption may require as much as 30 mmol (720 mg).

Patients with symptomatic or more severe hypomagnesemia require parenteral magnesium. Magnesium sulfate (2.1 mmol/mL) as a 50% solution is effective intramuscularly but should preferably be given intravenously. For life-threatening cardiac arrhythmias or seizures, 4 to 8 mmol (100–200 mg) of magnesium sulfate may be given intravenously over 5 to 10 minutes, followed by an intravenous infusion of 0.5 mmol/kg/day (12 mg/kg) or 4 mmol (~100 mg) intramuscularly every 3 to 4 hours. Approximately half of the administered magnesium will be excreted, and therapy may need to be continued for several days. The dose should be decreased in patients with renal insufficiency who require close monitoring.⁵¹

FE_{Mg}
 (fractional excretion of Mg) = $\frac{\text{Urinary Mg} \times \text{plasma creatinine} \times 100}{(0.7 \times \text{plasma Mg}) \times \text{urinary creatinine}}$

The Normal Metabolic Evaluation	431		

Kidney stones are a major cause of morbidity. The lifetime prevalence of symptomatic nephrolithiasis exceeds 10% in men and 5% in women,^{1,2} and more than \$2 billion is spent on treatment each year.³ Appropriate evaluation and intervention are required to prevent recurrent kidney stones.

DIAGNOSIS OF STONE DISEASE

Clinical and Laboratory Manifestations

Symptomatic nephrolithiasis classically presents with unilateral flank pain of sudden onset. The pain is precipitated by the passage of a kidney stone from the renal pelvis to the ureter and is due to ureteral spasm. Because the waxing and waning pain of a symptomatic stone does not completely remit, the term renal colic is technically inaccurate.⁴ The pain is often severe and can be accompanied by nausea and vomiting. The location of the pain depends on the location of the kidney stone: A stone in the upper ureter may cause pain to radiate anteriorly to the abdomen, whereas a stone in the lower ureter can cause pain to radiate to the ipsilateral testicle in men or to the ipsilateral labium in women. If the stone is lodged at the ureterovesical junction, the patient may experience urinary frequency and urgency. Less commonly, nephrolithiasis can manifest as gross hematuria without pain.

On physical examination, the patient will be in obvious pain and may constantly adjust position in an unsuccessful attempt to alleviate the discomfort. Ipsilateral costovertebral angle tenderness may be present. Signs and symptoms of sepsis can occur in cases of obstruction with infection.

Serum chemistries are usually normal, but leukocytosis may be present due to stress or infection.⁵ Although the urinalysis will often reveal hematuria and pyuria (and occasionally

crystalluria),⁵ the absence of red cells in the urine does not exclude a stone, particularly in cases in which a stone causes complete ureteral obstruction.⁶

Imaging

Helical computed tomography scan (HCT) is the preferred radiographic test to confirm or exclude the diagnosis of nephrolithiasis.⁷ HCT does not require radiocontrast and can visualize uric acid stones (traditionally considered radiolucent).⁷ Typically, the HCT will show a ureteral stone or evidence of recent passage (e.g., perinephric stranding or hydronephrosis). HCT can detect small stones that may be missed by intravenous urography.^{8,9}

Few studies have compared HCT with ultrasonography (US). However, in patients presenting with presumed renal colic, the sensitivity of HCT was 96% compared with 61% for US; the specificity for each was 100%.¹⁰ Although US has the advantage of avoiding radiation, it can only image the kidney and proximal ureter. Thus, ureteral stones can be missed on US. US may also miss renal stones less than 3 mm in size.¹¹

The conventional abdominal x-ray (x-ray examination of the kidney and upper bladder) is inadequate for diagnosis. It can miss a stone in the ureter or kidney (even when radiopaque) and provides no information on obstruction or recent stone passage.

Differential Diagnosis

In general, a kidney stone must pass into the ureter to cause pain. Therefore, the isolated presence of a renal stone on radiography is an inadequate explanation for acute abdominal or flank pain.⁵ The differential diagnosis of a patient with suspected renal colic includes musculoskeletal pain, herpes zoster,

acute cholecystitis, duodenal ulcer, appendicitis, diverticulitis, pyelonephritis, abdominal aortic aneurysm, gynecologic disease, and ureteral obstruction due to blood clot, sloughed papilla, or ureteral stricture.^{4,5}

MANAGEMENT IN THE ACUTE SETTING

Medical Treatment

Because renal colic is excruciating, analgesia is a primary goal in the acute setting. Randomized, controlled trials suggest that parenteral nonsteroidal anti-inflammatory drugs are as effective as narcotics in treating renal colic.¹² Newer medications that may be effective include antispasmodics,¹³ trigger point injection with lidocaine,¹⁴ desmopressin,¹⁵ and nonsteroidal anti-inflammatory drugs combined with nitrates.¹⁶ However, data on the utility of these interventions are limited.

Medical therapy has also been directed at treating kidney stones or hastening ureteral stone passage. Alkalinization of the urine may dissolve uric acid stones,¹⁷ and some experts believe that volume expansion will increase the likelihood of stone passage,¹⁸ but this is not proven. α -Blockers and calcium channel blockers also may facilitate the passage of ureteral stones.¹⁹

Surgical Treatment

See Chapter 36 for details.

Larger and more proximal ureteral stones are less likely to pass spontaneously and are more likely to require urologic intervention. If a stone does not pass rapidly, the patient can be sent home with oral analgesia and instructions to return for fever or uncontrollable pain. Most urologists prefer to wait several days before intervention unless there is evidence of infection, low likelihood of spontaneous passage (e.g., stone > 6 mm), presence of an anatomic abnormality that would prevent passage, or unrelenting pain.²⁰ Infection in the setting of obstruction is a surgical emergency and mandates emergent drainage.

The initial urologic approach may be directed at the relief of obstruction (generally by cystoscopic placement of a ureteral stent) rather than stone removal. Anatomy of the urologic tract, availability of technology, experience of the urologist, and the size, location, and composition of the stone determine the best option for stone removal. Extracorporeal shock wave lithotripsy is the least invasive option and is most effective for smaller calcium stones (<1 cm) located in the renal pelvis or proximal ureter.^{21–23} Cystoscopic stone removal by basket extraction or fragmentation is invasive but effective and can now be used to remove stones in the proximal ureter or kidney.²⁴ Percutaneous nephrostolithotomy is more invasive but may be necessary for large stone burdens or stones that cannot be removed cystoscopically.²⁵ It is rare that a patient requires open ureterolithotomy or nephrolithotomy.

CLINICAL AND METABOLIC EVALUATION

The First Stone

Disagreement exists about the benefit of performing a full clinical and metabolic evaluation after the first episode of nephrolithiasis.²⁶ Assuming that the patient is willing to participate

in a diagnostic work-up and to adhere to treatment recommendations, we encourage a full evaluation for most stone formers for the following reasons. First, although recurrence rates are uncertain, the chance of passing a second calcium stone may be as high as 30% to 50% after 5 years.^{1,27,28} Second, treatable systemic diseases of clinical importance, such as osteoporosis and primary hyperparathyroidism, may be diagnosed during the metabolic evaluation.²⁹ Third, allowing a stone former to progress to recurrence may hinder the effectiveness of subsequent prophylaxis.³⁰ Finally, some analyses suggest that medical prevention may be cost saving.³¹

For individuals with a large stone burden or at very high risk of recurrence, little disagreement exists about the utility of a complete work-up. Specifically, patients with a large first stone (e.g., >10 mm), multiple stones on initial imaging, recurrent stones, or stones requiring invasive intervention should be offered a complete evaluation.

Stone Composition

Because treatment recommendations vary by stone type, every effort should be made to retrieve a passed stone for chemical analysis. Approximately 80% of kidney stones contain calcium, and the majority of calcium stones consist primarily of calcium oxalate.²¹ Although most calcium oxalate stones contain some calcium phosphate, only 5% of kidney stones have hydroxyapatite or brushite (calcium monohydrogen phosphate) as their main constituent.^{21,32} Approximately 10% of calcium stones contain some uric acid.²¹ Other types of stones, such as pure uric acid, struvite, and cystine are less common but merit careful attention because of recurrence risk.

History and Laboratory Testing

Evaluation should be directed toward identifying risk factors for stone formation with the goal of devising appropriate, individualized therapy (Box 35-1 delineates risk factors for calcium oxalate nephrolithiasis). The evaluation should start with a detailed history, which will provide information crucial for treatment recommendations. The following should be covered: medical history to identify potentially predisposing conditions (e.g., gout, diabetes, bowel disease, obesity, primary hyperparathyroidism), dietary intake, vitamin and supplement use (particularly vitamin C), medication use before the stone event, family history of stone disease, total number of stones, evidence of residual stones, number and types of procedures, and types and success of previous preventive treatments. More severe stone disease will lower the threshold for early medical intervention in addition to recommended dietary changes.

The metabolic evaluation should include a determination of serum electrolytes, creatinine, calcium, phosphorus, and uric acid. Although usually normal, a low serum bicarbonate should prompt consideration of type 1 renal tubular acidosis, which is classically associated with calcium phosphate stones. Intact parathyroid hormone should be measured if the serum calcium is elevated or in the high normal range, if the serum phosphorus is low, or if the urinary excretion of calcium is elevated.

A urinalysis should be performed as part of the initial evaluation. A urine pH more than 7 with phosphate crystals

Family history of calcium stone disease

Obesity

suggests calcium phosphate or struvite stones. The presence of hexagonal cystine crystals is pathognomic for cystinuria. Uric acid or calcium oxalate crystalluria can be seen in individuals without stones and therefore is less informative. Red and white cells are frequently seen in the urine of asymptomatic individuals with residual kidney stones.

The cornerstone of the metabolic evaluation is the 24-hour urine collection. To tailor initial intervention and determine response to treatment, 24-hour urine collections are necessary even if the stone composition is known. The stone-forming patient should wait at least 6 weeks before performing 24-hour urine collection because individuals frequently alter their dietary habits immediately after an episode of nephrolithiasis.³³ In addition, two collections are necessary because of substantial day-to-day variability in urinary parameters: A single 24-hour urine collection is insufficient.³⁴ The factors that should be measured include total volume, creatinine (to assess the adequacy of collection), calcium, oxalate, citrate, uric acid, sodium, potassium, phosphorus, and pH. Algorithms for the evaluation and management of the patient with calcium stone disease, according to urinary abnormality, are provided in Box 35-2 and Figures 35-1, 35-2, and 35-3.

Estimates of relative supersaturation, based on measurements of the urine factors described, are offered by some laboratories and should be obtained whenever possible. The relative supersaturation can guide selection of and determine response to therapy. Because of controversy over the clinical importance of the classic schemata of Pak and colleagues,³⁵ most clinicians do not attempt to categorize individuals with

idiopathic hypercalciuria into absorptive, resorptive, or renal subtypes.

The Normal Metabolic Evaluation

Because kidney stones can remain asymptomatic for many years before they pass into the ureter and cause renal colic, the actual time of stone formation is usually unknown. Therefore, the metabolic evaluation may be completely normal. In this case, no intervention is required. However, repeat imaging in 1 year to identify active stone formation, in conjunction with another 24-hour urine, is warranted in recurrent stone formers.

PREVENTION OF STONE RECURRENCE: CALCIUM OXALATE NEPHROLITHIASIS**Fluid Intake**

Nephrolithiasis is a disease of concentration. Modifying the concentration of lithogenic factors is the focus of stone prevention. The concentration of calcium, for example, can be lowered by reducing urinary calcium or by increasing urine volume. Thus, fluid intake is a critical component of stone prevention. Observational studies^{36–38} and a randomized, controlled trial³⁹ have demonstrated that higher fluid intake decreases the risk of stone formation. However, patients need to be given specific advice on how much to drink to form at least 2 L of urine per day. In addition to fluid intake, other factors such as insensible loss and water contained in foods influence urine volume. Rather than broadly recommending eight glasses of water per day, the recommendation can be tailored to the individual patient by using the information on total volume from the 24-hour urine collections. For example, if an individual produces 1.5 L of urine per day, consuming an additional two 8-oz (240 mL) glasses of water would increase their output to the target of 2 L.

Patients often want to know what they should and should not drink. Despite previous beliefs to the contrary, alcoholic beverages, coffee, and tea do not increase the risk of stone formation.^{40,41} Individuals with stone disease should not drink sugar-sweetened soda. The intake of milk should not be restricted.

Some clinicians believe that a patient should have urine that is very light in color and should wake up at least once per night to void. There are no data to support the use of color as a guide, and the desire to have constantly dilute urine needs to be balanced against the need for sleep.

Dietary Recommendations

Individuals with calcium oxalate stone disease and elevated urinary calcium should restrict their intake of sodium and animal protein.⁴² Additional dietary recommendations should be based on the results of the 24-hour urine collection. For example, dietary oxalate restriction or discontinuation of vitamin C supplementation may be of limited utility in a calcium oxalate stone former with lower urinary excretion of oxalate. For low urinary citrate, the patient should increase intake of dietary alkali (fruits and vegetables) and decrease intake of

Box 35-2 Treatment of Idiopathic Hypercalciuria

Dietary Changes	Medications	Comments
Increase total fluid intake to maintain urine volume > 2 L/day Adequate dietary calcium intake Decrease animal protein intake (≤ 5 servings of animal flesh per week) Decrease sodium intake (<2.4 g/day)	Chlorthalidone or hydrochlorothiazide 25 mg/day; titrate to 50–100 mg/day as needed	Administer hydrochlorothiazide twice daily to maximize hypocalciuric effect Hypokalemia secondary to diuretic therapy can precipitate hypocitraturia High sodium intake may result in failure of thiazide to decrease urinary calcium

acid-producing foods such as animal protein. Of note, there is no evidence that dietary calcium restriction alone is helpful in preventing the formation of calcium stones, and there is substantial evidence that it may be harmful. Observational data showing an inverse relationship between dietary calcium and the risk of incident kidney stones suggest that dietary calcium may bind to oxalate in the gut, thereby limiting intestinal oxalate absorption (and subsequent urinary oxalate excretion). Indeed, the inhibitory effect of calcium ingestion on urinary oxalate excretion has been demonstrated in oxalate-loading studies.^{43,44} The role of calcium supplements deserves comment because their use is so common. A patient with calcium nephrolithiasis who wishes to continue calcium supplementation should collect 24-hour urine samples on and off the supplement. If the urinary supersaturation of the calcium salt in question increases during the period of supplement use, the supplement should be discontinued.

Drug Therapy

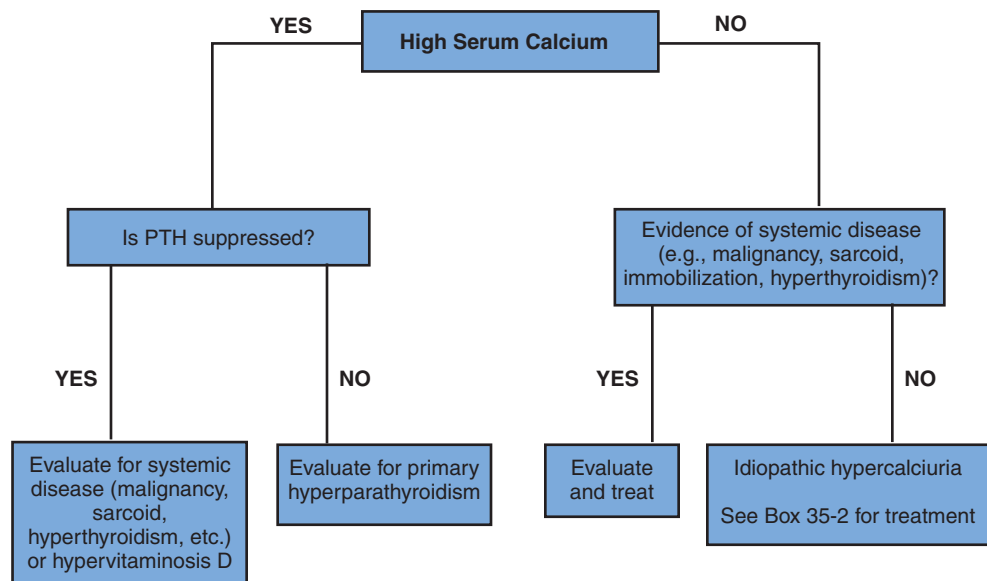

Medications are indicated for the stone-forming patient with severe disease or whose urinary abnormalities persist despite attempted lifestyle changes. Because the goal of

therapy is to prevent the additional formation and growth of calcium oxalate stones and because an existing calcium stone will not dissolve, the passage of another stone does not necessarily reflect failure of dietary interventions. As with dietary modification, the 24-hour urine collection is essential to select intervention and to gauge the success or failure of treatment.

Thiazide diuretics can lower the urinary excretion of calcium by as much as 150 mg/day, and treatment with a thiazide may reduce the rate of stone recurrence by as much as 90%.^{45,46} The diuretic dose is usually started at chlorthalidone or hydrochlorothiazide 25 mg/day (or its equivalent), but many patients will require 50 to 100 mg/day (with twice-daily dosing for hydrochlorothiazide) to achieve satisfactory decreases in urinary calcium excretion. Without dietary sodium restriction, the reduction in urinary calcium excretion obtained with treatment may be inadequate. In addition, serum potassium levels should be closely monitored during therapy because hypokalemia can result in a decrease in urinary citrate excretion. Thiazide diuretics may be beneficial even in patients without overt hypercalciuria.^{45,46}

Calcium stone formers with hyperuricosuria may be treated with allopurinol (100–300 mg/day). Allopurinol may reduce

Figure 35-1 Algorithm for the evaluation and management of higher urinary calcium. PTH, parathyroid hormone.

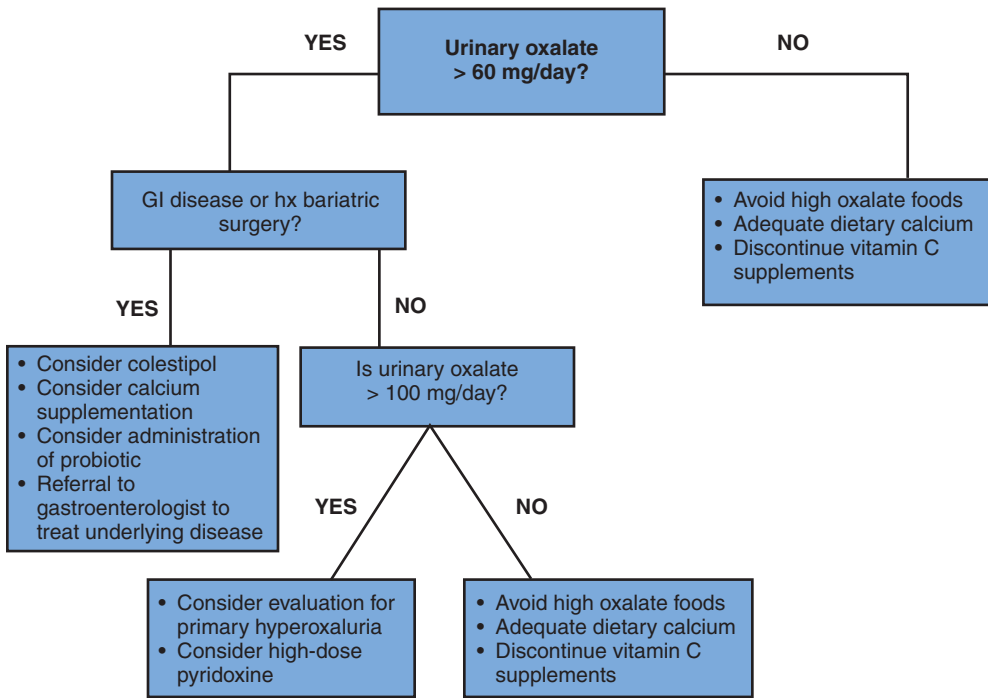

Figure 35-2 Algorithm for the evaluation and management of higher urinary oxalate. GI, gastrointestinal; hx, history.

new stone formation by as much as 80% in individuals with isolated hyperuricosuria.⁴⁷

Urinary citrate excretion can be increased by the administration of an oral alkali load, usually in the form of potassium citrate started at 20 mEq three times daily.^{48,49} In one study, stone recurrence in a group of hypocitraturic patients treated with potassium citrate decreased from 1.2 to 0.1 per patient year (versus no change with placebo).⁴⁹ Potassium salts should be administered cautiously to patients with chronic kidney disease or those taking drugs that decrease urinary potassium excretion.

To date, no satisfactory drug treatment exists to decrease the urinary excretion of oxalate. For patients with increased intestinal absorption of oxalate secondary to bowel disease, clinicians sometimes administer oxalate binders such as calcium

carbonate or colestipol. Experimental therapies include the oral administration of oxalate-consuming bacteria and the administration of high-dose pyridoxine (to decrease the endogenous production of oxalate).^{50,51}

PREVENTION OF STONE RECURRENCE: OTHER STONE TYPES

For the less common stone types, few data exist to support the role of specific dietary recommendations, and trial evidence for medical therapies is generally absent. Therefore, the following recommendations are based on the pathophysiology of the different stone types and clinical experience.

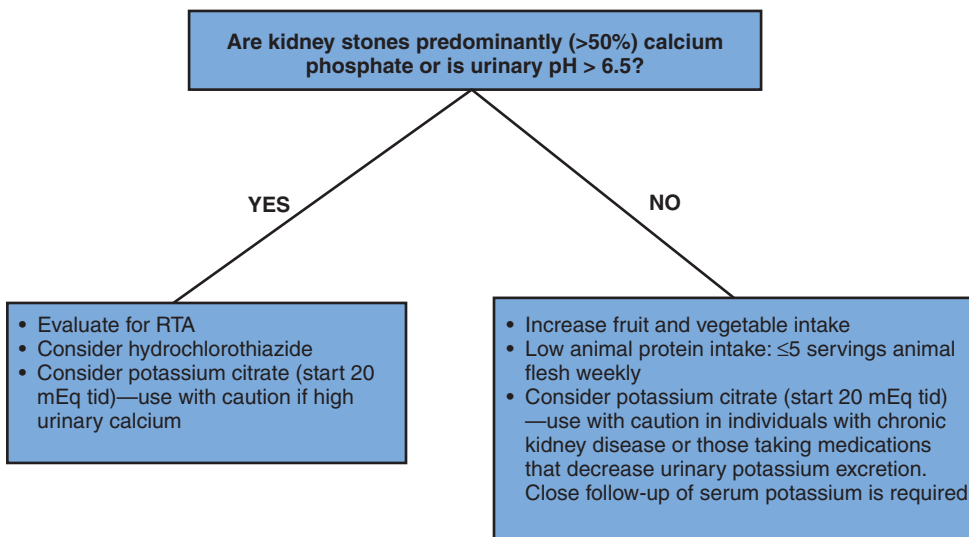

Figure 35-3 Algorithm for the evaluation and management of lower urinary citrate. RTA, renal tubular acidosis.

Uric Acid Stones

The primary risk factor for uric acid nephrolithiasis is low urinary pH, and alkali supplementation is the most effective treatment for pure uric acid stones.¹⁷ If urine pH is maintained at 6.5 or higher (which may require 30–40 mEq of supplemental alkali dosed three times daily), pure uric acid stones will dissolve. A lower pH target can be used to prevent new uric acid stone formation. If the patient has marked hyperuricosuria and is unable to maintain an elevated urine pH, allopurinol should be added to the medical regimen.

Decreasing the consumption of meat, chicken, and seafood will decrease purine intake and uric acid production and will also decrease the amount of endogenous acid production from the metabolism of sulfur-containing amino acids. Higher intake of fruits and vegetables, which are high in potential base (such as citrate), may increase the urine pH and decrease the risk of uric acid crystal formation.

Because of the relationships between insulin resistance, obesity, and low urinary pH,^{52–54} as well as data linking both obesity and diabetes to a higher risk of uric acid stones,^{55,56} patients with uric acid stone disease may benefit from weight loss. Currently, there is no evidence supporting the role for insulin-sensitizing agents as a modality for the treatment of uric acid nephrolithiasis.

Cystine Stones

Cystine stones result from cystinuria, an autosomal recessive disorder, and usually require medication for prevention. Tiopronin and penicillamine increase the solubility of filtered cystine, but have a high frequency of adverse side effects. Supplemental alkali may provide some benefit by increasing urinary pH,⁵⁷ but is rarely sufficient as the sole treatment.

Restricting dietary sodium may reduce the urinary excretion of cystine. Because the solubility of cystine increases as urinary pH increases, fruit and vegetable consumption may be beneficial. There is little evidence to support the dietary restriction of proteins high in cystine. However, reducing animal protein intake may be beneficial by increasing urine pH.

Struvite Stones

Struvite stones form in the setting of upper urinary tract infection with urease-producing bacteria. Struvite stones can be very large (“staghorn calculi”) and usually require urologic intervention. In addition to complete removal of all residual fragments, prevention of recurrent urinary tract infection is crucial to prevent recurrence. Acetohydroxamic acid inhibits urease, but has frequent and serious side effects.⁵⁸

Calcium Phosphate Stones

Information on dietary factors related to calcium phosphate stone formation is limited. Patients with type 1 RTA benefit from the administration of alkali supplementation, generally in the form of potassium citrate. However, alkali supplementation should be used with caution because an increase in urinary pH can increase the risk of calcium phosphate crystal formation. Thiazides can be used to decrease the excretion of urinary calcium using an approach similar to that recommended for calcium oxalate stones.

FOLLOW-UP

Close follow-up is essential to determine the efficacy of treatment and gauge the need for additional intervention. We recommend a repeat 24-hour urine collection 6 to 8 weeks after initiation of treatment. If a stone former is symptom free and on a treatment regimen that has adequately reduced urine lithogenicity, we recommend a follow-up 24-hour urine collection annually. Because x-ray examination of the kidney and upper bladder or US can identify new kidney stones or an increase in the size of a previous stone, annual imaging is a reasonable way to detect treatment failure in an asymptomatic patient. We do not recommend routine follow-up with HCT for asymptomatic individuals because of radiation dose and cost.

CONCLUSION

Nephrolithiasis is common, costly, and painful. Advances in imaging and urologic techniques have improved the diagnosis and management of stone disease in the acute setting. Because recurrence is common, a clinical and metabolic evaluation should be offered to patients willing to adhere to specific dietary and/or pharmacologic recommendations. Even if stone composition is known, a thorough evaluation requires at least two 24-hour urine specimens collected at least 6 weeks after resolution of an acute episode. The initial choice of dietary or medical intervention should be tailored to the individual patient based on stone type, if known, and the 24-hour urine results. Subsequent 24-hour urine collections are necessary to gauge the adequacy of treatment. Prevention of stone recurrence is an achievable goal with individualized therapy and regular follow-up.

EFFECT OF SURGICAL APPROACHES ON RENAL FUNCTION	439		

During the past 15 years, the management of urinary calculi has undergone revolutionary changes as a result of the increasing number and availability of nonsurgical therapeutic approaches. Pyelolithotomy, ureterolithotomy, and retrograde blind endoscopic procedures were previously the only treatment options for removal of symptomatic stones. Fortunately, the development of extracorporeal shock wave lithotripsy (SWL), percutaneous nephrolithotomy (PCNL), and ureteroscopic lithotripsy has provided urologists with less invasive and safer treatment possibilities. The use of SWL and PCNL has led to a dramatic reduction in morbidity and mortality and has hastened recovery and return to usual activities. Remarkable technologic advances in the methods of SWL and endourology have continued with the introduction of smaller and less expensive devices. Although new technology has rendered stone management safer and less invasive, the appropriate role of each modality remains unsettled and merits careful individualized consideration.

This chapter discusses the role of lithotripsy and surgery in the management of nephrolithiasis. All the procedures described require the skill of an experienced urologist. For a more detailed discussion of these techniques, there are several excellent reviews.^{1,2}

TYPES OF LITHOTRIPSY

There are two main categories of lithotripsy: extracorporeal and intracorporeal.

Extracorporeal Shock Wave Lithotripsy

Extracorporeal SWL, the most common technique, is performed by the generation of shock waves external to the body that are transmitted through the skin and soft tissues and

focused on the stone. The energy delivered causes fragmentation of the stone into smaller pieces that can then be passed spontaneously or removed endoscopically by the urologist. The original lithotriptors required the patient to be immersed in water to transmit the shock wave through the body to the stone; however, newer generation machines require only a small water cushion. Although SWL is often referred to as noninvasive lithotripsy, cystoscopic placement of ureteral stents before treatment may be needed to relieve obstruction or allow passage of a large (>1.5 cm) stone burden.

Intracorporeal Lithotripsy

Intracorporeal lithotripsy is performed through a nephroscope or cystoscope and is therefore more invasive than extracorporeal SWL. The four types of device currently available for intracorporeal lithotripsy (electrohydraulic, ultrasonic, laser, and pneumatic) differ according to the manner in which the energy for fragmentation is generated and delivered to the stone.

Electrohydraulic Lithotripsy

Electrohydraulic lithotripsy, the first method of intracorporeal lithotripsy to be introduced, fragments stones by the transfer of energy from the generated shock wave to the stone at the fluid-stone interface. An electrical spark vaporizes water and creates a shock wave. Ureteral damage may occur from exposure to the spark produced during shock wave generation.

Ultrasonic Lithotripsy

Ultrasonic lithotripsy makes use of mechanical vibration to break stones into smaller fragments that may be aspirated with specialized probes. This method requires direct contact between the probe and the stone and has several drawbacks. For example, it is often necessary to ensnare the stone in a

basket before treatment because pressure exerted on the stone during the procedure may cause upward migration of stone fragments. In addition, heat produced within the ureter by the probe may lead to the formation of ureteral strictures. Furthermore, the rigidity and large size of the probes prevent the use of small ureteroscopes.

Laser Lithotripsy

The flexibility and fine caliber of the fibers used to deliver the laser energy have allowed remarkable miniaturization of ureteroscopes. Moreover, laser fragmentation of stones can be performed with greater precision and control than by other methods and without propulsion of fragments or damage to surrounding tissue.

A number of laser types are available for stone fragmentation. The susceptibility to fragmentation by laser energy is dependent on stone composition and physical factors specific to each type of laser, such as pulse duration and wavelength. For example, the energy delivered by the pulsed dye laser has proved to be useful in the disruption of most stones and has the advantage of sparing the ureter from damage. Although this laser type does not fragment cystine stones well, its effectiveness can be enhanced by staining the cystine stone with an absorbing dye. In contrast, the holmium laser effectively disintegrates the surface of any stone with minimal propulsion, gradually cracking or boring a hole through the stone. However, ureteral tissue may absorb the wavelength from the holmium laser and is thus vulnerable to injury.

Pneumatic Lithotripsy

The Swiss Lithoclast, the least expensive intracorporeal device, has been used effectively for stone fragmentation at all levels of the urinary tract. Under direct visualization, a solid rigid probe is applied directly to the stone to cause mechanical disruption by repeated percussion of the probe tip, similar to the mechanical action of a pneumatic jackhammer. Grasping instruments may then be used to remove the stone fragments. However, retrograde displacement of a ureteral stone is a potential drawback of this procedure, and the precise positioning required to prevent tissue damage and the need for a rigid or semirigid endoscope limit its usefulness as well.

EFFICACY OF LITHOTRIPSY

Although there is general agreement that both extracorporeal and intracorporeal lithotripsy are effective, there are no large randomized, controlled trials comparing these two methods. A recent small randomized trial of 64 patients found comparable success rates for SWL compared with ureteroscopy for the treatment of distal ureteral calculi of 1.5 cm or smaller.³ Results from studies of the individual methods must be compared with caution because the success or effectiveness of treatment is not uniformly defined. Although stone free is the gold standard for a successful procedure, there is great variability in the ascertainment of this outcome with respect to both the time of assessment (e.g., immediately after the procedure, after 7 days, after 3 months) and the imaging modalities employed (e.g., radiograph of the kidneys, ureter, and bladder, intravenous pyelography, ultrasonography, computed tomography). When SWL was first introduced, a treatment session that produced clinically insignificant fragments was deemed a

success. However, this definition has fallen out of favor owing to its ambiguity and the reality that the retention of small fragments results in regrowth and recurrence of symptomatic stone disease. The definition of a treatment failure may vary as well, yet is most commonly defined as the need for a repeated treatment or another type of procedure.

Extracorporeal Shock Wave Lithotripsy

The success of SWL depends on the location, size, and composition of the stone. Thus, a comparison of success rates between different studies must consider all three of these factors. Stones in the kidney are treated with slightly greater success than are ureteral stones, and success rates are higher for proximal ureteral stones than for distal stones. Small stones, usually smaller than 2 cm, are more easily treated with SWL than are larger stones. Softer stones (calcium oxalate dihydrate, uric acid, apatite, and struvite) are more easily fragmented with SWL than are harder stones (calcium oxalate monohydrate, brushite, and cystine).

SWL is the treatment of choice for most renal stones, and success rates as high as 90% have been reported.⁴ However, further procedures may be necessary in as many as 20% of patients with stones of 1 to 2 cm. In general, SWL is more effective in the treatment of stones in the renal pelvis than in the calyces and, depending on size, composition, calyceal configuration, and infundibular pelvic angle, is least effective in treating lower pole stones.

There is an inverse relationship between stone size and stone-free rates. Stones larger than 2 cm in diameter are rarely successfully treated with SWL alone and may best be removed by PCNL in the upper urinary tract and ureteroscopically in the lower tract.

Stone-free rates of more than 80% for calcium oxalate and uric acid stones (softer stones) have been reported, although no distinction was made based on stone size.⁵ A study of retreatment rates in patients with stones of known composition, 1 to 3 cm in diameter, and treated with SWL found that calcium oxalate monohydrate calculi (hard stones) required the greatest number of retreatment procedures (10%), followed by struvite (6%), and calcium oxalate dihydrate (3%).⁶

First-generation lithotriptors caused enough pain to require anesthesia, either general or epidural. Most patients treated with newer generation devices require only moderate intravenous analgesia while undergoing SWL.

The early complications of SWL have been well described and are generally minor, with pain and hematuria most commonly reported. Direct injury to the kidney and surrounding tissues as well as complications due to the passage of stone fragments may also occur. Much less information is available on the long-term effects of SWL because most follow-up efforts have focused only on the short-term results and complications.

The morphologic changes that may occur after SWL and their mechanisms have been studied by a variety of imaging techniques. Imaging by computed tomography or magnetic resonance reveals that more than 75% of treated patients have changes in renal tissue and demonstrate edema in and around the kidney, as well as intraparenchymal, subcapsular, or perirenal hemorrhage. Although damage to nonrenal tissues has been rarely reported, pancreatitis, gastric erosions, ecchymoses of the colonic mucosa, splenic rupture, pulmonary contusions, and cardiac arrhythmias may occur. Although there

have been no reported adverse effects of SWL on fertility or the risk of birth defects, the impact of SWL on the reproductive tract, if any, has yet to be established. SWL should not be used on pregnant women.

Functionally, biochemical evidence of kidney damage directly after SWL has been documented. Although the results of these laboratory studies generally return to near-normal levels within days, it is unclear whether these changes represent only transient dysfunction or more consequential chronic damage. A small prospective, randomized study suggested that pretreatment with nifedipine or allopurinol may protect the kidney from shock wave–induced renal damage.⁷ Nevertheless, there is no clear evidence to indicate that SWL is associated with any long-term effect on renal function in humans.⁸

Ureteral stone fragments may cause obstruction after incomplete stone fragmentation or fragmentation of a large stone burden resulting in *steinstrasse*, literally “stone street.” Typically, partially obstructing *steinstrasse* will clear spontaneously within 2 to 4 weeks in asymptomatic patients. Otherwise, percutaneous nephrostomy tube decompression, ureteroscopic manipulation, PCNL, repeated SWL, or even open ureterolithotomy may be necessary to clear the stone fragments. Repeated SWL is often attempted in patients with minimal symptoms and no evidence of infection. In contrast, emergency decompression of the collecting system with a percutaneous nephrostomy tube is necessary for symptomatic patients or asymptomatic patients with significant obstruction. *Steinstrasse* that persist for longer than 1 or 2 weeks after placement of the percutaneous nephrostomy tube may be relieved with repeated SWL, ureteroscopy, or intracorporeal lithotripsy.

Although it has been suggested that SWL is associated with new-onset hypertension, this connection is not supported by all studies. The most persuasive study demonstrated that the incidence of hypertension is not higher in patients treated with SWL compared with other methods of stone removal. Nevertheless, there was a statistically significant increase in diastolic blood pressure of just less than 1 mm Hg in SWL-treated patients.⁹ This increase may be more pronounced in older patients.

To date, the safe upper limit of shock wave energy that can be delivered to one kidney during one session, the total amount of energy that can be delivered cumulatively, and the minimum safe interval between treatment sessions have yet to be defined. The variables to be considered include the number of shock waves and the power at which they are delivered. These vary for each type of machine and have not been standardized. However, despite these variations, there are few reports of renal injury to the hundreds of thousands of patients treated with SWL. Available data suggest that if chronic kidney damage does occur, it is most likely to be incurred by patients with some degree of preexisting renal dysfunction.¹⁰

SURGICAL MODALITIES

Stone surgery has changed so considerably over the past decade that the term has almost dropped out of use. The percutaneous approach was then introduced, which involved new technology both to approach the kidney and to enter it without damaging vital structures, and then to remove the stone if small or to fragment and aspirate it if larger.

Percutaneous Nephrolithotomy

The fact that stone removal from the kidney required an extensive flank incision long frustrated urologists. Eventually, the task was performed using a combination of radiographic and minimally invasive surgical techniques.¹¹

The procedure is usually performed in a single session with general anesthesia. A fine needle is inserted into the renal pelvis under ultrasound or radiographic guidance: the track is not made directly into the pelvis but through the parenchyma of the lower pole of the kidney, so that the track into the lower pole calyx is supported by the renal tissue itself. A nephroscope is passed, and if the stone is visualized, it can be broken up by intracorporeal lithotripsy. The fragments are then evacuated, and a non–self-retaining nephrostomy tube is inserted and sutured to the skin.¹²

Failure to remove the stone fragments completely is uncommon, particularly with increasing experience. The overall success rate of 95% throughout the world shows that this technique is an excellent way to clear, using one single method, all but the most refractory of stones.^{13–15}

The complication rate is low: hemorrhage requiring blood transfusion or surgical intervention is seen in 1% to 3% of patients, and residual stones are left behind in 2% to 8%.¹⁵ Sepsis can develop, especially if the preoperative urine culture is positive. In this case, antibiotic prophylaxis is needed.¹⁶

Open Surgery

The newer techniques for removing and fragmenting stones, alone or in combination, have eliminated the requirement for open surgery except in a small number of cases. The actual percentage of cases that today require open surgery is not known but is unlikely to be greater than 12%. Stones of large bulk and complexity should be managed in stone centers by urologists who have the experience required for this type of surgery.

One of two methods is used to incise the renal cortical tissue and to approach the peripheral stone fragments in the calyces: radical paravascular nephrotomy¹⁷ and anatomic nephrolithotomy.¹⁸ In the former approach, incisions are made between the branches of the renal artery. The calyx is approached and the fragments are removed. Several of these nephrotomies may have to be made, placed laterally in the kidney on either the anterior or posterior surface. After complete removal of the stone, the nephrotomies are closed with a fine suture, aiming to close only the renal capsule.

In anatomic nephrolithotomy, the incision follows the avascular line between the segments of the kidney that are supplied by the anterior and posterior segmented branches of the renal artery. After complete removal of the stone, the kidney incision is sutured and closed completely.

EFFECT OF SURGICAL APPROACHES ON RENAL FUNCTION

The overall effect on renal function of PCNL is usually minimal. Although there is a potential risk that increases with the size of the access track, no studies have reported any serious postoperative loss of function.

Two aspects of open surgery may interfere with postoperative renal function: renal ischemia and parenchymal incisions. To prevent excessive hemorrhage when the renal parenchyma is incised, the renal artery is traditionally clamped, exposing the kidney to ischemia. If the ischemic period is longer than 20 minutes, irreversible renal damage may occur. A number of methods have been described to preserve renal function during ischemia of more than 20-minute duration, including renal cooling and vasoactive agents. In a canine model, the function of kidneys subjected to radial paravascular nephrotomy was unchanged compared with that of controls.¹⁹ There was a statistically significant difference in postoperative function when the anastrophic nephrotomy was compared with control kidneys.

RECOMMENDATIONS

Contemporary Indications for Intervention

The generally accepted indications for intervention for the treatment of urinary calculi are summarized in Box 36-1. Absolute indications include persistent or progressive high-grade obstruction by the stone, urinary tract infection, and intractable pain. Infection in the face of obstruction is a medical emergency that requires immediate intervention to relieve the obstruction before SWL. Relative indications for intervention include occupational factors, significant hematuria requiring transfusion, substantial stone growth despite appropriate medical management, stone size judged too large to pass spontaneously, or failure of a ureteral stone to move during a 6-week period.

A finding of hydronephrosis, a sign of ureteral obstruction, at initial presentation is not necessarily an indication for intervention. However, if follow-up studies reveal a lack of improvement during a 1- to 2-week period, intervention is usually required whether or not symptoms are present.

The location, size, and composition of the stone are the most important factors guiding the decision to treat and with which method (Box 36-2). Realistically, the cost of purchasing and maintaining the different types of lithotripsy equipment is substantial, and most hospitals, even large academic centers, have only one extracorporeal and one or two intracorporeal lithotripsy devices available. Thus, treatment with

Box 36-1 Indications for Urological Intervention in Nephrolithiasis

Absolute Indications

- Persistent obstruction
- Urinary tract infection
- Intractable pain

Relative Indications

- Failure of ureteral stone to progress
- Significant hematuria
- Stone growth despite optimal medical treatment
- Social, economic, or occupational factors
- Stone too large to pass spontaneously

Availability of Technology

- Experience of urologist

extracorporeal or intracorporeal lithotripsy is the first decision to be made, based on the availability of devices. Second, the skill and familiarity of the treating urologist with the different methods are important. Third, the choice of approach depends on both economic factors and individual preferences (e.g., travel, time lost from work, retreatment rates). Fourth, other medical conditions, such as morbid obesity and severe scoliosis or kyphosis, and conditions associated with an increased risk of general anesthesia must be taken into consideration.

Renal Calculi

The majority of patients with renal stones smaller than 2 cm may be successfully managed with outpatient SWL and return to routine activities within 48 hours. In contrast, SWL treatment of stones 2 cm or larger presents a substantial risk of ureteral obstruction from stone fragments; therefore, PCNL is extremely effective and is the procedure of choice. Depending on stone composition and other clinical circumstances, stones 2 to 3 cm in size may occasionally be treated with SWL. A treatment algorithm for the management of renal calculi is presented in Figure 36-1.

Bilateral Stones

In the setting of bilateral stone disease, each kidney is commonly treated individually in separate sessions. However, patients with symptomatic bilateral stones may require bilateral intervention and can be treated with SWL during a single session if the stone burden is not too large and renal function is normal.¹⁰ Patients with abnormal renal function before bilateral SWL treatment may be more likely to develop acute renal failure.¹⁰ Potentially, patients with normal renal function and asymptomatic large bilateral stones may undergo bilateral SWL by an experienced endourologist in a single session for economic, social, or medical reasons (e.g., risk of anesthesia).

Calyceal Diverticula

Stones in calyceal diverticula are generally asymptomatic. Nevertheless, intervention is necessary in the setting of local symptoms such as pain, associated infection, hematuria, or progressive stone growth. Rarely, if there is adequate drainage from the calyceal diverticulum, SWL is the treatment of choice

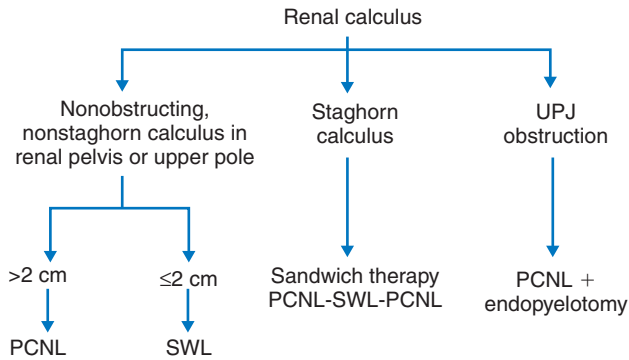

Figure 36-1 Treatment algorithm for the initial management of renal calculi. PCNL, percutaneous nephrolithotomy; SWL, shock wave lithotripsy; UPJ, ureteropelvic junction.

for stones smaller than 1.5 cm. PCNL is recommended for stones 1.5 cm or larger.

The management of asymptomatic calyceal calculi is more of a problem. One study suggested that 30% of patients with asymptomatic calyceal stones will present with a symptomatic episode within 3 years and 50% within 5 years of the initial evaluation.²⁰ Most urologists recommend a conservative approach and observe patients with asymptomatic calyceal diverticuli with calculi.

Horseshoe Kidney

Approximately 20% of individuals with a horseshoe kidney form a stone at some time. These stones may be composed of struvite, the result of infection due to abnormal urinary drainage, or calcium oxalate. SWL can be attempted if it is anatomically feasible. PCNL may be used as a primary or adjunctive procedure, particularly for larger stones. In general, stones 2 cm or smaller may be treated with either a first-generation lithotripter or PCNL; PCNL is the treatment of choice for stones larger than 2 cm.²¹

Medullary Sponge Kidney

SWL may be attempted for the treatment of renal calculi in patients with medullary sponge kidney, although the data on its effectiveness are limited.²² It is noteworthy that residual calcifications will likely be evident on kidney ureter bladder film owing to the presence of parenchymal calcifications. Thus, radiographic assessment of the success of the procedure and preventive medical therapies is difficult.

Staghorn Calculi

Struvite staghorn calculi are particularly concerning because they arise from infected urine and the stones harbor infection. Struvite staghorn calculi that fill the major part of the collecting system should be treated with a combination of percutaneous stone removal and SWL. The assessment of overall and split renal function is important when choosing which treatment to offer. The American Urological Association's treatment guidelines state that for struvite staghorn calculi, PCNL should be performed to debulk the stone mass occupying the renal pelvis, followed by SWL or flexible nephroscopy at a later date to remove fragments remaining in the calyces.²³ In

experienced hands, the stone-free rates with the combined approach should exceed 80%.²¹

Solitary Kidney

A solitary kidney, whether congenital or acquired, presents a unique set of difficulties. Obstruction of a solitary kidney can lead to acute renal failure. SWL with or without cystoscopic assistance is the best approach in this setting because it is preferable to avoid the use of a percutaneous nephrostomy owing to potential damage to the renal parenchymal tissue. Otherwise, the same criteria for treatment selection apply to a solitary kidney.

Transplanted Kidney

Fortunately, renal calculi form in less than 2% of transplanted kidneys. Hyperparathyroidism and nonabsorbable sutures are the most important risk factors. As for the native solitary kidney, it is preferable to avoid a percutaneous approach in a transplanted kidney. The transplanted kidney is typically located in the right or left lower quadrant of the abdomen and therefore is accessible by SWL. Alternatively, cystoscopic treatment with one of the intracorporeal methods may be attempted by an experienced endourologist.²⁴

Ureteral Calculi

Renal colic from a ureteral stone is the most frequent reason for a patient to present to a physician for acute treatment of nephrolithiasis. At the time of presentation, a radiographic study will usually be obtained that may consist of an intravenous pyelogram (also known as intravenous urogram) or an ultrasound examination; many centers have replaced these with the preferred spiral computed tomography, which is more rapid and provides greater resolution. For patients with a known history of stones whose renal and ureteral anatomy is known, kidney ureter bladder film may be sufficient to identify a new stone.

The size of the ureteral calculus is an important factor in the determination of the need for intervention. Historically, ureteral stones 4 mm or smaller were observed, in anticipation of their spontaneous passage. However, recent data suggest that both size and location influence the likelihood of spontaneous passage.²⁵ In a retrospective study of 378 patients with ureteral stones, overall 60% of the stones passed without requiring intervention. Notably, the more proximal the stone is, the lower the passage rate. For example, a 4-mm stone passed spontaneously only 20% of the time if it were located in the proximal ureter, whereas the same size stone in the distal ureter passed spontaneously in 55% of cases.²⁵ Currently, even with the new technology available, patients with stones 4 mm or smaller rarely undergo intervention because of the excellent chance of spontaneous passage. However, improvements in technology have altered the indications for intervention for those patients with slightly larger stones who in the past would have been observed expectantly.

When intervention is deemed necessary, the location of the stone within the ureter is an important consideration that influences the selection of the method to be used (Fig. 36-2). Approximately 70% to 80% of proximal ureteral stones (above the iliac vessels) can be successfully treated with extracorporeal SWL. Although there are no large prospective, randomized

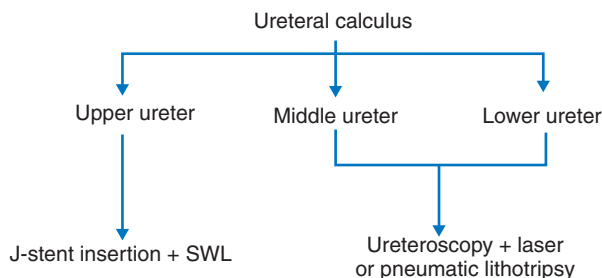

Figure 36-2 Treatment algorithm for the initial management of ureteral calculi. SWL, shock wave lithotripsy.

trials that compare SWL with other methods of removal, SWL is a reasonable choice for the initial management of proximal ureteral stones because of safety, noninvasiveness, and observed high success rates. Complications from SWL for proximal ureteral stones often result from stone manipulation before treatment, and ureteral stent placement does not increase the efficacy of treatment. However, in the setting of ureteral calculi larger than 1.5 cm, urosepsis, or complete ureteral obstruction, the placement of a ureteral stent or nephrostomy tube is often necessary. If SWL alone is unsuccessful, retrograde approaches are indicated. If the stone still cannot be removed, an antegrade (percutaneous) approach may be attempted. PCNL is a highly effective yet much more invasive option for the removal of a proximal ureteral stone.

The optimal treatment of distal ureteral stones is also controversial, primarily because of the lack of any prospective, randomized, controlled studies comparing SWL and ureteroscopy. SWL and endoscopic lithotripsy are both acceptable treatments of distal ureteral stones. SWL requires many more repeated treatments than endoscopic lithotripsy, but the latter is more invasive and occasionally may result in ureteral stricture formation.

SWL treatment of stones located in the distal ureter is technically more difficult than for stones in the renal pelvis or calyces. Thus, some urologists still employ ureteroscopy to manipulate the stone retrogradely into the renal pelvis and then proceed with SWL (referred to as “push-bang”). However, data suggest that this more invasive technique does not yield substantially higher stone-free rates than does SWL alone.²⁶

As with renal stones, the comparative efficacy of the different approaches to treatment of ureteral calculi is difficult to assess. Most likely, the choice of treatment will be based on availability and experience with the various methods. Similarly, the choice of ureteroscopic technique often depends on the availability of the equipment and the experience of the urologist. If it is available, the pulsed dye laser may be used for fragmentation of most ureteral calculi. However, ultrasonic lithotripsy may be more effective for the treatment of a calcium oxalate monohydrate stone larger than 1 cm. Small durable stones are best treated by grasping with forceps or a basket followed by extraction. Treatment of cystine stones is more easily performed by electrohydraulic lithotripsy or holmium laser than by coating with dye and fragmentation by the pulsed dye laser.²⁷

The treatment of infants, pregnant women, or extremely obese individuals merits special consideration. Minimal invasiveness and radiation exposure are particularly important in

pediatric and obstetric patients, and conservative management is prudent. SWL, preferably with ultrasound localization, may be used in infants. Ureteroscopic techniques are another treatment option. Nevertheless, pregnant patients who present with symptomatic ureteral stones may require urgent treatment because of the increased risk to the fetus from systemic maternal infection or premature labor. The potential for serious complications and the technical difficulties involved in the treatment of infants and pregnant women demand care by only the most experienced endourologists. Although endoscopic treatment of distal calculi can be accomplished under local anesthesia in pregnant women, the most prudent approach is to insert an indwelling stent and allow the patient to complete the pregnancy. Extreme obesity, conversely, may impede SWL localization and the ability of the shock wave to reach the calculus; thus, ureteroscopic methods are preferable in this setting.²⁸

Antibiotics and Shock Wave Lithotripsy

Historically, routine antimicrobial prophylaxis has been administered even in the absence of infection in the urinary tract. However, a prospective, randomized trial involving 360 patients revealed that the incidence of urinary tract infection after SWL was low in patients with sterile urine before intervention and suggested that prophylactic antibiotics may be unnecessary.²⁹ If bacteriuria is associated with calculi, prophylactic antibiotics are required whatever the planned surgical procedure.

SUMMARY 452

The term urinary tract infection (UTI) encompasses a group of clinical disorders that are quite diverse and that, together, constitute the most common form of bacterial infection affecting humans throughout their life span. UTI is primarily an infection of females (both adult and pediatric). Males have a significant incidence of UTI only at the two extremes of life because of the higher incidence of urogenital anomalies among male babies and the effects of prostatic disease in the geriatric population.¹ More than 7 million women seek medical attention each year for acute, uncomplicated UTI (cystitis), with more than 100,000 hospital admissions each year for the care of pyelonephritis at a total cost of more than \$1 billion per year. The incidence of cystitis in sexually active young women is 0.5% to 0.7% per year. Approximately 50% of women will have at least one UTI in their lifetime.^{2,3} UTI may involve deep tissue infection of the kidney and/or the prostate gland, or superficial mucosal infection of the bladder; an estimated 90% of infections in males involve tissue invasion, whereas 70% or more of UTIs in females represent superficial mucosal infection. Clinically, UTIs may be symptomatic or asymptomatic, may cause bloodstream invasion, and may occur in anatomically normal or abnormal urinary tract anatomy or in persons with or without underlying renal disease.¹⁻⁵

Over the years, it has been postulated that UTI, even if asymptomatic, had important effects beyond the inflammatory consequences of microbial invasion: hypertension, progressive renal disease, an increased mortality, and complications of pregnancy being the most notable. UTI does not by itself cause these effects. However, when UTI is combined with other conditions such as vesicoureteral reflux or obstruction, it will accelerate the damage to the kidneys, particularly in children. As far as increased mortality is concerned, which has been studied most in the elderly, it appears that UTI is a marker of ill health and other significant disease, but by itself does not cause increased mortality with or without antimicrobial therapy. In contrast, pregnant women should be screened for bacteriuria and aggressively treated because UTI during pregnancy can be associated with fetal loss, prematurity, and pyelonephritis in the mother. In renal transplant recipients, UTI is associated

with allograft rejection. Treatment of asymptomatic bacteriuria is not associated with a decrease in mortality.^{1,6-12}

Not surprisingly, different clinical syndromes of UTI require different patient management strategies. The purpose of this chapter is to outline the current concepts of pathogenesis, diagnosis, prevention, and treatment of this most common of human infections.

PATHOGENESIS OF URINARY TRACT INFECTION

Although bacteremia with such virulent organisms as *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Salmonella typhi* can infect the kidneys through the hematogenous route, more than 95% of UTIs occur because of ascension of organisms from the distal urethra to the bladder, the ureters, and, finally, the kidneys. Both bacterial virulence factors and certain host factors determine whether sustained infection is to occur. Gender is a major determinant of the incidence of UTI. In males with normal urinary tract anatomy and function, the incidence of UTI is quite low, at least in part due to the physical separation of the distal urethra from the fecal reservoir of bacteria and perhaps to the presence of antibacterial substances in the secretions of the normal prostate. In men, lack of circumcision, homosexual activity that involves anal intercourse, and, uncommonly, heterosexual vaginal intercourse with a woman colonized with a uropathogen have been associated with an increased risk of UTI. However, because sustained colonization of the distal urethra in males is difficult to accomplish, bacteriuria is unusual in the absence of prostatic dysfunction or other urogenital abnormalities.¹

Virtually all the studies of the pathogenesis of UTI have been carried out in women with *Escherichia coli* infection. However, the data that are clinically available now suggest that similar mechanisms are operative in males with UTI and also in other not uncommon bacterial causes of UTI such as *Proteus* and *Klebsiella* organisms. Therefore, it is not unreasonable to base our discussion of the pathogenesis of UTI primarily on the data generated in females with *E. coli* infection. A

few clones of *E. coli*, termed uropathogenic or nephritogenic *E. coli*, possess a variety of virulence properties that appear to be important in mediating the key steps in the pathogenesis of UTI in the normal urinary tract: sustained intestinal carriage, persistence in the vagina, and ascension and invasion of the urinary tract despite normal urine output.^{1,3,13}

These virulence properties are closely linked on the bacterial chromosome and are found in only a restricted number of *E. coli* serotypes (O1, O2, O4, O6, O7, O75, and O150 cause the majority of UTIs). The virulence properties of *E. coli* include the following: an intact O (somatic) antigen, a K (capsular) antigen, the production of hemolysin, the presence of the iron-binding protein aerobactin, the ability to resist the bactericidal effect of normal human serum, the production of colicin V, increased adherence to vaginal and uroepithelial cells, the production of both cytotoxic necrotizing factor type 1 and hemolysin, and the ability to induce an inflammatory response. Genes mediating these urovirulence factors are usually linked to large multigene chromosomal segments called pathogenicity islands and are absent in *E. coli* found in normal fecal flora.^{14–20} The most important of these bacterial virulence factors are adhesins present on the surfaces of the uropathogenic strains that mediate attachment and adherence via specific receptors on the uroepithelium. Although a variety of bacterial adhesin-host receptor systems have been defined, the best studied (and probably most important) surface adhesins are the p-fimbriae (also known as p-pili, or type II pili), which bind to the globoseries of glycolipid receptors that have a common disaccharide $\alpha\text{Gal}(1-4)\beta\text{Gal}$. These receptors are identical to the glycosphingolipids of the P blood group system and are found on the epithelial cells of the vagina, urinary tract, kidneys, and large intestine, but not on phagocytic cells.^{21–27}

Uropathogenic strains are able to attach to the host mucosal cells (thus effecting sustained carriage in the large intestine and adherence to the vaginal and uroepithelium) while avoiding binding to host polymorphonuclear cells.^{21,28–30} Type I fimbriae bind to mannose epitopes, for example, those found on such glycoproteins as secretory IgA and Tamm-Horsfall protein, and are thought to play a role in urovirulence in the presence of other virulence factors. In addition, there are uropathogenic strains that adhere in the absence of fimbriae.^{31–34}

Recently, a single clone of uropathogenic *E. coli* has been identified as the cause of a large number of UTIs in individual communities. Isolates of these bacteria were identified initially by being trimethoprim-sulfamethoxazole resistant (generally associated with multidrug resistance). Epidemiologic studies have suggested that the source of this clonal outbreak is contaminated food or water. Prolonged colonization of the intestine is the first step in the pathogenesis of these infections, and it is possible that long-term intestinal carriage provides the opportunity for acquiring plasmids that mediate drug resistance. That this is an important phenomenon is shown by the fact that this single clone accounted for 10% of all UTIs in California, Minnesota, and Michigan and for 38% to 51% of trimethoprim-sulfamethoxazole-resistant strains. Similar clusters of cases have occurred in south London, UK, and St. Louis, MO, and this clone has also been shown to be endemic in Barcelona, Spain. This clone (termed clone A) has played a significant role in the spread of antimicrobial resistance. A hitherto unusual stereotype to be isolated from the urinary tract, O15:K52:H1, is characteristic of this phenomenon. The epidemiologic pattern of this particular clone is very reminis-

cent of that seen when hemorrhagic enterocolitis due to *E. coli* O157:H7 was identified as a community-wide outbreak owing to the ingestion of contaminated food, and it is postulated that a similar epidemiologic pattern is operational here.^{35,36}

Host factors are at least as important as bacterial virulence factors in the pathogenesis of UTI. These include the following:

1. Normal vaginal flora, particularly the presence of lactobacilli, plays an important role in preventing the colonization of the vaginal vestibule with uropathogenic strains. Such colonization is a necessary, although not sufficient, first step in the pathogenesis of UTI. It is estimated that approximately 8% of patients with uropathogen colonization of the vagina develop UTI, and when it occurs, it is the same organism that is colonizing. Thus, spermicides, used with condoms or diaphragms for contraception, inhibit the normal flora, and the metabolic changes induced by menopause have a similar effect—the result being an increased propensity to recurrent UTI. Sexual intercourse will regularly introduce distal urethral and vaginal flora into the bladder. If the organisms are so introduced, they will be quickly eliminated by local host defenses, including voiding. If uropathogens are present, they will adhere, and sexual activity will have played an important role in the development of sustained UTI.
2. The normally functioning bladder has a significant capacity for eliminating bacteria that have been introduced. Three factors appear to contribute significantly to this ability: the elimination of bacteria by voiding, the presence of bacteriostatic substances in the urine, and the intrinsic mucosal defense mechanisms (including the ability to mount an inflammatory response starting when the bacteria adhere to the mucosal lining). It is worth emphasizing that these defenses are greatly attenuated when there is a significant postvoiding residual.^{37–41}
3. The ability to secrete blood group antigens into body fluids, including the urine and vaginal secretions, is an important host defense against UTI. These blood group antigens appear to block the adherence of bacterial adhesions to uroepithelial receptors and thus protect against the initiation of infection. Women who are nonsecretors have an increased incidence of recurrent UTI, and uropathogens have been shown to adhere to periurethral and vaginal mucosal cells from these women in much greater numbers than do those in women who are secretors.^{42–45}
4. A competent ureterovesical junction provides significant protection against the reflux of both sterile and infected urine into the kidney.¹

Thus, there are a number of conditions that predispose to UTI and do so by overcoming the host defenses delineated. These conditions either promote the occurrence of UTI or amplify its clinical impact. A corollary of these observations is that different antimicrobial programs are necessary for the prevention and treatment of UTI in patients with one or more of the following conditions:

1. Impedance of urine flow due to anatomic obstruction (e.g., a stone or an enlarged prostate gland) or a functional inability to empty the bladder (e.g., a neurogenic bladder due to spinal cord injury or neuropathy due to diabetes or multiple sclerosis) greatly increases the susceptibility to and the impact of UTI.¹

2. Vesicoureteral reflux predisposes to the spread of infection to the kidney, and the combination of reflux and infection appears to be synergistic in terms of producing chronic renal injury, especially in children, and most particularly in children younger than the age of 5.¹
3. The presence of foreign bodies such as an indwelling bladder catheter markedly increases the incidence of UTI. Even with modern closed drainage systems, once such a catheter is in place, after the first 3 days of its presence, there is an incidence of bacteriuria at a rate of 1% to 3% per day, with most patients becoming bacteriuric by the end of 1 month.¹

Notable by their absence from this analysis are immunosuppressed states. Defects in T-cell, B-cell, and polymorphonuclear leukocyte function do not appear to be associated with an increased incidence of UTI, although the impact of any infections that do occur may be increased in the face of such conditions. Similarly, there is little evidence that conditions such as diabetes mellitus are associated with an increased incidence of UTI until diabetic neuropathy affecting bladder function develops.¹

DIAGNOSIS OF URINARY TRACT INFECTION

The range of possible symptom complexes caused by UTI is very broad, ranging from asymptomatic bacteriuria to symptomatic abacteriuria (the acute urethral syndrome), from symptoms related to the lower urinary tract (dysuria and frequency) to symptoms suggesting kidney invasion and pyelonephritis (e.g., loin pain and costovertebral angle tenderness), to full-blown septic shock. The relationship of symptoms to the presence of bacteriuria and the anatomic site of infection is incomplete. Thus, 30% of women with symptoms of dysuria and frequency will have covert kidney involvement, whereas a similar or higher percentage of men with bacterial prostatitis will also have covert kidney involvement. Because the relationship between symptoms and either the presence of true infection or the anatomic site of infection is incomplete, the laboratory plays an important role in the diagnosis and management of UTI. This is particularly true given the difficulty of acquiring a voided urine specimen that is not contaminated by distal urethral or vaginal flora. The following observations can be used in deciding whether true UTI is present and that treatment is indicated.^{1,2}

In patients without bladder or ureteral catheters, more than 95% of infections are caused by a single species at any one time, with the *Enterobacteriaceae*, *P. aeruginosa*, enterococci, and *Staphylococcus saprophyticus* (this last being a particularly important uropathogen in sexually active young women) causing virtually all these infections. In contrast, the organisms that commonly colonize the distal urethra and skin of both men and women and the vagina of women (*Staphylococcus epidermidis*, diphtheroids, lactobacilli, *Gardnerella vaginalis*, and a variety of anaerobes) rarely cause UTI. The rare exception to this rule are patients with such complicating factors as an infarcted kidney or a necrotic tumor mass that has been invaded by these commensal organisms, particularly the anaerobes. Otherwise, the presence of one or more of these organisms in the urine suggests primarily a contaminated culture.^{1,15}

In the adult patient who has urinary symptoms, the presence of pyuria correlates closely with UTI. The measurement of leukocyte esterase activity in the urine may be used as a screening technique, but the preferred method is to examine the unspun urine in a counting chamber, with more than 10 leukocytes/mm³ being highly associated with true infection. The traditional method of testing for pyuria, by microscopic examination of spun urine, is fraught with error, carrying a high rate of both false positives and false negatives. A similarly useful low-technology approach to the diagnosis of UTI is to examine under a light microscope a Gram stain of unspun urine. The presence of one or more organisms per oil immersion field correlates with the presence of 10⁵ bacteria/mL or more in urine (otherwise known as significant bacteriuria).^{1,2,46-48}

The cornerstone of the diagnostic approach to UTI is the quantitative urine culture. More than four decades ago, Kass⁴⁸ and Savage and colleagues⁴⁹ defined the concept of significant bacteriuria (>10⁵ colony-forming units [CFU]/mL of a single uropathogenic species) as an epidemiologic tool for diagnosing true infection. However, it is now clear that, in as many as 20% to 30% of true bacterial UTIs in women with symptoms of infection, fewer organisms are present in the urine. These women respond appropriately to antibiotic therapy for the particular bacteria identified, just as those with significant bacteriuria do. The quantitative urine culture remains a useful diagnostic tool, however, but the guidelines have been revised, based on careful studies of patients who are symptomatic and respond to antimicrobial intervention.^{2,50,51}

1. *Acute, uncomplicated UTI in women.* A diagnostic criterion of more than 10⁵ CFU/mL has a specificity of 99%, but a sensitivity of 51%. Particularly in the symptomatic patient, a more appropriate criterion appears to be 10³ CFU/mL or more, which has a sensitivity of approximately 80% and a specificity of approximately 90%.
2. *Acute urethral syndrome in women* (also called *symptomatic abacteriuria*). This entity is probably a variant of acute, uncomplicated UTI in that symptoms of dysuria and frequency predominate, with two major causes being noted: bacterial infection with the usual uropathogens but with fewer (10²–10⁴ CFU/mL) being present or *Chlamydia trachomatis* infection. Patients from both these groups have pyuria on urinalysis and respond to appropriate antimicrobial therapy. It has been suggested that those patients with low-count bacteriuria have early UTI, with increasing counts as time passes without therapy. Occasionally, patients with *Neisseria gonorrhoeae* infection or vaginitis will present with symptoms of dysuria and frequency, but cultures and vaginal examinations should permit these individuals to be distinguished from the others. In addition, there is a group of women with similar symptoms but who lack pyuria on urinalysis. These appear not to have a microbial basis to their symptoms, do not respond to antimicrobial therapy, and should be managed symptomatically.
3. *Acute, uncomplicated pyelonephritis in women.* Approximately 80% of patients will have more than 10⁵ CFU/mL in their urine; 10% to 15% will have 10⁴ to 10⁵ CFU/mL in their urine; and the remainder will have fewer than 10⁴ CFU/mL in their urine. Thus, 10⁴ CFU/mL of a single uropathogen is the usual requirement for the laboratory diagnosis of acute, uncomplicated pyelonephritis.

4. *Urinary tract infection in men.* A diagnostic threshold of 10^4 CFU/mL or more offers sensitivity and specificity of more than 90%.
5. *Particular infections.* Infections due to *S. saprophyticus* and *Candida* species (as well as other fungal pathogens, presumably) usually have organism counts in the 10^2 to 10^4 CFU/mL range.

CLINICAL MANAGEMENT OF URINARY TRACT INFECTION

Acute, Uncomplicated Urinary Tract Infection in Women

Patients with this form of UTI are defined by their presenting symptom complex: symptoms of lower urinary tract inflammation (i.e., dysuria, frequency, urgency, or suprapubic discomfort) in the absence of signs and symptoms of vaginitis (vaginal discharge or odor, pruritus, dyspareunia, external dysuria without frequency, and vulvovaginitis on examination). Therapy for this form of UTI has three objectives: eradication of the lower UTI that is producing symptoms, identification of the minority of patients (~30%) who have silent renal infection and require more intensive therapy, and eradication of uropathogenic clones from the vaginal and gastrointestinal reservoirs that could produce rapid reinfection of the urinary tract.^{52,53}

The cornerstone of therapy for this clinical syndrome in otherwise healthy women is a short course of therapy (3 days) with trimethoprim-sulfamethoxazole, trimethoprim, or a fluoroquinolone (e.g., ofloxacin, ciprofloxacin, and undoubtedly other fluoroquinolones that have not as yet been subjected to rigorous study). β -Lactams appear to be far less effective, both in terms of eliminating the bacteriuria and in clearing the uropathogens of interest from the vaginal and colonic reservoirs, thus predisposing to recurrence. The macrocrystals of nitrofurantoin have not been studied as rigorously as the other compounds, but currently available information suggests that 3 days of therapy with this compound is not as effective as the recommended compounds, but that 7 days of therapy may yield results similar to those obtained with 3 days of trimethoprim-sulfamethoxazole. Another option would appear to be single-dose fosfomycin therapy. Although, at present, the standard of care is 3 days of trimethoprim-sulfamethoxazole therapy, the specter of resistance looms. If the incidence of resistance in a particular community is more than 20%, then a fluoroquinolone would become the empiric (before sensitivity data are known) treatment of choice. Because of the importance of the fluoroquinolones in the treatment of prostatitis and other forms of complicated infection, the recently published guidelines for the management of acute, uncomplicated UTI in women has recommended the use of other drugs to delay the emergence of resistance to the fluoroquinolones.^{52,53}

Because acute, uncomplicated UTI in healthy women is so common, and the efficacy, cost, and side-effects of short-course therapy so favorable, an efficient approach to such infections that minimizes laboratory studies and visits to the physician can be defined. The first step is to initiate short-course therapy in response to the complaint of dysuria and frequency without symptoms of vaginitis. If a urine specimen is readily available, a leukocyte esterase dipstick test can be carried out (which has a reported sensitivity of 75%–96% in this clinical setting); urine

culture and microscopic examination of the urine are reserved for the patient with an atypical presentation. Alternatively, a reliable patient who reports a typical clinical presentation by telephone should have short-course therapy prescribed without initial examination of the urine.^{1,52,53}

The important patient-physician interaction comes after completion of the therapy. If the patient is asymptomatic, nothing further needs to be done. If the patient is still symptomatic, both urinalysis and urine culture are necessary. If both of these results are negative and no clear microbial cause of symptoms is present, symptomatic relief is prescribed and attention is directed toward sexual practices, gynecologic conditions, personal hygiene, allergy to clothing dyes, and the like. If the patient is pyuric but not bacteriuric, then the differential diagnosis includes *C. trachomatis* (common in sexually active, reproductive-age individuals), tuberculosis, systemic fungal infection, and intra-abdominal inflammatory processes such as a diverticular abscess abutting the urinary tract. The presence of bacteriuria and pyuria should trigger a 10- to 14-day course of therapy, provided that the isolate was sensitive to the drug previously prescribed. If it has been resistant, then another trial of short-course therapy with a suitable drug would be appropriate.^{1,52–58}

Short-course therapy is prescribed for the eradication of superficial mucosal infection of the bladder and is contraindicated in patients with a high probability of tissue-invading infection. The following groups of patients, therefore, should never be considered as candidates for short-course therapy: any man with a UTI (tissue invasion of the prostate, kidney, or both should be assumed, and, as predicted, short-course therapy fails in men more than 80% of the time, even when both groups have identical presenting symptoms), patients with overt pyelonephritis, patients with symptoms of longer than 7 days' duration, patients with underlying structural or functional defects of the urinary tract, immunosuppressed individuals, and patients with indwelling catheters.¹

Acute, Uncomplicated Pyelonephritis in Women

The clinical syndrome in these patients includes recurrent rigors and fever; back and loin pain (with tenderness on percussion of the costovertebral angle), often with associated colicky abdominal pain; nausea and vomiting; dysuria; and frequency. These individuals, by definition, have invasive tissue infection, have or are at risk of bacteremia, and merit intensive antimicrobial therapy. The three goals of therapy in this group of individuals are control of possible urosepsis (bacteremia and its consequences), eradication of the invading organism, and prevention of recurrences. The therapeutic approach to acute, uncomplicated pyelonephritis can be divided into two parts: immediate control and final eradication of the process.^{1,2}

The initial antimicrobial program prescribed should have a more than 99% probability of being effective against the infecting organism. A urine Gram stain should be part of the initial evaluation. If a gram-positive organism is responsible, then ampicillin or amoxicillin/clavulanic acid therapy would be reasonable. More likely would be a gram-negative bacillus, with a variety of regimens then being useful: a fluoroquinolone, a β -lactam/aminoglycoside combination, or an advanced-spectrum β -lactam alone (e.g., imipenem, ceftazidime, piperacillin/tazobactam) can be prescribed to achieve

this goal. Although parenteral therapy is usually prescribed to ensure the prompt achievement of therapeutic blood levels, it should be recognized that, in patients with milder disease oral agents such as fluoroquinolones and trimethoprim-sulfamethoxazole with excellent antimicrobial spectrum and oral bioavailability can be employed throughout the course of treatment if the GI tract is functioning adequately. At present, provided adequate blood levels are achieved, there is no evidence that any one of the regimens listed is better than any other in terms of accomplishing the first task: initial control of systemic sepsis.^{1,2,52,53}

Following the establishment of control over sepsis, usually signaled by the temperature curve returning to a near-normal level, oral therapy can be instituted. Failure of this to occur within 72 hours of initiating therapy should trigger a search for some complicating problem (e.g., a stone, obstruction from any cause, poor bladder function). Once evidence of improvement has occurred, prescription of trimethoprim-sulfamethoxazole or a fluoroquinolone to complete a 14-day course of therapy appears to be the most effective means of eradicating both tissue infection and residual clones of uropathogen present in the gastrointestinal tract, which could cause early recurrence if left in place.^{1,2,52,53}

Urinary Tract Infection in Pregnancy

Pregnant women constitute the one group in whom screening for asymptomatic bacteriuria, and subsequent treatment, if found, is justified to prevent adverse consequences for both mother and fetus: a risk of symptomatic pyelonephritis later in pregnancy that can induce premature onset of labor and delivery. Some experts have attributed increased fetal loss and prematurity to UTI in the mother as well. Treatment of either asymptomatic infection or infection associated with symptoms of bladder inflammation is similar to that for nonpregnant women with acute, uncomplicated UTI, that is, short-course therapy. However, there are two major differences in the overall management when compared with the management of nonpregnant women with UTIs: (1) The drugs that can be used safely are somewhat limited because of toxicity issues and (2) continuing follow-up throughout pregnancy with treatment and prophylaxis instituted for positive cultures is indicated.⁵⁹

There is extensive experience with sulfonamides, nitrofurantoin, ampicillin, and cephalexin in the treatment of UTI during pregnancy, with sulfonamides being avoided near term because of their possible contribution to the development of kernicterus in the newborn. Fluoroquinolones are avoided because of possible adverse effects on fetal cartilage development. In pregnant women with overt pyelonephritis, hospital admission and parenteral therapy with β -lactam drugs and aminoglycosides should be considered the standard of care.¹

Recurrent Urinary Tract Infection in Women

The majority of recurrent UTIs in women of all ages are due to reinfection. The first steps in preventing such infections do not involve the use of antimicrobial agents. They do include voiding immediately after sexual intercourse and changing contraceptive practice to one in which a spermicide (which eliminates

the normal protective flora in the vagina, increasing the potential for colonization with a uropathogen) is not required (e.g., from a diaphragm to oral contraceptives).^{1,37-40} In postmenopausal women, two further measures have been shown to be of value: (1) local or systemic estrogen replacement, which will change the pH of the vagina, promotes the reappearance of the normal flora (particularly the lactobacilli) and protects against colonization with uropathogens⁶⁰ and (2) ingestion of moderate amounts of cranberry or blueberry juice, which has been shown to have a marked protective effect against UTI owing to the secretion in the urine and the vagina of organic molecules that block the critical interaction of uropathogen surface adhesions to epithelial receptors, the first step in the invasion of the anatomically normal urinary tract.⁶¹⁻⁶³ Although the data supporting the use of cranberry juice have come primarily from studies of postmenopausal women, our anecdotal experience with reproductive-age women suggests efficacy in this population as well.

Despite the institution of the previously listed maneuvers, there remains a group of otherwise healthy women who are subject to recurrent symptomatic infection. A small minority of these will have recurrent infection owing to a sequestered focus within the kidney that causes relapsing infection after courses of therapy of 14 days or less. Such relapsing infections deserve at least one attempt at cure with an extended course (4-6 weeks) of therapy, preferably with trimethoprim-sulfamethoxazole or a fluoroquinolone to which the infecting organism is susceptible. If some predisposing factor such as a renal calculus is present, the intensive antimicrobial therapy should be carried out in conjunction with correction of the underlying abnormality. Patients with relapsing symptomatic infection that only derives temporary benefit from extended treatment courses usually can be kept symptom free with long-term suppressive therapy.¹

The majority of women (at least 85%) with recurrent UTI have repeated reinfection. There are basically three antimicrobial strategies that are effective in this situation:

1. Low-dose, long-term prophylaxis with either trimethoprim-sulfamethoxazole or a fluoroquinolone (e.g., ciprofloxacin 250 mg or ofloxacin 200 mg) at bedtime. The efficacy of these prophylactic regimens is further delineated by their effectiveness in preventing UTI in the more challenging population of kidney transplant recipients.
2. A variant of continuous prophylaxis is for the woman to take a single dose of a fluoroquinolone or trimethoprim-sulfamethoxazole as postcoital prophylaxis.
3. Finally, many of these women prefer not to take antimicrobial drugs so continuously. These women may be given a supply of drug (again, either a fluoroquinolone or trimethoprim-sulfamethoxazole is preferable over other classes of drug in terms of efficacy) for single-dose therapy with the onset of symptoms of UTI.^{1,54,64-67}

Urinary Tract Infection in Men

UTI in men should always be assumed to mean tissue invasion of the prostate, kidney, or both. Thus, the standard of care is 10 to 14 days of fluoroquinolone or trimethoprim-sulfamethoxazole unless antimicrobial intolerance or an unusual pathogen requires an alternative approach. In men

younger than 50 years, the following conditions are associated with an increased risk of UTI: anal intercourse, intercourse with women colonized with uropathogens, and acquired immunodeficiency syndrome with a CD4 lymphocyte count of less than 200/mm³. Men without one of these risk factors, particularly those with recurrent infection after an appropriate treatment course, merit a urologic evaluation as well as a more intensive treatment course: 4 to 6 weeks at a minimum. Recurrent infection in men usually suggests a sustained focus within the prostate that is difficult to eradicate for one or more of the following reasons: many antimicrobial agents do not diffuse well across the prostatic epithelium into the prostatic fluid where the infection lies, the prostate may harbor calculi that can block drainage of portions of the prostate gland or act as foreign bodies around which persistent infection can be hidden, and an enlarged (and inflamed) prostate gland can cause bladder outlet obstruction, resulting in incomplete emptying and difficulty in eradicating infection.^{1,2,13,68,69}

Complicated Urinary Tract Infection

The term complicated UTI is used to describe a heterogeneous group of patients who have a wide variety of underlying structural and functional defects of the urinary tract. As a consequence, the range of organisms causing UTI is much greater than that for the general population, and antimicrobial resistance is common. As a result, the therapeutic principles employed in this patient population are somewhat different from those for other patient groups. In general, asymptomatic bacteriuria should not be treated, the major exception being when the bacteriuric patient is scheduled to undergo urinary tract manipulation; in this circumstance, sterilization of the urine before manipulation and continuation of antimicrobial therapy for 3 to 7 days after manipulation can prevent urosepsis.^{1,2}

Acutely septic patients with complicated UTI merit initial broad-spectrum therapy (e.g., ampicillin plus gentamicin, imipenem/cilastatin, piperacillin/tazobactam) until bacteriologic data are available and permit a more precise choice of therapy. For more subacutely ill individuals, a fluoroquinolone appears to be optimal initial therapy. In conjunction with antimicrobial therapy, thought should be given to correcting the abnormalities that led to the infection, whenever possible. If this can be accomplished, a prolonged 4- to 6-week curative course of therapy in conjunction with the surgical manipulation is appropriate. If such correction is not possible, shorter courses of therapy (7–14 days), aimed at controlling the symptoms, appear to be more reasonable. Spinal cord injury patients represent a particular challenge. In these patients, intermittent self-catheterization with clean catheters and methenamine prophylaxis has been shown to decrease the morbidity associated with UTI in this population.^{1,2,13,70}

Candidal Infection of the Urinary Tract

Candidal UTI has become increasingly common in recent years, particularly in individuals who are diabetic, have bladder catheters in place, or are receiving corticosteroids. Well-validated guidelines for managing candidal UTI are not available, particularly criteria for distinguishing trivial

colonization from clinically significant infection. The following represents the approach that we take at present, pending the availability of more data.^{1,2,71,72}

1. The first step is the correction of the underlying conditions that led to the infection in the first place: removal of the catheter, correction of the hyperglycemia, cessation of broad-spectrum antibacterial therapy, and marked reduction in corticosteroid dose, if possible. Once these are accomplished, if candiduria is persistent, then further therapy can be considered.
2. If an indwelling bladder catheter is still required, it is reasonable to insert a three-way catheter and administer an amphotericin or a nystatin rinse to the bladder; this has an efficacy rate of approximately 50% to 60%. However, if a catheter is not required, it is far better to treat with systemic antifungal therapy to avoid the risk of other organisms being introduced because of the catheter.
3. Fluconazole, at a dose of 200 to 400 mg/day, is an effective therapy for candidal UTI caused by *Candida albicans*, *Candida tropicalis*, and most of the other candidal species, because of the extremely high concentrations that are delivered into the urine. The two organisms associated with fluconazole failure are *Candida krusei* and *Candida glabrata*.
4. In individuals who do not respond to fluconazole, the combination of low-dose systemic amphotericin (e.g., 10 mg/day) plus flucytosine at full doses (100 mg/kg/day in three or four divided doses) is quite effective when prescribed for a 10- to 14-day course. Flucytosine administered alone results in the rapid emergence of resistance, so the role of the low-dose amphotericin (which penetrates the urine poorly) is primarily to protect the flucytosine, which reaches quite high concentrations in the urine.

SUMMARY

Improved understanding of the pathogenesis and impact of UTI has led to improved therapy. Perhaps the most important lessons of the past few decades are the following:

1. The normal vaginal flora in women is an important host defense against the occurrence of UTI, and strategies to reconstitute it (e.g., elimination of spermicides in premenopausal women and estrogen replacement in postmenopausal women) can be quite effective in preventing recurrent UTI.
2. The critical first step in the pathogenesis of UTI is adherence to the uroepithelium through the specific interaction of bacterial surface adhesions to specific receptors on the epithelial cell, and strategies such as the ingestion of cranberry juice (which delivers organic substances to the site that block such adhesions) can help prevent UTI.
3. Different clinical syndromes associated with UTI require different modes of antimicrobial prescription, although the optimal drugs for the treatment and prevention of UTI are trimethoprim-sulfamethoxazole and the fluoroquinolones.
4. In this regard, tissue-invasive infection (as all UTI in men should be assumed to be) needs more extended therapy than acute, uncomplicated UTI in women, for which the cornerstone of treatment is short-course therapy (3 days).

FUTURE DIRECTIONS 459

Carcinoma of the kidney is perhaps one of the most enigmatic of cancers. The myriad presenting features, which include paraneoplastic phenomena, can challenge the most astute diagnostician.¹⁻³ The disease is typically diagnosed during the sixth and seventh decades with a male-to-female ratio of 2:1. It is estimated that there will be 39,000 newly diagnosed cases with an estimated 13,000 deaths in 2007.^{4,5} Today, many renal cancers can be diagnosed at early, and potentially curable, stages owing to the more widespread use of ultrasonography and computed tomography (CT) of the abdomen, which may pick up early asymptomatic lesions of the kidney. Most malignant cancers of the kidney are adenocarcinomas; other pathologic varieties include transitional carcinomas of the renal pelvis and Wilms' tumor in children.⁶

RISK FACTORS

Risk factors for the development of renal cancer include cigarette smoking, occupational exposure to cadmium, obesity, excessive exposure to analgesics, acquired cystic disease in dialysis patients, adult polycystic kidney disease, and other industrial exposures, such as asbestos, leather tanning, and certain petroleum products. Genetic and familial forms of the disease occur, most notably with von Hippel-Lindau disease, an autosomal dominant disease characterized by the development of multiple tumors of the central nervous system, pheochromocytomas, and bilateral renal carcinomas.⁷ Several families have also been reported with a high incidence of renal cancer. Genetic analyses of these patients demonstrate a balanced translocation between the short arm of chromosome 3 and either chromosome 6 or chromosome 8. Tuberous sclerosis may also be associated with a risk of developing renal cell cancer, but this risk is considerably less than that of von Hippel-Lindau disease. Other abnormalities have been reported.⁸

More recent genetic advances have identified the *RASSF1* gene, a Ras association family 1 gene, which may possess tumor-suppressor activity. In one study, abnormalities of this gene were identified in a high percentage of patients with primary clear-cell cancers.⁹

PRESENTATION

Patients with renal cell cancer present with symptoms produced by the local neoplasm, with signs and symptoms of paraneoplastic phenomena, or by other aspects of systemic disease. Likewise, the patient may be totally asymptomatic and, as is quite common today, may be diagnosed by a radiographic abnormality detected on ultrasound or abdominal CT scanning. Less than 10% of patients present with the classic triad of hematuria, abdominal mass, and flank pain. In the patient who presents with signs or symptoms (as opposed to the diagnosis secondary to the asymptomatic finding radiographically), most common features include hematuria (70%), flank pain (50%), palpable mass (20%), fever (15%), and erythrocytosis (infrequent). Other features may include acute onset of lower extremity edema, or, in males, the presence of a left-sided varicocele, indicating an obstruction of the left gonadal vein at its point of entry into the left renal vein by a tumor thrombus. Other paraneoplastic/systemic manifestations include liver function abnormalities, high-output congestive failure, cachexia, fever, amyloidosis, anemia erythrocytosis, thrombocytosis, hypercalcemia, and manifestations of the secretion of substances such as prostaglandins, renin, glucocorticoids, and cytokines such as interleukin-6.

At presentation, a very small percentage of tumors are bilateral, whereas less than one third of patients have demonstrable metastatic disease in almost any organ of the body. The most common sites of metastases include the lung, bone, liver, and brain, but other sites such as the thyroid may be affected.

PATHOLOGY

In the past, renal carcinomas were divided pathologically into a classification that evaluated cell type and growth pattern. The former included clear-cell, spindle, and oncocytic types, whereas the latter included acinar, papillary, or sarcomatoid varieties. This classification has undergone a transformation to more accurately reflect the morphology and the histochemical and molecular bases of different types of adenocarcinomas.^{10,11} Based on these studies, five distinct carcinoma types have been identified, including clear-cell (75%–85% of tumors), chromophilic (15%), chromophobic (5%), oncocytic (uncommon), and collecting (Bellini's) duct (very rare) varieties. Each of these carcinoma types has a unique growth pattern, cell of origin, and cytogenetic characteristics. Table 38-1 summarizes this information and more accurately reflects the increased knowledge on molecular and genetic abnormalities of these lesions.

DIAGNOSTIC EVALUATION AND STAGING

Evidence from the history or physical examination that suggests a renal abnormality should be followed by either an abdominal ultrasound or abdominal CT scan. In the past, intravenous pyelography was commonly used, but this procedure has largely been replaced. There are emerging data using abdominal magnetic resonance imaging. Often, however, evidence of a space-occupying lesion in the kidney is found incidentally during radiographic testing for other unrelated conditions for which an ultrasound or abdominal CT scan is performed. Indeed, renal cancer, once dubbed the “internist's tumor” because of its multiple manifestations at presentation, can now be called the “radiologist's tumor” because many lesions are detected during radiographic evaluations.

Renal ultrasonography may help to distinguish simple cysts from more complex abnormalities. A simple cyst is de-

finer sonographically by a lack of internal echoes, the presence of smooth borders, and the transmission of the ultrasound wave. If these three features exist, a benign cyst is most likely to be present. At one time, cyst puncture was used but seems to be unnecessary today in the asymptomatic patient without hematuria. Periodic repeat ultrasound scans are suggested for follow-up. If a change occurs in the lesion, cyst puncture, needle aspiration, or CT should be considered to further evaluate the lesion.

If the criteria for a simple sonographic cyst are not met or the ultrasound scan suggests a solid or complex mass, a CT scan should be performed. If a renal neoplasm is demonstrated by CT scan, renal vein or caval involvement should be assessed by CT or by magnetic resonance imaging. Although used frequently in the past, selective renal arteriography has assumed a more limited use, mainly in further evaluating the renal vasculature in patients who are to undergo partial nephrectomy (nephron-sparing surgery). CT is also very helpful in determining the presence of lymphadenopathy. Figure 38-1 illustrates a modern-day algorithm for the diagnostic evaluation of a renal mass.

The differential diagnosis of a renal mass detected on a CT scan includes primary renal cancers, metastatic lesions to the kidney, and benign lesions. The latter two groups include angiomyolipomas (renal hamartomas), oncocytomas, and other rare unusual growths. If a renal cancer is considered based on the radiographic studies of the kidney, the patient should undergo a preoperative staging evaluation to assess the presence of metastases in the lung, bone, or brain. The operative and diagnostic approaches may be dictated dependent on the preoperative stage of the patient. For example, the patient who presents with stage IV disease by virtue of a positive bone scan may need only a needle biopsy of either the kidney lesion or the bone lesion to establish the tissue diagnosis and thus avoid more extensive surgery on the kidney. In contrast, a patient with an isolated pulmonary lesion may be considered for both a nephrectomy and a pulmonary nodulectomy in one operative intervention.

Table 38-1 Pathologic Classification of Renal Cell Carcinoma

Carcinoma Type	Growth Pattern	Cell of Origin	CYTOGENETIC CHARACTERISTICS		Incidence (%)
			Major	Minor	
Clear cell	Acinar or sarcomatoid	Proximal tubule	3p-	+5, +7, +12, -6q, -8p, -9, -14q, -Y	75-85
Chromophilic*	Papillary or sarcomatoid	Proximal tubule	+7, +17, -Y	+12, +16, +20, -14	12-14
Chromophobic	Solid, tubular, or sarcomatoid	Intercalated cell of cortical collecting duct†	Hypodiploid	-	4-6
Oncocytic	Typified by tumor nests	Intercalated cell of cortical collecting duct	Undetermined	-	2-4
Collecting duct	Papillary or sarcomatoid	Medullary collecting duct	Undetermined	-	1

*These tumors were previously classified as papillary tumors.

†This classification is based on the work of Storkel and associates.¹⁰

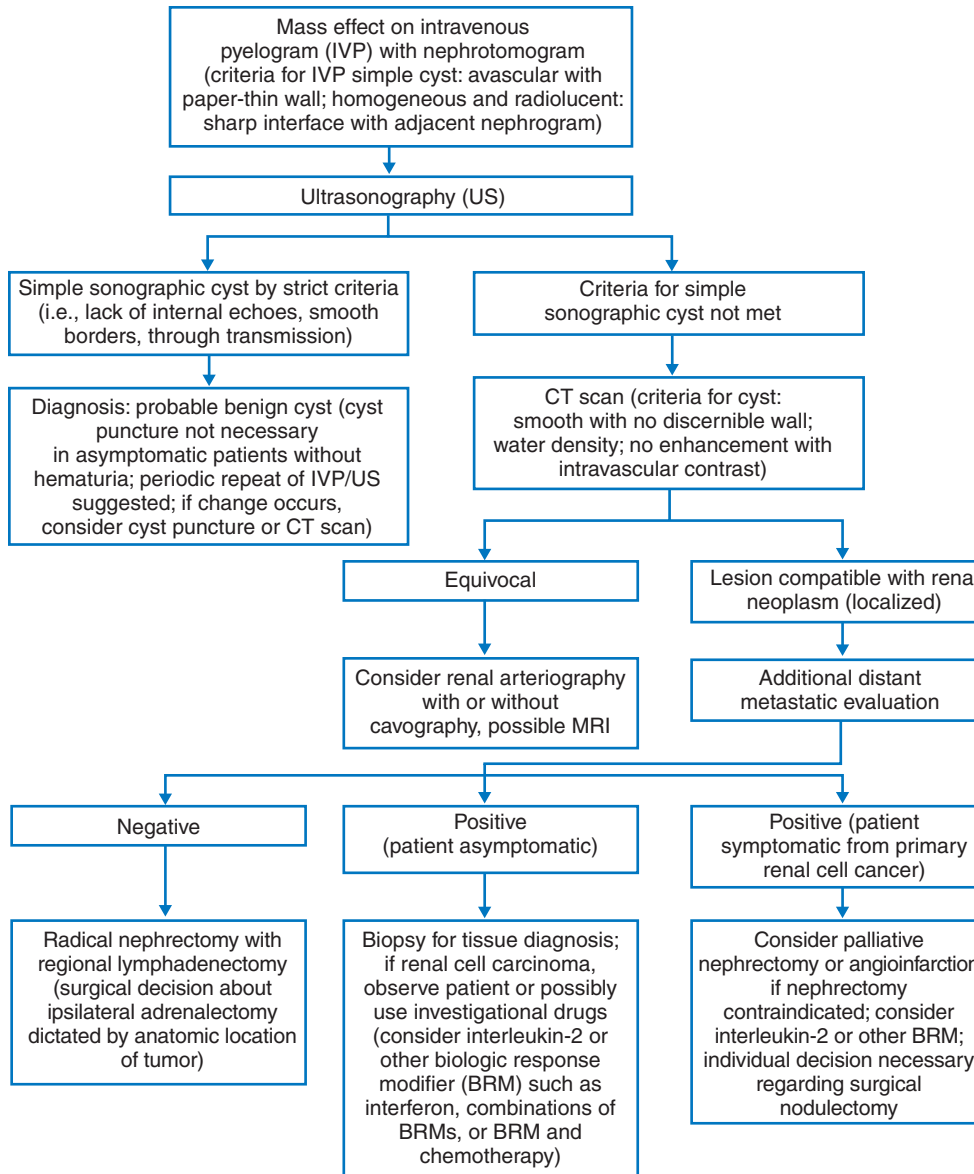

Figure 38-1 Algorithm for the diagnostic evaluation of a renal mass. CT, computed tomography. (Modified from Garnick MB, Brenner BM: Tumors of the urinary tract. In Isselbacher KJ, Braunwald E, Wilson JD, et al [eds]: Harrison’s Principles of Internal Medicine, 13th ed. New York: McGraw-Hill, 1994, p 1337.)

Renal cell cancer can be staged using one of two systems that are in common use.⁶ The TNM (tumor, nodes, metastasis) system has the advantage of being more specific but has the disadvantage of being cumbersome; a modification of the Robson staging system is more practical and more widely used in the United States. In this latter system, stage I represents cancer that is confined to the kidney capsule, stage II indicates invasion through the renal capsule but not beyond Gerota’s fascia, stage III reflects involvement of regional lymph nodes and the ipsilateral renal vein or the vena cava, and stage IV indicates the presence of distant metastases. In the sixth edition of the AJCC Cancer Staging Manual, the American Joint Committee on Cancer subdivides stage T1 into T1a, tumors as 4 cm or less; and T1b, tumors greater than 4 cm but less than 7 cm and all tumor limited to the kidney. Table 38-2 illustrates both systems. Other, newer staging systems used by the Eastern Cooperative Oncology Group have integrated the TNM classification with other variables such as performance status and histologic grade of the tumor. These systems provide prognostic categories and more accurately predict 2- and 5-year survival rates.^{12,13}

CLINICAL TRIALS AND SPECIFIC RECOMMENDATIONS

The standard therapy for localized renal cell carcinoma is radical nephrectomy, which includes removal of the kidney, Gerota’s fascia, the ipsilateral adrenal gland, and regional hilar lymph nodes. The value of an extended hilar lymphadenectomy seems to be related to its ability to provide prognostic information because there is rarely a therapeutic reason for performing this portion of the operation. In the past, the removal of the ipsilateral adrenal gland was performed routinely; however, most data suggest that it is involved in less than 5% of cases and occurs most frequently with large upper pole lesions.¹⁴ Therefore, ipsilateral adrenalectomy is reserved for patients with glands that appear to be abnormal or enlarged on the CT scan or for those patients with large upper pole renal lesions in whom the probability of direct extension of the tumor to the adrenal gland is more likely.

The surgical technique of performing a partial nephrectomy (nephron-sparing surgery) has become more popular,

Table 38-2 Comparison of Modified Robson and TNM Staging Systems for Renal Adenocarcinoma

Modified Robson Stage		T	N	M
I	Confined by renal capsule	T1 (small) T2 (large)	N0	M0
II	Through renal capsule confined by Gerota's fascia	T3a	N0	M0
IIIa	Renal vein involvement	T3b	N0	M0
IIIb	Lymphatic involvement	T1–3b	N1–4	M0
IV	Contiguous organ involvement or Metastatic spread	T1–3b	N0–4	M0 M1

TNM, tumor, node, metastasis.

From McDougal WS, Garnick MB: Clinical signs and symptoms of kidney cancer. In Vogelzang NJ, Scardino PT, Shipley WU, et al (eds): *Comprehensive Textbook of Genitourinary Oncology*. Baltimore: Williams & Wilkins, 1996, p 546.

especially for patients with small tumors, for those at risk of developing bilateral tumors, or for patients in whom the contralateral kidney is at risk of other systemic diseases such as diabetes or hypertension.^{15,16} The main concern associated with partial nephrectomy is the likelihood of tumor recurrence in the operated kidney because many renal cancers may be multicentric. Local recurrence rates of 4% to 10% have been reported, and even lower rates have been reported when a partial nephrectomy was performed for smaller lesions (<3 cm with a normal contralateral kidney). Lesions that are centrally located, however, still require a radical nephrectomy. Frequent follow-up, usually with CT or ultrasonography, is necessary for patients who undergo a partial nephrectomy.

Renal cancer involving the inferior vena cava occurs more frequently with right-sided tumors and is associated with metastases in almost 50% of patients. Obstruction of the vena cava may lead to the diagnosis; symptoms include abdominal distention with ascites, hepatic dysfunction, nephrotic syndrome, abdominal wall venous collaterals, varicocele, malabsorption, and pulmonary embolus. The anatomic location of the caval thrombus is important prognostically. Supradiaphragmatic lesions, which may involve the heart, can be resected, but the prognosis is poor; patients with subdiaphragmatic lesions have a better 5-year survival rate, but this usually occurs in less than 50% of cases.³ When approaching the surgical management of these patients, a team of specialists is required, especially if a cardiac tumor thrombectomy is contemplated.

The role of surgery in the management of metastatic disease, either at the initial presentation or later, remains controversial. Although most data that support nephrectomy plus metastasectomy are anecdotal, many patients with synchronous renal cell cancer and an isolated pulmonary nodule may be considered for surgical resection of both lesions. Likewise, patients who develop an isolated

lesion in the liver or lung some time after the removal of the kidney may also be considered for surgical removal of the metastasis. Nevertheless, even when such vigorous surgery is carried out, most patients do poorly. Additional controversy surrounds the practice of performing a nephrectomy on patients with widespread metastatic disease as a means of potentially improving their response to systemic therapy. Many investigative programs require such resection; at this point, the practice should be considered investigational. However, a patient who does experience an excellent response to systemic therapy should be considered for a nephrectomy after the response. Finally, because many renal tumors can become quite large, consideration should be given to palliative nephrectomy (in the setting of metastatic disease), especially if the patient experiences uncontrollable hematuria or pain or is catabolic secondary to the sheer mass of the tumor.

Systemic Management of Advanced Stages of Renal Cell Cancer

The management of patients with either locally advanced renal cancer or with metastatic disease provides a great challenge to physicians and clinical investigators. Although chemotherapy and hormone treatments have been studied extensively in patients with metastatic renal cancer, no single treatment protocol or program has been uniformly effective. Therefore, most physicians treating the disease usually rely on novel modalities of treatment, including biologic response modifiers, investigational anticancer agents, differentiation agents (e.g., retinoic acid), vaccines, and gene therapy.

It has been known for a long time that renal cancer may occasionally incite an immune response in the host, leading to spontaneous remissions of cancer. Although rare, this observation has led many to study agents that can augment the body's immune system. The agents that have been studied most extensively include the interferons, interleukins, cytokines, cell-based therapies, and combinations of the aforementioned.

Cytokine Therapies

Interferon therapy with interferon alfa, beta, or gamma moieties has led to responses in approximately 12% to 20% of treated patients.^{17,18} Although their effects are numerous, interferons demonstrate antiproliferative activity against renal cell cancers in vitro, are stimulatory to immune cell function, and can modulate the expression of major histocompatibility complex molecules. Although patients' responses have been seen in many anatomic areas, patients who have had a previous nephrectomy with isolated pulmonary metastases and who are otherwise well may have a higher response rate. The duration of the response is usually less than 2 years, although longer lasting remissions have been noted in a few selected patients. Interferons have been combined with other immune modifiers and with chemotherapy agents, with no real improvement in patient outcome in larger scale trials. However, several smaller trials have combined interferon with interleukin-2 chemotherapy agents (e.g., 5-fluorouracil), and the preliminary results have been encouraging in some cases. Today, most centers will reserve the use of interleukin-2 for those with clear-cell histologies, as its effectiveness is less in other histologies.

The toxicity of interleukin-2 is related to alterations in vascular permeability, leading to a capillary leak-type syndrome. Although the drug is approved for the management of patients with metastatic renal cell cancer by the U.S. Food and Drug Administration, its use should be restricted to patients who can tolerate the side effect profile and to patients with acceptable cardiac, renal, pulmonary, and hepatic function.

Tyrosine Kinase Inhibitors

The most important information surrounding the systemic management of renal cell cancer has been the introduction and approval of two new multikinase inhibitors. These agents inhibit a variety of tyrosine kinases including vascular endothelial growth factor receptors and platelet-derived growth factors. These factors play a critical role in cell signaling that enable cellular proliferation and the development of new blood vessel formation. The two drugs that have gained approval are sunitinib and sorafenib. Response rates in cytokine-refractory, previously treated patients have been in the range of 35% to 40% with sunitinib, with median time to progression of 8 months. The clinical data with sorafenib have demonstrated a longer progression-free survival compared with placebo in cytokine-resistant patients. Fatigue, diarrhea, hand-foot syndrome, skin discoloration, and abnormalities of pancreatic enzymes (rarely with pancreatitis) have been observed with this new class of agents.^{19,20}

These agents can be considered for either first- or second-line therapy (after development of cytokine resistance) in patients with metastatic renal cell cancer. Clear-cell histologies respond more favorably. The use of tyrosine kinase inhibitors will continue to be evaluated in a wide spectrum of circumstances, both as monotherapy and in combination with other biologic agents.

Investigational therapies continue to be studied for renal cell cancer.²¹ Many such approaches are under investigation and include novel cytokines such as interleukin-12, combinations of biologic agents with or without chemotherapeutic agents, circadian timing of chemotherapy administration, vaccine therapy, various forms of cellular therapy, and gene therapy. Although all these approaches have a solid scientific preclinical rationale, none, unfortunately, can be considered standard treatment. The sobering fact remains that almost 50% of patients diagnosed with renal cell cancer die of their disease within 5 years of diagnosis, and a substantial proportion initially present with advanced stages of cancer spread.

Wilms' Tumor (Nephroblastoma) and Neuroblastoma

Wilms' tumor and neuroblastoma are the two most common pediatric kidney tumors.² Wilms' tumor is usually found in children younger than 5 years of age and usually presents with abdominal mass, pain, hematuria, elevations in blood pressure, and systemic manifestations (e.g., fever). Genetic alterations of chromosome 11 have been associated with the disease. The diagnosis is usually established by CT or magnetic resonance imaging, identifying bilaterality in approximately 5% of patients. Less than 20% of patients have metastases at initial presentation; if they are found, metastases are usually in the lung and liver.

Neuroblastoma has many characteristics in common with Wilms' tumor, but is characterized by an elevation of catecholamines, vanillylmandelic acid, and homovanillic acid in

most patients. Both diseases are highly curable with a multimodal approach using aggressive surgery, multiagent chemotherapy (with or without bone marrow transplantation), and selective use of radiation therapy.

FUTURE DIRECTIONS

Clearly, the most important prognostic feature for a cure in managing renal cell cancers is the stage and the genetic makeup of the individual tumor. Identification of high-risk patient populations, such as those with a strong family history or genetic predisposition, should be attempted to allow an earlier diagnosis and a potential cure. However, for most patients, additional research is needed to develop strategies for eradication of metastatic deposits. Further testing of biologic modifiers, gene therapy, and chemotherapies directed at eliminating neoplastic cells are the ultimate goal, and patients should be encouraged to enter these types of clinical investigations.

CAST NEPHROPATHY 464

WALDENSTRÖM'S MACROGLOBULINEMIA 465

SUMMARY 466

This chapter reviews the current potential approaches to management of the three major renal lesions associated with immunoglobulin light-chain deposition: AL-type amyloidosis, monoclonal light-chain deposition disease, and cast nephropathy. A review of Waldenström's macroglobulinemia is also included. Detailed discussions of cryoglobulinemia, fibrillary glomerulonephritis, immunotactoid glomerulonephritis, and amyloidosis related to other causes are discussed in other chapters.

IMMUNOGLOBULIN LIGHT-CHAIN METABOLISM AND ASSOCIATED RENAL LESIONS

Renal failure is a common occurrence in multiple myeloma; in one large series, nearly half of the 1027 patients with newly diagnosed myeloma had associated serum creatinine concentrations that were 1.3 mg/dL or greater.¹ In the necropsy study of kidneys of 57 patients by Iványi,² the most common renal lesion was cast nephropathy or myeloma kidney (65%), whereas 21% had AL-type amyloidosis and 11% had monoclonal light-chain deposition disease. Although the traditional view has been to treat patients who have features of overt myeloma, the focus in recent years has shifted from estimating disease burden using techniques that assess the size of the clonal population of plasma cells to recognition that the circulating monoclonal protein product should also be addressed when it produces organ dysfunction. Although most, if not all, patients with documented cast nephropathy have multiple myeloma, only approximately 20% of patients with primary (AL-type) amyloidosis had multiple myeloma,³ and 26% of patients with monoclonal light-chain deposition disease manifested either myeloma or another lymphoproliferative disease over time.⁴ In some patients, renal failure may be the only clinical manifestation of an otherwise silent, but deadly, clone of plasma cells or occult malignancy.⁵ Despite the absence of extrarenal manifestations and degree of bone marrow plasmacytosis, as discussed in subsequent sections, the combined data support a therapeutic approach that decreases monoclonal

light-chain production in all patients with documented renal failure related to monoclonal light chains.

An understanding of the pathophysiology of the disease processes is important in the therapeutic interventions in this spectrum of diverse conditions. Although immunoglobulins and immunoglobulin heavy chains can be pathogenic, the immunoglobulin light chain is usually at the center of the pathogenesis of these diverse renal lesions. Identification of the nature of the renal injury allows tailoring of subsequent treatment (Table 39-1). The variable effects on the glomeruli, tubulointerstitium, and vasculature that are responsible for an inconstant set of presenting renal manifestations are related to sequence variations in the variable domain of the light chain. These sequence variations, for example, confer the propensity to polymerize to form AL-type amyloid.⁶⁻⁸ Only very rarely do heavy chains alone form amyloid.⁹ Amyloid expands the glomerular mesangium, compressing the capillary loops and subsequently producing the clinical manifestations of progressive kidney failure. Monoclonal light-chain deposition disease, the second most common glomerular lesion associated with monoclonal gammopathies, is characterized by deposition of monoclonal light chain, typically κ isotype, in the mesangium. Occasionally, heavy chains may also be present, prompting some authors to describe this lesion as monoclonal light-chain and light- and heavy-chain deposition disease. Very rarely, heavy chains alone can cause monoclonal heavy-chain deposition disease. Light chains from patients with monoclonal light-chain deposition disease stimulate mesangial cells to produce transforming growth factor β , which then serves as an autacoid to stimulate mesangial cell production of extracellular matrix proteins.¹⁰ Continued expansion of the mesangium compresses the capillary loops, which decreases glomerular filtration and ultimately produces glomerulosclerosis. Hydrophobic amino acid residues in the complementarity-determining region 1 and abnormal glycosylation of the variable domain have been identified in light chains responsible for monoclonal light-chain deposition diseases.¹¹⁻¹⁴

With a molecular mass of 22 kd (approximately one third that of albumin), monomeric free light chains are filtered at the

HDT/SCT, high-dose chemotherapy with autologous peripheral stem-cell transplantation.

glomerulus. Filtered light chains enter the proximal tubule where low molecular mass proteins are endocytosed and hydrolyzed, and the constituent amino acids are returned to the circulation. Some pathologic light chains undergo a similar reabsorption process but are hydrolyzed poorly and accumulate in lysosomes. Clinical manifestations of this altered process can include renal failure from proximal tubular cell necrosis or, in less severe cases, acquired Fanconi syndrome. Unusual nonpolar amino acid residues in complementarity-determining region 1 and absence of accessible side chains in the complementarity-determining region 3 loop appear to be responsible for the homotypic crystallization of the light chain in the proximal tubule in Fanconi syndrome.^{15,16}

Cast nephropathy is the most common kidney disease associated with monoclonal light chains, occurring in approximately one third of patients with myeloma. Light chains secreted by these patients are unique in that they demonstrate specific binding to Tamm-Horsfall glycoprotein in vitro. The complementarity-determining region 3 domain in the variable domain of the light chain determines binding to Tamm-Horsfall glycoprotein.¹⁷ Nephrotoxic light chains that escape proximal tubular reabsorption enter the thick ascending limb of Henle's loop, bind to Tamm-Horsfall glycoprotein, and produce casts that obstruct flow of tubule fluid. This results in proximal tubule

atrophy, interstitial inflammation and fibrosis, and subsequent renal failure.^{18–20}

In recent years, a quantitative immunoassay for serum free light chains has been developed and tested.^{21,22} This assay provides indication of response to treatment and removal of the offending light chain. Baseline serum free monoclonal light chain levels greater than 75 mg/dL correlated with depressed renal function (serum creatinine concentration ≥ 2 mg/dL) and more aggressive myeloma.²³ Patients with documented renal involvement from AL-type amyloidosis or monoclonal light-chain deposition disease can present a challenge in the identification of the monoclonal protein in the circulation,^{4,5,24–26} although the use of the serum free light chain assay offers promise in the detection of the abnormal protein and the response to treatment.^{27,28}

AL-TYPE AMYLOIDOSIS

The management of AL-type amyloidosis is in a state of flux. After the initial randomized trial that suggested improved survival in a subset of patients who did not have rapidly progressive disease and received chemotherapy in the form of melphalan and prednisone,²⁹ more aggressive anti-plasma cell therapy has been undertaken.^{30,31} A longitudinal analysis of six separate trials performed over 8 years suggested that patients with AL-type amyloidosis respond to high-dose chemotherapy with autologous peripheral stem-cell transplantation (HDT/SCT).³¹ Subjects with multiple myeloma were excluded from these trials. Although renal dysfunction was not an exclusion criterion, there were several other exclusion criteria that included age 80 years and older, uncompensated congestive heart failure, left ventricular ejection fraction less than 0.40, persistent pleural effusions, systolic blood pressure less than 90 mm Hg, oxygen saturation less than 95% on room air, and significant overall functional impairment. Median survival of the 312 patients who underwent HDT/SCT was 4.6 years with 46% achieving a complete hematologic response, and this 46% demonstrated improved long-term survival. Thus, HDT/SCT appeared to produce greater survival rates and opportunity for a hematologic response compared with historical controls who received other forms of therapy.^{29,32} Those patients who had evidence of multiorgan system dysfunction, particularly cardiac disease, and were considered ineligible for HDT/SCT, had a median survival of 4 months with only 16% (35 of the 225) alive at the time of publication.³¹ In a follow-up quality-of-life analysis from this group, those patients who underwent HDT/SCT had demonstrably sustained improvement in their quality of life; this outcome was particularly true for those patients who achieved a complete hematologic response.³³

In another retrospective case-control study, 63 patients with AL-type amyloidosis undergoing standard therapy were matched according to a series of biochemical and functional parameters to 63 consecutive patients with AL-type amyloidosis undergoing HDT/SCT. A good attempt was made to match the characteristics of two groups, including age, gender, degree of organ involvement (primarily cardiac, renal, neural), and time from diagnosis to initiation of therapy. After 4 years of follow-up, those patients who received HDT/SCT demonstrated a significantly greater survival rate compared with the control group.³⁴ Although these studies support a more

aggressive treatment intervention for AL-type amyloidosis in suitable patients, the limitation of these observations is the lack of a randomized, prospective trial.

A consistent finding from therapeutic trials was the observation that survival was adversely affected by functional involvement of two or more organs (cardiac, renal, gastrointestinal, neurological, and soft tissue) by amyloid infiltration at the time of presentation. Cardiac involvement in particular was a major predictor of overall survival.³⁵ Another important observation was that organ function could improve with successful chemotherapy. At 1 year, 42% of patients treated with HDT/SCT therapy demonstrated improved organ function, including those patients with kidney disease.³⁵ Other investigators have reported complete resolution of nephrotic syndrome as well as acute kidney injury after HDT/SCT.³⁶ Despite reports that amyloid deposition may regress with successful treatment and recent demonstration that endogenous cysteine proteases can degrade AL-type amyloid *in vitro*,³⁷ functional kidney improvement can occur without regression of glomerular AL-type amyloid deposition.³⁸

Although patients with AL-type amyloidosis die of organ dysfunction and not tumor burden, the current approach to treatment is a therapeutic regimen that targets the monoclonal plasma cell population and is available in the community.³⁹ Increasingly, the approach will consist of HDT/SCT if the patient is younger than 70 years of age and renal functional impairment is not severe (creatinine clearance > 50 mL/min or serum creatinine concentration < 3.0–4.0 mg/dL).³⁹ A beneficial renal response—decrease in proteinuria and stabilization or improvement in renal function—was associated with prolonged survival.⁴⁰ Some centers report that the presence of severe disease requiring renal replacement therapy is not a contraindication, and recovery from kidney failure and nephrotic syndrome can occur, but because procedure-related mortality is increased, HDT/SCT should probably be performed at centers with special expertise.^{39,41} Patients who have systolic blood pressures less than 90 mm Hg or who have poor overall functional capability have exceedingly high procedure-related mortality rates with HDT/SCT.⁴²

The recent success of thalidomide as an alternative treatment of multiple myeloma⁴³ has led to more frequent treatment of AL-type amyloidosis with this agent in an uncontrolled fashion. Because thalidomide is not well tolerated in these patients, some authors have recommended initial doses of 50 mg/day.⁴⁴ Although dose modifications of thalidomide are not required in renal failure, caution is advised⁴⁵; hyperkalemia, perhaps related to tumor lysis, may occur, especially during the first few weeks of treatment.^{46,47} Randomized, controlled trials are needed to guide therapy of AL-type amyloidosis, but the limitations of long-term treatment with alkylating agents make HDT/SCT, thalidomide, and the analogue lenalidomide⁴⁸ potentially attractive therapies in AL-type amyloidosis.

Kidney transplantation is an option in patients with end-stage kidney failure due to AL-type amyloidosis, although experience with this approach is limited and evidence of a lasting (12-month) reduction in the offending light chain should be confirmed before proceeding with transplantation. This approach might be particularly beneficial for those patients who manifest renal-limited amyloidosis. In one study of 62 patients, eight of whom had AL-type amyloidosis, 65% survived 5 years after kidney allograft implantation. In this study, amyloid was

found to involve the graft in 10% and 3% lost the graft as a result of this involvement at the time of publication.⁴⁹ Another small study performed living donor kidney transplantation followed by HDT/SCT in eight patients; this study demonstrated the feasibility of this approach, but the early mortality rate was significant (two of eight) and kidney function worsened in one patient after HDT/SCT.⁵⁰

MONOCLONAL LIGHT-CHAIN DEPOSITION DISEASE

As reviewed by Ronco and colleagues,⁵¹ monoclonal light-chain deposition disease represents a prototypical model of glomerulosclerosis whose pathogenesis is related to production of transforming growth factor β .¹⁰ The dominant clinical manifestation is progressive renal failure, although the disease is systemic and other organs, including heart and liver, may be involved.⁵¹ Randomized, controlled trials for treatment of monoclonal light-chain deposition disease are unavailable, but these patients appear to benefit from the same chemotherapy as that given for multiple myeloma, particularly if the renal failure is mild at presentation.⁴ The 5-year patient survival rate approaches 70%,⁴ but is decreased by coexistent myeloma. The serum creatinine concentration at presentation is an important predictor of subsequent kidney function: five of eight patients with serum creatinine concentrations less than 354 $\mu\text{mol/L}$ (4.0 mg/dL) did not progress with chemotherapy, whereas 9 of 11 patients with creatinine concentrations greater than 354 $\mu\text{mol/L}$ at presentation progressed to end-stage kidney injury despite therapy.

Encouraged by the early success of melphalan/prednisone,⁴ three small nonrandomized trials examined the use of HDT/SCT in monoclonal light-chain deposition disease.^{52,53} The first study consisted of a retrospective analysis of 11 patients; 10 were considered to have myeloma and most were stage I. All patients had clinically apparent renal disease, with four manifesting severe kidney failure requiring renal replacement therapy at the start of treatment. Four patients had congestive heart failure. Despite the high frequency of renal and cardiac involvement, procedure-related death from stem-cell harvesting and HDT/SCT did not occur. Three of the four patients on dialysis, however, developed morbid complications from which they eventually recovered. Five patients had a complete hematologic response as well as improvement in organ function. Histologic confirmation of regression of the light-chain deposits in affected organs was also shown. During the median follow-up period of 51 months, three patients required additional treatment because of a relapse of myeloma; one patient died 93 months after HDT/SCT from complications related to myeloma.⁵² The second report⁵³ also described the feasibility and success of HDT/SCT in five patients with monoclonal light-chain deposition disease. In the third report, all patients had concomitant myeloma and advanced renal disease requiring renal replacement therapy, but successful therapy improved renal function in a subset; 5 of 10 patients with biopsy-proven monoclonal light-chain deposition disease became dialysis independent after HDT/SCT.⁵⁴

The high incidence of progressive kidney disease in monoclonal light-chain deposition disease has prompted treatment with kidney transplantation at several institutions, but the disease will recur in the allograft if the underlying plasma-cell

dyscrasia is not addressed.⁵⁵⁻⁵⁷ The largest collection⁵⁷ reported the outcome of seven patients who received kidney transplants (four deceased donor and three living related). Recurrence of the disease was observed in five of the seven allografts. The median time to reach end-stage kidney failure after recurrence was 33.3 months, with an overall median graft survival of 37.3 months. Median patient survival was 6.1 years, which is worse than age-matched kidney transplant recipients. However, one patient remained alive with a functioning allograft and no evidence of recurrence 13 years after transplantation. The authors concluded that long-term kidney allograft survival is significantly decreased in monoclonal light-chain deposition disease, emphasizing the need to control monoclonal light-chain production before kidney transplantation.

CAST NEPHROPATHY

A cornerstone of acute management of cast nephropathy is prevention of aggregation of light chains with Tamm-Horsfall glycoprotein. Volume repletion, normalization of electrolytes, and avoidance of complicating factors such as furosemide, radiopaque contrast material, and nonsteroidal anti-inflammatory agents are mainstays of therapy in the prevention of cast nephropathy. Tubule fluid flow rates should be kept high to avoid obstruction from light chains.^{20,58} Daily fluid intake of as much as 3 L in the form of free water should be encouraged as long as defects in osmoregulation do not manifest. Although alkalinization of the urine prevents renal failure due to light chains in rats,⁵⁹ in one inadequately controlled trial in humans, alkalinization of the urine was not beneficial.⁶⁰ Until better studies are available, because increasing the ambient sodium concentration also facilitates binding *in vitro*,²⁰ administration of sodium bicarbonate (or citrate) should probably be avoided.

Hypercalcemia develops in 20% to 30% of patients with multiple myeloma. Hypercalcemia is both directly nephrotoxic and enhances the nephrotoxicity of light chains.^{19,20} For these reasons, aggressive intervention to achieve normalization of the serum ionized calcium concentration is necessary. Initial management includes volume expansion with 0.9% NaCl intravenously, provided kidney function is not irreversibly impaired. Loop diuretics facilitate renal calcium excretion, but may facilitate nephrotoxicity from light chains.²⁰ Consequently, loop diuretics should be administered judiciously and only after the patient is clinically euvolemic. Glucocorticoid treatment, such as intermittent high-dose dexamethasone, is frequently helpful for the management of hypercalcemia. Bisphosphonates, particularly pamidronate and zoledronic acid, are used to treat moderate hypercalcemia (serum calcium > 3.25 mmol/L or 13 mg/dL). Although hypercalcemia of myeloma responds to bisphosphonates, these agents are nephrotoxic and should be administered only to euvolemic patients. Bisphosphonates have also been used to treat myeloma. In one prospective study, patients who received monthly intravenous infusions of pamidronate 90 mg had fewer skeletal events (pathologic fractures, cord compression, bone radiotherapy) and less bone pain with improved quality of life compared with the group who received placebo.⁶¹ Many authorities recommend the use of monthly pamidronate therapy, particularly in those patients with

advanced myeloma. Kidney function and proteinuria should be monitored during treatment with these agents and the dose adjusted accordingly should kidney function or proteinuria worsen.

Virtually all patients with cast nephropathy have criteria for the diagnosis of multiple myeloma, and the primary approach to treatment is antitumor therapy. The traditional treatment, which consisted of alkylating agents and steroids, has been replaced, particularly in younger patients, with high-dose chemotherapy with autologous peripheral stem-cell transplantation (HDT/SCT). A randomized trial showed that patients who received HDT/SCT had improved event-free survival and overall survival rates than did patients who received conventional chemotherapy. The mean serum creatinine of patients at the time of entry into this study was 1.3 mg/dL (113 μ mol/L).⁶² A multicenter, randomized trial determined that, compared with conventional chemotherapy, HDT/SCT was a more effective first-line treatment for myeloma when patients were younger than 65 years of age at diagnosis.⁶³ Patients with advanced renal disease were accepted into this trial, and, perhaps not surprisingly, survival rates were higher among patients who had serum creatinine levels less than 1.7 mg/dL than among patients with creatinine concentrations 1.7 mg/dL or greater.⁶³ As experience with the use of HDT/SCT has increased, more institutions are using this approach even in patients with advanced renal disease.⁶⁴ HDT/SCT performed on 59 dialysis-dependent patients with myeloma resulted in improvement in kidney function in 24%; the rate of recovery was higher in patients who were on dialysis for less than 6 months.⁵⁴ Twenty-eight patients had a kidney biopsy in this study, and 15 had biopsy-proven cast nephropathy; of these 15 patients, six became dialysis independent after HDT/SCT.⁵⁴

At present, most clinicians prefer to treat myeloma with a combination of vincristine, doxorubicin, and dexamethasone (VAD) before HDT/SCT because this combination of agents can produce a rapid decrease in the plasma cell clone.⁶⁴⁻⁶⁶ Typically, long-term treatment with alkylating agents is avoided before HDT/SCT because these drugs may impede peripheral stem-cell harvest and are associated with myelodysplasia and acute myelogenous leukemia.⁶⁷

Several as yet unproven therapies are on the horizon. Patients with advanced renal failure and refractory myeloma have been treated with bortezomib⁶⁸ and thalidomide,⁶⁹ with encouraging results. Both agents are now in experimental use in induction chemotherapeutic regimens before HDT/SCT^{70,71} and may eventually replace the combination of vincristine, doxorubicin, and dexamethasone. Myeloablative therapy with allogeneic stem-cell transplantation may prove effective in controlling kidney failure in myeloma, but has significant mortality and is currently limited to a small population who are deemed suitable for such treatment and have an HLA-compatible relative. Whether nonmyeloablative allogeneic stem-cell transplantation, so-called mini-allograft therapy, will provide beneficial results in myeloma^{72,73} without the attendant complications such as severe graft-versus-host disease remains uncertain. However, a recent nonrandomized study enrolled 162 patients who had newly diagnosed myeloma and were younger than 65 years of age to examine the potential benefit of tandem transplants. After therapy with vincristine, doxorubicin, and

dexamethasone and HDC/APSCT, they were divided into two groups, with patients who had HLA-identical siblings receiving nonmyeloablative total-body irradiation and allogeneic stem-cell transplantation and the remaining patients receiving a second HDT/SCT using autologous stem cells. In follow-up, the 80 patients who received the allografts fared significantly better than the 82 patients who received two HDT/SCT. Graft-versus-host disease accounted for most of the treatment-related mortality in the allograft group.⁷⁴

Plasmapheresis in the setting of acute renal failure related to cast nephropathy is controversial. The standard protocol has consisted of five daily plasma exchange sessions, with an additional exchange on days 7 and 10 if necessary. Zucchelli and colleagues⁷⁵ randomized 29 patients with myeloma, light-chain proteinuria, and acute renal failure to receive either plasma exchanges with chemotherapy or chemotherapy alone. Plasmapheresis dramatically decreased light-chain proteinuria and increased urine output; 13 of 15 patients recovered renal function. Of the 14 patients who did not receive plasma exchange therapy, only two recovered function. As a result, plasma exchange therapy significantly improved survival at 1 year post-treatment. An uncontrolled, nonrandomized study has also suggested that patients with advanced multiple myeloma (stage IIIB) and coexistent renal failure may benefit from plasma exchange therapy performed every 5 weeks on three consecutive days just before combination chemotherapy; survival in the plasmapheresis group improved compared with a group who received melphalan and prednisone alone (median survival, 17 vs. 2 months).⁷⁶ A recent randomized trial suggested no clinical benefit from plasma exchange for patients with acute kidney injury,⁷⁷ although there were limitations to this study that should be considered. Kidney biopsy was not a prerequisite for entry into the study, and in perhaps one third of patients with myeloma and acute kidney injury, the cause was not cast nephropathy but related instead to obstruction (nephrolithiasis, papillary necrosis, and amyloid deposition in the ureters), hypercalcemia, and hyperviscosity syndrome, in addition to other causes seen in the general population, such as drug-related allergic interstitial nephritis and contrast nephropathy. Serum free light chains were not determined either before or after the plasma exchange. Despite the significant number of patients, the study may have been underpowered to detect differences between the groups, especially because biopsy-proven cast nephropathy was not a criterion for inclusion in the study. Until additional data are provided, it is prudent not to recommend plasmapheresis for every patient with acute kidney injury, although there may be a subset of patients who do respond to plasmapheresis. If plasma exchange is performed, demonstration of the efficacy of treatment by quantifying changes in serum free light-chain levels should be performed. Finally, hyperviscosity syndrome remains an indication for plasma exchange.

A significant issue related to plasma exchange therapy is the relatively inefficient removal of circulating light chains, and other techniques for rapid decrease in serum light-chain concentrations may become available in the near future. In a recent nonrandomized trial, eight patients who had acute kidney injury from biopsy-proven cast nephropathy received dialysis using a dialyzer with a very large effective pore size (~50 kd). This approach effectively decreased serum free light-chain concentrations, providing the potential to accelerate recovery

from acute kidney injury. In this trial, 5 of 13 patients recovered kidney function by the time of publication of the report.⁷⁸

Renal replacement therapy in the form of hemodialysis or peritoneal dialysis is generally recommended in patients with kidney failure from monoclonal light chain–related renal diseases. Recovery of kidney function sufficient to survive without dialysis occurs in as many as 5% of patients with multiple myeloma, although in some patients, this requires months to achieve, probably because the traditional chemotherapeutic regimens slowly reduce circulating light-chain levels. Despite the susceptibility to infection in multiple myeloma, the peritonitis rate for continuous ambulatory peritoneal dialysis (one episode every 14.4 months) was not unacceptably high.⁷⁹ Neither peritoneal dialysis nor hemodialysis appears to provide a superior survival advantage in patients with myeloma.

Kidney transplantation has also been successfully performed in highly selected patients with multiple myeloma. Extrarenal manifestations should be absent and serum light-chain levels controlled for more than 1 year in patients before considering kidney transplantation. Despite rigorous pre-transplantation surveillance, however, myeloma may recur and cast nephropathy can occur in the allograft. These complications notwithstanding, kidney transplantation remains a therapeutic option in highly selected patients who have persistent end-stage kidney disease after treatment.

WALDENSTRÖM'S MACROGLOBULINEMIA

This rare disorder constitutes approximately 5% of monoclonal gammopathies and is a monoclonal B-cell malignancy whose transcription profile resembles that of chronic lymphocytic leukemia.⁸⁰ This condition clinically behaves more like lymphoma, although the malignant lymphoplasmacytic cell line also secretes IgM (macroglobulin), which is usually responsible for the renal symptoms at presentation. IgM is a large molecule that is not excreted and accumulates in plasma to produce hyperviscosity syndrome and cryoglobulinemia. Neurological symptoms (headaches, dizziness, deafness, stupor), visual impairment (from hemorrhages and exudates and sluggish flow through the venous system), bleeding diathesis (complexed clotting factors with IgM and platelet dysfunction), kidney failure, and symptoms of hypervolemia are classic manifestations of this disease. Osteolytic lesions are uncommon. Kidney failure is usually mild but occurs in approximately 30% of patients. Although lymphoplasmacytic cell infiltration can produce nephromegaly and renal failure, hyperviscosity syndrome and precipitation of IgM in the glomerular capillaries are the most common causes of renal failure. Approximately 10% to 15% of patients also develop AL-type amyloidosis, but cast nephropathy is rare in these patients.

The typical course of Waldenström's macroglobulinemia is protracted, but occasionally the disease is more aggressive. Prognostic modeling of Waldenström's macroglobulinemia suggested that age older than 65 years, organomegaly, and perhaps elevated β_2 -microglobulin levels (>4 mg/L) were adverse prognostic factors that were associated with a

reduction in life span. Patients with none of these risk factors had a median survival of 10.6 years, whereas the group who were of advanced age or had organomegaly had a median survival of 4.2 years.⁸¹ In sorting out this process further, molecular analysis may also be of benefit; for example, a 6q gene deletion may discriminate Waldenström's macroglobulinemia from IgM monoclonal gammopathy of undetermined significance.⁸² In the typical presentation consisting of an advanced age (sixth to seventh decades) and slowly progressive course, the major therapeutic goal is relief of symptoms. Randomized, controlled therapeutic trials are lacking in this disorder. Plasmapheresis is indicated for hyperviscosity syndrome, followed by alkylating agents alone. All patients with monoclonal IgM levels greater than 3 g/dL should have serum viscosity checked. A relative serum viscosity more than 4 or whole blood viscosity more than 8 centipoise usually correlates with symptoms of hyperviscosity, although significant individual variation exists.⁸³ Occasionally, clinically apparent hyperviscosity syndrome is associated with only mild increases in serum viscosity, particularly if the IgM forms cryoprecipitate and the serum viscosity is determined at room temperature. Alternatively, some patients with marked increases in serum viscosity manifest no symptoms. Plasmapheresis is indicated in symptomatic patients only and should be continued until symptoms resolve and serum viscosity normalizes. Blood transfusions, which can further increase viscosity, should be avoided in patients with hyperviscosity syndrome. Initial chemotherapy is usually chlorambucil 0.1 mg/kg/day PO, with titration to control serum IgM concentration and organomegaly without inducing cytopenias. More aggressive chemotherapy (cyclophosphamide, vincristine, prednisone), given monthly, has also been used in patients who do not respond to chlorambucil. However, a recognized complication of long-term therapy with alkylating agents is the development of myelodysplasia and acute myelogenous leukemia.⁸⁴ Other agents have been tried in small clinical studies, including rituximab, because, unlike plasma cells, the lymphoplasmacytic cells appear to express CD20.⁸⁵ Severe renal failure requiring renal replacement therapy is uncommon in this disorder.

SUMMARY

Advances in understanding the pathophysiology of monoclonal light chain-related kidney diseases have produced improvements in management and prolongation of survival in this population. Approaches designed to lower circulating monoclonal light chains and attack the basic mechanisms of kidney damage, along with judicious use of renal replacement therapies, provide the best results. For most monoclonal light chain-related kidney diseases, the most aggressive cytotoxic therapies appear to offer the best long-term kidney prognosis but also produce greater morbidity and mortality, particularly in elderly patients. As is true for most diseases, the treating physician must weigh the risks of a particular treatment versus the potential benefit for the individual patient. Even with the recent advances in treatment, however, overall prognosis remains suboptimal, so the clinician should remain receptive to new therapies for this unique family of potentially reversible kidney lesions.

Obstructive uropathy is defined as any functional impedance to the antegrade flow of urine. This obstruction may occur in the upper tract (renal pelvis, ureters), lower tract (bladder, urethra), or both, and may be the result of an intrinsic defect or extrinsic process. A common cause of renal function compromise, urinary obstruction may be diagnosed and treated with multiple modalities, depending on the nature and location of the obstruction. Timely diagnosis and treatment of acute obstruction, as well as the appropriate management of chronic obstruction, is a multidisciplinary effort requiring contributions by primary care providers, internists, nephrologists, urologists, and radiologists.

OVERVIEW

The degree of urinary obstruction typically correlates with the patient's clinical presentation. Complete bilateral obstruction results in anuria, whereas partial or unilateral obstruction may present with intermittent episodes of oliguria and polyuria. Clinical symptoms of urinary obstruction may include flank, suprapubic, or groin discomfort; recurrent urinary tract infections; dysuria; hematuria; stranguria; and acute or chronic renal failure. Acute bilateral obstruction results in postrenal failure. The serum blood urea nitrogen-to-creatinine ratio approximates 10:1 and the urine-to-plasma urea and urine-to-plasma creatinine ratios are indistinguishable from intrarenal failure. Complete anuria requires a prompt evaluation for an obstructing process.

Management of obstruction relies on adequate drainage of the urinary system. Bladder decompression may be achieved by placement of either a urethral catheter or suprapubic cystostomy tube. Drainage of the renal collecting system is possible both endoscopically in a retrograde fashion with a ureteral stent or percutaneously with a nephrostomy tube. Endoscopic procedures typically require administration of spinal or general anesthesia. In the setting of a critically ill patient with

other significant comorbidities, nephrostomy tube placement is often the preferred technique because this can be performed under ultrasound guidance with either minimal intravenous sedation or local anesthesia. In either scenario, definitive intervention is necessary for the ultimate preservation of renal function.

Although acute urinary obstruction must be managed expeditiously, chronic urinary tract obstruction also requires timely diagnosis and management. Chronic obstruction may predispose the afflicted patient to a variety of conditions that are wide-ranging in severity. Urine stasis often leads to bacterial colonization, with sequelae ranging from urinary tract infections and pyelonephritis to fulminant urosepsis and concomitant cardiovascular collapse. Long-standing partial obstruction may also compromise the functional integrity of various structures, particularly the bladder and upper tracts of the renal collecting system, both of which are fairly sensitive to intraluminal pressure changes. This chapter discusses the multiple causes of urinary obstruction as well as the diagnostic considerations and available treatment modalities of each.

CALCULI

Urolithiasis is the most common cause of urinary obstruction, accounting for approximately \$2.1 billion in health care expenditures annually.¹ In the United States, 13% of men and 7% of women will be diagnosed with kidney stones at some point throughout their lifetime.² Peak age at diagnosis in men is 30 years, whereas women exhibit a bimodal distribution, with peaks at 35 and 55 years. Although many of these stones are found incidentally and are not associated with symptoms of pain, obstruction, or infection, the risk of hospitalization and surgical intervention is ever present and increasing as the general population grows. Furthermore, 50% of patients with a history of urolithiasis will re-form stones within 5 years.²

The majority of calculi are composed of uric acid, calcium oxalate monohydrate, calcium oxalate dihydrate, cystine, or ammonium magnesium phosphate (struvite) or some combination thereof. Stones typically form within the collecting system of the kidney and subsequently travel to distal portions of the urinary tract. However, they may also form at the site of a foreign body (i.e., stent, catheter, suture material, human hair). Depending on their size, composition, and conformation, stones may either pass spontaneously in the urine or impact anywhere along the course of the urinary tract. The three most common sites for stone impaction are the ureteropelvic junction (UPJ), the mid-ureter at the level of the iliac vessels, and the ureterovesicle junction. The ureteric caliber at the UPJ and ureterovesicle junction is generally smaller than that along the course of the ureter. Extrinsic compression by the iliac vessels where the mid-ureter crosses causes a narrowing of the ureteral lumen at this level.

The likelihood of spontaneous passage of calculi is dependent on several criteria. These include stone size and shape, as well as patient anatomy and history of stone passage.³ However, due to the intrinsic variability of an individual's ureteral caliber, as well as the conformation of calculi, these criteria serve merely as a guide and must be appropriately incorporated into each clinical setting. Reported percentages of spontaneous stone passage vary widely in the literature, ranging from 29% to 98% for stones 0.5 cm or smaller located in the proximal ureter compared with rates of 71% to 98% for those of comparable size located in the distal ureter.³ Stones ranging from 0.5 to 1.0 cm have a lower likelihood of spontaneous passage, with rates ranging from 10% to 53% for those in the proximal ureter; rates are somewhat better for the distal ureter, ranging from 23% to 53%.³ Moreover, recent studies have demonstrated the utility of α -adrenergic blockers, calcium channel blockers, and nonsteroidal anti-inflammatory medications in facilitating spontaneous stone passage via ureteral smooth muscle relaxation.^{4,5}

Treatment Options

Dissolution therapy is an appropriate first-line treatment modality for uric acid and cystine stones. Uric acid stones, comprising 5% to 10% of all urinary stones, typically form in an acidic urine (pH \leq 5.5).⁶ They are relatively soft compared with calcium oxalate and cystine stones and are associated with hyperuricosuria, low urinary volume, and persistently acidic urine. These stones are often radiolucent on radiographic imaging and measure a density of 500 Hounsfield units or less on computed tomography. Dissolution therapy with oral urine alkalinizing medications (potassium citrate) has been shown to be efficacious in as many as 80% of patients.⁶ Those patients failing dissolution therapy may then be further treated with a surgical intervention.

Cystine stones, which account for approximately 1% of all urinary calculi, also form in acidic urine. Cystinuria results from a defect in the renal tubular absorption of the amino acids cystine, ornithine, lysine, and arginine. Patients with the inherited autosomal recessive disorder excrete in excess of 600 mg of cystine daily in their urine (normal $<$ 100 mg/day). In addition to increasing urine volume, first-line therapy remains urine alkalization with a goal urine pH of more than 7.0. Should dissolution therapy be ineffective, patients may also be treated with oral chelating agents, such as D-penicillamine (250 mg

every 6 hours) or α -mercaptopyropionylglycine (250 mg every 6 hours) to increase urine cystine solubility.⁷ Cystine stone formers will often present with staghorn calculi. These stones are extremely dense ($>$ 1200 Hounsfield units) and are therefore not amenable to certain treatment modalities, such as extracorporeal shock wave therapy (ESWL).

Struvite stones, in comparison, form in alkaline urine. Commonly associated with chronic urinary tract infections secondary to urea-splitting pathogens (*Proteus mirabilis*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*), these stones exist in a urine pH of more than 7.5. Urease splits urea into component ammonia groups, resulting in alkaline urine. Because these stones are closely associated with infection, definitive treatment relies on clearance of all stone burden and maintenance of a sterile urine, typically through antibiotic prophylaxis.

Prevention

Prevention of recurrent urolithiasis is based on maintaining high urine volume, increasing the concentration of stone-inhibiting substances in the urine, and decreasing the concentration of lithogenic substances. Patients are encouraged to consume more than 2.5 L of fluid daily and to supplement their fluid intake with citrate-rich fluids, such as lemonade.⁸ Citrate binds calcium in the urine and inhibits calcium oxalate crystal formation. Foods rich in oxalate, such as tea, coffee, leafy green vegetables (spinach), rhubarb, nuts, and beer should be avoided. Meats and other protein-rich foods should also be consumed in moderation, as degradation of these purine-heavy foods results in elevated serum uric acid concentrations. Allopurinol may also be prescribed for those patients with hyperuricemia. Cystine stone formers should be counseled to reduce their intake of methionine-containing foods, such as meats and dairy products.

Surgical Intervention

Recent advances in the endoscopic treatment of calculi and the significant improvement of lithotripsy devices have allowed the majority of surgical treatments to be performed in an outpatient setting. Holmium pulsed-dye lasers have become ever more powerful and are relatively easy to use. Furthermore, ureteroscopes and imaging equipment have dramatically improved, allowing excellent visualization of ureteral and renal pelvic anatomy and calculi. Renal stones measuring as large as 2 cm may now be treated with staged ureteroscopic procedures or ESWL, depending on the location and hardness of the stone. Selection criteria for surgical stone management include stone location, size, composition, collecting system/ureteral anatomy, patient health/performance status, and patient preference.

ESWL involves delivery of shock waves generated by electromagnetic energy sources. These shock waves are propagated through water and delivered to the stone burden under direct, real-time fluoroscopic imaging. To reliably use ESWL, patient selection is vitally important. The stone must be radiopaque and visualized on standard radiographs because fluoroscopy or ultrasonography is used intraoperatively to identify and target the stone. Shock waves are then delivered to the stone until evidence of fragmentation is identified. ESWL may often be performed under conscious sedation, although some

patients may require administration of general anesthesia for improved tolerability. Although ESWL is noninvasive, it has been associated with specific risks, including cardiac arrhythmias, renal contusions, hemorrhage, and bruising. Recent studies also suggest that ESWL may be associated with the delayed development of diabetes due to pancreatic fibrosis secondary to shock wave injury.⁹

ESWL is appropriate for stones measuring as much as 1.5 cm located above the bony pelvis. The ischial body may impede shock wave propagation and mute the fragmentation effects on stones located in the distal ureter. Moreover, patients undergoing ESWL treatment must be warned of the risks of *steinstrasse*, literally translated as “a road of stone.” This occurs when a stone is broken into multiple smaller fragments and the lead fragment is unable to spontaneously pass, which causes ureteral obstruction proximal to the stone burden. Classic symptoms of flank pain, dysuria, and hematuria may result, and a secondary procedure (e.g., stent or nephrostomy tube placement, salvage ureteroscopy) is often necessary because the lead fragment will not pass.

Ureteroscopy is defined as any endoscopic manipulation of the ureter and its contents. Since its development in the early 1980s, ureteroscopy has revolutionized the treatment of ureteral and renal stones.¹⁰ Whereas open ureterolithotomy for stone extraction was commonly performed through the 1970s and required an inpatient hospitalization, ureteroscopy allows outpatient treatment of most urinary stones today. Rigid and flexible ureteroscopes are currently available and are used either independently or in tandem depending on stone size and location. Standard ureteroscopes measure approximately 8 French in size and are introduced via the urethra to the level of the stone. Various tools, including holmium lasers and nitinol extraction baskets, are then used to fragment, retrieve, and remove the stone. A ureteral stent is typically placed for temporary renal decompression and to allow residual stone fragments to pass. This stent also mitigates the risk of ureteral obstruction from posttreatment ureteral inflammation and edema.

If dissolution therapy fails or is not feasible, staghorn calculi and large renal stones are best treated with percutaneous nephrolithotomy, which requires nephrostomy access to the kidney via the flank. This procedure allows for high stone-free rates with fewer secondary procedures necessary.¹¹ Open surgery, including pyelolithotomy and anastrophic nephrolithotomy, is rarely performed and reserved for those patients with highly complicated anatomy (e.g., crossed-fused ectopia, horseshoe kidney) or grossly enlarged stone burden (>5 cm). With the increased popularity of laparoscopic procedures, minimally invasive pyelolithotomy is also frequently offered for large renal pelvic or ureteropelvic junction stones.

URETEROPELVIC JUNCTION OBSTRUCTION

UPJ obstruction accounts for approximately 50% of prenatally diagnosed hydronephrosis. Classically, UPJ obstruction presents as a unilateral process; however, bilateral obstruction may occur. Causes of UPJ obstruction may be both intrinsic and extrinsic in nature. In some instances, there is a crossing anatomic vessel (an accessory renal artery or vein), which kinks the ureter at the level of the UPJ. Surgical correction of

the anomaly with pyeloplasty and vessel transposition is the definitive treatment. Intrinsic defects within the ureter, including an aperistaltic segment secondary to malformation of the ureteral musculature as well as ureteral valves (Ostling's valves) are a cause of UPJ obstruction in children.¹² Diagnosis typically is made based on a ^{99m}Tc-mercaptoacetylglycine study or intravenous pyelography. Again, treatment involves a pyeloplasty and excision of this aperistaltic segment. Impacted ureteral stones and previous endoscopic ureteral manipulation, with concomitant ureteral inflammation and fibrosis, may also result in ureteral strictures, leading to UPJ obstruction. Excision of this stenotic segment and primary reanastomosis is the recommended treatment. Endopyelotomy or ureteroscopic incision of ureteral strictures and balloon dilatation have been reported as other initial management options with varying degrees of success.¹³

Before a major surgical repair, the degree of function in the affected kidney should be calculated. This is commonly performed using a dimercaptosuccinic acid scan, a radionuclide study that measures the uptake of tracer material within the renal tubules and is a reliable means of assessing renal function. Because the goal of therapy is to maintain existing renal function, which is not apt to improve after pyeloplasty, a simple nephrectomy as definitive treatment should be considered.

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) is a commonly diagnosed condition that is responsible for a significant proportion of lower urinary tract complaints in middle-aged and elderly men. In the United States in 2000, this condition accounted for 117,000 emergency department visits and 105,000 hospitalizations, accounting for \$1.1 billion in expenditures.¹ A consequence of persistent testosterone stimulation, BPH occurs as a result of growth of adenomatous prostatic tissue. This is a benign condition and may be managed expectantly, pharmacologically, or surgically. Chronic obstruction, left untreated, results in recurrent bladder overdistention, which may lead to bladder trabeculation and formation of diverticula and cellules. These outpouchings of bladder epithelium can further predispose the patient to urinary tract infections, stone formation, and, most importantly, deterioration of the upper tracts leading to compromised renal function and ultimately renal failure.

Patients with significant lower urinary tract symptoms should be evaluated by a urologist. Although symptoms of urinary frequency, hesitancy, and urgency may be attributed to BPH, evaluation of the lower urinary tract is required. Thorough physical examination should include suprapubic palpation and inspection of the penis for evidence of meatal stenosis or phimosis. A digital rectal examination is required, and patients are encouraged to complete a symptom score questionnaire. This questionnaire rates symptoms of nocturia, urgency, frequency, stranguria, force of urine stream, intermittency, and the need for second voiding and serves as a baseline for subsequent comparison after initiation of medical therapy or surgery. Cystoscopy is recommended for specific indications, such as hematuria, suspected bladder stones, or early bladder cancer. Transition cell carcinoma *in situ* is often associated with irritative urinary symptoms.¹⁴ A postvoid residual and uroflow are

also important studies in the diagnosis of BPH. A postvoid residual greater than 200 mL is significant, as is a uroflow rate of less than 15 mL/sec.¹⁵ Ultimately, because this is a benign condition, informed treatment decisions should be based on patient satisfaction and perceived quality of life.

Treatment Options

Medications

There are two main classes of medications prescribed for treatment of symptoms of BPH: α_1 -adrenergic receptor blockers and 5 α -reductase inhibitors. α -Blockers (terazosin, doxazosin, tamsulosin, alfuzosin) result in blockade of sympathetic peripheral α_1 receptors, resulting in relaxation of both prostatic and bladder neck smooth muscle. These medications are generally well tolerated but, given their mechanism of action, may cause hypotension, dizziness, or syncope. α -Blockers have been definitively shown to exhibit efficacy in the treatment of men with urinary symptoms attributable to BPH, but do not decrease the incidence of acute urinary retention episodes.¹⁶

5 α -Reductase inhibitors (finasteride, dutasteride) inhibit the enzyme 5 α -reductase, thus preventing conversion of testosterone to dihydrotestosterone, which is chemically active within the prostate and stimulates prostatic tissue growth. Such deprivation of dihydrotestosterone results in prostatic epithelial atrophy. Dutasteride (Avodart) inhibits both the type I and II forms of 5 α -reductase and may provide an increased benefit to patients.¹⁷ These medications are often used in tandem with α -blockers and have been shown to demonstrate great efficacy in multiple studies.^{16,18} 5 α -Reductase inhibitors do affect serum prostate-specific antigen (PSA) levels, typically decreasing them by 50%. Therefore, this decrease must be noted before initiation of 5 α -reductase therapy because treatment may influence the subsequent care of patients managed with routine PSA screening and monitoring tests. Furthermore, patients applying topical 5 α -reductase for hair growth (Propecia) must be informed that their serum PSA level will be reduced, typically by 50% as well.¹⁹ Combination therapy with both α -blockers and 5 α -reductase inhibitors appears to have a synergistic effect, as studies have shown an approximately 50% decrease in disease progression compared with monotherapy.¹⁶ Of note, medications are not effective in patients with enlarged prostatic median lobes. The median lobe may serve as a ball valve, intermittently obstructing the bladder neck, resulting in outflow obstruction. These patients are best served by transurethral resection of this tissue.

BPH may result in an elevated PSA, although not typically to the levels seen in aggressive prostate cancer. However, an elevated PSA may not simply be attributed to prostatic hyperplasia, and an appropriate evaluation and work-up is warranted.

Surgery

Several technologic advances have vastly improved the urologist's armamentarium of surgical options for treatment of BPH. In addition to the standard transurethral resection of prostate tissue using the electrosurgical resectoscope, new devices incorporating laser and microwave energy have resulted in safer, faster, and more cost-effective treatment strategies. Various laser vaporization technologies, including holmium

and KTP (potassium titanyl phosphate), allow for significantly smaller intraoperative blood loss as well as fewer risks of postprocedure absorptive hyponatremia.²⁰ Many patients are catheter free after these procedures and do not require an inpatient hospitalization. These devices use a wavelength of light (523 nm) that is absorbed by both blood and tissue, allowing for more exact tissue destruction and simultaneous hemostasis. Microwave therapy has also exhibited efficacy as an office-based treatment modality, using a special urethral catheter with a thermal coil that delivers highly focused energy to the prostatic bed with resultant tissue necrosis. After administration of mild sedatives and topical urethral lidocaine, this catheter is inserted in the standard fashion by a urologist and left in place for approximately 30 to 60 minutes.

Expanding titanium urethral stents (UroLume) have also been developed for treatment of bladder outlet obstruction. These devices are endoscopically placed within the prostatic urethra and serve to stent open the urethral lumen by inhibiting coaptation of the prostatic lobes. Although success rates vary considerably for this procedure, these stents are associated with significant morbidity and are difficult to remove once urothelium has grown into them.²¹ These devices are often reserved for poor surgical candidates who are unable to endure general anesthesia for more invasive procedures, such as transurethral resection.

GENITOURINARY MALIGNANCY

Occasionally, bladder, prostate, and urethral tumors may cause urinary obstruction. Muscle invasive bladder cancer arising from the trigone or base of the bladder can obstruct the ureteral orifices, resulting in hydronephrosis. Transurethral resection of the tumor may alleviate this obstruction, but the cancer may recur if the resection is incomplete. Highly advanced prostate cancer may present with bladder outlet obstruction. Transurethral resection of the obstructing lesion is again the preferred treatment of choice. Both bladder and prostate cancers may often present in this situation with gross hematuria or clot retention. Urethral tumors, albeit rare, may also result in an intrinsic obstruction of urinary flow. Often, a catheter may be placed around the obstructing lesion as a temporary measure, followed by further workup and definitive treatment.

URETHRAL STRICTURE/STENOSIS

A urethral stricture is a narrowing of the urethral lumen, resulting in a slowing or cessation of urine flow.²² Urethral strictures are significantly more common in males, given the far longer course of the male urethra compared with that of the female. Risk factors for urethral stricture disease include recurrent urinary tract infections or urethritis (i.e., gonococcal), trauma, previous urethral instrumentation or surgery, pelvic irradiation, and advanced age. Diagnosis is typically based on direct vision with cystoscopy as well as retrograde urethrography to delineate the anatomic location and length of the stricture. Treatment modalities include manual dilatation (metal sounds, balloon dilators), transurethral incision/resection, and open primary repair. Because these strictures are typically composed of dense scar tissue, they tend to recur

in the absence of definitive open surgery. A biopsy of the tissue at the stricture site should always be performed to rule out a coincident urethral tumor as the obstructing lesion.

Presenting symptoms of urethral strictures often include urinary urgency and hesitancy, decreased force or caliber of the urine stream, persistent suprapubic fullness, recurrent urinary infections, the need for frequent second voids, and urinary retention. In some patients, the stricture is such that urethral catheter placement in the standard blind fashion is not possible, requiring placement of a catheter over a wire under cystoscopic guidance or placement of a suprapubic cystostomy tube for acute bladder decompression.

BLADDER DYSFUNCTION

In the normal state, voiding is a reflex function under voluntary control. Coordinated voiding, characterized by external sphincter relaxation and subsequent detrusor contraction, is controlled by the pontine micturition complex's effect on the sacral cord (S2-S4).²³ The pontine micturition complex, in turn, is under cortical control. Detrusor hyperreflexia with coordinated external sphincter activity results from suprapontine lesions (e.g., stroke, Parkinson's disease). This is in contrast to detrusor hyperreflexia without coordinated external sphincter activity, which is caused by a suprasacral spinal lesion (e.g., myelodysplasia, multiple sclerosis). Detrusor areflexia is caused by damage to the sacral reflex arc (e.g., neuropathy, disk herniation), and also occurs during the acute spinal shock phase after a spinal cord injury. Urodynamics, a real-time study that measures bladder pressure, abdominal pressure, sphincter activity, bladder compliance, and flow rate, is commonly used to delineate these disorders.

Optimal bladder function relies on adequate maintenance of filling and emptying pressures in both the storage and expulsion of urine. During the filling stage, bladder pressures must be low enough to allow for transit of urine from the ureter to the bladder. Should the bladder pressure exceed the ureteral and renal pelvic pressures, urine will reflux in a retrograde fashion, resulting in ureteral dilatation. The ureter can withstand continuous intravesicle pressures as high as approximately 40 cm H₂O. Higher resting pressures lead to ureteral damage and resultant renal compromise.

The voiding stage is dependent on an important interplay between the bladder detrusor smooth muscle and the external skeletal muscle sphincter. At the initiation of a void, the external sphincter is relaxed under voluntary control, followed by contraction of the detrusor muscle. This allows for the coordinated flow of urine in an anterograde fashion. A defect in the detrusor muscle, external sphincter, or signaling neuron pathways therein results in bladder dysfunction. The result is a high-pressure bladder with inadequate voiding. Treatment modalities include anticholinergic medications (e.g., tolterodine, oxybutynin) to inhibit detrusor contraction.

Clean intermittent catheterization is the ideal modality for bladder decompression in the patient with urinary obstruction secondary to neurogenic bladder dysfunction.²⁴ Long-term indwelling catheters are not recommended because these can result in a host of complications, including recurrent urinary tract infections, urethral meatal erosion,

orchitis, epididymitis, prostatitis, bladder calculi, and squamous metaplasia of the bladder epithelium, a premalignant condition.²⁵ Clean intermittent catheterization requires diligent attention to patient hygiene, catheter care, and catheterization technique.

Those patients with detrusor-sphincter dyssynergia, characterized by bladder hyperreflexia with coordinated external sphincter relaxation, are plagued by poor bladder compliance and outlet obstruction. Bladder augmentation with subsequent clean intermittent catheterization may be recommended for these patients to ensure adequate urine storage and drainage. However, in those not suitable for augmentation or the necessary maintenance techniques required, urinary diversion is also a viable option. A sphincterotomy may also be performed, but this ultimately results in incontinence.

EXTRINSIC COMPRESSION

A variety of other oncologic and inflammatory conditions may result in obstructive uropathy as a result of extrinsic compression of one or both ureters, the bladder, or the urethra. Gynecologic malignancies arising from pelvic organs, such as the cervix, ovary, and uterus, may result in a mass effect on the ureters or trigone of the bladder, resulting in urinary obstruction. This may also result from masses of the colon and inflammatory processes, such as sigmoid diverticulitis, Crohn's disease, and ulcerative colitis. Such inflammatory reaction may result in a reactive fibrosis around one or both ureters, leading to proximal obstruction of urine. With regards to tumor compression, this typically occurs as a chronic process, with the gradual onset of flank pain. Ultrasonography or computed tomography will often demonstrate unilateral or bilateral hydronephrosis in the setting of an enlarging pelvic mass, potentially in the absence of symptoms (silent hydronephrosis). Decompression of the renal collecting system with either a percutaneous nephrostomy tube or ureteral stent is indicated, as this obstruction may predispose the patient to renal failure in the setting of chemotherapy for the primary tumor. Moreover, as many of these patients are immunosuppressed due to immunotherapy or as a consequence of the disease, an obstructed collecting system may be a setup for urinary tract infections and subsequent urosepsis, which may prove fatal in the debilitated patient.

POSTOBSTRUCTIVE DIURESIS

Urinary obstruction, either unilateral or bilateral, may result in fluid overload, renal insufficiency, and electrolyte abnormalities. However, relief of this obstruction may also result in profound effects on the patient's volume status and electrolyte homeostasis. Acute decompression of the bladder will often result in polyuria and, in some cases, hematuria. This hematuria is due to decompression of previously dilated mucosal cystic vessels, which rupture in the setting of intravesicle pressure changes. It may be fairly significant and require clot evacuation and continuous bladder irrigation.

Postobstructive diuresis may be physiologic, pathologic, or a combination of the two. Physiologic diuresis occurs as a result of fluid overload and elevated urea levels, which are

excreted when the obstruction is relieved. Pathologic diuresis occurs as a result of increased tubule permeability and lack of an osmotic gradient in the renal medulla. Postobstructive polyuria is characterized by increased salt and water excretion and may vary widely with respect to volume. As many as 10% of patients will exhibit excessive diuresis, requiring intravenous fluid replacement. To accurately assess clinical improvement and normalization of volume status, daily weight, urine output, and orthostatic blood pressures are recorded. Plasma electrolytes should be monitored carefully (every 6–12 hours in the acute setting), particularly potassium, sodium, and magnesium, because these values demonstrate the degree of nephron recovery post-obstruction. Urine output is replaced with half normal saline, as the sodium content of the diuresis is typically approximately 70 mEq/L. Careful attention must be paid to avoid overhydration of the patient, thereby perpetuating the disease. Many patients with modest diuresis may eat and drink their way back to a normal volume state. Intermittent bladder drainage, once believed to mitigate hematuria, is not recommended as this typically serves only to confuse the accurate recording of urine output.

FETAL AND PEDIATRIC UROPATHIES

Advances in diagnostic and treatment modalities for fetuses, infants, and children have had a tremendous impact on the management of urinary obstruction in this patient population. Congenital malformations, such as posterior urethral valves, a persistent prostatic utricle, or the sequelae of such neurological disorders as spina bifida may all result in obstruction. Posterior urethral valves, present in males, are remnant flaps of mucosal tissue within the urethra, typically at the level of the veru montanum in the prostatic urethra. These patients often present with prenatal oligohydramnios, bladder distention, and bilateral hydronephrosis. Diagnosis is confirmed with a voiding cystourethrogram, and treatment includes endoscopic valve ablation. Temporary decompression of the obstructed bladder in the setting of posterior urethral valves may be accomplished with a cutaneous vesicostomy, which is an incontinent urinary diversion. Long-term sequelae of renal obstruction may include an inability of the kidney to maximally concentrate urine. This predisposes affected children to polydipsia and intolerance to fluid deprivation.

Hypertension in Pregnancy

Mounira Habli and Baha M. Sibai

CHAPTER CONTENTS

DEFINITIONS AND CLASSIFICATIONS	479
Gestational Hypertension	479
Chronic Hypertension	480
Management	480
Preeclampsia and Eclampsia	481
Maternal and Perinatal Outcome	483

Management of Mild and Severe Preeclampsia	483
Counseling	484
Contraception	485

Hypertensive disorders are the most common medical complications of pregnancy, affecting 5% to 10% of all pregnancies.^{1,2} The incidence of disease depends on many different demographic parameters including maternal age, race, and associated underlying medical conditions. These disorders are responsible for approximately 16% of maternal mortality in developed countries. Classification of hypertensive disorders in pregnancy includes chronic hypertension and the group of hypertensive disorders unique to pregnancy called gestational hypertension and preeclampsia. Approximately 30% of hypertensive disorders in pregnancy are due to chronic hypertension and 70% are due to gestational hypertension.¹ The spectrum of disease ranges from mildly elevated blood pressures with minimal clinical significance to severe hypertension and multiorgan dysfunction. Understanding the disease process and the impact of hypertensive disorders on pregnancy is of the utmost importance because these disorders remain a major cause of maternal and perinatal morbidity and mortality worldwide.

DEFINITIONS AND CLASSIFICATIONS

Making an appropriate diagnosis can be difficult at times in the gravid patient; however, adhering to the following definitions and classification schemes will help to eliminate confusion. Hypertension in pregnancy is defined as a systolic blood pressure of 140 mm Hg or greater or a diastolic blood pressure of 90 mm Hg or greater. These measurements must be present on at least two occasions at least 6 hours apart, but no more than a week apart.

Abnormal proteinuria in pregnancy is defined as the excretion of 300 mg or more of protein in 24 hours. The most accurate measurement of proteinuria is obtained with a 24-hour urine collection. A value of 1+ or greater correlates with 30 mg/dL. Proteinuria by dipstick is defined as 1+ or more on at least two occasions at least 6 hours apart but no more than 1 week apart. The accuracy of semiquantitative dipstick measurements on spot urine samples compared with 24-hour urine collections is highly variable. Therefore, should time allow, a 12- or 24-hour urine collection should be performed as part of the diagnostic criteria to define

proteinuria. Care should be taken when obtaining urine protein measurements to use a clean sample because blood, vaginal secretions, and bacteria can increase the amount of protein in the urine.¹⁻³

Edema is a common finding in the gravid patient, occurring in approximately 50% of women. Lower extremity edema is the most typical form. Pathologic edema is seen in nondependent regions such as the face, hands, or lungs. Excessive, rapid weight gain of 5 pounds or more per week may be sign of fluid retention.^{1,2}

The classification system of hypertension in pregnancy was proposed originally by the American College of Obstetricians and Gynecologists Committee on Terminology in 1972. Further modifications by the National High Blood Pressure Education Program Working Group in 2000 arrived at the classification scheme used today, which offers simple, concise, and clinically relevant features for each of the four categories. This system recognizes four major categories of hypertension in pregnancy: gestational hypertension, preeclampsia or eclampsia, chronic hypertension, and preeclampsia superimposed on chronic hypertension. Table 41-1 lists these categories and the features of each.¹⁻³

Gestational Hypertension

Gestational hypertension is the most frequent cause of hypertension during pregnancy. The rate ranges between 6% and 17% in healthy nulliparous women and between 2% and 4% in multiparous women.⁴ Gestational hypertension is considered severe if there is sustained systolic blood pressure to at least 160 mm Hg and/or diastolic blood pressure to at least 110 mm Hg for at least 6 hours without proteinuria.⁴ Treatment generally is not warranted because most patients have mild hypertension. However, approximately 46% of patients diagnosed with preterm gestational hypertension will develop proteinuria and progress to preeclampsia. In general, the majority of cases of mild gestational hypertension are diagnosed at or beyond 37 weeks and have a pregnancy outcome similar to term normotensive pregnancies. However, higher rates of induction and cesarean sections are seen in pregnancies complicated by gestational hypertension.⁴

Table 41-1 Classification of Hypertension in Pregnancy with Definitions

Diagnosis	Definition
Gestational hypertension	Hypertension developing after 20 wk of gestation or during the first 24 hr postpartum without proteinuria or other signs of preeclampsia
Transient hypertension	Hypertension resolves by 12 wk postpartum
Chronic hypertension	Hypertension that does not resolve by 12 wk postpartum
Preeclampsia or eclampsia	Hypertension typically developing after 20 wk of gestation with proteinuria; eclampsia is the occurrence of seizure activity without other identifiable causes
Chronic hypertension	Hypertension diagnosed before pregnancy, before 20 wk of gestation, or after 12 wk postpartum
Preeclampsia superimposed	The development of preeclampsia or eclampsia in a woman with preexisting on chronic hypertension

Based on data from references 1, 2, and 3.

Chronic Hypertension

Chronic hypertension is defined by increased blood pressure occurring before pregnancy or increased blood pressure measurements before 20 weeks of gestation.⁵ The rate of chronic hypertension is 1% to 5% in pregnancy. This number is affected by factors such as maternal age, obesity, and race.⁵ The incidence of chronic hypertension among African Americans is 2.5% compared with 1% among other racial groups. Given the trend in delayed childbearing as women pursue careers and educational goals and the epidemic of obesity, increasing numbers of pregnancies will be complicated by chronic hypertension.

Determination of associated underlying medical conditions and the classification of hypertension are important in the management and counseling of patients with chronic hypertension in pregnancy. The cause of chronic hypertension can be either primary or secondary.³ Primary hypertension, also referred to as idiopathic hypertension or essential hypertension, occurs in 90% of pregnancies. Secondary hypertension occurs in the remaining 10% of pregnancies and is associated with the following underlying medical conditions: renal disease, endocrine disease, collagen vascular disease, and coarctation of the aorta.³

Women with chronic hypertension in pregnancy are at increased risk of the development of superimposed preeclampsia, abruptio placentae, intrauterine growth restriction, and preterm delivery.⁶⁻⁸ The rate of superimposed preeclampsia in women with chronic hypertension is 15% to 25%.^{7,8} If the patient has chronic hypertension of more than 4 years' duration or renal insufficiency or had hypertension in a previous pregnancy, the rate of superimposed preeclampsia increases. Overall, abruptio placentae occurs in 1.5% of pregnancies complicated by chronic hypertension.^{6,9} This rate varies from 1% in women with uncomplicated chronic hypertension to 3% in women with superimposed preeclampsia. Proteinuria is an independent risk factor for an adverse perinatal outcome, regardless of the development of superimposed preeclampsia. A maternal serum creatinine level greater than 1.4 mg/dL at conception is another risk factor for increased fetal loss and progressive worsening of maternal renal disease. Fetal loss is increased 10-fold in women with

uncontrolled chronic hypertension and impaired renal function at conception compared with normotensive women and women with well-controlled hypertension.¹⁰ Therefore, management of women with chronic hypertension should begin before conception.

Women with chronic hypertension should be counseled regarding the increased risk of adverse maternal and fetal outcomes as discussed previously. The diagnosis of superimposed preeclampsia may be difficult to make in the patient with chronic hypertension, particularly with baseline nephropathy. To make the diagnosis, the patient should have increasing or difficult-to-control blood pressure, thrombocytopenia, significant increase in liver enzymes, new-onset proteinuria, or significant increase in preexisting proteinuria. Any patient with chronic hypertension who develops headache, right upper quadrant pain, or visual disturbances requires further evaluation for superimposed preeclampsia. If superimposed preeclampsia develops in a patient with chronic hypertension, she should be hospitalized for close maternal and fetal evaluation.

Management

The management of pregnancies complicated by chronic hypertension differs for the low-risk group versus the high-risk group. Patients considered in the low-risk group have, by definition, mild hypertension without evidence of organ damage (Fig. 41-1). The high-risk group has either severe hypertension (systolic blood pressure > 160 mm Hg or diastolic blood pressure > 110 mm Hg) or mild hypertension with evidence of organ involvement (Fig. 41-2). Patients with low-risk chronic hypertension who do not develop superimposed preeclampsia have pregnancy outcomes similar to those of the general population. Prenatal care in low-risk patients should include 24-hour urine collection for total protein determination in the first trimester and at least monthly visits in the first and second trimesters. Visits should be every 1 to 2 weeks after 32 weeks, looking carefully for the development of superimposed preeclampsia.

Central to the management of the high-risk chronic hypertensive pregnancy is the use of antihypertensive pharmacotherapy (Table 41-2). The choice of agent depends on the pharmacologic actions and is covered in the next section. Prenatal care of the high-risk patient includes a first-trimester 24-hour urine collection for total protein level. The frequency

*For women with target organ damage.

Figure 41-2 Antepartum management of chronic hypertension.

of visits in the first and second trimesters should be every 2 weeks and weekly in the third trimester if clinically indicated. In general, pregnancies in patients with high-risk chronic hypertension should not be continued past 40 weeks. As for fetal surveillance for low- or high-risk patients, there is general agreement to perform them as described in Figure 41-2.

Preeclampsia and Eclampsia

The rate of preeclampsia ranges between 2% and 7% in healthy nulliparous women.¹¹ The rate is substantially higher in women with twin gestation (14%) and those with previous preeclampsia (18%).¹¹ Preeclampsia may be subdivided further into mild

Table 41-2 Antihypertensive Medications: Indications/Precautions

Drug	Starting Dose	Maximum Dose	Comments
Acute Treatment of Severe Hypertension			
Hydralazine	5–10 mg IV every 20 min	30 mg	
Labetalol	20–40 mg IV every 10–15 min	220 mg	Avoid in women with asthma or congestive heart failure
Nifedipine	10–20 mg PO every 30 min	50 mg	
Long-Term Treatment of Hypertension			
Methyldopa	250 mg bid	4/day	Rarely indicated
Labetalol	100 mg bid	2400 mg/day	First choice
Atenolol	50 mg qd	100 mg/day	Associated with IUGR
Propranolol	40 mg bid	640 mg/day	To be used with associated thyroid disease
Hydralazine	10 mg tid	100 mg/day	To be used in cases of left ventricular hypertrophy
Nifedipine/diltiazem	10 mg bid	120 mg/day	To be used in women with diabetes
	120–180 mg qd	540 mg/day	
Thiazide diuretic	12.5 mg bid	50 mg/day	Use in salt-sensitive hypertension and/or CHF; may be added as second agent; not to be used if pre-eclampsia develops or IUGR present
ACE inhibitors/ARB			Not to be used due to teratogenicity

CHF, congestive heart failure; IUGR, Intrauterine growth restriction. Based on data from references 1, 2, 4, 10, and 19.

and severe forms. The distinction between the two is made based on the degree of hypertension and proteinuria and the involvement of other organ systems. The criteria for mild preeclampsia and severe preeclampsia are presented in Box 41-1. A particularly severe form of preeclampsia is the HELLP syndrome, which is an acronym for hemolysis, elevated liver enzymes, and low platelet count. This syndrome is manifest by laboratory findings consistent with hemolysis, elevated levels of liver function, and thrombocytopenia. The diagnosis may be deceptive because hypertension and proteinuria might be absent in 10% to 15% of women who develop HELLP and in 20% to 25% of those who develop eclampsia. A patient diagnosed with HELLP syndrome is automatically classified as having severe preeclampsia.¹² Another severe form of preeclampsia is eclampsia, which is the occurrence of seizures not attributable to other causes.

Several risk factors for preeclampsia have been identified such as advanced maternal age (older than 35 years), especially if conception was secondary to assisted reproductive technology, and primigravid. Obesity is another important factor.¹¹ The causal agent responsible for the development of preeclampsia remains unknown. The syndrome is characterized by vasospasm, hemoconcentration, and ischemic changes in the placenta, kidney, liver, and brain. These abnormalities usually are seen in women with severe preeclampsia.¹³ Theories as to the causative mechanisms include placental origin, immunologic origin, and genetic predisposition, among others.¹³

No good screening test for the prediction of preeclampsia exists. Doppler ultrasonography is a useful method to assess the velocity of uterine blood flow in the second trimester. Abnormal velocity waveform is characterized by a high resis-

Box 41-1 Criteria for the Diagnosis of Preeclampsia

Mild

SBP > 140 mm Hg and/or DBP > 90 mm Hg on two occasions at least 6 hours apart, typically occurring after 20 weeks of gestation (no more than 1 week apart)
Proteinuria of 300 mg in a 24-hour urine collection or >1+ on two random sample urine dipsticks at least 6 hours apart (no more than 1 week apart)

Severe

SBP > 160 mm Hg and/or DBP > 110 mm Hg on two occasions at least 6 hours apart
Proteinuria of ≥ 5 g in a 24-hour urine specimen or 3+ or greater on two random urine samples collected at least 4 hours apart
Oliguria < 500 mL/24 hours
Thrombocytopenia platelet count < 100,000/mm³
Elevated liver function test results with persistent epigastric or right upper quadrant pain
Pulmonary edema
Persistent severe cerebral or visual disturbances

DBP, diastolic blood pressure; SBP, systolic blood pressure. Based on data from references 2 and 11.

tance index or an early diastolic notch (unilateral or bilateral). Data still do not support this test for routine screening. Recently, investigators have begun to examine soluble fms-like tyrosine kinase-1 receptors (sFlt-1) and placental growth factor as early markers for preeclampsia.¹⁴ Future studies done

using proteomic and other markers as soluble endoglin and fms-like tyrosine kinase receptors (sFlt) are still ongoing.

Preventive interventions for preeclampsia could affect maternal and perinatal morbidity and mortality worldwide. As a result, during the past decade, several randomized trials reported several methods to reduce the rate and/or severity of preeclampsia. In summary, several trials assessed protein or low-salt diets, diuretics, bed rest, zinc, magnesium, fish oil or vitamin C and E supplementation, and heparin to prevent preeclampsia in women, but results showed minimal to no effect.^{11,15}

Maternal and Perinatal Outcome

Maternal and neonatal outcome in patients with preeclampsia relates largely to one or more of the following factors: the gestational age at delivery, severity of disease, quality of management and presence of preexisting disease. Perinatal mortalities are increased in those who develop the disease before 34 weeks of gestation. Risk to the mother can be significant and includes the possible development of disseminated intravascular coagulation, intracranial hemorrhage, renal failure, retinal detachment, pulmonary edema, liver rupture, abruptio placentae, and death.¹¹ Therefore, experienced clinicians should be caring for women with preeclampsia.

Management of Mild and Severe Preeclampsia

Ideally, a patient having preeclampsia should be hospitalized at the time of the diagnosis. Management of the patient with mild preeclampsia should include baseline laboratory evaluation including 24-hour urine collection for protein, hematocrit, platelet count, serum creatinine value, and aspartate aminotransferase level. At the time of diagnosis, ultrasonography should be performed to evaluate amniotic fluid volume and estimated fetal weight and confirm gestational age. The only definitive cure for preeclampsia is delivery. The main

objective of the management of preeclampsia must always be the safety of the mother and a mature newborn who will not require intensive and prolonged neonatal care. The general consensus for management of mild preeclampsia and severe preeclampsia are listed in Figures 41-3 and 41-4.

Intrapartum Management

While in labor, patients with severe preeclampsia will receive intravenous magnesium sulfate for seizure prophylaxis. This is controversial in regard to mild preeclampsia. There are only two double-blind, placebo-controlled trials evaluating the use of magnesium sulfate in patients with mild preeclampsia.^{16,17} In both trials, patients with well-defined mild preeclampsia were randomized during labor or postpartum, and there was no difference in the percentage of women who progressed to severe preeclampsia (12.5% vs. 13.8%; relative risk = 0.90; 95% confidence interval: 0.52–1.54). There were no instances of eclampsia among 181 patients assigned to placebo. Thus, we recommend individualizing the use of magnesium sulfate in each case.

Pain management in labor should be individualized as well. Intravenous narcotics and regional anesthesia are both appropriate options. Close monitoring of blood pressure intrapartum is necessary. Antihypertensive medications may be needed to keep blood pressure less 160 mm Hg systolic and less than 110 mm Hg diastolic. The most commonly used intravenous medications for this purpose are labetalol and hydralazine. The recommended doses of medications for the immediate treatment of hypertension are listed in Table 41-2. Care should be taken not to decrease the blood pressure too rapidly because a marked decrease in mean arterial pressure may lead to decreased renal perfusion and decreased placental perfusion. Preeclamptic women receiving magnesium sulfate are also at risk of postpartum hemorrhage due to uterine atony.

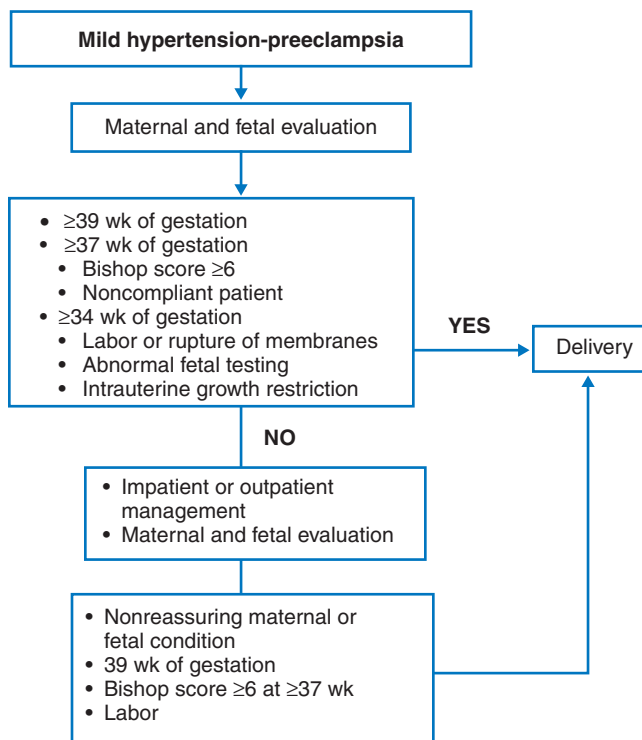

Figure 41-3 Management of mild preeclampsia. (From Sibai BM: Diagnosis and management of gestational hypertension and preeclampsia. *Obstet Gynecol* 2003;102:181–192.)

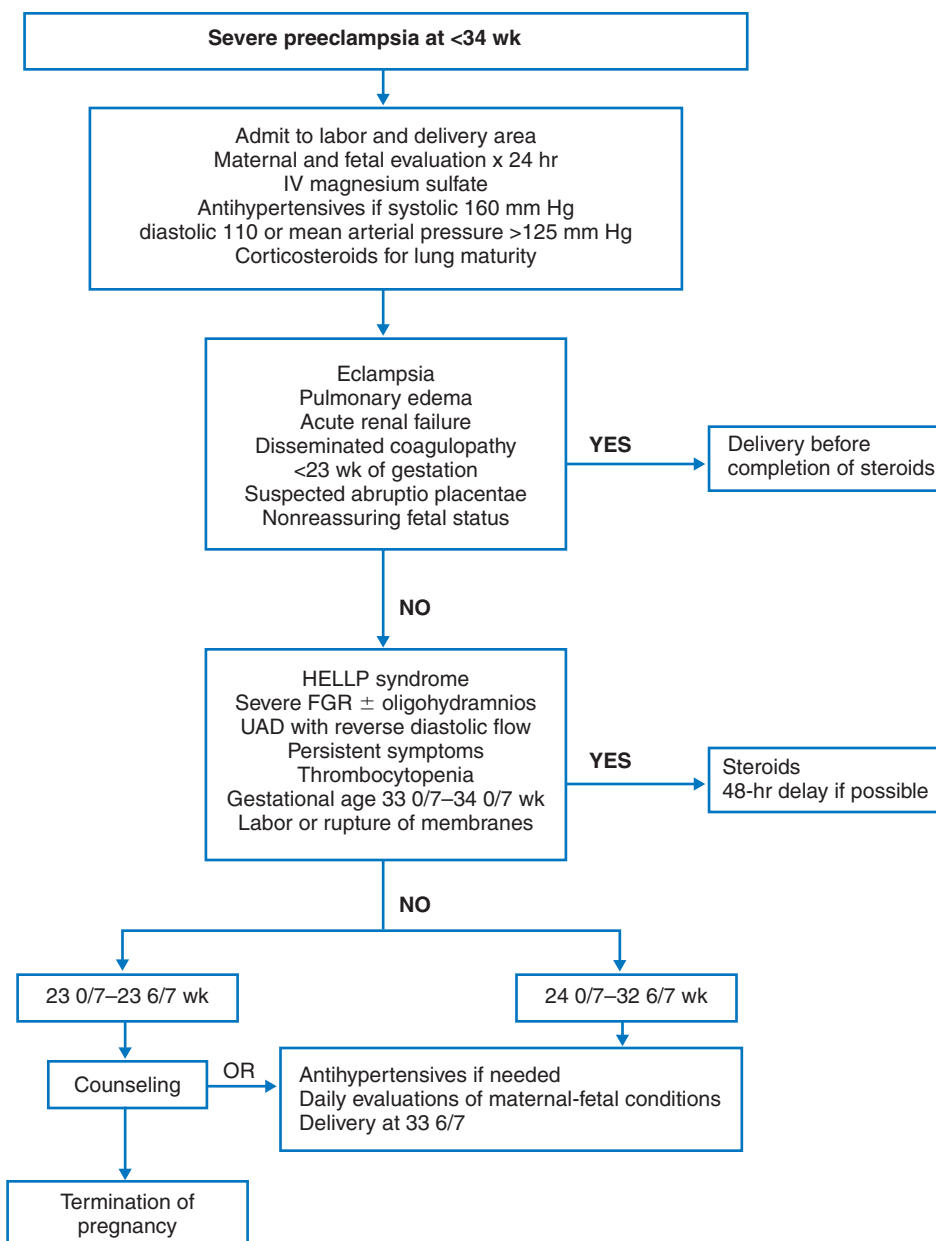

Figure 41-4 Management of severe preeclampsia. FGR, fetal growth restriction; HELLP, hemolysis, elevated liver enzymes, and low platelet count (syndrome). UAD, umbilical artery Doppler. (From Sibai BM, Barton JR: Expectant management of severe preeclampsia remote from term: Patient selection, treatment, and delivery indications. *Am J Obstet Gynecol* 2007;196:514:e1–e9.)

Patients should be monitored closely for at least 12 to 24 hours postpartum. Postpartum eclampsia occurs in 25% of patients. There is no need for continued seizure prophylaxis beyond 24 hours postpartum.

Counseling

Any patient diagnosed with preeclampsia is at significantly greater risk of having an underlying medical condition than is a normotensive gravida. A study by Dekker and Sibai¹⁸ found 39% of patients with a history of early-onset severe preeclampsia developed chronic hypertension. Another study by Nisell and coworkers¹⁹ found that 37% of patients with a history of pregnancy-induced hypertension and 20% of patients with a history of preeclampsia were noted to have hypertension at

7-year follow-up. It is thus essential that women diagnosed with preeclampsia receive close follow-up. With regard to future pregnancies, patients with preeclampsia are at increased risk of developing preeclampsia during subsequent gestations. The risk depends on the severity of preeclampsia as well as gestational age at onset in the index pregnancy. The recurrence rate is 65% if preeclampsia develops in the midtrimester and 20% if it develops at term. Sibai and associates²⁰ reviewed recurrence rates of preeclampsia and HELLP syndrome in patients who had pregnancies complicated by HELLP syndrome. Their findings noted that the recurrence risk of preeclampsia in the otherwise normotensive group was 19% and the risk of recurrence of HELLP syndrome was 3%. This is in contrast to a group of patients with underlying chronic hypertension who

had recurrence rates of preeclampsia and HELLP syndrome of 75% and 5%, respectively. The rate of recurrence of eclampsia is approximately 1% to 2%.

Contraception

Women with hypertensive disease in pregnancy, whether preeclampsia or chronic hypertension, will seek advice regarding contraceptive methods postpartum. It is important to be familiar with options available to patients and be able to discuss potential risk factors. No contraindications exist with the use of barrier methods with regard to hypertension. There are no contraindications for hypertensive patients desiring to use an intrauterine device. The greatest concern in finding appropriate contraception for the hypertensive patient is with regard to hormonal contraception. Oral contraceptive pills are the most widely used reversible form of birth control in the United States. Combination oral contraceptives are known to elevate blood pressure minimally, increase clotting factors, and increase total cholesterol levels.²¹ Once again, it is extremely important to be familiar with any coexisting disease in a hypertensive patient. Overall, the contraceptive choices afforded hypertensive patients are the same as in normotensive patients. The risks and benefits of contraception must be weighed and patients counseled accordingly. Avoiding the morbidity associated with pregnancy in some patients may be a benefit that outweighs the risk of contraceptive use.

PREGNANCY OUTCOME BASED ON SEVERITY OF RENAL DISEASE	489		

There has been marked improvement in maternal and perinatal outcome for pregnancies complicated by renal disease in the past 40 to 50 years. An understanding of the disease processes and improvements in obstetric care, with more successful and earlier intervention, have led to the improved outcomes. Renal disorders in pregnancy can range from asymptomatic bacteriuria (ASB) to end-stage renal disease requiring dialysis and transplantation, all being influenced by the physiologic changes of pregnancy. This chapter reviews the physiology of renal changes during pregnancy and provides a summary of renal disorders.

PHYSIOLOGIC CHANGES DURING PREGNANCY

Several renal physiologic changes occur during pregnancy. These changes include renal anatomy, hemodynamics, acid-base regulation, and metabolic regulation (e.g., water, mineral) (Table 42-1). Thus, tests of renal function in pregnancy must be interpreted in relation to the changes in plasma volume, glomerular filtration, and tubular reabsorption that normally occur with advancing gestation. Many of the commonly used tests of renal function yield lower results in pregnancy than in the nonpregnant state. Consequently, values that may be regarded as normal in the nonpregnant state may well indicate renal dysfunction in pregnancy.

RENAL DISEASE COMPLICATING PREGNANCY

Asymptomatic Bacteriuria, Urinary Tract Infections, and Acute Pyelonephritis

The prevalence of ASB in pregnancy is 4% to 7%.¹ The risk of ASB increases with increasing parity, lower socioeconomic status, increased age, sexual activity, sickle cell trait or disease,

diabetes, and previous urinary tract infection (UTI). The diagnosis of ASB is based on a clean-catch voided urine culture revealing more than 100,000 colonies/mL of a single organism.² It is important to diagnose and treat ASB in pregnancy. Untreated ASB will develop into symptomatic UTI in as many as 40% of these patients.^{3,4} Recognition of and therapy for ASB can eliminate 70% of acute UTIs in pregnancy. Women should be screened for bacteriuria at their first prenatal visit. Therapy for ASB should be continued for 3 to 7 days. The patient should have another culture performed 1 to 2 weeks after discontinuing therapy. The most commonly used agent in ASB and uncomplicated UTI is nitrofurantoin. ASB is associated with an adverse perinatal outcome. Evidence combined from multiple studies suggests that ASB is associated with both preterm delivery and low birth weight.¹

UTIs are the most common medical complication of pregnancy. Acute cystitis occurs in 1.3%⁵ and acute pyelonephritis in 1%⁶ of pregnant women. The causal agents of UTIs in pregnancy are the same as those of acute uncomplicated UTI in nonpregnant women. *Escherichia coli* causes 80% to 90% of UTIs in pregnancy, and *Proteus mirabilis*, *Klebsiella pneumoniae*, *Staphylococcus saprophyticus*, and enterococci are the usual isolates from the remainder of patients with uncomplicated infections. In pregnancy, group B β -hemolytic streptococci are also potential urinary tract pathogens.⁷ The treatment goals of UTI in pregnancy are to eradicate the infection with the shortest possible course of antibiotics and to maintain sterile urine for the remainder of pregnancy. A 3- to 7-day course of antibiotic therapy is recommended to treat ASB or uncomplicated acute UTI in pregnancy.

Pyelonephritis is the most common nonobstetric cause of hospitalization during pregnancy.⁸ Acute pyelonephritis should be initially treated on an inpatient basis, using intravenous antibiotics. Empiric therapy should be begun as soon as the presumptive diagnosis is made. Therapy can be tailored to the specific organism after sensitivities have been obtained approximately 48 hours later.

Table 42-1 Physiologic Changes during Pregnancy

	Changes in Pregnancy	Mechanisms
Renal anatomy	Increase in kidney size 1 cm in length Dilatation of the collecting system with a pelvicalceal diameter up to 2 cm is physiological hydronephrosis Increased GFR, urine formation, and urine flow Changes persist until 12 wk postpartum	Increase in renal vascular volume and kidney hypertrophy Estrogen and progesterone effects Mechanical obstruction of ureters (right > left)
Renal hemodynamics	GFR increases by 50%, then decreases by 20% in the last trimester RBF increase by 85% in second trimester Creatinine clearance increase by 50% to 150–200 mL/min No increase in glomerular capillary pressure	Increase in CO by 30%–40% Increase in renal vasodilation of both afferent and efferent arterioles secondary to EDRF/NO
Metabolic regulation	Water retention especially in late third trimester with transient diabetes insipidus Sodium retention Potassium balance maintained Calcium absorption from gastrointestinal increases Increase in urate clearance until 24 wk, then back to prepregnant state Increase in filtered glucose and protein and less efficient tubule reabsorption leads to renal glucosuria, proteinuria (not exceeding 300 mg/24 hr)	Secondary to high placental vasopressinase By increasing sodium reabsorption both in proximal and in distal tubules Progesterone plays a role in preventing kaliuresis High 1,25(OH) ₂ D ₃ levels produced by kidney and placenta leading to hypercalciuria (>300 mg/day)
Acid-base regulation	Mild respiratory alkalosis compensated by metabolic acidosis	Increase in minute ventilation compensated by more bicarbonate excretion by kidneys
Hormonal changes	Increase in erythropoietin, renin, and vitamin D Increase in level of antinatriuretic hormones, especially mineralocorticoids, aldosterone, and desoxycorticosterone Increased serum atrial natriuretic peptide levels Decrease in parathyroid hormones	

1,25 (OH)₂ D₃ 1,25-dihydroxycholecalciferol; CO, cardiac output; EDRF/NO, endothelin-derived relaxing factor/nitric oxide; GFR, glomerular filtration rate; RBF, renal blood flow.

Acute Renal Failure

Since the 1960s, the overall incidence of pregnancy-related acute renal failure (PR-ARF) has decreased from 1 per 3000 to 1 per 15,000 to 1 per 20,000. Similarly, the proportion of total cases of PR-ARF has decreased from 20% to 40% in the 1960s to 2% to 10% in the 1980s.^{9–11}

PR-ARF ranges from serum creatinine of more than 0.8 mg/dL to dialysis requirement and urine output less than 400 mL in 24 hours. Conceptually, ARF has been described as a deterioration of renal function over a period of hours and days, resulting in the failure of the kidney to excrete nitrogenous waste products and to maintain fluid and electrolyte hemostasis.¹² The Acute Dialysis Quality Initiative developed a model for diagnosis of ARF based on creatinine, glomerular filtration rate, and urine output (Table 42-2).⁸ ARF is divided into prerenal, intrarenal, and postrenal.¹² The cause of ARF in pregnancy could be due to either pregnancy-

related conditions (such as preeclampsia, acute fatty liver, amniotic fluid embolism, and hypovolumic shock) or other causes related to reproductive age women. Thus, PR-ARF is treated based on the underlying cause. Thus, every PR-ARF patient should have a detailed history, physical examination, and the laboratory assessment including complete blood count, platelet count, blood urea nitrogen, creatinine level, electrolyte, glomerular filtration rate, urinalysis, urine sodium concentration, urine osmolality, and fractional excretion of sodium. The main goal of treatment involves treatment of underlying disease, prevention of further damage, and supportive treatment until recovery. Management of PR-ARF begins with correction of the underlying causal factors by removal of renal toxins, proper dosing of medications, and prevention and treatment of infection because sepsis is the most common cause of mortality in ARF. Fluid resuscitation is the single most important intervention to restore and maintain renal perfusion. Pharmacologic

Table 42-2 Diagnostic Scheme for Acute Renal Failure

	GFR Criteria	Urine Output Criteria
Increase risk (RIFLE-R)	Increased serum creatinine $\times 1.5$ or GFR decrease $> 25\%$	UO < 0.5 mL/kg/hr $\times 6$ hr
Renal injury (RIFLE-I)	Increased serum creatinine $\times 2$ or GFR decrease $> 50\%$	UO < 0.5 mL/kg/hr $\times 12$ hr
Renal failure (RIFLE-F)	Increased serum creatinine $\times 3$, GFR decrease 75% or serum creatinine ≥ 4 mg/dL in the setting of an acute increase ≥ 0.5 mg/dL	UO < 0.3 mL/kg/hr $\times 24$ hr or anuria $\times 12$ hr
Loss of renal function (RIFLE-L)	Persistent acute renal failure = complete loss of kidney function > 4 wk	
End-stage kidney disease (RIFLE-E)	End-stage kidney disease (> 3 mo)	

GFR, glomerular filtration rate; RIFLE, risk injury failure loss end-stage kidney disease; UO, urine output. From Bellomo R: Defining, quantifying, and classifying acute renal failure. *Crit Care Clin* 2005;21:223–237.

measures as low-dose dopamine (no significant clinical benefit¹³), loop diuretics (controversial evidence, reserved for treatment of ARF in volume overload conditions to avoid renal replacement therapy.¹⁴)

Other pharmacologic drugs such as calcium channel blockers, dopamine agonists, theophylline, *N*-acetylcysteine, and osmotic agents such as mannitol are controversial with no clear clinical benefit.¹² Complications of PR-ARF include anemia, hyperkalemia, and metabolic acidosis. Hyperkalemia can be treated with glucose and insulin or potassium-binding resins.¹² Anemia in ARF could be due to either hemolysis (uremia-induced red blood cell membrane fragility) or decreased hematopoiesis due to decreased erythropoietin levels.¹⁵ Anemia is treated initially with transfusion and then if needed erythropoietin supplementation. Renal replacement therapy, including dialysis, is initiated if these measures are insufficient or there are volume overload, refractory hyperkalemia, metabolic acidosis, symptomatic uremia including pericarditis, neuropathy, and mental status changes. In PR-ARF, the most common problems that neonates face are related to prematurity. Adverse perinatal outcome is mainly related to altered uteroplacental hemodynamics. Thus, a multidisciplinary team approach including a neonatologist, nephrologist, and perinatologist is crucial to optimize the pregnancy outcome.

Underlying Renal Disease or Renal Insufficiency

The diagnosis of renal disease before pregnancy ranges between 0.03%¹⁶ and 0.12%.¹⁷ The prevalence of moderate to severe renal insufficiency ranges between 2 per 10,000¹⁸ to 6 per 10,000.¹⁹ In pregnancy, renal insufficiency could be mild (serum creatinine levels of 0.9–1.4 mg/dL), moderate (1.4–2.5 mg/dL), or severe (> 2.5 mg/dL).^{20,21} There are many different causes of chronic renal disease including diabetes, glomerulonephritis, hypertension, lupus nephritis, IgA nephropathy, and polycystic kidney disease. The natural history of renal disease during and after pregnancy depends mostly on the prepregnant renal function status and the presence or absence of hypertension.

EFFECT OF PREGNANCY ON RENAL DISEASE

The long-term effect of pregnancy on renal disease remains controversial. These patients may experience deterioration of renal function (increase in serum creatinine and worsening of proteinuria) and may be more prone to escalating hypertension. Early in pregnancy, an increase in glomerular filtration rate and a decrease in serum creatinine occur in all patients with renal disease except those with severe renal impairment.

The serum creatinine level begins to increase to and beyond prepregnancy levels during the second trimester.²² It is not possible, however, to predict which patients with renal insufficiency will experience a permanent reduction in renal function. This deterioration occurs more frequently in women with diffuse glomerulonephritis. If renal function significantly worsens during gestation, termination of pregnancy may not reverse the process. Abortion therefore cannot be routinely recommended for patients who become pregnant and whose baseline serum creatinine level exceeds 1.5 mg/dL. Ideally, patients with chronic renal disease should be thoroughly counseled about the possible consequences of pregnancy before conception. Hypertension is the greatest threat in pregnancies complicated by preexisting renal disease. Approximately 50% of these patients will have worsening hypertension as pregnancy progresses, and diastolic blood pressures of 110 mm Hg or greater will develop in approximately 20% of cases.²³ Those patients with diffuse proliferative glomerulonephritis and nephrosclerosis are at greatest risk of developing severe hypertension. Blood pressure control is the cornerstone of successful treatment of chronic renal disease in pregnancy. Furthermore, worsening proteinuria is common and often reaches the nephrotic range.²³ Another important factor in determining development of fetal complications is maternal urea level. An increased urea level of more than 10 mmol/L is associated with polyhydramnios. A high maternal urea level leads to osmotic load in the fetus and polyuria. A maternal urea level greater than 20 to 25 mmol/L is associated with the risk of fetal death.

EFFECT OF RENAL DISEASE ON PREGNANCY

Although pregnancies complicated with chronic renal disease are at an increased risk of both maternal and perinatal morbidity, still more than 85% of women with chronic renal disease will have a surviving infant if renal function is well preserved (serum creatinine \leq 1.4 mg/dL) and in whom hypertension is absent or well controlled. Morbidities associated with chronic renal disease include development of preeclampsia, end-stage renal disease, preterm delivery, anemia, chronic hypertension, growth restriction, and cesarean section (Table 42-3). Moreover, hypertension is an indicator of poor pregnancy outcome. A pregnant woman with minimal renal dysfunction and normal blood pressure has more than a 90% chance of successful pregnancy outcome.²⁴ Conversely, adverse obstetric outcomes range from 7% to 55% in the presence of both hypertension and renal dysfunction.

PREGNANCY OUTCOME BASED ON SEVERITY OF RENAL DISEASE

The severity of renal disease indirectly affects pregnancy outcome. Patients with mild renal insufficiency have a low complication rate (4.4%–22%) and no stillbirths.²⁰ The rate of complications is higher in pregnant women with moderate to severe renal insufficiency than in women with milder disease (see Table 42-3). Almost 50% of the pregnant women with a serum creatinine level of 1.4 mg/dL or more had an increase in serum creatinine during pregnancy to a mean of 2.5 mg/dL in the third trimester.²¹ The risk of accelerated progression to end-stage renal disease is highest when the serum creatinine level is more than 2.0 mg/dL at the beginning of pregnancy.²¹ Within 6 months after delivery, 23% of such women had progression to end-stage renal disease. Moreover, women with a serum creatinine level greater than 2.0 mg/dL should be counseled that they have a one in three chance of progressing to end-stage renal disease within 1 year postpartum.²⁵

SPECIFIC PREEXISTING RENAL DISEASE IN PREGNANCY

Still, maternal and perinatal outcomes differ based on the cause of the preexisting disease. Diabetic nephropathy complicates 4% to 10% of pregnancies in women with

diabetes. It is unclear whether diabetic nephropathy is accelerated by pregnancy. A few studies have shown that pregnancy has an adverse effect on diabetic nephropathy, increasing proteinuria.²⁶ Other studies have not observed any progression or development of nephropathy in women with diabetes.²⁷ Most studies involve a small number of patients and are observational. Women with diabetic nephropathy are at increased risk of adverse maternal and fetal outcome, especially preterm delivery, intrauterine growth restriction, preeclampsia, and hypertensive complications. The rates of preterm delivery at less than 34 weeks' gestation range from 16% to 31%,²⁶ and the rates of intrauterine growth restriction range from 9% to 22%.²⁸ In addition, the rate of preeclampsia may be as high as 50%.²⁶ It is very important to maintain the blood pressure at less than 130 mm Hg systolic and less than 80 mm Hg diastolic. Angiotensin-converting enzymes and angiotensin receptor blockers are antihypertensive agents that are renoprotective but should not be used in pregnancy. Calcium channel blockers seem to have no major adverse effects on the fetus and may be renoprotective.

Collagen vascular diseases are systemic disorders of unknown cause characterized by multiorgan inflammation and unpredictable remissions and exacerbations. Renal involvement is generally an unfavorable prognostic sign. Systemic lupus erythematosus is by far the most common collagen vascular disorder encountered in obstetric practice. The activity status at conception provides no guide to the course of lupus nephropathy. The prognosis is most favorable when patients are in remission at least 6 months before conception. Proteinuria may increase during pregnancy, and the serum creatinine level may either increase or not decrease normally. Exacerbations of lupus nephropathy are usually moderate and can easily be controlled by steroid therapy. However, the course of maternal lupus nephritis is especially poor when systemic lupus erythematosus (SLE) presents during pregnancy.²⁹ SLE with superimposed preeclampsia may present with signs and symptoms indistinguishable from a flare-up of lupus nephritis. Antibody assays may help to differentiate these conditions. Increasing titers of anti-DNA antibodies or decreasing levels of complement C3 or C4 are compatible with an exacerbation of SLE.²⁹ Patients with SLE in pregnancy should receive steroid therapy if clinical or immunological signs or symptoms of disease activity develop. Hypertension should be treated with antihypertensive agents. Bobrie and colleagues²⁹ favor routine administration of steroids postpartum to prevent a flare-up.

Table 42-3 Outcome in Pregnancy Complicated by Chronic Renal Disease

Author/Pregnancy Outcome	Preeclampsia	Anemia	Chronic Hypertension	Growth Restriction	Preterm Delivery	Cesarean Rate
Trevisan et al ¹⁹	25%	48%	56%	—	60%	52%
Bar et al ²¹ (mostly mild renal insufficiency)	22%	—	—	13%	22%	24%
Jones et al ²⁰	—	—	—	37%	59%	59%

MANAGEMENT

Management should begin with prepregnancy counseling. Fertility is dependent on the degree of renal impairment. Women should be counseled about the possible deterioration of renal function during pregnancy and pregnancy-related complications such as preeclampsia and worsening hypertension. Fetal outcome should be discussed thoroughly including preterm delivery, growth restriction, and the possibility of a higher risk of fetal death, especially if there is severe renal disease or the patient is on dialysis. Factors that affect pregnancy outcome such as hypertension and the urea and serum creatinine level should be well controlled to optimize pregnancy outcome.

During pregnancy, management guidelines are based on observational and retrospective studies. The care of such high-risk pregnancies should entail a multidisciplinary approach at a tertiary center with closer surveillance and frequent visits. Maternal assessment should include serum creatinine and blood urea levels, electrolytes, albumin, cholesterol, complete blood count, platelet count, 24-hour urine collection, and urinalysis and urine culture as well as other laboratory assessments such as antinuclear antibody and complement levels if indicated. Proper control of blood pressure and the underlying cause of renal disease is crucial to improve pregnancy outcome. Prenatal visits every 2 weeks until 30 to 32 weeks and then weekly for the remainder of the pregnancy are preferable. As for fetal surveillance, we usually start at 30 to 32 weeks with weekly biophysical profiles and fetal growth assessment every 4 to 6 weeks. Uterine and umbilical Doppler flow can be used as of 24 weeks. This approach can change based on the severity of disease and other variables such as hypertension.

The role of renal biopsy during pregnancy is generally limited. The theoretical concerns are mainly the possible increased morbidity of the procedure in pregnancy. Dennis and colleagues³⁰ demonstrated complication rates of 1.6% to 4.4% including perirenal bleeding and perirenal hematoma and 17% gross hematuria. Some authors reported the following indications for renal biopsy in pregnancy: new-onset hematuria, proteinuria, or impaired renal function in the first or second trimester.³¹ However, recent reviews suggest that the invasiveness of the procedure and complications should factor in the decision to perform a renal biopsy in pregnancy.

PREGNANCY IN WOMEN WITH END-STAGE RENAL DISEASE (DIALYSIS)

The medical literature reporting outcome of dialysis in pregnancy is limited to case reports and retrospective studies from the dialysis registry. Since the first case report of a successful pregnancy in a woman on dialysis in 1971³² and an initial case series in the 1980s that suggested high rates of preterm birth, low birth weight, and refractory hypertension,³³ the overall prognosis for these patients has improved significantly. However, these pregnancies continue to be high risk, and outcomes remain quite variable. There is evidence to suggest that these improvements may be due to several modifications to the dialysis dose, frequency, and other variables³⁴⁻⁴⁰ (Table 42-4). The goal of these adjustments is to improve the pregnancy outcome by having a less uremic fetal environment, more liberal

maternal diet and fluid intake, a decrease in the amplitude of blood volume and fluid shifts, controlling hypertension, and lowering the risk of hypotension. These recommendations have significantly improved perinatal outcomes. Okundaye and colleagues³⁴ reported a 2.2% incidence of conception with a 45.6% spontaneous abortion rate, 40.2% surviving infants with 5.7% stillbirth rate, and 2.8% neonatal death. The average gestational age at delivery was 32.4 weeks in this series. Other reported fetal complications include polyhydramnios, intrauterine growth restriction, premature preterm rupture of membranes, and preterm deliveries. Historically, the standard dialysis treatment was hemodialysis. Most reported series suggest both peritoneal dialysis and hemodialysis with no major differences in morbidity. These reported series also suggest hemodialysis due to the ease of fluid control and fewer complications. Dialysis should be initiated as early as possible in pregnancy. To minimize solute and fluid shift changes, continuous renal replacement therapy was introduced.³⁴⁻⁴⁰ There is no recommendation as yet with regard to continuous renal replacement therapy use. For fetal surveillance, we recommend weekly visits at the time of fetal viability (24 weeks), fetal ultrasound scan every 4 weeks for growth assessment, weekly amniotic fluid assessment if polyhydramnios is present, frequent Doppler evaluation of umbilical and uterine arteries, and a weekly biophysical profile beginning at 28 weeks of gestation.

PREGNANCY IN WOMEN WITH A RENAL ALLOGRAFT

In women of childbearing age with a functioning renal transplant, the pregnancy rate has recently improved from 2% to 5%.⁴¹ However, many aspects must be carefully considered before a conscious decision can be made in such conditions, considering both sides, that is, on the maternal side, the influence that the pregnancy can have on renal graft outcome and maternal morbidity and, on the fetal side, the influence that the renal graft can have on fetal outcomes in both short and long term.

Maternal Effects

During pregnancy, hemodynamic, anatomical, and immunologic changes all exert an effect on the renal allograft. Both increased glomerular filtration rate and renal blood flow occur during normal pregnancy as well as in pregnancies complicated by a renal transplant and chronic renal disease.⁴² It has been suggested that this glomerular hyperfiltration can cause progressive damage to the renal allograft and eventually to glomerular sclerosis.⁴³ The short-term effects of this can be seen as increased proteinuria, especially in the last 3 months of pregnancy, and they resolve 3 months postpartum.⁴³ Pregnancy, conversely, is a state of immunologic tolerance due to immunodepressant function of lymphocytes and fetal microchimerism in the mother. This raises the concern of acute rejection as well as long-term worsening of the renal allograft. There is consensus that acute rejection during pregnancy and for 3 months postdelivery is similar to nonpregnant transplant recipients.⁴⁴ The incidence ranges from 3% to 14.5%.⁴⁴ Risk factors for acute rejection are a high serum creatinine level at conception and changes in the immunosuppressive

Table 42-4 Modifications to Dialysis in Pregnancy

Dialysis Parameters	Specific Considerations
Indications	Severe refractory metabolic acidosis Retention of toxins Refractory hyperkalemia volume overload
Dialysis frequency and procedure	>20 hr/wk with 5–6 sessions/wk Should be initiated when serum creatinine is 3.4–5.0 mg/dL or GFR <20 mL/min A nonreusable biocompatible less teratogenic Smaller surface area dialyzer can decrease ultrafiltration rate during treatments
Urea, serum bicarbonate level, and electrolyte level	Maintain serum urea level <50 mg/dL Low bicarbonate dialysate (25 mEq/L) because serum bicarbonate level decreased from 24–30 mEq/L to 18–21 mEq/L Prevent hyperphosphatemia because it can affect fetal skeletal development
Anemia	Exogenous erythropoietin needed, because therapeutic doses are higher in pregnancy Observe for side effects of erythropoietin such as hypertension Target hemoglobin 10–11 g/dL, hematocrit 30%–35% Transfusion requirements may increase IV iron may be needed; this is monitored by transferrin level (should be maintained >30%)
Nutritional consideration	Proper weight gain for better outcome; recommend 1–1.25 kg total in first trimester and 0.3 to 0.5 kg/wk in second and third trimesters Need to increase supplementation of vitamins and folate because they are removed by dialysis Avoid hypercalcemia; calciferol doses must often be reduced Protein intake should be 1.8 g/kg/day Serum albumin and transferin used to evaluate protein status
Hemodynamics	Avoid hypotension, fluid fluctuations, and volume changes to lessen the chance of fetal hypoperfusion Hypertension should be treated aggressively Maternal diastolic blood pressure should be maintained at 80–90 mm Hg Careful monitoring of maternal respiratory rate, oxygen saturation
Anticoagulation	Increased dose of heparin to prevent clotting of dialysis lines because pregnancy is a hypercoagulable state

Data from references 34–40.

drug level. Diagnosis could require a renal biopsy due to the resemblance to other diseases such as preeclampsia. High doses of steroids are the first-line treatment.

There are several medical problems in a pregnancy complicated by a renal transplant. In this population, hypertension and preeclampsia are four times more frequent than in the general population.⁴⁵ UTI is the most common complication during gestation in transplant recipients (19%–40%), particularly in women with chronic pyelonephritis or ureteral reflux as the primary cause of their renal disease.⁴⁶ Keep in mind that

UTI can be painless due to complete loss of nerve connection. This can lead to secondary complications such as rejection and papillary necrosis.⁴⁷ Thus, preventive measures such as monthly urine culture screening are recommended.

With all these changes, renal function progression in transplant recipients becomes a concern. Uncontrolled studies, mainly provided by international registries, demonstrated the persistent worsening of renal function in 15% of cases and graft loss within 2 years of pregnancy in 7% to 10% of women treated with cyclosporine and cyclosporine in emulsion and

tacrolimus.^{48,49} The majority of these studies suggested that at least two important criteria strongly affect long-term maternal renal prognosis: the serum creatinine level at conception and the interval between transplantation and conception.

Pregnancy does not have a detrimental effect on renal function if serum creatinine at conception is less than 1.5 mg/dL. However, patients with serum creatinine more than 2 mg/dL are at risk of renal impairment progression and will require dialysis within 2 years after birth.⁴⁵ Indeed, recipients with serum creatinine more than 2.5 mg/dL were three times more likely to have graft loss compared with patients with serum creatinine less than 1.5 mg/dL, as well as an increased rejection rate before (54 vs. 33%), during (13 vs. 2%), and after

pregnancy (28 vs. 5%).⁴⁵ As to the interval between transplantation and conception, the important conclusion from the available studies is that the optimal interval for conception is more than 2 and less than 5 years post-transplantation. In fact, recipients who became pregnant less than 2 years after transplantation experienced more frequent rejections and long-term worsening in renal function as well as worse fetal prognosis.⁵⁰ However, too long an interval (>5 years) can have a deleterious effect on pregnancy outcome because of older maternal age and renal function deterioration over time.⁵⁰ Thus, renal function, blood pressure, proteinuria, and adequate interval from transplantation to conception are the most important factors in predicting good maternal and graft outcomes.

Table 42-5 Recommendations for Management of Pregnancy in Kidney Transplant Recipients

Please refer to the printed publication.

Another major concern is the impact of a renal transplant on maternal mortality. It is estimated that 10% of renal transplant patients die within 7 years of pregnancy and 50% within 15 years.

Fetal Effects

These pregnancies have several perinatal complications including intrauterine growth restriction (20%–30%), prematurity (40%–60%), perinatal mortality, neonatal death (10-fold more than general population), congenital malformations, and long-term developmental effects. As for long-term effects, there are few data on long-term effects on offspring and pediatric follow-up is scarce. Stanley and colleagues⁵¹ reported during a follow-up period of 4 months to 12 years among 175 children of 133 women on steroids plus cyclosporine, 29 children (16%) had delayed development or at the age of 5 to 12 years, 10 (14%) needed educational support and eight (11%) required medication for attention-deficit/hyperactivity disorder.

Based on the described maternal and fetal outcomes, there should be a multidisciplinary team approach used in these pregnancies with very close follow-up before conception, during pregnancy, and in the postpartum period (Table 42-5). Cesarean delivery is only recommended for obstetric indications. However, studies have shown more frequent cesarean deliveries in women with a transplant, ranging between 25% and 80%.

All women of childbearing age with a renal transplant should have prepregnancy counseling. Generally, women with chronic renal disease should plan a pregnancy before the serum creatinine level reaches values greater than 2 mg/dL and with well-controlled blood pressure and minimal protein. If the serum creatinine is more than 2 mg/dL, women might consider delaying pregnancy until after transplantation. Post-transplantation, all women should be advised to use an effective contraceptive method for at least 1 year. Fertility and ovulation usually return to normal as of the first month after transplantation. The use of intrauterine devices is discouraged due to risk of infection. Low-dose birth control pills are recommended.

Although few children are afflicted with serious renal disease, a wide variety of nephrologic problems may present in childhood. Many of these same problems may also be found in adults, but in children, there are often significant differences in the etiology, the approach to diagnostic evaluation, and therapy. Moreover, the low incidence of pediatric renal disease has often precluded the execution of large controlled studies to provide evidence-based assessments of specific treatments. As a result, many therapies in children are either empiric or based on experiences drawn from treating adults. An additional distinguishing and important feature of the approach to therapy in the child is the need to consider the effect of any intervention on the child's ongoing physical and cognitive development. In this chapter, many of the more common renal conditions in children are discussed, with particular attention to the aspects of management or therapy most germane to the pediatric patient that may contrast with the approach to the adult patient with a similar problem.

PROTEINURIA

As a common and readily detected sign of renal disease, proteinuria often triggers a diagnostic evaluation for significant underlying renal pathology. As with adults, all children excrete a small amount of protein daily in their urine. Normal parameters are related to both size and age, and, as a general rule, children younger than 10 years of age rarely excrete more than 100 mg of urinary protein per day.¹ In older children and adolescents, urinary protein excretion can increase to as much as the 150 to 200 mg/day threshold considered normal in adults.² In most children, proteinuria is asymptomatic and detected as part of a general examination during which a random sample of urine is assayed by a qualitative colorimetric test strip. In urine samples in which a more precise estimation of protein excretion is needed, a urinary protein-to-creatinine ratio

can prove more useful and has been demonstrated to be an accurate method for assessing daily protein excretion in children.³ A ratio less than 0.5 in a child younger than 2 years old or less than 0.2 in an older child is considered normal. These ratios can be followed to assess changes in proteinuria over time and have, for the most part, replaced routine 24-hour urine collections, which are often cumbersome to collect and inaccurate in pediatric patients.

Isolated proteinuria is a relatively common finding in children. As reported in several studies, mass screening of schoolchildren for proteinuria points to a prevalence between 5% and 10%.^{4,5} Proteinuria appears to be more common in adolescence than early childhood. Most proteinuria in childhood is transient and not indicative of renal disease. When nearly 9000 schoolchildren in Helsinki were followed for 1 year with intermittent urine samples, 10% were found to have proteinuria more than 1+ on urinary dipstick on an initial screen.⁶ Only 2.5% were found to have persistent proteinuria on one of an additional three follow-up collections. Similarly, in a large survey done in pediatric office practice, only 10% of children initially found to have proteinuria on dipstick still manifested proteinuria 1 year later.⁴ Such studies have called into question the utility of regular urinary screenings to detect early kidney disease because, in the vast majority of asymptomatic children, any detected abnormality tends to clear spontaneously.

Transient proteinuria often accompanies stress, acute febrile illness, or exercise. Such isolated proteinuria is thought to be most likely mediated by intrarenal hemodynamic changes, decreasing renal plasma flow out of proportion to glomerular filtration rate (GFR) and enhancing the concentration gradient of protein into Bowman's space.⁷ There is no long-term residual renal damage with transient proteinuria, and these children do not require a diagnostic evaluation.

With persistent proteinuria, fixed proteinuria should be distinguished from orthostatic proteinuria. With fixed proteinuria,

every urine sample has significant proteinuria; with orthostatic proteinuria, protein excretion is linked to body position. Thus, with orthostatic proteinuria, abnormally high rates of protein excretion occur while the child is upright or ambulatory and normal protein excretion ensues when the child is recumbent. The mechanism of orthostatic proteinuria is thought to arise from an enhanced renal sensitivity to the normal hemodynamic and hormonal alterations that occur with changes in position, resulting in enhanced glomerular protein permeability.⁸

Orthostatic proteinuria is quite common and accounts for as much as two thirds of pediatric proteinuria, especially in adolescents. Generally, in orthostatic proteinuria, excretion of urinary protein is less than 1 g/day.^{5,6} Many children go on to clear their postural proteinuria with time, but some may always demonstrate orthostatic proteinuria. Most follow-up studies of individuals found to have postural proteinuria point to no increased incidence of long-term renal disease as long as the proteinuria is an isolated finding and not accompanied by hematuria, an active urinary sediment, or hypertension.⁹ However, some patients with orthostatic proteinuria followed for more than 35 years did demonstrate late-onset renal insufficiency.¹⁰

With persistent nonorthostatic proteinuria, a diagnostic evaluation usually ensues to rule out any underlying glomerular or renal parenchymal disease. With increasing daily excretion of urinary protein of more than 1 g in the adolescent or more than 600 mg/m² in the younger child, there must be an increased index of clinical suspicion that there may be more serious ongoing renal disease, and these children often proceed to renal biopsy.¹¹

In children with lower grade fixed isolated proteinuria, the majority exhibit no evidence of progressive renal disease. Most of these children demonstrate normal or nonspecific changes on renal biopsy. However, some children will have evidence of focal segmental glomerulosclerosis on renal biopsy.^{12,13} These children often have higher levels of proteinuria that may exceed nephrotic range over time and nearly 50% progress to end-stage renal disease (ESRD). Thus, in children with any element of fixed proteinuria, there should be long-term follow-up to monitor the degree of proteinuria and to assess for the development of hematuria, hypertension, or renal insufficiency.

The diagnostic evaluation of the child with proteinuria is best done in phases (Box 43-1). The evaluation is focused on confirming and quantifying proteinuria, distinguishing fixed proteinuria from orthostatic proteinuria, and identifying whether the proteinuria is isolated or whether there are accompanying clinical signs or symptoms suggestive of increased likelihood of renal disease. The child who has proteinuria as part of the nephrotic syndrome should be considered separately because the evaluation, as well as the management and prognosis, varies.

NEPHROTIC SYNDROME

Because of the overwhelming preponderance of minimal change disease as the cause of nephrosis in the prepubertal child (Table 43-1), the initial evaluation and management of nephrotic syndrome in children differ from the approach

for adults.¹⁴ It is much less likely for children to undergo an extensive initial laboratory evaluation or a renal biopsy and much more likely for them to be placed on empiric steroid therapy. Moreover, the vast majority of children with nephrotic syndrome eventually outgrow this as a recurrent problem, with no long-term compromise of renal function.¹⁵

Nephrotic syndrome in children is characterized by massive proteinuria exceeding 50 mg/kg/day or 40 mg/m²/hr. Serum albumin levels will be less than 2.5 g/dL and may often be profoundly depressed (<0.5 g/dL). Edema may be quite problematic, especially at presentation or during protracted relapses. Hyperlipidemia may also be quite pronounced, especially in light of normal pediatric cholesterol levels rarely exceeding 180 mg/dL.

In children younger than 16 years of age, the annual incidence of nephrotic syndrome is 2 per 100,000, with a cumulative prevalence of just less than 20 per 100,000.¹⁶ Presentation in the first year of life is uncommon and especially in the first 3 months of life should raise the suspicion of congenital nephrotic syndrome, a condition quite unlike minimal change nephrosis both in its cause and long-term prognosis.¹⁴ Typically, most children with nephrosis present between 2 and 6 years of age, and in younger children, there is up to a 2:1 ratio of affected boys to girls.¹⁷ In older children and adolescents

Box 43-1 Diagnostic Evaluation of Asymptomatic Proteinuria in the Child

Phase 1

Reconfirm proteinuria in random urine sample
Microscopic urinalysis to assess for red or white blood cells, casts, or crystals
Focused history and physical examination: urinary tract infection, family history of renal disease, growth parameters, blood pressure, presence of edema or rash

Phase 2

Serum creatinine
Assess for postural proteinuria by comparing proteinuria in first morning urine sample with random void later in day
If postural proteinuria confirmed with normal renal function, no further evaluation. Child needs annual follow-up

Phase 3

Quantitate proteinuria with urinary protein-to-creatinine ratio or timed collection
Other blood work as clinically indicated: albumin, cholesterol, antinuclear antibody, serologies
Renal ultrasonography
Consider voiding cystourethrography if ultrasonography suggests reflux or scarring

Phase 4

Consider renal biopsy if active urinary sediment, significant microhematuria or macrohematuria, fixed proteinuria that is exacerbating or .600 mg/m²/day, hypertension, renal insufficiency, or family history of end-stage renal disease

Table 43-1 Etiology of Nephrotic Syndrome in Children Who Had a Biopsy at Presentation

Histologic Category	Frequency (%)
Minimal change	77
Focal and segmental glomerulosclerosis	9
Membranoproliferative glomerulonephritis	7
Other or unclassified	5
Mesangial proliferative glomerulonephritis	2

Based on data from International Study of Kidney Disease in Children: Nephrotic syndrome in children: Prediction of histopathology from clinical and laboratory characteristics at time of diagnosis. *Kidney Int* 1981;13:159–165.

who present with nephrotic syndrome, this ratio is closer to 1:1.¹⁸ There appear to be racial differences in the virulence of nephrotic syndrome in children. For instance, in North America, data suggest that African American and Hispanic children are more likely to have steroid-resistant disease that progresses to end-stage renal failure.¹⁹

Minimal Change Disease

The typical child with minimal change disease presents following a nonspecific viral illness. Many children are first brought to medical attention because of periorbital edema, and it is quite common to elicit a history that the child has been given diphenhydramine for “allergies,” but the edema has not abated. Clinically, minimal change disease can be distinguished from nephritis or other chronic glomerulopathies by the absence of signs or symptoms consistent with glomerular inflammation. Thus, it is quite uncommon to see a child with minimal change disease present with macroscopic hematuria, severe hypertension, or azotemia.¹⁴ Pertinent clinical characteristics and their frequency in minimal change disease are outlined in Table 43-2.

In a prepubertal child with nephrosis, normal blood pressure, nonnephrotic urinary sediment, and normal renal function, the presumed diagnosis is minimal change disease, and empiric steroid therapy is indicated. Most pediatric centers start such children on prednisone 60 mg/m²/day or its equivalent to a maximum dose of 80 mg/day. The steroid dose may be given in one total daily dose or divided according to local practice or parental preference. Most children with minimal change disease respond to steroid therapy within 2 weeks, and more than 90% of children who are steroid responsive respond by 4 weeks of daily steroid therapy.²⁰ Lack of response to oral steroids after 6 to 8 weeks of daily therapy should prompt reassessment of the treatment regimen and may call for renal biopsy.

Treatment lengths vary for the child who presents with presumed minimal change disease, but there is evidence to suggest that an initial 3- to 4-month steroid regimen combining daily and then alternate-day therapy may result in fewer relapses.²¹ A typical regimen for a newly diagnosed case of pediatric nephrosis would be prednisone 60 mg/m²/day for

Table 43-2 Frequency of Clinical Characteristics in Pediatric Nephrosis at Presentation

Clinical Characteristic	Minimal Change (%)	Focal Sclerosis (%)
Age < 6 yr	80	50
Male gender	60	70
Hypertension	20	50
Microhematuria	25	50
Increased serum creatinine	30	40

Based on data from International Study of Kidney Disease in Children: Nephrotic syndrome in children: Prediction of histopathology from clinical and laboratory characteristics at time of diagnosis. *Kidney Int* 1981;13:159–165.

4 weeks. If remission has yet to be achieved, this dose would be continued for as much as an additional 4 weeks. If remission is achieved, then after 4 weeks of daily therapy, prednisone would be tapered to 40 mg/m² on alternate days for 1 to 2 months, and then the dose tapered by 10 mg/m² every 1 to 2 weeks over the next 1 to 2 months.

In relapses, daily steroid therapy at a dose of 60 mg/m²/day is often used until remission is induced, and then a tapering steroid course is initiated over weeks to months depending on the patient’s individual history. With frequent relapses, long-term use of low-dose alternate-day therapy in the range of 10 to 15 mg/m² may actually reduce overall steroid burden by sustaining remission and minimizing exposure to daily high-dose steroid therapy.

Minimal change disease in children is a relapsing condition. Less than 20% of affected children have only one episode of nephrosis, whereas nearly 50% frequently relapse, with three or more relapses within 6 months of presentation.²² Between 30% and 40% of children become steroid dependent, having relapses while still being treated with steroids or within 2 weeks of concluding steroid therapy. Sequelae of steroid therapy are common and include hypertension, loss of bone density, cataracts, gastritis, emotional lability, and increased susceptibility to infection. An adverse effect of chronic steroid use of particular concern in children is growth impairment. A child’s somatic growth must be monitored quite closely and standardized growth charts used to assess growth velocity.

The development of significant steroid sequelae is the most common impetus for consideration of alternative drug therapy in minimal change disease. Most commonly, alkylating agents such as cyclophosphamide and chlorambucil are used. A daily dose of cyclophosphamide 2 to 3 mg/kg for 8 to 12 weeks to a cumulative dose of 168 mg/kg has proved quite effective.^{23,24} Nearly 70% of steroid-sensitive children are in remission for at least 1 year and 40% remain in a sustained remission for at least 5 years.²³ Alkylating agents seem most efficacious in steroid-sensitive children who have frequent relapses but are somewhat less effective in inducing long-term remission in children with steroid-dependent disease.²⁵ Cyclophosphamide

has also been shown to be effective in converting approximately one third of children with steroid-resistant disease to steroid responsiveness.^{26,27} In steroid-sensitive children, these agents seem to work best if given while the child is in remission and on concomitant steroid therapy.

There are multiple toxicities associated with the use of alkylating agents. Acutely, bone marrow suppression is common, and patients must be monitored for leukopenia. Other acute toxicities include alopecia, gastrointestinal discomfort, and hemorrhagic cystitis. With chlorambucil, there is also a small risk of idiosyncratic seizures. Longer term complications include dose-related gonadal toxicity and concerns regarding future malignancies, although no direct data exist linking alkylating agent use in nephrotic children with increased rates of future malignancies.

In children with particularly recalcitrant minimal change disease, calcineurin inhibitors such as cyclosporine may induce remission.^{28–30} An initial dose of 6 mg/kg/day divided into two doses often induces and sustains a remission, and most children with minimal change disease can be weaned off steroid therapy and steroid sequelae will improve. After a period of remission, cyclosporine may be tapered or discontinued. If relapses occur, the child may be placed back on steroids to see whether the nephrotic syndrome now follows a less relapsing and more steroid-sensitive course or, if necessary, placed back on cyclosporine therapy. Cyclosporine levels need to be monitored closely and changes in renal function carefully assessed. Some children on long-term cyclosporine therapy with increasing serum creatinine values may require interval renal biopsies to assess for histologic changes compatible with cyclosporine-induced nephrotoxicity. Interestingly, cyclosporine-associated arteriopathy seems to recede after cessation of cyclosporine in children with nephrotic syndrome, whereas tubulointerstitial changes and focal glomerular lesions do not regress.³¹

In an attempt to prolong remission and to spare overall steroid burden, multiple medications have been used as adjunctive therapy in minimal change disease. Levamisole, an anthelmintic immunostimulant, appears to be beneficial in maintaining remissions.^{32,33} Levamisole is generally given orally concurrently with tapering doses of steroids over the course of many months to several years. Unlike the alkylating agents, levamisole does not seem to have as dramatic an effect on the natural history of minimal change disease, and children who had frequent relapses tend to begin to have relapses more frequently again after levamisole therapy is discontinued. Although widely used in parts of Europe and Asia, the drug has been employed less commonly in North America due to problems with its availability and clinician inexperience with its prescription. Adverse effects are rare with levamisole therapy but include agranulocytosis, liver function abnormalities, and an antineutrophil cytoplasmic antibody-positive vasculitis syndrome after protracted therapy.³⁴

Azathioprine and, more recently, mycophenolate mofetil (MMF) have also been used as steroid-sparing agents. Although there is no indication that azathioprine is advantageous as monotherapy, its concurrent use with steroids may allow tapering of steroids to low enough doses to ameliorate or preclude steroid sequelae.³⁵ There have been several case reports or small series of children with minimal change disease treated with MMF. In the largest multicenter study, 32 children with frequently relapsing nephrotic syndrome were treated

with MMF 600 mg/m² (maximal dose 1 g) twice daily for 6 months.³⁶ For the first 16 weeks of MMF therapy, steroids were also provided at 1 mg/kg on alternate days for the first 8 weeks and then 0.5 mg/kg on alternate days for weeks 9 to 16. Persistent remission was seen in 24 children (75%) during MMF therapy. After MMF was discontinued, eight children remained in a sustained remission off all therapy, with follow-up ranging from 18 to 30 months.

Most children with minimal change disease eventually outgrow their disease and by early adulthood are in long-term remission and considered cured. These children do not appear to be at increased risk of other renal disease or of developing functional renal impairment. Early follow-up studies identified that nearly 15% of affected children may continue to have relapses as adults.¹⁵ Newer longitudinal data from two large pediatric centers point toward as many as one third of adults with a history of pediatric minimal change disease having at least one relapse of nephrosis as an adult.^{37,38} Most often, the relapses are infrequent and continue to follow a steroid-sensitive pattern.

Focal Segmental Glomerulosclerosis

Approximately 10% to 15% of prepubertal children with nephrotic syndrome have focal segmental glomerulosclerosis (FSGS). This incidence increases to more than one third of affected adolescents.³⁹ The median age at onset of FSGS is 6 years, and, similar to minimal change disease, there seems to be a male gender predisposition in young children. Most affected children present acutely with nephrotic syndrome, but nearly one fourth can present initially with asymptomatic proteinuria. Children with FSGS are more likely to manifest microhematuria, hypertension, and renal insufficiency at presentation than children with minimal change disease¹⁴ (see Table 43-2).

Almost all children with FSGS are likely to have the idiopathic or primary form. Renal biopsy reveals focal involvement, with some areas of the kidney appearing absolutely normal and other areas showing segmental capillary collapse, mesangial matrix proliferation, and frank sclerosis.⁴⁰ The same histology may be seen in secondary FSGS, in which focal glomerular disease arises as a result of a concomitant renal insult, a nephrotoxin, or systemic disease such as reflux nephropathy, heroin-induced nephropathy, or human immunodeficiency virus.⁴¹

The clinical course of idiopathic FSGS in children is often characterized by steroid-resistant disease. Although as many as one third of children with FSGS respond to an 8-week trial of oral steroids, many initial responders later go on to become steroid unresponsive.⁴² With steroid-unresponsive disease, there are few data to suggest that an oral alkylating agent by itself is likely to have a beneficial effect; in fact, one study comparing alternate-day steroid therapy with alternate-day steroids and cyclophosphamide found equivalent remission rates.⁴³ Children who do show sensitivity to initial oral therapy with steroids or alkylating agents are more likely to have less aggressive disease and may follow a course with few relapses or with sustained remissions.^{44,45}

In children with FSGS who do not respond to initial therapy, more aggressive immunosuppressive regimens have met with some success in inducing partial or complete remission. Unfortunately, evaluation of treatment efficacy and comparison of

treatment approach have been complicated by the lack of randomized or well-controlled studies in children with this disease. Many clinicians now use a 10-week induction course of frequent pulse intravenous methylprednisolone and concomitant oral prednisone to achieve a remission and then attempt to maintain a remission with continued oral steroids and less frequent intravenous pulses.⁴⁶ Initial treatment failure or any improvement with relapse leads to reinduction and the addition of a 3-month course of oral cyclophosphamide. In some reports, nearly three fourths of children achieve a long-term partial or complete remission of their FSGS following this type of protocol.⁴⁷ Other reports have demonstrated considerably less long-term efficacy and have also raised the issues that black children may not respond as well to such treatment and that there may be serious clinical complications that arise related to the high-dose steroids and the potential for repeated courses of alkylating agents.^{48,49}

Cyclosporine has also been shown capable of inducing a partial or complete remission in many children with FSGS.⁵⁰⁻⁵² Doses of 5 to 6 mg/kg in one single daily dose or divided into two equal daily doses have been used. Although this approach avoids many of the sequelae of therapy with high-dose steroids or alkylating agents, children with FSGS who respond to cyclosporine almost always have a relapse if cyclosporine therapy is withdrawn and thus remain cyclosporine dependent. As a result, some children treated with cyclosporine are at risk of developing long-term nephropathy due to chronic exposure to calcineurin inhibitors.⁵³ Consequently, attention to cyclosporine levels and serum creatinine must be part of the regular follow-up, and some patients may require intermittent renal biopsy to assess possible drug nephrotoxicity. There are data to suggest that children with FSGS who are treated with cyclosporine may have a less rapid progression to ESRD, with one trial demonstrating only one fourth of cyclosporine-treated patients progressing to ESRD within 5 years of diagnosis compared with more than three fourths of historical controls who had been steroid and cyclophosphamide resistant.⁵⁴

In children resistant to cyclosporine, tacrolimus therapy may also be beneficial. In a report of 16 Canadian children with steroid- and cyclosporine-resistant nephrosis, 13 with confirmed FSGS on biopsy, 13 went into a complete remission and 2 went into a partial remission after a mean of 2 months on tacrolimus therapy.⁵⁵

Many clinicians have begun to use angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers as adjunctive therapy in children with FSGS.^{56,57} These agents decrease glomerular filtration through their interaction with the homeostatic mechanisms involved with maintaining glomerular perfusion. As a result of the decrease in GFR, there is concomitantly less proteinuria. Although serum albumin levels may increase with the decreased proteinuria, they do not generally become normal in children with FSGS. However, the decreased proteinuria and the alteration in glomerular hemodynamics are thought to be beneficial in decreasing the rate of glomerulosclerosis.

Similar to the experience with minimal change disease, there are limited data as to the utility of therapy with MMF in FSGS.^{58,59} Some reports point toward its efficacy in children with FSGS who have been unresponsive to oral steroids or a combination of oral steroids and alkylating agents. It is often used in combination with ACE inhibitors or angiotensin

receptor blockers to see whether there is a synergistic effect on reducing proteinuria.

A multicenter trial of therapy in pediatric FSGS is now ongoing, comparing a regimen of cyclosporine, alternate-day steroids, and angiotensin blockade with a second regimen using MMF, alternate-day steroids, and angiotensin blockade. Other therapies reported successful in very small numbers of children include plasmapheresis and the use of the anti-CD 20 receptor monoclonal rituximab, but more data are needed to substantiate the efficacy of either approach. Unlike the uniformly excellent long-term prognosis seen in minimal change disease, a substantial number of children with FSGS manifest eventual renal insufficiency. Approximately one fourth of affected children reach ESRD as early as 5 years after disease onset.⁶⁰ Pediatric registry data confirm that FSGS is the most common glomerular disease leading to renal replacement therapy in children.⁶¹

In children undergoing renal transplantation for FSGS, recurrent disease may commonly be seen, often in the immediate postoperative period. Although recurrent disease can be treated successfully, generally using a combined approach of plasmapheresis and intensification of immunosuppression, there is accelerated graft loss in recurrent FSGS, and the usual graft survival advantage seen with kidneys donated from living donors is lost in children with FSGS who undergo transplantation.⁶²

The cause of idiopathic FSGS in children is unknown. However, in many children with FSGS, a circulating lymphokine has been isolated that increases the albumin permeability of perfused rat glomeruli *in vitro*.⁶³ Some children with recurrent FSGS after renal transplantation appear to manifest more permeability in this assay, leading to speculation that they may have a more virulent circulating factor. The ability to induce a remission with the use of therapies aimed at immunomodulation and lymphokine removal, such as pheresis, also seems to support the role of some systemic factor in this disease.⁶⁴

Recent genetic studies in children with FSGS point toward both an autosomal dominant and autosomal recessive mode of inheritance in some children with steroid-resistant disease.⁶⁵⁻⁶⁸ These studies arose initially from the observation that although nephrotic syndrome is rare in the sibling of an affected child, in those cases of apparent familial nephrosis, steroid-unresponsive FSGS was the common lesion. Unlike idiopathic FSGS, this form of the disease is less likely to respond to any immunomodulatory therapy and also unlikely to recur in a renal allograft. As the molecular genetics of this condition continue to be discerned, it may lead to an ability to screen children with nephrotic syndrome and avoid exposure to unnecessary and potentially toxic drug therapies in children with certain genotypes. Currently, most pediatric nephrologists advise genetic screening for children with steroid-resistant FSGS or a family history of consanguinity or previously reported nephrosis.

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome is a rare condition generally diagnosed in the initial months of life. Although prenatal diagnosis has been reported as a result of alterations in amniotic fluid volume and protein content, infants may also present with edema and the associated proteinuria and hypoalbuminemia are then discerned. The etiology of

congenital nephrotic syndrome generally follows one of three subtypes: (1) related to intrauterine or congenital infection, (2) related to diffuse mesangial sclerosis (DMS) as part of Denys-Drash syndrome or as an isolated mutation in the *WT1* gene, or (3) related to a defect in the podocyte protein nephrin as part of a mutation in the *NPHS1* gene commonly referred to as Finnish-type congenital nephrotic syndrome (CNF). A recent review of 89 European children with infantile nephrosis (presentation at younger than 1 year of age) confirmed that genetic mutations can be detected in two thirds of affected families, and in the children with congenital nephrosis in this cohort, 85% had *NPHS1* mutations linked to CNF.⁶⁹

History and physical examination often help guide the initial diagnostic evaluation, and renal biopsy can provide a definitive histologic diagnosis. Congenital infections such as syphilis can be excluded with negative TORCH titers (a panel antibody screen for toxoplasmosis, syphilis, rubella, cytomegalovirus, and herpesvirus) and the absence of early rash, jaundice, or hepatosplenomegaly in the infant. In the extremely rare instance of congenital infection, treatment of the underlying infection should lead to resolution of nephrosis. With other forms of congenital nephrotic syndrome, the long-term renal prognosis is guarded and most of these children inevitably progress to ESRD.

DMS may be isolated or related to Denys-Drash syndrome with associated pseudohermaphroditism and Wilms' tumor. Mutations in the *WT1* gene, a transcription factor that plays a key role in normal development and function of the urogenital tract, are associated with Denys-Drash syndrome.⁷⁰ Abnormalities in *WT1* are well described in Wilms' tumor and other urogenital anomalies, but its exact role as a mediator of glomerular pathology in DMS is unclear.

Detection and appropriate resection and follow-up of Wilms' tumor or other urogenital malignancy are critical components of the care of an infant with DMS due to Denys-Drash syndrome. Other therapy is aimed at management of the sequelae of nephrosis-range proteinuria and may involve frequent infusion of 25% albumin, intensive nutritional therapy, and other supportive care. Children with DMS may have slower progression of their renal insufficiency than children with CNF and may have less profound protein losses, making their management somewhat less complex and more open to options such as unilateral nephrectomy or the use of high-dose ACE inhibitors or prostaglandin inhibitors to decrease glomerular filtration and overall protein losses in the urine to more acceptable levels.⁷¹

Renal transplantation is the ultimate treatment for children with DMS. Most children do well after transplantation without disease recurrence.⁷² Because of concerns regarding an incomplete Denys-Drash syndrome, even in children with apparently isolated DMS, bilateral nephrectomy at the time of transplantation or onset of ESRD is recommended.⁷³

CNF is an autosomal recessive disorder most common in, but not exclusive to, people of Finnish heritage. It results from genetic mutations in the *NPHS1* gene that encodes for nephrin, an adhesion protein exclusively expressed in the podocyte and a main component of the slit diaphragm.⁷⁴ The exact mechanism of nephrosis due to nephrin anomalies remains unclear. If there is no family history

of CNF, it may be suspected in an infant with congenital nephrotic syndrome and none of the manifestations of Denys-Drash syndrome. Infants with CNF are often born prematurely and have a large placenta, weighing more than 25% of the infant's birth weight.⁷³ There is often elevated maternal serum or amniotic fluid alpha fetoprotein in the absence of neural tube defects or other structural abnormalities.⁷⁵

Infants with CNF are at significant risk of morbidity and mortality if not treated aggressively for the sequelae of their nephrosis (Box 43-2).⁷⁶ They must receive intravenous albumin and diuretics to manage edema and are at profound risk of sepsis and thrombosis due to loss of immunoglobulin and coagulation factors in the urine. Significant improvement in long-term outcome has been accomplished by intensive medical support through early infancy until the child reaches 6 to 9 months of age, at which point bilateral nephrectomy can be performed and peritoneal dialysis initiated for several months until the child reaches an appropriate size for renal transplantation. Some infants may need to be nephrectomized earlier in infancy if they have life-threatening infections, severe thrombotic events, or failure

to thrive despite intensive therapy aimed at minimizing these complications.⁷⁷

Long-term neurodevelopmental and renal allograft outcome is quite good in children with CNF managed in this fashion.⁷⁸ In a subset of children, there can be recurrent proteinuria within a year after renal transplantation that may progress and cause renal allograft loss.⁷⁹ This posttransplantation proteinuria appears to be related to the extent of the initial nephrin mutation and whether the child has immunologically encountered nephrin before renal transplantation. In the absence of native nephrin, as seen with some CNF mutations, there may be production of antinephrin antibodies and ensuing damage to the slit diaphragms and podocytes of the transplanted kidney.⁸⁰ Some children with recurrent proteinuria have been successfully treated with plasmapheresis or the addition of cyclophosphamide to their immunosuppressive regimen.⁷⁸

HEMATURIA

Despite its rare association with malignancy or a renal condition that is progressive or requires treatment, the presence of blood in a child's urine sample often provokes significant anxiety and requires a thoughtful, cost-effective evaluation. The increased availability and use of very sensitive urinary dipsticks for screening has facilitated the identification of children with microhematuria.

In general pediatric practice, isolated microscopic hematuria is now a relatively frequent finding, with an overall prevalence rate of 1.5% of asymptomatic children screened. In a 5-year prospective study of hematuria in 12,000 schoolchildren between the ages of 6 and 12 years, the prevalence was as high as 3.3% when hematuria was defined as five or more erythrocytes per high-power microscopy field occurring in at least two of three consecutive urine samples.⁸¹ Hematuria frequency increased steadily with advancing age and was found more often in girls. In a Finnish study of nearly 9000 healthy children, 4.2% had more than six erythrocytes per high-power microscopy field.⁸² However, this number decreased to 1.1% when hematuria was defined as occurring in two or more specimens. Of note, the number of children with isolated microscopic hematuria in these studies is disproportionately large compared with the number of children who have serious functional kidney disease or a threatening anatomic anomaly, suggesting that the majority of children with microhematuria have benign or self-limited conditions.

Gross hematuria occurs far less frequently in children than microhematuria. The frequency of gross hematuria in a pediatric emergency department over a 24-month period was 0.13% of all patient encounters.⁸³ Urinary tract infection (UTI) was documented or suspected in 49% of these cases. The combined diagnoses of perineal irritation, meatal stenosis, and trauma accounted for an additional 25% of cases. Apparent glomerular disease accounted for only 9% of cases of gross hematuria. At the time of this study, it was not routine to screen for hypercalciuria in children. In a later study, 43% of children presenting with gross hematuria were found to be hypercalciuric.⁸⁴ Thus, it is likely that a significant number of these children may also have had excessive urinary calcium excretion.

Cause and Evaluation

The differential diagnosis of pediatric hematuria is large (Box 43-3). The ability to localize the source of hematuria greatly facilitates further evaluation. Urine that is tea- or cola-colored with concomitant proteinuria suggests glomerular pathology. Urine that is red or pink and is associated with clots or dysuria is most consistent with lower urinary tract

Box 43-3 Causes of Childhood Hematuria

Renal Parenchymal Disease

Glomerular

Inherited

- Benign familial hematuria
- Alport's syndrome

Primary

- IgA nephropathy
- Focal segmental glomerulosclerosis
- Membranoproliferative glomerulonephritis
- Membranous glomerulonephritis

Systemic

- Hemolytic uremic syndrome
- Henoch-Schönlein purpura
- Systemic lupus erythematosus
- Wegener's granulomatosis
- Microscopic polyarteritis
- Goodpasture's syndrome

Infectious

- Poststreptococcal glomerulonephritis
- Hepatitis B-associated glomerulonephritis
- Shunt nephritis
- Subacute bacterial endocarditis

Tubulointerstitial

Inherited

- Polycystic kidney disease
- Juvenile nephronophthisis
- Cystinosis
- Oxalosis
- Tuberous sclerosis

Acquired

- Hypercalciuria
- Nephrotoxic drugs
- Interstitial nephritis
- Renal transplant rejection

Vascular

- Renal vein thrombosis
- Renal artery thrombosis
- Sickle cell disease

Urinary Tract Disorders

- Nephrolithiasis
- Urinary tract infection
- Urethritis
- Trauma

Coagulation Disorders

- Anticoagulant use
- Hemophilia
- Thrombocytopenic purpura

bleeding. Phase-contrast microscopy allows assessment of urinary erythrocyte morphology and the presence of red cell casts is pathognomonic of glomerular hematuria. Hematuria in urine samples from a parent or sibling points to an inherited etiology. Crystalluria may connote abnormal solute excretion predisposing to nephrolithiasis.

The evaluation of hematuria begins with a careful history and physical examination. In infants, the history should include questions regarding birth asphyxia, umbilical vessel catheterization, and abnormalities detected on prenatal ultrasonography. In older children, the history should include questions regarding pain and accompanying voiding symptoms. If macroscopic hematuria exists, determining the timing of the visible hematuria during voiding is important. Gross hematuria at initiation of urination that subsequently clears suggests urethral irritation. Terminal gross hematuria suggests trigonitis. Urine that is persistently tea colored or brown is likely due to glomerulonephritis. In many children who are already independently toilet trained, there may be a significant delay between the onset of symptoms and evaluation because of the failure of the child to recognize the ramifications of hematuria.

As some causes of hematuria may be inherited, a thorough family history is invaluable. A family history of isolated microhematuria without progression to renal insufficiency would suggest benign familial hematuria (BFH). However, a family history of hematuria, proteinuria, and progressive renal failure with associated high-frequency sensorineural hearing loss or visual impairment would raise concern for a familial nephritis such as Alport's syndrome (AS). A family history of cystic kidney disease, IgA nephropathy, nephrolithiasis, coagulopathies, and sickle cell disease would also be significant.

Associated signs and symptoms often provide further etiologic clues. Dysuria, frequency, flank pain, and fever point to UTI. Radiating pain in the loin or groin is consistent with renal colic from nephrolithiasis. The presence of acute edema formation and hypertension would suggest glomerulonephritis. As glomerular disease can be part of a systemic illness, the presence of rash, abdominal pain, and joint inflammation may suggest Henoch-Schönlein purpura (HSP), systemic lupus erythematosus, or a vasculitis.

Laboratory and Radiographic Studies

If the child has at least five urinary erythrocytes per high-power microscopy field on at least two samples over a 2- to 3-week period, further investigation should proceed. Urine studies include culture and quantification of urinary calcium and creatinine. If there is a history of nephrolithiasis, quantification of urinary citrate, oxalate, and uric acid should also be considered. If the protein is greater than trace on the dipstick, especially in a dilute sample, then urinary protein and creatinine should also be quantified. Recommended serum studies include creatinine and C3 complement level to screen for renal insufficiency and chronic hypocomplementemic glomerulonephritis. When clinically appropriate, screening for systemic lupus erythematosus, hepatitis, or coagulopathies should be considered. Renal ultrasonography should be checked in all children younger than 7 years of age to rule out Wilms' tumor and in older children if there are concerns regarding structural anomalies or stones. Urine samples from parents and siblings should also be assessed for the presence of a familial hematuria.

In the absence of a history suggestive of lower urinary tract bleeding, cystoscopy is seldom indicated in the child with

isolated microhematuria. Unlike adults, bladder malignancies are quite uncommon and sonography usually suffices as a screen to detect rare structural anomalies.

Benign Familial Hematuria and Alport's Syndrome

In children, the differential diagnosis of isolated microscopic hematuria often includes BFH and AS. The ability to distinguish between these two conditions is critical because it allows accurate prognosis, although this may be difficult as the microscopic examination of the urine and early glomerular basement membrane (GBM) changes may be identical.

The renal biopsy specimen in patients with BFH is normal by light microscopy and immunofluorescence. The abnormality in BFH is apparent by electron microscopy, which demonstrates thinning of the lamina densa of the GBM. Thinning of the GBM may also be the only abnormality seen in patients with early AS or in female carriers of X-linked AS. However, the GBM abnormalities in AS continue to evolve, resulting in areas of irregular thinning, thickening, splitting, and multilamination, clearly distinguishing AS from BFH.^{85,86}

Whereas BFH is inherited in an autosomal dominant manner, AS is most often inherited in an X-linked pattern. An autosomal recessive form of AS accounts for 15% of cases, whereas the autosomal dominant form is quite rare.⁸⁵ Type IV collagen is the major structural component of the GBM, and mutations of this gene are the molecular basis for AS. X-linked AS has been attributed to mutations of the *COL4A5* gene, whereas the recessive and dominant forms are linked to mutations of the *COL4A3-COL4A4* locus.⁸⁵ Two families with BFH have had their disease linked to the *COL4A4* gene.^{87,88} These reports suggest that these BFH patients may be carriers of autosomal recessive AS. Those patients who are heterozygous for certain *COL4A4-COL4A3* locus mutations have BFH, whereas patients who have homozygous or compound heterozygous mutations in the same locus develop autosomal recessive AS.

Clinical features and family history are critical in distinguishing between BFH and AS.^{86,89} Unlike patients with AS who typically develop proteinuria and progressive renal failure, patients with BFH do not develop significant proteinuria and preserve renal function over time. In addition, patients with AS may have a family history of high-frequency sensorineural hearing loss and lenticonus. Although BFH can be distinguished from AS with some certainty based on clinical features and family history, without a confirmatory renal biopsy, it is a diagnosis of exclusion. Thus, in children with BFH as a putative diagnosis, regular follow-up must make sure that no concerning clinical or laboratory features, such as the development of proteinuria or decreasing renal function, evolve. In this event, a diagnostic renal biopsy should be performed.

Although patients with AS typically progress to ESRD as young adults, angiotensin blockade has been used with success to blunt the associated proteinuria and to slow down the loss of effective renal function, although there is significant variability among patients as to an efficacious dose.⁹⁰

Idiopathic Hypercalciuria

Hypercalciuria is present in approximately 5% of healthy white children and is diagnosed in as many as 35% of children evaluated for hematuria.^{84,91} Hypercalciuria may be secondary

to hyperparathyroidism, metabolic acidosis, distal renal tubular acidosis, vitamin D intoxication, ketogenic diet, immobilization, and therapy with loop diuretics. Most children, however, have normocalcemic idiopathic hypercalciuria. The pathogenesis of idiopathic hypercalciuria is unknown and could be secondary to increased intestinal absorption, reduced renal tubular reabsorption, increased osseous resorption, or a combination of these factors.⁹² A recent study demonstrated no major alterations of intestinal calcium absorption based on an oral strontium load test.⁹³

Hypercalciuria exists when urinary calcium excretion exceeds 4 mg/kg/day. In young children, a 24-hour collection may be impractical and calcium excretion can be estimated by a spot-urine calcium-to-creatinine ratio. Urinary calcium-to-creatinine ratios vary with geographic area and age. The variation related to geography is likely determined by race, climate, exposure to sunlight, mineral content of drinking water, and nutritional habits.⁹⁴ The ratios are much higher in infants than in older children and adults. When children and adults were studied in the northeastern United States, the 95th percentile urinary calcium-to-creatinine ratios for infants and children younger than 7 months, 8 to 18 months, and 19 months to 6 years were 0.86, 0.6, and 0.42, respectively, whereas the 95th percentile for adults was 0.22.⁹⁵ When a child's urinary calcium-to-creatinine ratio is elevated based on the normative data for the population, a definitive diagnosis of hypercalciuria should be established with a 24-hour urinary collection when possible.

Presenting clinical features of hypercalciuria include microscopic hematuria, gross hematuria, frequency dysuria, abdominal or flank pain, and urolithiasis.⁹⁶ Although there is considerable clinical overlap, macroscopic hematuria and a family history of urolithiasis have been found to be more common in hypercalciuric patients. The reported incidence of documented urolithiasis at presentation varies depending on the population studied. In a report of the Southwest Pediatric Nephrology Study Group, all children with painless isolated hematuria and hypercalciuria underwent excretory urography or renal ultrasonography at presentation, and no child had urolithiasis at diagnosis.⁸⁴ In comparison, another study focused on children with hypercalciuria who presented with painless microhematuria, dysuria, recurrent abdominal or flank pain, and a family history of nephrolithiasis.⁹⁷ All children underwent renal ultrasonography at entry; 57% had microcalculi and 5% had urolithiasis.

The natural history of idiopathic hypercalciuria is persistent hematuria and possible urolithiasis. In a longitudinal study of 58 untreated children with hematuria and hypercalciuria, 40% continued to have hematuria and 70% had hypercalciuria at 1 year.⁹⁸ At 2 and 3 years, 21 children were available for study; 40% still had hematuria and 50% had hypercalciuria. During the follow-up period, 16% of children developed urolithiasis. Children who developed stones were older when initially evaluated and were more likely to present with macroscopic hematuria, and all had a family history of urolithiasis. In the Southwest Pediatric Nephrology Study Group study, 13% of hypercalciuric patients developed urolithiasis or stone-like episode over a follow-up period of as long as 4 years.⁸⁴ In addition to hematuria and urolithiasis, idiopathic hypercalciuria has been associated with UTIs in children.⁹⁹

Hypercalciuria and hematuria clearly identify a group of children at high risk of subsequent urolithiasis. Conservative

measures should be taken, including high fluid intake and a diet low in sodium. A restricted calcium diet is not recommended and may even predispose to increased stone formation.¹⁰⁰ If citrate excretion is found to be low, citrate supplementation should be provided, preferably as the potassium salt.¹⁰¹ Children with idiopathic hypercalciuria associated with hypocitraturia may be at risk of reduced bone mineral density when compared with children with hypercalciuria and normal citrate excretion, although further studies are needed.¹⁰² If conservative measures are unsuccessful, thiazide diuretics can be considered. Thiazides can predispose, however, to electrolyte abnormalities and increased total cholesterol and low-density lipoprotein. Decisions regarding the use of thiazides for idiopathic hypercalciuria should take into consideration the clinical circumstances of the individual case, such as personal or family history of urolithiasis.

GLOMERULONEPHRITIS

Glomerulonephritis is the leading cause of acquired chronic renal failure during childhood.¹⁰³ As with adults, glomerulonephritis may be a manifestation of systemic disease, such as vasculitis or lupus, or may be due to a primary renal process. Similarly, the clinical course may be acute with subsequent full recovery or may progress to renal insufficiency. Certain forms of glomerulonephritis, such as HSP nephritis, are seen more commonly in children. In other chronic forms of glomerulonephritis, such as membranoproliferative glomerulonephritis (MPGN) and IgA nephropathy, therapeutic approaches in children have often differed from those used in adults.

Henoch-Schönlein Purpura

HSP is a multisystem IgA-mediated vasculitis predominantly affecting the skin, joints, gastrointestinal tract, and kidneys. HSP and IgA nephropathy share many immunologic and pathologic features, although HSP is a systemic disease and IgA nephropathy is clinically confined to the kidneys. Despite great research efforts, the exact pathogenesis of HSP and IgA nephropathy remains unclear. Both enhanced IgA synthesis and decreased IgA clearance have been implicated.¹⁰⁴ Total serum IgA levels are increased in 40% to 50% of these patients. Patients who develop HSP nephropathy were found to have abnormal glycosylation of serum IgA, and it has been proposed that the abnormal glycosylation may contribute to the immune complex deposition.¹⁰⁵

Histologically, both IgA nephropathy and HSP nephritis are characterized by mesangial proliferation and matrix expansion with varying degrees of epithelial cell crescent formation. Unlike IgA nephropathy, HSP nephritis may be associated with polymorphonuclear leukocyte infiltration of the glomerular tufts. Tubulointerstitial changes may be apparent but generally reflect the severity of the glomerular lesions. Immunofluorescence staining invariably reveals IgA in the mesangium, often with weaker staining for C3 and IgG. Deposits may also be seen segmentally in the capillary wall.

Although HSP can occur at any age, most cases affect children between the ages of 2 and 10 years^{106–108} and children who present at an older age may have a worse prognosis than younger children.¹⁰⁹ Unlike HSP in adults, which affects men and women equally, boys are as much as two times more likely

to develop HSP than girls.¹¹⁰ The disease is somewhat more prevalent during the winter months and early spring. The onset is usually sudden, frequently preceded by an acute illness that often involves a mucosal upper respiratory tract infection.

The clinical manifestations of HSP are due to the small-vessel vasculitis of affected organs. Hallmark signs and symptoms are a nonthrombocytopenic purpuric rash, arthralgias or a nonerosive arthritis, abdominal pain, and nephritis. The rash is often the most distinctive feature of the disease and characteristically involves the buttocks and extensor surfaces of the lower extremities in a symmetric pattern. When skin biopsies are performed, the pathology reveals leukocytoclastic vasculitis. The rash can persist for weeks, with some patients having recurrent episodes of new lesions. Angioedema may be present and involves the eyelids, lips, and dorsa of the hands and feet.

Approximately two thirds of patients have arthralgias or arthritis. Ankles and knees are the most commonly affected joints. The arthritis is nonerosive and not deforming. Gastrointestinal symptoms occur in approximately two thirds of patients, and one study found that the abdominal symptoms preceded the rash in as many as 14% of patients. The most frequent abdominal symptoms are periumbilical pain, vomiting, diarrhea, and hematochezia. Surgical emergencies develop in approximately 5% of patients, with ileoileal intussusception being the most common.¹¹¹ The acute morbidity of HSP is usually related to severe gastrointestinal complications.

The exact prevalence of nephritis in children is unknown, although rates as high as 54% have been reported.^{112,113} If nephritis is to develop, 90% of cases present within 6 weeks of diagnosis of HSP, and rarely do urinary abnormalities present later than 6 months. Therefore, if a child's urinalyses remain normal during the first 6 months after presentation, further screening for nephritis is generally not required.¹¹⁴

The long-term outlook for children with HSP depends on the extent of renal involvement, but the overall prognosis of HSP nephritis is good. In a longitudinal study of 270 patients with HSP, 1.1% developed chronic renal insufficiency.¹¹² Poor prognosis has been associated with the development of nephritic or nephrotic syndrome, initial renal insufficiency, and more than 50% crescent formation on biopsy.¹¹⁴⁻¹¹⁷ Nephritis is manifested in the majority of children as microscopic hematuria with or without proteinuria, and these patients have a good long-term prognosis.¹¹⁶ In one series, 33% of patients with HSP nephritis had nephritic features or a combined nephritic-nephrotic syndrome.¹¹² Long-term follow-up of a similar cohort of more severely affected patients found that 44% developed chronic hypertension or renal insufficiency.¹¹⁶ The majority of children have mild nephritis, recover fully, and require no specific therapy.

Once HSP has developed, there are conflicting reports about the efficacy of early prednisone therapy to prevent significant nephritis.^{117,118} More recently, two randomized, placebo-controlled studies have been published to determine the effect of 2- and 4-week courses of oral prednisone. The first study included 40 patients and reported no effect of early steroid therapy on the risk of renal involvement at 1 year.¹¹⁹ The subsequent study included 171 patients who were followed for 6 months.¹²⁰ Early prednisone treatment was effective in decreasing abdominal and joint symptoms but did not prevent renal involvement. Therapy with prednisone appeared, however, to improve the course of the

nephritis with resolution of renal symptoms in 61% of the treated patients compared with 34% of those who received placebo.

The optimal treatment of children with more extensive renal disease remains controversial. Numerous uncontrolled studies have shown benefit when patients are treated with steroids with or without other agents such as azathioprine, cyclophosphamide, and anticoagulants.¹²¹⁻¹²⁵ A randomized, controlled trial of 6 weeks of oral cyclophosphamide at 90 mg/m²/day with mean follow-up of 6.9 years did not show a difference in outcome between the two groups.¹²⁶ Plasmapheresis has also been reported to improve prognosis in a small number of children with rapidly progressive HSP nephritis.^{127,128} A recent retrospective analysis reviewed the course of 14 children with severe HSP nephritis and 2 children with IgA nephropathy who were treated with plasmapheresis and no steroids, immunomodulators, or antiplatelet agents.¹²⁹ One child with HSP was referred late and had a poor renal outcome. The remaining children with HSP who were referred early were doing well at 4 years (range, 1-7.5 years) with normal estimated GFR, no or mild proteinuria, and no need for antihypertensive agents. Well-designed, randomized, controlled studies are needed to better assess the outcomes of patients treated with various immunosuppressive regimens. ACE inhibitors should be given to patients with persistent proteinuria and glomerular scarring.

IgA Nephropathy

IgA nephropathy is the most common form of pediatric primary glomerulopathy. Initially considered a benign disease, long-term follow-up studies suggest that a significant proportion of adult patients progress to ESRD. Similarly, study of the natural history of IgA nephropathy diagnosed in childhood demonstrates progression in many patients. In a study of 103 American children diagnosed with IgA nephropathy before 18 years of age, ESRD developed in 6% of children by 5 years, 13% by 10 years, 18% by 15 years, and 30% by 20 years.¹³⁰ Similarly, a study in Japan found that 5% of children with IgA nephropathy developed chronic renal failure by 5 years after diagnosis and 11% by 15 years from onset.¹³¹

The clinical presentation of IgA nephropathy varies from asymptomatic hematuria to a mixed nephritic-nephrotic syndrome.¹³² The presence of heavy proteinuria and more active urinary sediment indicates more severe glomerular changes. The incidence of macroscopic hematuria is higher in children than adults and often occurs in association with a mucosal infection of the upper respiratory tract. The interval between the precipitating illness and an episode of macroscopic hematuria is generally 1 to 2 days. Acute renal failure is sometimes seen in flares of IgA nephropathy, although it is usually reversible. However, a small subset of patients with significant crescentic changes have a rapidly progressive course to renal failure. Other histologic correlates with poor clinical outcome include diffuse mesangial proliferation, a high proportion of glomeruli with sclerosis or capsular adhesions, and moderate to severe tubulointerstitial disease.¹³³ Persistent hypertension and heavy proteinuria also predict a more progressive course.¹³⁴

As the outcome of IgA nephropathy may be so variable, therapy remains challenging. Well-controlled studies are lacking, especially those focusing exclusively on children. Selecting the patients most likely to benefit from therapy is critical.

Patients with more severe histologic changes, heavy proteinuria, persistent hypertension, and decreased GFR at presentation should be considered for specific therapy. Studies assessing the benefit of tonsillectomy alone or in combination with other therapies have arrived at conflicting conclusions.^{135–137} A regimen of alternate-day prednisone (40–60 mg/m²) and daily azathioprine (2 mg/kg) for at least 1 year has been successful in children with severe IgA nephropathy.¹³⁸ Therapy resulted in significant decreases in proteinuria and improvement in biopsy results, most notably decreased cellular crescents. Benefits from corticosteroids, including decreased proteinuria and lower incidence of chronic renal failure, were also seen in another small cohort of children with risk factors for progressive IgA nephropathy.¹³⁹ A recent report of 181 Japanese children younger than 15 years old with biopsy-proven IgA nephropathy suggested efficacy of immunosuppressive therapy if there were proliferative changes on the renal biopsy specimen. After 7 years of follow-up, of those children with original histologic evidence of more aggressive disease, 50% had normal urinalyses and renal function and only 14% demonstrated loss of GFR.¹⁴⁰ The Japanese Pediatric IgA Nephropathy Treatment Study Group treated 78 children with IgA nephropathy with either a combination of prednisolone, azathioprine, heparin-warfarin, and dipyridamole (group 1) or heparin-warfarin and dipyridamole (group 2) for 2 years.¹⁴¹ Children in group 1 showed decreased proteinuria and a tendency toward decreased progression of glomerulosclerosis compared with group 2. In a more recent report, this group compared combination therapy with prednisone alone, demonstrating significant increased efficacy in terms of clearing proteinuria and preventing further renal scarring with combination therapy.¹⁴²

Use of fish oil and angiotensin blockade seems to decrease the loss of renal function in certain adult cohorts.^{143–146} A recent report from the Southwest Pediatric Nephrology Study Group compared outcomes in 96 patients with IgA nephropathy, normal GFR, and 1.4 to 2.2 g/day of proteinuria who were treated with one of three regimens for 2 years: fish oil (4 g/day of ω -3 fatty acids), a tapering course of alternate-day oral prednisone (60 mg/m² on alternate days for 3 months, then 40 mg/m² for 9 months, then 30 mg/m² for 1 year), or a placebo.¹⁴⁷ Hypertensive children received concomitant angiotensin blockade. Among these groups, children receiving steroids or placebo did equally well, with only 9% in each group showing a decrease in GFR less than 60% of baseline. With children receiving fish oil, 19% showed such a decrease in GFR. None of these changes were, however, statistically significant.

Studies of ACE polymorphisms have demonstrated that genotypes leading to higher levels of ACE are associated with more progressive disease.^{148,149} Angiotensin blockade remains a mainstay of therapy in IgA nephropathy when there is any significant proteinuria, and although there are not the same data as in adults, combination therapy with both ACE inhibitors and angiotensin receptor blockers is used in the hope of decreasing proteinuria and slowing progressive loss of GFR.

Postinfectious Glomerulonephritis

Postinfectious glomerulonephritis is the leading cause of acute glomerulonephritis in children and has been associated with a host of bacteria, viruses, and parasites. In children, group A β -hemolytic streptococci are the most frequently implicated

organisms, and pyoderma and pharyngitis are the classic preceding illnesses. Streptococcal pharyngitis occurs most frequently in school-age children during the cooler months. The latent period from onset of pharyngitis to acute poststreptococcal glomerulonephritis (APSGN) is typically a few weeks. Streptococcal impetigo occurs more frequently in younger children during the warmer months, and APSGN after impetigo has a longer latent period of 2 to 6 weeks. Over the past two decades, the prevalence of APSGN has been decreasing in children in the United States and South America.^{150,151}

In children who become symptomatic with APSGN, the clinical onset is typically abrupt. Approximately 85% of patients develop edema, as many as 80% have varying degrees of hypertension, as many as one third have gross hematuria, and oliguria is common.¹⁵² Hypertension may be severe during the first week of clinical nephritis, with accompanying headaches, somnolence, or seizures, and should be aggressively treated. Generally, the clinical symptoms of APSGN begin to resolve within 1 to 2 weeks as evidenced by diuresis and normalization of blood pressure. The gross hematuria fades rapidly, but microscopic hematuria may persist for years. Proteinuria typically improves rapidly and resolves within 6 months. Recurrences are rare but have been reported.^{153–155} More commonly, recurrence of gross hematuria should raise the suspicion for an underlying chronic glomerulonephritis such as IgA nephropathy, MPGN, or membranous glomerulonephritis.

Laboratory studies during a typical episode of APSGN reflect a nephritic process with activation of the alternative complement pathway. The urine sediment shows erythrocytes and leukocytes and may contain red cell casts. Proteinuria is found frequently but is rarely in the nephrotic range. GFR is often decreased, although severe azotemia is rare and should raise the concern for a rapidly progressive process. If azotemia is significant, electrolyte abnormalities including hyponatremia, hyperkalemia, and acidemia may be present. Serologic tests to document recent streptococcal infection are helpful but do not prove causation. When interpreting serologies, it is important to realize that antibiotic use may blunt the increase in titer and that a significant number of children are asymptomatic carriers of streptococci.^{156–158} Serologic tests available include antibodies against streptolysin O and the streptozyme test. The streptozyme test assesses several antibodies including streptolysin O, antideoxyribonuclease B, and antihyaluronidase. Streptolysin O binds to lipids in the skin and results in blunting of the immune response in cases of streptococcal impetigo. The antideoxyribonuclease B titer is therefore more sensitive in detecting evidence of recent streptococcal skin infection.

The majority of patients have a low total hemolytic complement and a low C3 complement with a normal C4. The C3 level typically recovers in 6 to 8 weeks, although prolonged hypocomplementemia has been reported in as many as one fourth of patients.¹⁵⁹ If the C3 remains depressed after 3 months or the C4 is low, diagnostic considerations include chronic forms of nephritis such as MPGN and lupus nephritis. The possibility of a chronic form of glomerulonephritis warrants close surveillance, and a renal biopsy should be considered. Renal biopsy is generally not indicated in typical APSGN, but may be necessary if the diagnosis is in question or if the course is consistent with rapidly progressive glomerulonephritis. The biopsy shows diffuse endocapillary proliferation, predominant IgG and C3

deposition in the capillary loop on immunofluorescence, and subepithelial dense humps on electron microscopy.

The mainstay of therapy for APSGN is supportive care. Hospitalization is recommended if the child is hypertensive or has decreased creatinine clearance. Blood pressure should be checked regularly early in the illness, and if hypertension is present, diuretic therapy with concomitant salt and fluid restriction is considered. If needed, short-acting calcium channel blockers or hydralazine can also be used. In most cases, significant improvement in hypertension, edema, and azotemia is seen within 2 weeks. In children with more persistent hypertension that does not directly respond to diuretics or vasodilation, angiotensin blockade is often used, especially if there is concomitant proteinuria. In a cohort of children with postinfectious glomerulonephritis half of whom received enalapril therapy for 6 weeks after diagnosis, enalapril-treated children had significantly earlier decreases in blood pressure as well as better short-term echocardiographic parameters.¹⁶⁰

In children whose course is consistent with rapidly progressive glomerulonephritis, an immediate renal biopsy for histologic diagnosis is warranted to guide any necessary therapeutic intervention. Intravenous methylprednisolone, with or without other agents such as cyclophosphamide, has been beneficial in the therapy of rapidly progressive glomerulonephritis of various causes in children.^{161,162} With poststreptococcal glomerulonephritis, such immunomodulation including prednisone, azathioprine, and cyclophosphamide has not been shown to change the natural course of the disease, even with significant crescentic changes.¹⁶³

In the absence of rapidly progressive disease, the prognosis for complete recovery is considered to be good even in the face of initial concerning clinical features such as renal insufficiency and significant histologic aberrations.¹⁶³ Several groups have studied the long-term prognosis of patients who initially recovered and found that 3.4% to 20% of patients developed mild residual symptoms, including proteinuria, hematuria, and hypertension.^{164–166} Azotemia develops in less than 3% of patients.¹⁶⁷ Although outcomes are good overall, these results indicate the need for regular monitoring to detect late sequelae.

Membranoproliferative Glomerulonephritis

MPGN is a chronic glomerulonephritis characterized histologically by diffuse thickening of the GBM and endocapillary proliferation and subcategorized by the location of deposits on electron microscopy. Most MPGN in children is idiopathic, although occasional secondary cases of MPGN related to hepatitis virus or other infectious etiologies occur.

Either the classical or alternative complement pathways may be involved, resulting in a low serum C3 and, less commonly, a normal or low serum C4. Hypocomplementemia has been reported in as many as 95% of children at presentation.^{168–171} In type 2 MPGN, also termed dense deposit disease, abnormal complement regulatory proteins such as aberrant factor H have been described in some patients, and these anomalies have been hypothesized to affect the alternative complement cascade and predispose to renal disease.¹⁷² MPGN is primarily a disease of older children, adolescents, and young adults and is rarely reported in children younger than 6 years of age. MPGN was diagnosed in 7.5% of children referred to

tertiary centers for renal biopsy for evaluation of nephrotic syndrome.¹⁴ At presentation, one third of children had macroscopic hematuria or hypertension, as many as two thirds had nephrosis, and one third had renal insufficiency.^{168–171} The long-term renal prognosis in children with MPGN is guarded, and natural history studies suggest that as many as 50% progress to ESRD within 10 years of onset.¹⁶⁸

The small number of affected children has hampered evaluation of putative therapies. Treatment regimens have included corticosteroids, alkylating agents, and anticoagulants. Corticosteroids have not proven beneficial in adults, although various combinations of aspirin, dipyridamole, and warfarin have resulted in diminished proteinuria and an inconsistent impact on maintaining the GFR.^{172–175} In the pediatric population, corticosteroids have shown greater benefit.^{176,177} In 71 children followed at a single center for an average of 7.7 years and mainly treated with alternate-day oral steroids, the cumulative renal survival was 82% at 10 years and 56% at 20 years after onset.¹⁷¹

The International Study of Kidney Disease in Children conducted a randomized, double-blind, placebo-controlled clinical trial in children with primary MPGN.¹⁷⁸ Criteria for enrollment included nephrosis-range proteinuria and normal renal function. Children received alternate-day oral prednisone or a lactulose placebo for a mean duration of 41 months. At 130 months, 61% of patients receiving prednisone showed stable renal function compared with only 12% of patients receiving placebo. Similarly, data from the Japanese school urinary screening program have shown efficacy to long-term steroid therapy, with 15 of 19 children receiving alternate-day steroids for 4 to 12 years manifesting normal urinary findings and complement levels, with the remaining members of this cohort having mild proteinuria alone.¹⁷⁹ Intravenous pulses of methylprednisolone followed by alternate-day oral prednisone have also been used in children, with improvement of hematuria, proteinuria, serum albumin, and creatinine clearance.¹⁷⁷ More recent data from a small cohort of children treated with either pulse intravenous steroids or oral steroids suggested greater benefit with pulse therapy. After an average follow-up of 5 years, only 1 of the 11 children receiving pulse therapy progressed to ESRD versus 4 of the 8 children on oral therapy.¹⁸⁰

Although these studies support the use of corticosteroids in children with MPGN with nephrosis-range proteinuria, benefit of the same therapy in MPGN with nonnephrosis-range proteinuria is less clear. In a retrospective study of 39 children with MPGN, the outcome of the 11 nonnephrotic patients was excellent, with 100% renal survival at 10 years¹⁷⁰; of these nonnephrotic patients, seven were untreated. In this report, the absence of nephrosis was predictive of a good long-term outcome, regardless of therapy, and suggests that a more tailored treatment approach in nonnephrotic children with MPGN may be useful.

Given the identification of complement pathway regulatory protein anomalies in some children with dense deposit disease, new approaches to its therapy have been proposed including plasma infusion or plasmapheresis and the use of specific monoclonal antibodies. These therapies are aimed at normalizing alternative pathway complement activity and, as further insight is gained into some of the genetic underpinnings of some forms of MPGN, other treatments are likely to be introduced.¹⁷²

HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome (HUS) is defined by the clinical triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. HUS is the cause of ESRD in approximately 3% of children who have received renal transplants and is a frequent cause of acute renal failure in children.^{61,181} HUS can be broadly divided into typical forms associated with prodromal diarrhea (D⁺ HUS) and atypical cases distinguished by the absence of diarrhea (D⁻ HUS). The majority of childhood cases of HUS include a diarrheal prodrome and are frequently due to infection with enterohemorrhagic *Escherichia coli* (EHEC).¹⁸² Atypical HUS is a heterogeneous disorder accounting for approximately 10% of cases in children and generally carries a poorer prognosis. Atypical HUS may result from abnormalities in complement regulatory proteins or can be precipitated by numerous triggers, including drugs, malignancies, bone marrow transplantation, and nonenteric infections such as streptococcal pneumonia.

D⁺ Hemolytic Uremic Syndrome

Although outbreaks of diarrhea-associated HUS are dramatic and draw considerable public attention, only approximately 10% of cases in children arise from epidemics.^{183,184} A variety of organisms have been implicated in the pathogenesis of HUS, including *Shigella dysenteriae* type 1, *Salmonella*, and *Yersinia*. The majority of cases, however, have been linked with EHEC, which produces a potent cytotoxin known as Shiga-like toxin or verotoxin. *E. coli* O157:H7 is the serotype isolated in more than 90% of EHEC infections in the United States.¹⁸² EHEC may be carried in the intestines of asymptomatic cattle, and higher carriage rates are noted in the summer months and early fall, mimicking the seasonal variation of human disease that peaks from June through September.¹⁸⁵

Ground beef, vegetables, unpasteurized milk or juice, and water all serve as possible vectors of disease via contamination with bovine feces. Rarely, child-to-child transmission also occurs via oral-fecal contamination.¹⁸⁶ Although children of all ages can be infected, the highest attack rate for *E. coli* O157:H7 infection occurs among children younger than 5 years of age.¹⁸⁷ Infected children may excrete the organism in stool for as long as 3 weeks. Approximately 10% to 15% of children who develop culture-confirmed *E. coli* O157:H7 gastroenteritis progress to HUS, and the risk of progressing to HUS may be increased with use of antimotility agents early in the course of colitis.^{183,188}

Central to the pathogenesis of HUS is microvascular endothelial cell injury. Only a small inoculum of 50 to 100 EHEC organisms is required to colonize the intestine.¹⁸⁷ Once established, EHEC elaborates verotoxin leading to intestinal hemorrhagic and ulcerative lesions. With the integrity of the intestinal mucosa compromised, verotoxin gains access to the circulation and extraintestinal sites. Verotoxin is composed of one A subunit and five B subunits. The B subunits are required for binding of the toxin to the high-affinity glycolipid receptor glycosphingolipid globotriosyl ceramide, a protein especially expressed on renal microvascular endothelium. After binding, the A subunit is internalized and undergoes partial proteolysis to become an active enzyme capable of inactivating the 60S ribosome, thereby suppressing protein synthesis.¹⁸⁸

During the acute phase of HUS, numerous proinflammatory cytokines are elaborated. Along with released bacterial products, these cytokines activate and promote adhesion of leukocytes and platelets to vascular endothelium. The pathogenic cascade results in swollen and detached endothelial cells, exposing the thrombogenic basement membrane and promoting microvascular thrombosis.

In D⁺ HUS, colitis typically precedes the development of the classic triad of HUS by several days.^{182,189} The diarrhea may be bloody and associated with vomiting and severe abdominal pain and often resolves at the time microangiopathy becomes clinically apparent. Gastrointestinal complications include bowel wall necrosis, toxic megacolon, intussusception, and rectal prolapse.¹⁸⁹⁻¹⁹¹

The severity of the acute nephritis varies widely. The clinical course ranges from microscopic hematuria and mild proteinuria without renal insufficiency to fulminant renal failure. In a retrospective review of D⁺ HUS in Utah over a 20-year period, 60% of children experienced anuria or oliguria lasting a median of 6 days (range, 1–32 days).¹⁹² Dialysis was performed in 43% of cases. Hypertension was present in two thirds of children but was usually mild and resolved by the time of discharge. Severe disease, including oliguria for more than 14 days, anuria for more than a week, and extrarenal structural damage such as central nervous system infarct, occurred in one fourth of children and was found to be associated with age younger than 2 years, anuria during the diarrheal prodrome, and an elevated white blood cell count at presentation. With oliguria, metabolic derangements including metabolic acidosis, hyperkalemia, and dilutional hyponatremia can be seen.

The hematologic abnormalities reflect the microangiopathic process with microthrombi formation. Laboratory studies show decreasing hemoglobin, increased reticulocytes, and increased lactate dehydrogenase coupled with a blood smear demonstrating fragmented erythrocytes and schistocytes. Coagulation studies are generally normal, distinguishing HUS from sepsis and disseminated intravascular coagulation. The indirect and direct Coombs' test should be negative. Thrombocytopenia may be severe, although a small minority of patients have a normal platelet count. The degree of hemolysis and thrombocytopenia does not correlate with the degree of renal involvement. An increase in the platelet count is one of the first signs of recovery, denoting decreased microangiopathy.

Special mention of central nervous system involvement in HUS is warranted because this results in significant morbidity and is the most common cause of death in children.¹⁹³ As in other organs, the major insult to the central nervous system is thrombotic microangiopathy. The majority of children demonstrate some degree of encephalopathy as irritability and somnolence. Seizures and cerebral infarct occur in 10% and 4% of children, respectively, and predict a poorer prognosis.^{192,194}

Essentially any organ can be affected by the microangiopathy of HUS to varying degrees. Pancreatitis occurs and can be associated with transient or permanent diabetes mellitus. Liver involvement results in hepatomegaly and elevated transaminases. Clinical involvement of the heart or lung is not usually apparent, although rare cases of severe myocardial suppression have been reported.¹⁹⁵

The mainstay of therapy for D⁺ HUS is meticulous supportive care. As children often present after several days of

gastrointestinal losses and poor oral intake, judicious fluid resuscitation with isotonic saline should be provided when indicated to ameliorate prerenal physiology. A recent prospective study of 29 children with *E. coli* O157:H7 associated HUS found that fluid management in the pre-HUS course could affect the renal outcome. The children whose renal failure was characterized by nonoligoanuria had received more intravenous fluid and sodium before microangiopathy developed compared with the children who developed oligoanuric renal failure. This suggests that early recognition and parenteral volume expansion during *E. coli* O157:H7 infections before the development of HUS may attenuate the renal outcome.¹⁹⁶ After the initial volume resuscitation, strict attention should be given to the patient's fluid status, with daily assessment of weight and accurate accounting of fluid input and urine output.

In the oligoanuric child, both intravenous and oral intake should match any measurable output and insensible water losses, estimated at 300 mL/m²/day. The choice of replacement fluid can be guided by serum and urine electrolytes, with avoidance of potassium and phosphorus supplementation. If oligoanuria develops despite expansion of the intravascular volume, one or two doses of furosemide (1–3 mg/kg) are justified. Renal and bladder ultrasound scans should be performed in patients with progressive renal failure to rule out rare instances of urinary tract obstruction.

A large percentage of children with acute HUS will need renal replacement therapy. Indications for dialysis include clinically significant volume overload such as evolving pulmonary edema or congestive heart failure, progressive azotemia, hyperkalemia unresponsive to conservative therapy, and the need for blood product transfusions or nutritional support in the oligoanuric patient. Adequate nutritional support is imperative to reverse the catabolic state associated with the acute disease. Many patients are unable to tolerate enteral nutrition, necessitating the use of total parenteral nutrition.

Packed red blood cell transfusions should be provided for symptomatic anemia or vigorous hemolysis with a hematocrit decreasing to less than 16% to 20%. Directed transfusions from blood relatives should be avoided as this may sensitize the patient against a potential kidney donor should ESRD develop. In the setting of thrombotic microangiopathy, transfused platelets will be consumed quickly and not result in a sustained increase in the platelet count. Platelets should therefore be transfused only if the patient is actively bleeding with significant clinical sequelae or a surgical procedure is intended.

Hypertension is common in acute HUS. If there are prolonged episodes of blood pressure higher than the 95th percentile for a child's height and age, medical therapy should be considered. Vasodilatory agents such as hydralazine or calcium channel blockers are effective and are preferred over ACE inhibitors in the setting of fluctuating glomerular perfusion.

D⁺ HUS is a potentially preventable disease. Ground beef should be cooked thoroughly and unpasteurized food products should be avoided. Children who are infected should be excluded from day care, and enteric precautions should be taken until stool cultures are negative. Antibiotic treatment of *E. coli* O157:H7 infection is not recommended as this has been shown to increase the risk of developing HUS.¹⁹⁷

The renal prognosis of self-limited *E. coli* O157:H7 gastroenteritis appears to be excellent, without findings of hypertension, proteinuria, or decreased renal function 4 years after the

acute illness.¹⁹⁴ Although the majority of children with D⁺ HUS recover fully from the acute illness, the long-term renal prognosis is guarded. Acute mortality rates as high as 5% have been reported, and a small percentage of children remain dialysis dependent from disease onset.^{192,198} Predictors of fatality at the time of hospital admission included oligoanuria, increased white blood cell count more than 20 × 10⁹/L, and hematocrit more than 23%.¹⁹³ In a study of 140 cases of pediatric D⁺ HUS over a 20-year period, after the acute HUS episode, half of the children went on to develop one or more abnormalities including hypertension, proteinuria, and chronic renal insufficiency.¹⁹² ESRD had already developed in another 4% of patients. A study of 29 French children with a distant history of D⁺ HUS also suggested significant long-term sequelae.¹⁹⁹ After 15 to 25 years of follow-up, only 35% had no renal abnormalities, whereas 41% had hypertension, significant proteinuria, or a slightly decreased GFR, 10% had chronic renal insufficiency, and 14% had already progressed to ESRD. The best indicator of prognosis was the extent of patchy cortical necrosis on a renal biopsy specimen obtained at the time of recovery from the acute HUS episode. These studies underscore the importance of long-term and regular follow-up of children after D⁺ HUS.

In children with ESRD secondary to D⁺ HUS, renal transplantation is generally quite successful. The North American Pediatric Renal Transplant Cooperative Study reviewed the data from 61 patients with all types of HUS who received 68 renal transplants.²⁰⁰ HUS recurred in six (8.8%) allografts in five patients. Four of these patients had D⁻ HUS. In all but one graft, the HUS recurred within 33 days. The time elapsed before transplantation and the use of cyclosporine did not seem to affect the risk of HUS recurrence. In support of this relatively low rate of recurrent disease in children undergoing transplantation after D⁺ HUS, another review of 18 children in Argentina found no recurrences.²⁰¹

Atypical or D⁻ Hemolytic Uremic Syndrome

Atypical or D⁻ HUS is distinguished by the absence of diarrheal prodrome and accounts for approximately 10% of HUS cases.²⁰² A heterogeneous disorder, a variety of triggers have been identified, including infection with *Streptococcus pneumoniae*, human immunodeficiency virus, malignancies, drugs such as cyclosporine and tacrolimus, and transplantation. Evidence of a pathologic role of the alternative pathway of complement has been identified, and an increasing number of genetic mutations associated with atypical HUS have been described.²⁰³ Mutations of the complement regulatory proteins factor H, factor I, and membrane cofactor protein (MCP) have been found in approximately 50% of patients studied.²⁰⁴ Factor H mutations are most commonly detected, occurring in approximately 25% to 30% of cases. The frequency of reported mutations of factor I and MCP are 5% to 13% and 10% to 15%, respectively.^{204,205} The importance of genetic screening has been emphasized because the identification of specific mutations may predict the disease course or outcome after renal transplantation. In addition to genetic mutations, autoantibodies to factor H were found in three of 48 pediatric patients with atypical HUS. This resulted in an acquired factor H dysfunction in patients who had no genetic mutations and normal plasma antigenic levels.²⁰⁶

Given the heterogeneous nature of atypical HUS, the reported clinical presentation and outcome has varied. A single-center experience retrospectively compared the clinical features and outcome of 28 episodes of atypical HUS (22 children) with 266 cases of typical HUS (265 children).²⁰² Four patients with atypical disease demonstrated a recurrent course. The presence of prodromal features, other than the presence or absence of diarrhea, was similar in the two groups. Atypical HUS was significantly less likely to result in oliguria or anuria or to require dialysis. At follow-up, there was no statistically significant difference in the incidence of hypertension, decreased renal function, or proteinuria. Although there was no difference in the incidence of ESRD, two of the four patients with recurrent atypical HUS eventually developed ESRD. With the exception of the patients with a recurrent course, those with atypical HUS did not experience a worse outcome in this series.

A subsequent study compared the hospital course and short-term outcome of 24 children with atypical HUS with 145 children with typical HUS. Nearly 40% of the cases of atypical HUS followed a pneumococcal infection. The patients with atypical HUS required dialysis more often and had longer hospital admissions.²⁰⁷ Although clinical characteristics vary, atypical HUS may carry a worse prognosis, which is most apparent in patients with recurrent disease.²⁰⁸

Although the clinical course of atypical HUS varies, the recently identified mutations in the complement regulatory proteins have allowed genotypic-phenotypic correlations.²⁰⁹ The most severe prognosis is seen in those with mutations of factor H and factor I. Approximately 70% of patients with these mutations had onset before 1 year of age, whereas none of the patients with mutations of MCP had onset before the age of 1 year but typically presented in early childhood. Patients without an identified mutation may have onset at any age. Sixty percent of patients with factor H mutations reached ESRD or died within 1 year. The course of patients with factor I mutations was more variable, with half progressing to ESRD rapidly and half recovering. The clinical course of MCP mutation-associated HUS was more favorable. These patients had a relapsing course, although none reached ESRD at 1 year and complete recovery was common. The 5-year renal survival for mutations of factor H, factor I, MCP, and disease without detected mutation was 27%, 50%, 62%, and 68%, respectively.

In addition to meticulous supportive care as described for cases of typical HUS, plasma therapy may result in clinical improvement. Plasma therapy will likely be initiated before results of genetic testing are available, and approximately one third of patients will demonstrate a favorable response.²⁰⁹ Mutation of the MCP results in reduced surface expression, and therefore patients with this mutation would not be predicted to have a response to plasma therapy. In patients with an identified MCP mutation, remission was achieved in approximately 90% of plasma-treated and plasma-untreated episodes.²⁰⁵ If response to plasma therapy is evident, a gradual taper of therapy should be pursued with close monitoring of parameters. Complement inhibitor therapies may provide hope for the future.

When ESRD results and renal transplantation are to be considered, a full assessment of regulators of complement should be pursued, including determination of C3, complement factors H and I, MCP levels, ADAMTS-13 activity, and genetic testing of factor H, factor I, and MCP for specific mutations.²⁰³ The overall

success rate of renal transplantation has been poor, with only one third of grafts functioning at follow-up. Of note, vascular thrombosis has been a leading cause of graft failure, accounting for approximately 50% of graft loss in one pediatric series; post-transplantation HUS recurrence occurred in 53% of the whole group and in 80% of patients with factor H mutation.²⁰⁹ Given the surface expression of MCP, it is predicted that recurrence should be of relatively low risk because the renal allograft should express normal MCP.

In patients who lose their initial graft to recurrence, they generally have a very poor chance of success with a second graft.²¹⁰ Of note, many centers do not recommend living-related donor transplantation because of the risk of recurrence. In addition, *de novo* disease in donors has been reported.²¹¹ In cases of factor H mutations with recurrence of disease after transplantation, a small number of combined liver and renal transplantations have been pursued to restore normally functioning factor H that is synthesized in the liver. Initial reports of such procedures had poor outcomes with two of the three patients dying and the third left with neurological disability.²¹² A more recent report of a combined liver-kidney transplant with preoperative plasma exchange was successful, although overall experience with combined transplantation is limited.²¹³

HYPERTENSION

In marked contrast to the adult population, the prevalence of hypertension in children has historically been low (1%–3%) and its etiology less likely to be primary or essential and more likely to be due to an underlying renal anomaly.²¹⁴ Unlike adults, in whom normal blood pressure values have been established based on epidemiological assessment of end-organ damage, blood pressure parameters in children are based on screening data aimed at identifying the normal distribution of blood pressures in the pediatric population. In 2004, the National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents updated blood pressure tables for children based on the screening of more than 60,000 children.²¹⁵ These data demonstrated that there are several clinical factors that affect blood pressure in children, particularly age, gender, and height. Blood pressure increases with age during childhood and reaches adult levels as the child becomes an adolescent. For any given age, boys tend to have somewhat higher normal blood pressures than girls. Heavier and taller children also have higher blood pressures than their more average-sized peers.

These tables statistically defined hypertension in relation to a sample group of children of the same age, gender, and height. Normal blood pressure is a preponderance of readings lower than the 90th percentile. Prehypertension or what used to be considered high-normal range is between the 90th and 95th percentiles. Children are considered hypertensive if blood pressure readings are higher than the 95th percentile persistently on at least three separate occasions. Stage I hypertension refers to readings between the 95th and 99th percentiles and stage II hypertension encompasses readings higher than the 99th percentile.

These tables serve as a resource for the clinician in determining whether a child should be considered hypertensive compared with his or her peers of a similar size. They also provide data for the 50th percentile to give clinicians a better sense of average readings for a child of any size and age. Blood

pressure tends to decrease with repeated measurements due to accommodation; thus, although 5% of pediatric blood pressure readings are statistically in the hypertensive range by definition, a significantly smaller number of children will be persistently hypertensive.

Most children should have their blood pressure checked annually as part of their visit to the pediatrician. In addition, blood pressure should be assessed in any child hospitalized or in an emergency facility, not only because hypertension may complicate an acute illness but also because the detection of transient hypertension in children during stressful occasions may serve as a marker for the development of future hypertension. Abnormal blood pressure readings require follow-up. High-normal or marginally increased readings should prompt a repeat blood pressure in 3 to 6 months. Asymptomatic blood pressure readings as much as 10 mm Hg higher than normal require follow-up within 2 to 4 weeks. Higher blood pressure elevations demand speedier follow-up or, in the case of a child with potential symptomatic hypertension or complicating comorbid medical conditions, immediate attention.

Measuring blood pressure in children can be problematic. The cuff must be appropriately sized, with the width of the cuff's bladder equaling 40% of the mid-upper arm circumference or the cuff bladder encircling three fourths of the upper arm length as measured from the olecranon to the acromion.²¹⁶ Some surveys have estimated that as many as 50% of patients have their blood pressure measured with an incorrectly sized cuff.²¹⁷ Before blood pressure measurement, children should be inactive and acclimated to the examination room for at least 5 minutes. With auscultation, systolic blood pressure is the first Korotkoff sound (K1) and diastolic pressure in all children and adolescents is the fifth Korotkoff sound (K5) when all sounds disappear. In some small children, the diastolic pressure may be auscultated down to 0 mm Hg. Although this is not the true diastolic pressure, it does eliminate any concern of diastolic hypertension.

Small uncooperative children or older children suspected of anxiety-induced hypertension may be relaxed by allowing a parent or nurse to measure their blood pressure in a familiar setting, so that the reading is more representative of the child's usual blood pressure. Some facilities have access to ambulatory blood pressure monitors, small devices worn by the patient that measure and record blood pressure frequently. Advantages of ambulatory monitoring include the ability to record blood pressure during a child's usual daily routine and during sleep so as to determine whether hypertension exists, how often it occurs, how extensive it may be, and if the measured blood pressure manifests a normal circadian variation.²¹⁸

The normative blood pressure tables are based on auscultation of blood pressure using a cuff on an upper extremity. In many clinical settings, oscillometry is used to measure blood pressure. Although adequate for screening, studies in children demonstrate that oscillometry regularly overestimates auscultated blood pressures, often averaging readings 5 to 10 mm Hg higher.^{219,220}

Because an organic cause of hypertension is more common in a child, the diagnostic evaluation is slanted very much toward excluding renal parenchymal or vascular diseases. In fact, more than three fourths of nonobese hypertensive children can be found to have a renal etiology of their hypertension (Table 43-3).²²¹ The child's history is elicited with emphasis on potential renal insults or other medical conditions

Table 43-3 Cause of Hypertension in Children

Cause	Specific Diagnoses	Frequency (%)
Renal parenchymal disease	Acute or chronic glomerulonephritis, reflux nephropathy, cystic disease, hemolytic uremic syndrome	70
Renal vascular disease	Renal artery stenosis, vascular thrombosis	10
Primary hypertension		10
Cardiovascular disease	Aortic coarctation	5
Endocrine disease	Pheochromocytoma, hyperthyroidism, hyperaldosteronism, Cushing's disease	3
Central nervous system anomaly	Increased intracranial pressure	0.5
Medication effect	Sympathomimetics	0.01

suggesting a secondary cause of hypertension (Box 43-4). The physical examination includes careful general assessment for a unifying condition such as Williams or Turner's syndrome or a disorder such as tuberous sclerosis or neurofibromatosis that may have been overlooked and that commonly includes renally mediated hypertension. Four extremity blood pressures should be measured and a focused examination conducted for pertinent findings such as adenoma sebaceum, café-au-lait marks, abdominal bruits, retinal vessel abnormalities, peripheral pulse variations, and aberrant sexual characteristics.

Obesity significantly predisposes children to the development of hypertension. In one longitudinal study of cardiac disease and cardiac risk factors in nearly 10,000 children in the southern United States, obese children were shown to be much more likely to show evidence of the metabolic syndrome including hypertension and to mature into adults with hypertension and obesity.²²² In a survey of schoolchildren in

Box 43-4 Pertinent Medical History in Pediatric Hypertension

Birth history: prematurity, prolonged ventilation, umbilical catheter
 Medical history: urinary tract infection, unexplained fevers, recent systemic infections, changes in appearance of urine
 Family history: hypertension in first- and second-degree relatives, history of stroke or myocardial infarction, endocrine or neurocutaneous disease, renal disease
 Medication history: decongestants, oral contraceptives, street drugs, chewing tobacco, cigarettes, ethanol
 Review of systems: headache, palpitations, sweating, flushing, visual changes

Texas, the relative risk of hypertension was more than three times greater in obese than normal weight children.²²³ The percentage of obese children is increasing and in some populations now approaches 25%.²²⁴ With this epidemic of obesity in children, the likelihood of a child manifesting hypertension without a discernible organic cause other than obesity is increasing. Certainly a large population of obese and hypertensive children has profound public health implications, especially as these children mature and face the potential earlier onset of cardiovascular and renal complications from long-term obesity and hypertension.

A phased laboratory evaluation consists of some general studies in almost every hypertensive child and tailored follow-up studies that depend on these results and the child's history, physical findings, and overall level of clinical suspicion. Baseline screening tests should include a microscopic urinalysis of a freshly voided urine, serum electrolytes to rule out acidosis or hypokalemia, as seen in some of the mineralocorticoid-excess states, serum creatinine to assess renal function, and renal ultrasonography to assess renal anatomy.

In some children, screening tests will be normal and a diagnosis of primary hypertension strongly suspected. Although primary hypertension in children is often considered a diagnosis of exclusion, many children with primary hypertension follow a typical clinical profile: older child or adolescent, low-grade hypertension, cardiovascular reactivity with stress, high resting pulse rates, obesity, and a family history of primary hypertension.²²⁵ In these children, no further diagnostic work-up is needed immediately; after a review of cardiac risk factors, the child's hypertension should be treated if necessary and followed with regular blood pressure checks and emphasis on adjunctive therapies for hypertension, such as weight reduction, exercise, and dietary counseling.

In children who do not meet the clinical profile for primary hypertension and who have otherwise unremarkable screening test results, further renal imaging with renal scintigraphy can be useful to determine whether there is any renal scarring. If this is negative and the patient is significantly hypertensive, renal arteriography should be performed to diagnose any renal vascular abnormalities. Noninvasive imaging of the renal vasculature with computed tomography or magnetic resonance angiography can be entertained with the caveat that children may be more likely than adults to have lesions in smaller segmental vessels that may be better appreciated by conventional arteriography. Ideally, any invasive arteriography should be performed by a physician experienced with transluminal angioplasty in children so that this technique can be performed at the same time if an appropriate lesion is identified.

Other laboratory evaluation is of low yield unless there are appropriate concerns from the child's history or physical evaluation. Random serum renin and aldosterone levels are rarely useful unless they are extremely skewed. For instance, in some families with a pedigree suggestive of glucocorticoid-remediable aldosteronism (difficult to treat, early-onset hypertension in many family members), a random plasma renin level should be nearly nonexistent, prompting more specific genetic testing. Similarly, in rare patients, there may be consideration of urinary catecholamine measurement or abdominal magnetic resonance imaging for a catecholamine-secreting tumor, but again this should be guided by individual signs and symptoms and any potential confounding variables such as

the coexistence of neurofibromatosis or a family history of pheochromocytoma.

Therapy for hypertension is tailored for two basic populations of children. If there is relatively mild hypertension, a cardiac echocardiogram should be considered to rule out left ventricular hypertrophy or other evidence of end-organ effect of sustained high blood pressure. In the absence of end-organ damage, nonpharmacologic therapy could be instituted involving weight reduction, exercise, and dietary counseling. If the blood pressure remains increased despite these interventions or if there is significantly increased blood pressure, then pharmacologic therapy should be instituted along with counseling about weight, diet, and exercise.

As with adults, drug therapy in pediatric hypertension involves selecting an initial therapeutic agent and then stepping up therapy if it proves inadequate. In general, an agent based on the underlying presumed physiology is chosen. A submaximal dose of the drug is begun and then titrated to a maximal dose as needed, aiming to decrease the blood pressure to at least the 90th percentile for age, gender, and height. If there is an inadequate response to the maximal dose of the first medication, a second medication is usually begun, also in a gradual fashion.

Many antihypertensive drugs have not been studied in children, although in the past 5 years an increasing number of antihypertensives have received U.S. Food and Drug Administration labeling for pediatric use after undergoing specific pediatric trials. As with most medications in children, dosing is based on body weight rather than standard dosing amounts and, in agents not studied specifically in children, dosing has largely arisen from clinical experience. Moreover, with the pediatric population, there can be limitations in the ability of the patient to take a medication: the drug may not be available in a liquid or crushable form if pills cannot be swallowed, and issues of palatability are often troublesome. Table 43-4 lists some of the more commonly used antihypertensive medications and their effective doses in children.

Rarely, children present with a hypertensive urgency or a hypertensive crisis. Often, these children have concomitant significant renal pathology, such as an acute nephritis or renal insufficiency. The initial aim of therapy is to decrease the blood pressure by approximately 30% over the first few hours of care to prevent or minimize end-organ or central nervous system damage. Table 43-5 lists medications and dosing guidelines that are often effective in treating hypertensive emergencies in children. After the child's blood pressure has been stabilized, it can then be returned more deliberately to an acceptable range by use of more routine antihypertensive medications. Treatment of a child with a hypertensive emergency is best accomplished in a pediatric intensive care unit by clinicians familiar with blood pressure management in children.

URINARY TRACT INFECTION AND VESICOURETERAL REFLUX

Unlike adults, in whom UTI and especially cystitis is more commonly encountered, UTI in children is infrequent, affecting 3% to 8% of girls and 1% to 2% of boys. Of more concern, however, is that as many as one half of girls and two thirds of boys with UTIs have accompanying high fever, suggestive of an upper tract UTI or pyelonephritis rather than simple

Table 43-4 Blood Pressure Medication in Children

	Initial Dose (mg/kg/day)	Maximal Dose (mg/kg/day)	Dosing Frequency
ACE Inhibitors			
Captopril (neonate)	0.03–0.15	2	bid/tid
Captopril (child)	1.5	6	bid/tid
Enalapril	0.15	Up to 40 mg/day total	qd/bid
Calcium Channel Blockers			
Nifedipine	0.25	3	XL or SR form bid
Amlodipine	0.1	0.4	qd/bid
Diuretics			
Hydrochlorothiazide	1	2–3	qd/bid
Furosemide	0.5–1.0	10	qd/bid
Spironolactone	1	3	bid/tid
Adrenergic Agents			
Atenolol (β -blocker)	0.5	2–3	qd/bid
Propranolol (β -blocker)	1	6–8	bid
Labetalol ($\alpha\beta$ -blocker)	1	3	bid
Prazosin (α -blocker)	0.05–0.1	0.5	bid/tid
Vasodilators			
Hydralazine	0.5	10	tid/qid
Minoxidil	0.1–0.2	1	qd/bid
α-Agonist			
Clonidine	0.05–0.1 mg/day total	0.6 mg/day total	bid/tid, patch every week

ACE, angiotensin-converting enzyme; SR, sustained release; XL, extended release.

cystitis.²²⁶ The propensity for upper tract infection in children stems in part from the association between UTI and vesico-ureteral reflux (VUR). In some series, as many as one half of children with UTI have VUR, whereas in children with no history of UTI, only 2% have VUR.²²⁷

The signs and symptoms of UTI and pyelonephritis may be far less specific in children than in adults. Infants and young children generally have fever, but their symptoms are otherwise often vague and include anorexia, lethargy, and irritability. In older children and adolescents, there is an increased likelihood of localizing symptoms such as dysuria, frequency, and flank pain. Because significant delay in the diagnosis and treatment of pyelonephritis in children has been associated with an increased likelihood of significant long-term renal damage, appropriate diagnostic and therapeutic interventions become all the more crucial.

The clinical diagnosis of pyelonephritis in children is usually based on finding bacteria and white blood cells in the urine of a febrile child. Gram stain of the urine and then subsequent urine culture confirms the diagnosis and helps to tailor therapy. Obtaining the best possible urine specimen for

culture poses more problems in the pediatric patient than with adults. In toilet-trained children, meticulous attention to collecting a midstream urine sample is usually successful. In younger children and infants, a catheterized specimen or a suprapubic aspirate may be required. Urine collected from a bag taped to the child's perineum is easily contaminated and is only useful if there is ultimately no bacterial growth.

Most UTIs in children are caused by gram-negative bacteria of the family *Enterobacteriaceae*, such as *Escherichia*, *Klebsiella*, *Enterobacter*, and *Citrobacter*.²²⁸ Less commonly, gram-positive bacteria may be pathogens, especially in patients with urinary tract malformations, voiding dysfunction, or instrumentation.

In the child with a febrile UTI, antibiotic therapy should be started quickly. In neonates and older infants and children with more complicated illness, hospitalization for parenteral therapy is warranted. Empiric therapy for hospitalized children is most often a third-generation cephalosporin or an aminoglycoside and ampicillin pending urine culture results. In older children with suspected pyelonephritis who do not appear toxic, therapy can commence on an ambulatory basis

Table 43-5 Medications for Hypertensive Emergencies in Children

	Mechanism	Dose	Onset	Duration
Hydralazine	Arteriolar dilator	0.15–0.25 mg/kg IV to maximum dose of 20 mg	5–15 min	3–8 hr
Labetalol	$\alpha\beta$ -Blocker	Initial IV bolus 0.25 mg/kg; repeat every 15 min at increasing doses up to 1 mg/kg until effective or total dose of 4 mg/kg Maintenance IV infusion: 1–3 mg/kg/hr	5 min	2–6 hr
Nifedipine	Calcium channel blocker	0.25–0.5 mg/kg oral or sublingual	10–20 min	3–6 hr
Diazoxide	Arteriolar dilator	Rapid IV bolus 1 mg/kg; repeat after 10–15 min if insufficient response; maximum dose 5 mg/kg	3–10 min	4–10 hr
Nitroprusside	Venous and arteriolar dilator	Start at 0.5 μ g/kg/min IV	1–2 min	3–5 min

with an injection of a third-generation cephalosporin such as ceftriaxone and then transition to appropriate oral therapy to complete a 10- to 14-day course of therapy. In children with suspected cystitis, oral therapy may commence with a medication such as trimethoprim-sulfamethoxazole, nitrofurantoin, or cefixime that has antimicrobial coverage for the usual gram-negative organisms associated with UTI. Empiric antibiotic choice can be guided by Gram stain results and knowledge of community antibiotic sensitivity patterns for usual urinary pathogens. Ultimate oral therapy can be chosen after appropriate sensitivities are obtained from urine culture. In all children treated for UTI, a repeat urine culture should be obtained sometime after appropriate therapy has been initiated to document sterilization of the urinary tract. A short duration of oral therapy of 3 to 5 days in children with uncomplicated cystitis seems to be as effective as longer therapy, but most clinicians still treat febrile UTIs or smaller children with a longer duration of therapy.²²⁹

In any child with a first episode of febrile UTI, renal ultrasonography should be performed to assess urinary tract anatomy. In children older than age 7 years, a normal renal ultrasound scan may preclude further urinary tract imaging. In the younger child or the older child with sonographic abnormalities such as hydronephrosis or renal scarring, a voiding cystourethrogram (VCUG) should be obtained to exclude VUR. A VCUG may be performed at any time after the child is no longer symptomatic and the urine is sterile. If the child has completed the therapeutic course of antibiotics before a VCUG, prophylactic antibiotic therapy with once-daily trimethoprim-sulfamethoxazole or nitrofurantoin should be initiated until a VCUG is obtained.

If the diagnosis of pyelonephritis is in question, renal scintigraphy with technetium-labeled dimercaptosuccinic acid is a sensitive and specific test. Renal scintigraphy has been shown to be superior to intravenous pyelography, computed tomography, or ultrasonography in documenting renal cortical injury.²³⁰ Its use is most helpful in children with chronic or recurrent infections to determine whether parenchymal scarring is occurring.

In children with VUR, higher grades of reflux and especially intrarenal reflux predispose to renal scarring. Less than

5% of children with grade I VUR manifest renal scars compared with 50% of children with grade V VUR.²³¹ In a series of 200 children followed for as long as 20 years after an episode of pyelonephritis, renal scarring was almost always associated with moderate to severe VUR.²³² Infants and young children appear more prone to developing renal scars with pyelonephritis. As children reach elementary school age, it becomes increasingly less common to see renal scarring, even in the presence of continued VUR.²³³

Most children with low-grade VUR (grades I–III) can be managed with nightly oral antibiotic prophylaxis and monitored with an annual VCUG or radionuclide cystogram to determine whether VUR has spontaneously resolved. In children with higher grade reflux, VUR is less likely to spontaneously resolve. All children younger than 1 year of age are usually managed initially with oral antibiotic prophylaxis. In children with persistent grade V VUR, ureteral reimplantation is generally recommended given its infrequent spontaneous resolution. In children with grade IV VUR, there seems to be no advantage of reimplantation over medical therapy in terms of preventing further renal scarring.²³⁴ Over time, there is a decreasing incidence of VUR even in children with higher grades of reflux at presentation, leading many to favor medical therapy unless repeated breakthrough infection, poor compliance, or parental request favor surgical correction with ureteral reimplantation.^{235,236} There is also increasing use of endoscopic correction of reflux with periureteral polymer injection of dextranomer/hyaluronic acid with good short- and longer term results.²³⁷

Because the risk of parenchymal scarring seems to decrease with age, the need for long-term antibiotic prophylaxis in VUR has been questioned in older children who have had a benign clinical course. One study of 51 children (mean age, 8 years) with persistent VUR but no history of voiding abnormalities or renal scarring demonstrated that prophylaxis could be stopped successfully with no long-term effect on renal scarring.²³⁸ Studies are under way that look more systematically at the provision or withdrawal of prophylactic antibiotic therapy in children with VUR, and it is likely that prophylactic antibiotic therapy with VUR may become less widespread if more

data accumulate suggesting that rapid therapy of any UTI in a child with VUR is as good a long-term strategy as daily antibiotics.

Children who develop extensive renal scarring have an increased incidence of proteinuria, hypertension, and renal insufficiency. The risk of developing these sequelae seems to be most closely linked to the severity of the scarring and the length of follow-up.²³⁹ In children with significantly decreased renal reserve due to parenchymal scarring, there is the risk of hyperfiltration injury in remnant glomeruli and the development of secondary focal glomerulosclerosis and renal insufficiency. Such a consequence of chronic pyelonephritis or reflux nephropathy accounts for as many as 10% of the cases of pediatric ESRD.⁶¹

SUMMARY 531

The management of children and adolescents with end-stage renal disease (ESRD) differs from that for adults. Children have unique problems that are not only associated with renal failure itself but can also be related to current therapies. The optimal treatment of ESRD in a child is one that not only reverses the biochemical and hematologic abnormalities related to the disease but also achieves normal physiologic patterns of growth and neurodevelopment. Such a treatment facilitates maximal educational and vocational opportunities and optimizes the quality of life of the child.

ESRD occurs in one to three per million total population of children per year.^{1,2} The most common diagnoses of ESRD in small children are noted in Table 44-1.³ Chronic renal insufficiency in children is associated with many biochemical and hematologic abnormalities as well as hypertension, hyperparathyroidism, anemia, and growth retardation, all of which require specific therapeutic interventions. Indications for renal replacement therapy include hypervolemia, hyperkalemia, symptoms of uremia not responsive to conservative therapy, failure to thrive due to limitations in total caloric intake, severe refractory hypertension, growth retardation not responsive to growth hormone therapy, and delayed psychomotor development.⁴ The Kidney Disease Outcomes Quality Initiative clinical practice guideline and Center for Medicare and Medicaid Services recommend initiation of renal replacement therapy at a glomerular filtration rate less than 15 mL/min/1.73 m².^{5,6} All children can undergo dialysis therapy, although the mortality associated with dialysis can be especially high in infants. In older children, the mortality of dialysis is similar to that seen in adults.

Renal transplantation is a feasible treatment for ESRD and is widely recognized as the treatment of choice for all children.^{7,8} In contrast to children on dialysis, children with a functioning renal transplant can have adequate growth, psychomotor development, and school achievements.⁹⁻¹⁵ Absolute contraindications for renal transplantation are few but include active malignancy, active infection with hepatitis B or human immunodeficiency virus, severe multiorgan failure, and a positive direct cross-match within the previous 3 to 12 months.^{4,8}

SPECIAL CLINICAL ISSUES IN CHILDREN WITH END-STAGE RENAL DISEASE

Nutrition

Inadequate nutrition in children with ESRD inevitably results in growth failure when caloric intake is less than 70% of the recommended dietary allowance.^{16,17} Current recommendations are that children on dialysis should receive an energy intake that is at least 100% of the recommended dietary allowance (Table 44-2).^{18,19} For infants on peritoneal dialysis, a slightly higher caloric intake (130%–140% recommended dietary allowance) and a high protein intake of 2.5 to 3 g/kg/day is needed for adequate growth.¹⁹⁻²² Likewise for prepubertal and pubertal children receiving peritoneal dialysis, high protein intakes (1.5–2 g/kg/day) are advised to maintain physiologic growth patterns and to avoid protein malnutrition. The higher protein intake may result in a slightly higher blood

Table 44-1 Primary Diagnoses (%) of Children with End-Stage Renal Disease Who Received a Renal Allograft

Primary Diagnosis	Percent
Congenital abnormalities of the urinary tract	39.6
Obstructive uropathy	15.8
Aplastic/hypoplastic/dysplastic kidneys	15.9
Reflux nephropathy	5.2
Prune-belly syndrome	2.7
Glomerulonephritis	18.3
Focal segmental sclerosis	11.7
Membranoproliferative glomerulonephritis	2.7
Idiopathic crescentic glomerulonephritis	1.8
Membranous nephropathy	0.5
Systemic lupus erythematosus	1.6
Chronic glomerulonephritis	3.4
Medullary cystic/juvenile nephronophthisis	2.8
Hemolytic uremic syndrome	2.7
Congenital nephrotic syndrome	2.6
Polycystic kidney disease	2.9
Miscellaneous	27.7

Adapted from Smith JM, Stablein DM, Munoz R, et al: Contributions of the Transplant Registry: The 2006 Annual Report of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS). *Pediatr Transplant* 2007;11:366–373.

urea nitrogen level, which needs to be treated with adequate and efficient dialysis. Urea kinetic modeling is thus an important tool for monitoring optimal protein intake and delivery of dialysis.²³

The management of fluid intake can be difficult in children, especially those with minimal urine output. In these children, as just discussed, high-calorie nutrition must be administered. To achieve nutritional goals without problems of fluid overload, small volumes of high-calorie supplements containing additional glucose polymers and/or medium-chain triglycerides are required. Many infants and small children are treated through either nasogastric or gastrostomy tubes to ensure adequate intake because they may be unwilling or unable to consume the required amount of nutrition orally.^{22,24,25} It is important to note that gastrostomy feeding is not contraindicated for children receiving peritoneal dialysis.²⁶ Several studies have documented that this nutritional strategy is effective, and long-term enteral nutrition may prevent or reverse weight loss and growth retardation in infants and young children. Furthermore, if growth failure has already occurred, adequate nutrition can result in catch-up growth if started before the age of 2 years.^{22,27} In addition, aggressive nutritional therapy can contribute to favorable psychomotor development in infants who develop ESRD in early infancy.¹⁵ Together these data suggest that provision of adequate nutrition is critical for effective treatment of ESRD in children.

Growth and Other Endocrine Disorders

Growth retardation is common in children with ESRD and occurs even with mild renal insufficiency. The correction of growth is of paramount importance in the treatment of ESRD in children. Growth is calculated as centimeters of growth per year and is measured frequently and plotted on a standard growth curve chart, as is typical for any normal child. As the glomerular filtration rate decreases, the rate of growth

Table 44-2 Recommend Daily Intakes for Energy,* Protein,* Calcium,† and Phosphorus† for Children with Renal Disease

Age (yr)	Energy RDA (g/kg)	Protein RDA (g/kg)	Protein Intake for Hemodialysis (g/kg)	Protein Intake for Peritoneal Dialysis (g/kg)	Calcium (mg)	Phosphorus (mg)
0–0.5	108	2.2	2.6	3.0	210	100
0.5–1	98	1.6	2.0	2.4	270	275
1–3	102	1.2	1.6	2.0	500	380
4–6	90	1.2	1.6	2.0	800	400

decreases; it is at this time that treatment must begin to correct any rate of decline in linear growth. If untreated, growth failure will be progressive and catch-up is difficult to achieve. Treatment involves ensuring that (1) recommended caloric and protein intakes are achieved, (2) metabolic disturbances (e.g., acidosis, hyponatremia) are normalized, and (3) parathyroid hormone (PTH), calcium intake, and phosphorus load are normalized to correct any problems related to renal osteodystrophy. These factors may all contribute to decreased linear growth. For children on dialysis, more efficient clearance can also improve growth.^{28,29} If growth retardation occurs despite these treatment measures, growth hormone therapy is indicated.³⁰ Growth hormone therapy significantly accelerates short- and long-term growth.^{31–33} Thus, the clinician must not wait until growth retardation has occurred but must maintain normal growth patterns with the use of growth hormone.³⁰ However, in a large study from Centers for Medicare and Medicaid Services, only 39% of children on hemodialysis with short stature received growth hormone.³⁴ Growth hormone therapy consists of 0.05 mg/kg or 4 U/m² injected subcutaneously as a daily dose (usually in the evening). The dose of growth hormone is adjusted to achieve normal growth patterns; some children require decreased dosing, whereas others require increased dosing. Children receiving growth hormone should be monitored regularly for response, including assessment of growth velocity and bone age. Nonetheless, final adult height was retarded in 57% of renal allograft recipients and therefore continues to be suboptimal.³⁵

As discussed above, achievement of normal growth rates is a mainstay of therapy for children with chronic renal insufficiency either before or during dialysis as well as after transplantation. Renal transplantation alone was once thought to be a good treatment for growth retardation as catch-up growth could occur, whereas this was not possible on dialysis. However, recent reports of renal transplantation with regard to growth have been disappointing. Results of multicenter studies have demonstrated that catch-up growth after renal transplantation occurs in only 25% of children, predominantly young children. Indeed, even in this group, catch-up growth is seen in only 47% of children aged 0 to 5 years.^{3,36} This implies that the treatment of growth retardation must begin before the initiation of renal replacement therapy, whether this therapy is dialysis or renal transplantation. After renal transplantation, growth hormone can be given to children and can improve final adult height, without adversely affecting renal function.^{37–39} Also after renal transplantation, the use of alternate-day steroid dosing versus daily dosing can result in improved growth patterns without increased rejection or allograft loss.⁴⁰ To optimize growth, several centers in the United States are currently participating in a randomized, placebo-controlled, steroid-withdrawal trial to assess its potential for optimizing growth patterns without altering long-term graft function. The pilot study suggests that growth with steroid avoidance is not better than alternate-day steroid dosing; it is only promising in that other steroid side effects are avoided.^{41,42}

In addition to its effects on growth, ESRD is also associated with other endocrine disorders. These are thought to be related to inappropriate circulating hormone concentrations or changed hormonal action at the target site. Children with ESRD have an average delay of puberty of 2.5 years and two thirds of adolescents with ESRD enter puberty beyond the

normal range.⁴³ Furthermore, in children with ESRD, there is a marked decrease in tissue sensitivity to insulin, in glucose uptake, and in metabolic clearance of insulin that can lead to glucose intolerance.⁴⁴ Thyroid abnormalities have also been reported in association with ESRD. All these endocrine disorders should be managed according to standard therapeutic regimens to achieve normal patterns of hormonal homeostasis.

Renal Osteodystrophy

Renal osteodystrophy is an important problem in children with chronic renal failure. Its incidence increases as the glomerular filtration rate approaches 50% of normal. Once established, osteodystrophy leads to deceleration of linear growth, muscle weakness, and bone pain; when severe, it results in skeletal deformities such as bowing of lower extremities, fractures, and epiphyseal slipping. Renal osteodystrophy represents a spectrum of activity, from high-turnover to low-turnover bone disease. Renal osteodystrophy occurs in children due to a lack of 1,25-dihydroxyvitamin D₃, hypocalcemia, and hyperphosphatemia. A detailed review of the pathophysiology of renal osteodystrophy can be found in Chapter 69 and Martin and Slatopolsky.⁴⁵ All children with renal insufficiency (glomerular filtration rate < 70 mL/min/1.73 m²) should be monitored by frequent assessment of serum calcium, phosphorus, alkaline phosphatase, and PTH and by occasional radiographs of the hand. Bone densitometry can also be used, but normal values are not known for children younger than 5 years of age.

The most common type of renal osteodystrophy seen in children is high-turnover bone disease, which is associated with high PTH levels and secondary hyperparathyroidism. In recent years, aggressive management of calcium, phosphorus, and PTH has led to a decreasing incidence of secondary hyperparathyroidism.⁴⁶

Prevention of renal osteodystrophy consists of avoidance of hyperphosphatemia using phosphate restriction (80% of dietary reference intake; see Table 44-2) and/or calcium-containing phosphate binders (calcium carbonate or calcium acetate) or non-calcium-containing phosphate binders (sevelamer) taken with all meals (see Table 44-2). Serum phosphate levels should be maintained at normal levels for age.^{47–49} Aluminum-containing phosphate binders should be avoided because the aluminum accumulates in bone and can lead to low-turnover aluminum bone disease. Furthermore, excess aluminum can lead to central nervous system dysfunction.⁵⁰ Optimal management also involves following PTH levels carefully, administration of active vitamin D₃, and assessment of biochemical response. Various active forms of vitamin D are used, preparations include 1 α -hydroxyvitamin D₃ (alfacalcidol), and 1,25-dihydroxyvitamin D₃ (calcitriol).^{49,51,52} The mode of administration of the active metabolite of vitamin D, oral or intravenous, has the same efficacy.⁵³ To avoid adynamic bone disease, plasma PTH should be maintained at a level two to four times above the upper limit of normal.^{19,47–49,54} Hypercalcemia as a result of excessive vitamin D supplementation must be avoided because calcium deposits can form in various tissues, particularly if serum calcium \times phosphate product exceeds 60 mg/100 mL or 5 mmol/L.^{48,49}

Bone disease also occurs in children after renal transplantation. Steroid therapy has been shown to exacerbate preexisting

bone disease; 70% of young children who received a renal transplant in childhood already have osteopenia. In a multiple regression analysis, it was found that the cumulative dose of steroids was inversely related to bone mineral density score. Steroids are associated with osteoporosis and avascular bone necrosis after transplantation.⁵⁵

Anemia

The management of anemia in the pediatric population is similar to that in adults (discussed in Chapter 68). Most pediatric patients with ESRD (glomerular filtration rate < 30 mL/min) require erythropoietin therapy to maintain normal hematocrit. The use of erythropoietin has dramatically improved the outcome of dialysis and quality of life in children and has abolished the typical iron-overload syndromes that were associated with frequent transfusions as a result of dialysis anemia.^{56–58}

Dosing recommendations when starting erythropoietin therapy for patients younger than 1 year are 350 U/kg per week; 275 U/kg/week for those 2 to 5 years; 250 U/kg/week for those 6 to 12 years; and 200 U/kg/week subcutaneously in one to three doses for those older than 12 years. For children on hemodialysis, intravenous administration is preferred because it is less painful.⁵⁹ Although infrequently performed, patients on peritoneal dialysis can have erythropoietin administered in the peritoneal dialysis fluid; however, the amount required to correct anemia is much higher.⁶⁰ Subsequently, the dose is titrated to achieve a hemoglobin concentration of 11 to 13 g/dL (6.8–8.1 mmol/L).⁵⁹ The median maintenance dose is age dependent and is higher for younger children. Children on hemodialysis generally require a higher dose than those on peritoneal dialysis therapy.⁵⁹ Iron deficiency is common in children receiving erythropoietin therapy and supplementation with oral (3 mg/kg/day in three doses) or intravenous iron (1 mg/kg/week, not to exceed 125 mg) is often necessary.^{57,59,61–64} Serum iron levels should be maintained in the normal range, transferrin saturation at more than 20%, and serum ferritin levels greater than 100 ng/mL.⁵⁹ When starting therapy with erythropoietin, blood pressure and hemoglobin should be measured regularly.

Recently long-acting darbepoetin was proven to have a similar efficacy as erythropoietin.⁶⁵ Two hundred units of erythropoietin is approximately equivalent to 0.5 µg darbepoetin. A starting dose of 0.5 µg/kg/week IV/SC effectively treats anemia in children with chronic renal failure. For many, this dose may be proportionally increased and injected less than once weekly.⁶⁶ However, darbepoetin generally produces an increased degree of pain at the injection site compared with most short-acting erythropoietins.⁶⁷ Darbepoetin can also be administered intraperitoneally starting with 0.45 µg/kg/week and increasing to a median of 0.63 to 0.79 µg/kg/week.⁶⁸

Hypertension and Cardiovascular Disease

Although isolated blood pressure measurements are typically used in children with ESRD, it is recommended that 24-hour ambulatory blood pressure is monitored at intervals.^{69,70} When evaluated by ambulatory blood pressure monitoring, 70% of peritoneal dialysis and 33% of hemodialysis patients were found to be hypertensive. In contrast, isolated blood pressure

measurements demonstrated hypertension in only 47% of peritoneal dialysis and 44% of hemodialysis patients.⁶⁹ Nevertheless, the primary goal of antihypertensive therapy is to decrease blood pressure to less than the 90th percentile for age, gender, and height.^{71,72} Choice of medication depends on the likely cause of the hypertension. For instance, an angiotensin-converting inhibitor is a good choice for treatment of hypertension associated with renal insufficiency. In contrast, a vasodilator and/or β-blocker is the most usual choice for therapy in a dialysis patient in whom hypertension may be associated with fluid overload. Blood pressure increases can be marked and very difficult to control. Hypertension is a highly significant and independent predictor for the progression of chronic renal insufficiency in children.⁷³ Furthermore, cardiovascular issues were the cause of 20% to 25% of all deaths in children with ESRD. This proportion increases to more than 40% in long-term studies of children with ESRD starting in childhood.^{74,75} It is thus most important to be aggressive and to lower blood pressure into the normal range in all children.

In children with hypertension, one should consider evaluation of cardiac function and structure with echocardiography at initial presentation and yearly thereafter.^{76,77} Severe left ventricular hypertrophy is seen in almost half of all young dialysis patients.⁷⁸ Better control of blood pressure, anemia, and hypervolemia may be important in preventing left ventricular hypertrophy and improving long-term cardiac outcome. ESRD patients younger than 20 years of age rarely have evidence of coronary artery calcification, whereas patients aged 20 to 30 years are more likely to show disease.⁷⁹

All children, regardless of symptoms, require assessment for cardiovascular disease and should be screened for traditional cardiovascular risk factors such as dyslipidemia and hypertension at initiation of dialysis and at regular intervals thereafter.⁸⁰ Assessment of dyslipidemia should consist of a fasting profile with total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, and triglycerides.⁸¹ Hyperlipidemia is defined as lipid levels higher than the 95th percentile for age and gender. All children with dyslipidemia should follow the recommendations for therapeutic lifestyle changes, which involve a decrease in saturated fat intake, increase in fiber intake, and moderate physical activity. Kidney Disease Outcomes Quality Initiative guidelines recommend treatment with statins for adolescents if LDL cholesterol is more than 130 mg/dL (>3.36 mmol/L) and non-HDL cholesterol (total cholesterol – HDL) is more than 160 mg/dL (>4.14 mmol/L).⁸¹ In the United States, atorvastatin (10–20 mg once daily) is the only drug approved by the U.S. Food and Drug Administration for use in children.

Neurodevelopmental Outcome, Psychosocial Adjustment, and Quality of Life

It is well established in the literature that neurodevelopmental delay, cognitive and motor abnormalities, cerebral cortical atrophy, and progressive encephalopathy are associated with chronic renal insufficiency in children, especially within the first year of life.^{10,82} However, improvements in nutrition, elimination of aluminum binders from treatment regimens, psychomotor therapy, and access to play specialists have all been shown to improve cognitive function and long-term

outcome.¹⁵ Furthermore, early renal transplantation is known to be beneficial for normalization of neurodevelopmental outcome.^{13,83}

Current data indicate that 77% of children on peritoneal dialysis and 46% on hemodialysis attend school full time.⁸⁴ Dialysis patients function below their age and grade levels in all areas. In contrast, transplant recipients achieve at or above the levels achieved by dialysis patients.¹² Data suggest that ESRD, not dialysis/transplant status, is still a risk factor for lower IQ and academic achievement. Cognitive development or low IQ is most notable in younger children and in children whose mothers/caregivers have lower educational levels.⁸⁵

Last, it is important to note that children with chronic renal disease are at risk of psychosocial adjustment disturbances, as occurs with many chronic diseases. In addition, low self-esteem, anxiety, and depressed mood are more severe in children on dialysis.⁸⁶ Thus, most pediatric centers involve psychologists and social workers in the treatment of children with ESRD.

Quality of life has increasingly been studied in children requiring renal replacement therapy. Not surprisingly, health-related quality-of-life scores were significantly lower than in healthy controls. Transplant recipients reported better physical and psychosocial health than dialysis patients. No difference was noted between hemodialysis and peritoneal dialysis patients for any quality-of-life domain.⁸⁷ Furthermore, caring for children on dialysis has significant adverse psychosocial effects on the caretakers. The prevalence of depression was significantly more common in parents of children treated for ESRD (28%) compared with parents of healthy children (5%).⁸⁸ In addition, prolonged dialysis during childhood may decrease the ability to gain high-skilled professions and social independence. Unemployment is twice as high in patients with childhood-onset ESRD compared with healthy persons, but more than twice as low compared with patients with adult-onset ESRD.⁸⁹

Mortality of Children on Renal Replacement Therapy

There is a high mortality associated with dialysis therapy in children, especially young children.^{90,91} Furthermore, it is clear that time on dialysis is associated with mortality. The most common causes of death in children are infection and cardiopulmonary disease.⁹² In children younger than 2 years of age, it has been shown that ESRD associated with oliguria or anuria, multiorgan failure, and the presence of nonrenal disease, especially pulmonary disease and/or pulmonary hypoplasia, are all risk factors for mortality.⁹³ Long-term survival among children requiring renal replacement therapy in the Australia and New Zealand Dialysis and Transplant Registry was 79% at 10 years and 66% at 20 years. Overall, a trend toward improved survival was observed over the four decades of the study. In this cohort, the most common cause of death was cardiovascular disease (45%), and the second most common cause was infection (21%).⁹⁴

In contrast, patient survival after transplantation is excellent. Overall patient survival at 1, 2, and 5 years after transplantation is 97.7%, 96.8% and 94.3%, respectively.⁹⁵ When patient survival is analyzed by age, it appears that younger children are more at risk of death after transplantation. Infants who receive cadaver donor transplants have a higher mortality than those who receive living donor renal transplants. Also, even in the

youngest age groups, the mortality after renal transplantation is less than that seen with dialysis alone.⁹⁵

DIALYSIS THERAPY

All children are candidates for peritoneal dialysis or hemodialysis. In general, the decision to perform either form of dialysis involves patient preference, distance from a pediatric hemodialysis center, and center bias. In young children, there is a preference for peritoneal dialysis because hemodialysis is associated with vascular access problems and also involves significant expertise on the part of personnel. Thus, peritoneal dialysis has become the more common treatment in many centers. Nearly 60% of the pediatric dialysis population are currently maintained on peritoneal dialysis.⁹² Some reports suggest that younger children fare better with peritoneal dialysis, although data indicate that as long as efficiency is maintained, there are no significant therapeutic differences between peritoneal dialysis and hemodialysis.

Peritoneal Dialysis

Peritoneal dialysis is discussed in great detail in Chapters 81 to 83. Here, we focus on specific issues pertaining to peritoneal dialysis in childhood. Peritoneal dialysis is preferred for infants as it obviates the need for vascular access, which can be especially difficult in this group of children.⁵⁶ Another advantage of peritoneal dialysis over hemodialysis is that it requires less fluid restriction. As discussed earlier, this may be important for adequate administration of nutrition. Automated continuous cycler-assisted peritoneal dialysis at night is used most frequently in younger children.⁵⁶

In older children and especially adolescents, compliance with dialysis prescription can be a problem and can thus affect dialysis efficiency. The requirement for a permanent intra-abdominal catheter can distort body image and its presence becomes unwanted. This can lead to treatment issues and puts parents in a compromising situation if they wish to be caregivers. Therefore, peritoneal dialysis in an adolescent needs careful monitoring. Hemodialysis has become the more common form of renal replacement therapy in this group because it provides adequate treatment and also enables assessment of compliance and adequacy.

Initiation of peritoneal dialysis in all children involves the use of a curled catheter, typically pointing downward and situated in the lower half of the abdomen.⁹⁶ In younger children with lax abdominal musculature, the catheter preferably has two cuffs to avoid leakage and infections. The catheter and cuff are typically allowed to heal for a minimum of 2 weeks before the initiation of dialysis to prevent leakage. Omentectomy during the insertion of the catheter is especially important in young children because it decreases the incidence of obstruction to 2% compared with 15% to 32% incidence in the absence of omentectomy (15%–32%).⁹⁷

Dialysis Prescription

When prescribing peritoneal dialysis, volume input according to nutritional needs, residual urine output, and renal function must all be taken into account. In children, initial target peritoneal dialysis exchange volume of 1000 to 1200 mL/m² is used with a maximum of 1400 mL/m² and up to at least 8 L/m² per

session.^{98,99} In young children, eight to 10 exchanges are performed over 12 to 16 hours at night by an automated peritoneal dialysis cycler (continuous-cycling peritoneal dialysis). In older children, continuous ambulatory peritoneal dialysis is the usual mode of therapy, performed in a manner similar to that for adults. In addition to normalizing biochemical abnormalities, it must also be administered in a manner to facilitate growth. With all forms of peritoneal dialysis, ultrafiltration is adjusted to facilitate adequate volume intake according to nutritional needs. Typically, the ultrafiltration goal depends on analysis of the nutritional needs and the requirement for administration of volume.

Dialysis Adequacy

A peritoneal equilibration test can be used to study the transport capacity of the peritoneal membrane. Peritoneal equilibration test values for children have been calculated.^{100,101} Warady and colleagues¹⁰¹ found that the peritoneal membrane was stable in children over a mean interval of 20 months. However, peritonitis is a risk factor for peritoneal dialysis failure. Follow-up of peritoneal solute kinetics is recommended in patients with a history of peritonitis to permit early identification of patients at risk of dialysis failure.^{102,103} Dialysis adequacy can be expressed as urea Kt/V, calculated as the ratio of 24-hour dialysate (+ urinary) urea clearance divided by total body water, where K is urea clearance (L/hr), t is time on dialysis (hours), and V is urea distribution volume and equals total body water volume (L). The target dialysis adequacy in children is a total weekly urea Kt/V of at least 1.8 to 2.0.^{99,104} Higher values for weekly urea Kt/V as high as 2.75 to 3.1 can be achieved and have been correlated with improved clinical outcome.^{19,105,106} However, a report from the Endstage Renal Disease Network of New England indicates that a urea Kt/V more than 2.75 may result in albumin loss and may thus hinder nutrition.¹⁰⁷

Complications

Complications of peritoneal dialysis in children include exit-site/tunnel infections, peritonitis, catheter-related problems (leakage and blockage), and the development of hernias due to increased intra-abdominal pressure and relatively weak musculature. In one report, 11% of pediatric patients on peritoneal dialysis had an exit-site/tunnel infection at 1 month, 26% between 1 and 6 months, and 30% between 6 months and 1 year of follow-up.¹⁰⁸ Patients with tunnel infections have twice the risk of developing peritonitis and the need for access revision.

Peritonitis is the major complication of peritoneal dialysis in children. The mean occurrence of peritonitis has been reported to be once every 13.2 patient-months.¹⁰⁸ Peritonitis rates decrease with age and are significantly lower when catheters with two cuffs and downward-pointed exit sites are used.^{56,84,109} There is no difference in peritonitis in children treated with curled or straight catheters. Overall, 25% of patients on peritoneal dialysis switch to hemodialysis, and in most patients, the switch is due to repeated infections.^{56,108}

Hemodialysis

Improvements in technology have enabled pediatric centers to perform hemodialysis in infants and young children effectively and efficiently. Important advances relate to dialysis ac-

cess catheters and lines, complex machines that allow control of low blood volume, the ability to exactly control ultrafiltration, and compatible dialysis membranes and the composition of dialysates.^{110,111}

Overall, one third of children who are on dialysis use hemodialysis. Hemodialysis is the preferred dialysis modality for children older than 12 years of age, who comprise 64% of all children requiring dialysis.⁵⁶ In contrast, only 12% of children younger than 5 years of age receive hemodialysis.

Permanent access in the form of a fistula or graft is the preferred form of vascular access for pediatric patients on maintenance hemodialysis therapy.^{5,112,113} However, in small children, surgical expertise in placing fistula or grafts may be limited and the use of percutaneous catheters may be unavoidable. In addition, many children on hemodialysis are taken to renal transplantation fairly quickly, thus further limiting the use of fistulas.

Dialysis Prescription

For all patients, the dialysis prescription is calculated by dialyzer type, blood flow, and dialysate flow. The duration of each treatment can be easily calculated to optimize urea clearance. In infants and small children, blood flow rates as low as 50 mL/min can be used such that the dialysis prescription can be calculated according to the ability of the patient to tolerate a given flow rate. In older children and adults, blood flow rates of 200 to 300 mL/min are frequently used. Knowledge of the clearance curve of the dialyzer is essential in estimating the total urea clearance at a given blood flow rate. Extracorporeal blood volume (dialyzer priming volume plus blood tubing volume) should be kept to less than 8 mL/kg (<10% of total blood volume) to avoid hemodynamic instability and hypoxemia. Routine determination of target dry weight, using non-invasive hematocrit monitoring, decreases both the risk of chronic fluid overload and the need for antihypertensive medication and does not lead to increased intra- or interdialytic symptomatology.¹¹⁴ Adequate anticoagulation can be achieved with standard heparin dosing. To attain adequate clearance, three hemodialysis treatments are usually given each week. Although the optimal dialysis dose requirement for children remains uncertain, reports of longer duration and/or daily dialysis show that they are more effective for phosphate control and may improve growth than conventional hemodialysis. Therefore, longer duration and/or daily dialysis should be considered at least for some high-risk patients with cardiovascular impairment or to overcome the free diet of very uncompliant patients.^{29,115,116} As in adults, nocturnal home hemodialysis is also feasible in selected children. However, the burden on the family is substantial, and home nocturnal hemodialysis requires support of a dedicated multidisciplinary team.¹¹⁷

Dialysis Adequacy

Adequate dialysis combined with adequate nutrition reduces mortality and promotes growth in children.^{28,118} Urea kinetic modeling is used to assess dialysis adequacy and nutritional status.²³ Hemodialysis efficiency is expressed as Kt/V, where K is urea clearance (L/hr), t is session length (hours), and V is urea distribution volume and equals total body water volume (L). Goldstein and colleagues¹¹⁹ found no difference between the results of a formal urea kinetic modeling technique for obtaining Kt/V and results obtained by using Daugirdas's¹²⁰ formula

for the single-pool natural logarithm approximation equation for Kt/V. Thus, the ease with which Kt/V can be calculated using the natural logarithm supports its regular use in the monitoring of children on hemodialysis.^{19,121} An appropriate goal is to achieve a single-pool Kt/V of 1.2, at least equal to that recommended for adults.⁵ There is a controversy over whether higher Kt/V values are necessary for growing children.^{5,19,28,122} The Kidney Disease Outcomes Quality Initiative guideline for hemodialysis adequacy advises that for young pediatric patients, prescription of higher dialysis doses and higher protein intakes at 150% of the recommended nutrient intake for age may be important.⁵ In a large study from the Centers for Medicare and Medicaid Services in adolescents, more than 79% had a mean Kt/V more than 1.2.¹²³

Complications

The most common complications of hemodialysis are clotting and infection of the hemodialysis catheter, arteriovenous fistula, or graft. Infection of the hemodialysis access site when using a catheter can easily lead to septicemia, which is the most frequent cause of death in children on hemodialysis.⁵⁶ Other complications, such as disequilibrium syndrome, hypotension, anaphylactic reactions, hemolysis, and hypoxemia, are discussed in detail in Chapter 80.

RENAL TRANSPLANTATION

Renal transplantation is the optimal treatment for ESRD in children because it offers the best hope for normalization of physiologic processes. Most important is the ability of renal transplantation to normalize growth and cognitive function and to enable a child to enjoy a relatively normal quality of life. Because of the mortality associated with dialysis therapy in young children and the risk/benefit ratio, the National Organ Allocation System in the United States has given preference to children on waiting lists to receive cadaver transplants.

In the United States, an approximately equal number of renal transplantations in children are performed with living and cadaver donors.¹²⁴ As a therapy, renal transplantation is very successful and, with current immunosuppressive regimens, 1- and 5-year graft survival rates are excellent: the 5-year graft survival rates are currently 85.1% for living related donor grafts and 76.1% for cadaver donors.¹²⁴ The projected half-life of renal transplants in pediatric recipients is equal to or even better than that in adult recipients.^{125,126} However, as discussed later, rejection remains a major cause of graft loss in the first posttransplantation year.¹²⁴ Newer immunosuppressive agents have decreased the incidence of acute rejection and have improved 1-year graft survival rates, especially for recipients of cadaver donor transplants. The current 1-year graft survival rates for cadaver donor and living related donor transplants are approximately equal at 93.7% and 95.4%.¹²⁴ Most importantly, increased numbers of acute rejection episodes (more than two rejections, see “Chronic Rejection”) has been found to correlate with a high risk of developing chronic rejection. Moreover, in the most recent era of immunosuppression, the decrease in acute rejection episodes in pediatric transplant recipients has been reported to decrease graft failures due to chronic rejection.¹²⁷ Interestingly, although the youngest recipients (younger

than 2 years) have higher risks of early graft loss, their risk of later graft attrition is the lowest.¹²⁸

Preparation for Pediatric Renal Transplantation

Every transplantation center has its own practices regarding the preparation of a child for renal transplantation. However, there are certain issues that have been recommended as key factors for consideration. These are reviewed and detailed elsewhere.⁴ Of paramount importance is the evaluation of living donors who must be carefully examined by an independent advocate so that they are not put at risk. Living donor advocacy is such an important issue that it was recently reviewed and a national consensus was published.¹²⁹ Living donor advocacy is uniquely important in pediatrics because donors tend to be parents; they are highly motivated but are also the caregivers. Siblings can also feel pressure to donate. Thus, the concept of donor advocacy (that of being a separate individual from those in the transplant program) ensures that donors are treated in a fair manner.

Donor

If available, a living donor has clear advantages over a cadaver donor. Living donation ensures adequate transplantation preparation and optimizes elective transplantation, particularly for pediatric patients. Preemptive transplantation is much easier to accomplish and improves graft survival.¹³⁰ Furthermore, long-term survival of living donor renal allografts is superior to cadaver donor allografts. For details of selection and preparation of a living donor, see Chapter 85. Contrary to early reports, it has become clear that allografts from young cadaver donors (younger than 6 years of age) do not fare well in young recipients (due to higher thrombosis rates) and that the best donor for a young child is an adult donor. A cadaver donor for children should ideally be 20 to 40 years of age and not younger than 6 years of age because the youngest donors are associated with an increased risk of graft failure.³ Thus, the best donor is an adult, whether living or dead (Table 44-3).

Recipient

An important aspect of renal transplantation is that success can also be determined by careful management of the recipient before transplantation. Most pediatric centers use a multispecialty team to ensure that hematologic, biochemical, neurological, and urologic parameters and potentially serious infections are corrected before transplantation. Many centers have adopted specific screening mechanisms, and some of the major considerations are reviewed in Box 44-1. Assessment of bladder function and correction of bladder dysfunction before transplantation is essential for patients in whom bladder disease or obstructive uropathy was the original cause of ESRD. Some patients may require bladder augmentation and/or medication to improve bladder function before transplantation. Transplantation into a dysfunctional bladder or the use of ileal loops or other forms of urinary drainage are not optimal for long-term success. Thus, it is important to have a pediatric urology team assess

Table 44-3 Relative Hazard of Individual Prognostic Risk Factors for Graft Failure by Donor source

	LIVING DONOR		DECEASED DONOR

a child before transplantation and be involved with the entire transplantation process.

Prevention of infections, especially viral infections, involves analysis of patient status and the use of chemoprophylaxis. This is a high priority with all pediatric patients because they typically acquire these infections during childhood and are not immune to many viruses before transplantation.¹³¹ Knowledge of titers of varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, diphtheria, tetanus, poliovirus, measles, mumps, rubella, *Haemophilus influenzae* B, *Streptococcus pneumoniae*, hepatitis B, hepatitis C, and human immunodeficiency virus before transplantation is of paramount importance. Vaccination can prevent

morbidity and mortality after transplantation.^{132,133} All live viral vaccines should be administered before transplantation as best as possible. Cytomegalovirus and Epstein-Barr virus prophylaxis must be considered for patients at high risk, that is, seronegative recipients receiving seropositive organs and patients who have received antilymphocyte antibodies.¹³⁴ Trimethoprim prophylaxis has reduced the incidence of *Pneumocystis carinii* pneumonia after transplantation from 3.7% to 0%.¹³⁴

Bilateral native kidney nephrectomy before transplantation is currently performed in 24% of patients in the United States to avoid urinary tract infection in patients with reflux nephropathy, native kidney-related hypertension, and a steal

Box 44-1 Preparation of Pediatric Renal Transplant Recipient

Nutrition

Adjustment of caloric, protein, sodium, and potassium balance

Growth

Supply adequate nutrition, correct metabolic disturbances (e.g., acidosis, hyponatremia), renal osteodystrophy; consider growth hormone therapy

Renal Osteodystrophy

Phosphate binders, calcium supplement, active vitamin D₃

Anemia

Correct iron deficiency; consider erythropoietin

Infection Prevention

Check titers of DTP, MMR, Hib, VZV, pneumococcus, HBV, HCV, CMV, EBV, and HIV

Vaccinate if necessary (e.g., VZV, HBV, influenza); check tuberculosis status

Bladder Work-up

VCUG and bladder work

Psychosocial Status

Social work assessment

CMV, cytomegalovirus; DTP, diphtheria/tetanus/pertussis; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; Hib, *Haemophilus influenzae* B; MMR, measles/mumps/rubella; VCUG, voiding cystourethrogram; VZV, varicella-zoster virus.

syndrome resulting in diminished blood flow through the allograft.³ Most renal allografts are transplanted extraperitoneally into the retroperitoneal cavity, even when a large adult kidney is used for a small child recipient. This technique does not seem to affect surgical complication rates and has the advantage of fewer gastrointestinal complications.^{135–138} However, occasionally adult-sized kidneys are transplanted intraperitoneally in small children. There are other issues that require consideration, but these are beyond the scope of this chapter and are discussed in detail elsewhere.⁴

Immunosuppressive Therapy

There are currently many immunosuppressive agents available to the transplantation physician. This has resulted in multiple protocols each with a center bias, such that therapy can be center dependent. Induction therapy, predominantly with anti-interleukin-2 receptor antibodies (anti-CD25: daclizumab, basiliximab) is followed by triple therapy, consisting of steroids, a calcineurin inhibitor, and an antiproliferative agent.¹³⁹ The calcineurin inhibitor tacrolimus is the primary immunosuppressant, with 63% of pediatric renal transplant recipients receiving the drug during the first month; 12% of recipients receive cyclosporine. Azathioprine has been replaced by mycophenolate mofetil, which is currently given to more than 90% of transplant recipients in the United States.¹²⁴ Approximately one third of patients who receive maintenance steroid therapy in the long-term receive alternate-day therapy to achieve better catch-up growth.^{3,124,139,140}

The advent of new immunosuppressive agents has enabled therapy to be administered on an individual basis and based on risk. The newer more potent immunosuppressive agents and protocols that have been shown to limit acute rejection have provided tremendous advantages for the transplant recipient but they come at a price, which is the risk of infections and posttransplantation lymphoproliferative disease (PTLD). Posttransplantation infections have increased over time and now exceed acute rejection as the cause for hospitalization. In the first 24 months after transplantation, 52% of patients were hospitalized, 40% for infection and 23% for acute rejection¹⁴¹ (see “Posttransplantation Infections”). Adverse effects of immunosuppressive therapy besides infection and malignancy include hypertension, hyperlipidemia, diabetes mellitus, osteoporosis, and, in the case of long-term steroid use, growth failure (see “Growth and Other Endocrine Disorders”).¹⁴²

Exciting new immunosuppressive drugs have been introduced into practice based on their ability to further decrease acute rejection. It is hoped that they will also improve long-term graft survival. The most exciting agents include alemtuzumab (anti-CD52), a newer anti-T-cell agent that has been introduced to limit acute rejection in the early posttransplantation period. Leflunomide, a promising immunosuppressive drug that inhibits de novo pyrimidine biosynthesis, also has antiviral activity, in particular against BK virus. Belatacept, an inhibitor of costimulation of T cells, is nonnephrotoxic, but in clinical studies, it was found that this agent is a potent immunosuppressive and thus its use may increase the risk of PTLD.¹⁴³

A recent study evaluating the elimination of calcineurin inhibitors and conversion to a rapamycin (sirolimus)-based immunosuppressive regimen after pediatric living donor renal transplantation has had promising results.¹⁴⁴ Furthermore,

a strategy of lymphoid depletion with antithymocyte globulin and tacrolimus monotherapy appears safe and effective for pediatric kidney recipients.¹⁴⁵ Although new protocols are currently in clinical trials, the optimal immunosuppressive strategy for a given patient will likely be individualized in the future; risk stratification for each type of protocol for individual patients will be forthcoming.¹⁴⁶

Posttransplantation Infections

Newer immunosuppressive agents have dramatically reduced the rates of acute graft rejection over the past decade but may have exacerbated the problem of posttransplantation infections. Posttransplantation infections currently exceed acute rejection as the cause of posttransplantation hospitalization and are the most frequent cause of mortality.^{124,141} Younger children are at higher risk of hospitalization for infection, and there is an association with the use of anti-T-cell antibodies as induction therapy.¹⁴¹

Typical infections after renal transplantation are urinary tract infections, BK virus infections, and PTLD. Febrile urinary tract infection is a frequent (33%–36%) posttransplantation complication, especially in girls and in children with urinary tract malformation and neurogenic bladder.^{147,148} Polyoma BK virus nephropathy is emerging as a significant early and late complication of renal transplantation, which may lead to renal dysfunction and graft loss.¹⁴⁹ Limited prospective studies screening for BK virus document the presence of viruria in 19% to 33% of patients and viremia in 5.6% to 13.4% of patients. Of the latter, nearly half have BK nephropathy on renal biopsy.^{150–152} These findings support the routine screening of pediatric renal transplant recipients for BK virus. Treatment of BK nephropathy consists of a decrease in immunosuppression and/or treatment with cidofovir.¹⁴⁹

The prevalence of Epstein-Barr virus-induced PTLD shows a significant increase per year and currently is 2.0%.¹²⁴ Cadaver donor source and white race are risk factors for PTLD.¹⁵³ In an analysis of PTLD after polyclonal antibody induction, only equine antithymocyte globulin was associated with a twofold higher risk of PTLD, whereas rabbit antithymocyte globulin and antilymphocyte globulin were not.¹⁵⁴ Recent North American Pediatric Renal Transplant Cooperative Study data show that tacrolimus and mycophenolate mofetil are not associated with increased risk of PTLD after pediatric kidney transplantation.¹⁵⁵ Treatment of PTLD consists of a decrease in immunosuppression, anti-CD20 antibody treatment (rituximab), and occasionally chemotherapy. Experimental data suggest that rapamycin (sirolimus) may inhibit the growth of Epstein-Barr virus-infected B cells and may be helpful in the treatment of PTLD.¹⁵⁶

Causes of Graft Failure in Pediatric Recipients

The North American Pediatric Renal Transplant Cooperative Study, which includes data on more than 8990 transplantations, analyzes risk factors for graft loss after pediatric renal transplantation.^{3,124,139,140,157} The most common cause of graft failure is chronic rejection.¹²⁴ Vascular thrombosis is also a major cause of graft failure, especially in young children, and accounts for approximately 12% of all pediatric renal allograft failures. Risk factors for vascular thrombosis include recipient

age and cadaver donor age, especially donors younger than 6 years of age.^{3,158} Long-term graft survival rates for teenage recipients are significantly lower compared with all age groups, including infants. Adolescents have a significantly higher incidence of late acute rejection episodes and higher rates of incomplete rejection reversal than any other age group.¹⁵⁹ Noncompliance among teenagers is well recognized.^{128,159–161} Strategies to address noncompliance in adolescents must have a high priority.

Acute Rejection

With new immunosuppressive therapies, acute rejection episodes occur less frequently after pediatric transplantation. Indeed, acute rejection in 1987 at the beginning of the North American Pediatric Renal Transplant Cooperative Study was as high as 54% and 69% for living and cadaver donors, respectively, and has now decreased to 13% and 16% in the first posttransplantation year. It has become evident that more aggressive therapy, including the use of induction therapy regimens, and surveillance biopsies to establish a diagnosis of “silent” rejection are associated with improved short-term outcome.^{162,163} Acute rejection is of special concern because of its relationship to the development of chronic rejection.³ Even one episode of acute rejection increases the risk of developing chronic rejection. Thus, strategies that decrease acute rejection rates and improve short-term graft survival rates can translate into improved long-term survival.^{127,164}

Chronic Rejection

Chronic rejection is characterized histologically by progressive fibrosis and mononuclear cell infiltration with interstitial cell atrophy. Chronic rejection can be diagnosed as early as 3 months after transplantation, and its presence in biopsy specimens 6 months posttransplantation is prognostic for long-term outcome.¹⁶⁵ Thus, early biopsy 3 to 6 months after transplantation can be evaluated for surrogate markers that may predict the ultimate development of chronic rejection.¹⁶⁵ Once established, chronic rejection is progressive and ultimately leads to graft failure. For pediatric patients receiving a renal allograft, chronic rejection is responsible for approximately 41% of graft losses.¹²⁴

Understanding risk factors for chronic rejection in pediatric patients has been a major undertaking of the North American Pediatric Renal Transplant Cooperative Study. Preventing or minimizing risk factors has been proposed to have an impact on long-term graft survival. Risk factors for chronic rejection have been defined and are multifactorial. They include human leukocyte antigen mismatch, ischemia reperfusion injury, repeat transplantations, acute rejection, and other factors such as hypertension and hyperlipidemia. However, an extensive study established that acute rejection is the most important risk factor for the development of chronic rejection. Two or more acute rejection episodes increases the risk of chronic rejection four-fold, and late initial acute rejection increases the risk of chronic rejection by 3.6-fold.¹²⁷ These data are similar to those of studies performed in adults that also identified acute rejection as a harbinger of chronic rejection.¹²⁵ It is proposed that acute rejection establishes an immune reaction within the graft that facilitates positive feedback loops for immune inflammation and persistent graft injury and the production of cytokines and growth factors such as the fibrogenic cytokine transforming growth factor β .¹⁶⁶ Another possible etiology contributing to

the development of chronic rejection is decreased renal mass leading to hyperfiltration, which has a damaging effect on the renal parenchyma and produces the characteristic histology of chronic rejection.¹⁶⁶

Currently there is no specific therapy for chronic rejection, so efforts must be directed toward preventing major risk factors such as acute rejection. Aggressive induction therapy to prevent acute rejection has not translated into better long-term graft survival but is associated with increased risk of infections.¹⁶⁷ Other ideas include limiting calcineurin inhibitor–based immunosuppressive therapy, which is associated with progressive renal injury as a result of profound nephrotoxicity.^{144,166}

SUMMARY

In this chapter, we discuss unique problems associated with the management of ESRD in children. We discuss strategies to understand and prevent malnutrition and growth retardation in children with ESRD. In addition, we review important issues for the optimization of neurodevelopment and cognitive function. Last, we review current available treatment options including peritoneal dialysis and hemodialysis and discuss renal transplantation as a successful therapeutic option. All these treatments are options for children with ESRD.

Kidney Pain in Autosomal Dominant Polycystic Kidney Disease	542
Therapeutic Modalities to Slow Disease Progression in Autosomal Dominant Polycystic Kidney Disease	544

Renal cystic disorders include a variety of genetic and acquired diseases, such as autosomal dominant polycystic kidney disease (ADPKD), autosomal recessive polycystic kidney disease, simple renal cysts, acquired cystic disease, von Hippel-Lindau disease, juvenile nephronophthisis/medullary cystic kidney disease, medullary sponge kidney, and tuberous sclerosis. We review ADPKD because of its high prevalence, the improved understanding of its pathogenesis and disease progression, and potential new therapies currently under clinical investigation.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD is a systemic disorder affecting 1 in 700 to 1000 individuals.¹ It is the most common inherited renal disorder, the fourth most common cause of end-stage renal disease (ESRD) after hypertension and diabetes and accounts for 2.5% of incident cases in the United States. Renal enlargement in ADPKD is progressive from birth; however, serum creatinine levels typically do not increase until the fourth or fifth decade of life. The majority of patients with ADPKD reach ESRD by the fifth decade of life.²

The Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease was established by the National Institute of Diabetes and Digestive and Kidney Disease to determine whether change in renal and cyst volume measured by magnetic resonance imaging could be detected over a short period of time and whether structural measures correlate with a decline in renal function. A total of 243 patients with ADPKD underwent iothalamate glomerular filtration rate measurements and magnetic resonance imaging of the kidneys and the liver annually for 3 years. Age-adjusted renal ($R = 0.31$), cyst ($R = 0.36$), and percentage of cyst volume ($R = 0.35$) inversely correlated with the glomerular filtration rate³ and larger renal volumes (>1500 mL; normal, 200 mL) demonstrated a significant decline in the glomerular filtration rate (approximately 5.2 mL/min/yr).⁴ Polycystic kidney disease 1 (PKD1) patients demonstrated larger renal volumes than PKD2 patients, and renal volume increased at a similar rate. PKD2 individuals demonstrated fewer renal cysts than PKD1, accounting for the

differences in renal size seen. These results have important design implications for clinical trials aimed at targeting new interventions in ADPKD before massive kidney enlargement has occurred.

ADPKD is a systemic disease characterized by the presence of renal, hepatic, pancreatic, and thyroid cysts, intracranial aneurysms (ICAs), inguinal and ventral hernias, and cardiac valvular abnormalities, mitral valve prolapse, and aortic insufficiency.⁵ Renal manifestations of ADPKD include pain, gross hematuria, cyst hemorrhage, nephrolithiasis, infections, and a common early presence of hypertension. Table 45-1 lists the common manifestations and summarizes the recommended therapies.

Extrarenal Manifestations

Polycystic Liver Disease

Polycystic liver disease (PLD) (two or more liver cysts in an ADPKD individual) is a common manifestation of ADPKD, historically presenting later than renal cystic disease.^{6,7} PLD occurs in the majority of both men and women, although more frequently and earlier in women. Magnetic resonance imaging of the liver in 243 participants in the Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease cohort demonstrated liver cystic disease in 55% by age 25 and 94% by age of 45.⁸

Estrogen or progesterone exposure is associated with more frequent and severe PLD.^{6,9,10} In a study of 11 patients, 1 year of postmenopausal estrogen therapy was associated with greater liver cyst growth compared with placebo-treated controls ($N = 8$).¹¹ Liver cyst growth can be massive, associated with significant pain, shortness of breath, early satiety, weakness, and fatigue. Although PLD can result in massive involvement of liver, noncystic liver parenchymal volume is increased with minimal loss of drug clearance and metabolism.¹² Rarely, massive PLD can be fatal secondary to inferior vena cava obstruction, infection, or Budd-Chiari syndrome or due to the development of end-stage liver disease with portal hypertension.¹³

Current approaches to the treatment of PLD have relied on medical, surgical, or radiological interventions. Attempts to avoid extensive estrogen exposure include minimizing use of

Table 45-1 Management of Complications of Autosomal Dominant Polycystic Kidney Disease

Complication	Frequency	Management
Extrarenal		
Hepatic cysts	83%	Minimize estrogen use, fenestration, decortication, resection, liver transplantation
Cholangiocarcinoma	Rare	
Congenital hepatic fibrosis	Rare	
Caroli's disease	Rare	
Budd-Chiari syndrome	Rare	
Hepatocellular carcinoma	Rare	
Pancreatic cysts	10%–11%	
Thyroid cysts	Rare	
Intracranial arterial aneurysms	5%–8%	MRA if positive family history; clip, coil, or inject if >5–10 mm
Intracranial arterial dolichoectasis	2%–3%	
Pineal cysts		
Mitral valve prolapse	20%–25%	
Aortic insufficiency	5%	
Hernias (inguinal and ventral)	15%	
Seminal vesicle cysts	40%	
Renal		
Multiple cysts	100%	
Infection	30%–50% lifetime risk	4–6 wk trimethoprim-sulfamethoxazole, fluoroquinolone for cyst infection; cyst decompression
Hypertension	60% (normal renal function), 90% (CKD)	ACE inhibitor
Hematuria	50% lifetime risk	
Pain (due to cyst size, infection, rupture, nephrolithiasis)		
Nephrolithiasis (uric acid and calcium oxalate)	20%	
Subnephrosis-range proteinuria	27%	
Decreased concentration ability	100%	

ACE, angiotensin-converting enzyme; CKD, chronic kidney disease; MRA, magnetic resonance angiography

oral contraceptives. When postmenopausal estrogen replacement therapy is indicated, administration of cutaneous estrogen patches should be considered to avoid higher biliary estradiol concentrations that occur with oral ingestion.

Surgical fenestration-resection or partial hepatic resection results in symptomatic improvement in those with massive PLD.¹⁴ Laparoscopic liver cyst decortication is also available; its advantages include shorter recovery and smaller surgical incisions.¹⁵ Both surgical procedures have marginal success for diffuse PLD where multiple small cysts predominate.¹⁶ Postoperative complications include pleural effusions, ascites,

lower extremity edema, hypertension, and infection. Finally, individuals have undergone either liver or combined liver-renal transplantation for massive PLD.¹⁷

Intracranial Aneurysms

ICAs occur more frequently in ADPKD (5%–8%) than in the general population (1%–2%).^{18,19} Hypertensive strokes and subarachnoid hemorrhage are responsible for the majority (75%) of cerebrovascular deaths in ADPKD.²⁰ Dolichoectasia is found in increased frequency (3%)²¹ and subarachnoid or pineal cysts are not uncommon in ADPKD. Saccular as opposed to fusiform

dilations are the most frequent ICA in ADPKD, and ICAs are found in the anterior portion of the circle of Willis in 75%. Only a family history of ICA has been found to be associated with the presence of ICA in ADPKD.¹⁹ Given the difficulty in obtaining an accurate family history of the cause of cerebrovascular events, when in doubt, a positive or suspicious family history should be assigned to the individual. ADPKD individuals with ICA rupture¹⁹ are more often women, relatively young (mean age, 34 years), and with a higher frequency of family history of ICA (20%).¹⁹ Neuroimaging demonstrates a new ICA in 12% of patients who have suffered a ruptured ICA.²² ICAs cluster in less than 5% of ADPKD families and the 5' position of mutations in PKD1 is more commonly associated with ICAs. Other genetic modifiers may also be responsible for ICA in ADPKD.²³

Magnetic resonance angiography is the appropriate screening imaging modality for cerebral aneurysms and can identify ICAs as small as 3 mm. Four-vessel cerebral angiography is the gold standard for confirmation of questionable ICAs.¹⁹ Given the relatively low frequency of ICA in ADPKD, it is only cost-effective to screen those at risk of ICA (a positive family history) or whose current occupation (e.g., airline pilot) or lifestyle (e.g., scuba diving) significantly increases the likelihood or consequences of rupture. In addition, for those individuals in whom knowledge of a positive or negative result would improve their quality of life, a screening test for the presence of an ICA is warranted. In 130 asymptomatic ADPKD individuals with initial negative magnetic resonance screening studies who underwent repeat imaging 3 to 15 years later (mean, 9.7 years), no ICAs were found. Therefore, repeat screening in asymptomatic ADPKD subjects should be after more than 10 years.

Mortality and morbidity associated with a ruptured ICA remain more than 50%. However, in the general population, 50% of ICAs remain intact throughout life. The risk of rupture of ICA is related to the size of the aneurysm, with risk of rupture for ICAs more than 10 mm increasing exponentially with an estimated rupture rate of one in 5 patient-years. Longitudinal imaging of asymptomatic ADPKD individuals with intact ICAs less than 5 mm demonstrate little or no change in size. Less reliable data also suggest that those less than 10 mm do not change; however, the number of individuals studied is small.^{24,25}

The outcome of surgical interventions for intact ICAs is extremely good compared with those presenting with rupture. Rare surgical complications include death or cerebrovascular accident with permanent neurological sequelae. However, recovery from elective neurosurgery for ICAs is usually associated with significant neurocognitive dysfunction as well as mood and sleep disorders for 6 to 12 months. Therefore, the decision to undergo elective surgery, clipping, coiling, or injection of intact small ICAs should be done only after discussion with the neurosurgeon, neurologist, and nephrologist and should take into account the patient's expectations and general health.

Renal Manifestations

Infections

Lower and upper urinary tract infections are common (30%–50%) and may be associated with a faster rate of renal functional loss in ADPKD.²⁶ Differentiating upper and lower tract infections is important. Upper urinary tract infections may be due to pyelonephritis, nephrolithiasis, obstruction, or cyst infection. Differentiating among these conditions

relies on laboratory and radiographic studies. Pyelonephritis and stone-related infections often have urinary abnormalities (leukocyturia and bacteriuria) and positive urine cultures as opposed to cyst infections. With cyst infections, blood cultures are more likely (50%) to be positive than urine cultures. The triad of localized pain, fever, and the presence of a complex cyst on an ultrasound scan, magnetic resonance imaging, or computed tomography (CT) are the diagnostic features of renal cyst infection. Nephrolithiasis can be identified using CT. Cyst calcifications must be ruled out. Complex cysts, either consolidated hemorrhagic or infected, can be identified more often by CT. If symptoms are present in the area of the complex cyst, empiric antibiotic coverage is warranted.

The majority of cysts are detached from the parent nephron resulting in inadequate intracystic drug levels for aminoglycosides, penicillins, or cephalosporins. In pharmacologic studies during elective surgical cyst reduction procedures, good intracystic antibiotic levels have been demonstrated with trimethoprim-sulfamethoxazole, fluoroquinolones, chloramphenicol, and vancomycin.²⁷

Given that cysts are detached from their parent nephron, cyst infections are equivalent to abscesses and require prolonged therapy (4–6 weeks) to ensure successful treatment. In individuals with cysts larger than 5 cm, antibiotic therapy alone is often unsuccessful and percutaneous or surgical cyst decompression with parenteral antibiotic treatment may be necessary.²⁸ Early identification of cyst infection and prolonged treatment with antibiotics is the key to successful eradication of cyst infections in ADPKD. Failure to use this approach can result in pyelonephritis and loss of the kidney.

Perinephric abscesses and refractory infected cysts may need surgical drainage. Nephrectomy should be the treatment of last resort and can be performed by laparotomy or laparoscopy.²⁹ Indications for nephrectomy include gas-forming pyelonephritis, recurrent infections in pretransplantation setting, and staghorn calculi in a nonfunctioning kidney.

Hypertension

Sixty percent of ADPKD adults with normal renal function (mean age, 31 years) and 10% to 22% of children with ADPKD have hypertension.^{1,30} The frequency of hypertension defined by ambulatory measures is approximately 33% in children when 24-hour ambulatory blood pressure monitors are used.³¹ Hypertension early in ADPKD is usually mild and adequately controlled with one to two antihypertensive medications. Importantly, hypertension is a significant independent predictor of progression to renal failure in ADPKD.

The mechanisms responsible for the development of hypertension in ADPKD include activation of the renin-angiotensin-aldosterone system (RAAS).^{32,33} Individuals with ADPKD with hypertension and normal renal function demonstrate larger kidney volumes compared with their age- and gender-matched ADPKD normotensive counterparts. This suggests that cyst growth and expansion lead to compression and stretch of renal arterioles and activation of the intrarenal RAAS similar to bilateral renal artery stenosis.³³ Relative improvement in effective renal plasma flow and a decline in filtration fraction occur in hypertensive patients with ADPKD undergoing single-dose or short-term therapy with angiotensin-converting enzyme (ACE) inhibitors compared with matched essential hypertensives.

Left ventricular hypertrophy is present in approximately 50% of hypertensive ADPKD individuals.³⁴ Increased left ventricular mass index is also present in normotensive ADPKD individuals compared with age-matched controls. Hypertensive and normotensive ADPKD patients have a higher myocardial performance index, a measure of right ventricular dysfunction.³⁵ The left ventricular mass index also correlates with both diurnal and nocturnal systolic blood pressure based on 24-hour ambulatory blood pressure monitoring in normotensive adults as well as in children with ADPKD and normal kidney function.^{36,37}

Proteinuria in ADPKD is usually low grade (<1 g/day) and occurs in a minority (17%) of patients. However, proteinuria is more common in hypertensive versus normotensive ADPKD individuals and is related to the level of blood pressure control.³⁸ Proteinuria is more common in ADPKD children (27%) and is also related to blood pressure level.³⁹ Microalbuminuria is present in approximately 27% of adults with ADPKD and 34% of children with ADPKD and is also a predictor of poor renal outcome in ADPKD.

Hypertension is associated with a faster rate of progression to renal failure in ADPKD and is the most treatable risk factor associated with disease progression. Importantly, when other factors related to renal progression are taken into account, age, renal volume, proteinuria, and blood pressure level or hypertension status are important risk factors for progression to ESRD. Progression to ESRD in ADPKD has significantly slowed since 1980 with an increasing age at onset of ESRD of 4 to 10 years on average.⁹ Better blood pressure control, being followed by a nephrologist, and increased use of ACE inhibitors have all been implicated as being responsible for the slowing of progression to renal failure. Long-term ACE inhibitor therapy (7 years) of hypertension in ADPKD has improved left ventricular mass index and decreased the frequency of left ventricular hypertrophy and albuminuria⁴⁰ with the greatest decrease in albuminuria found in those whose blood pressures were treated to less than 125/75 mm Hg. The improvement in the left ventricular mass index and frequency of left ventricular hypertrophy after treatment may not be specific to ACE inhibitors because rigorous (mean arterial pressure < 93 mm Hg) compared with moderate (mean arterial pressure 100–107 mm Hg) blood pressure control demonstrated beneficial effects. Although ACE inhibitors have renoprotective effects with regard to proteinuria, no clear benefit in slowing the rate of progression to renal failure has been demonstrated in ADPKD.^{40–42} However, studies have been of short duration, using multiple simultaneous interventions (i.e., protein restriction and different blood pressure levels) and included patients with advanced renal disease. Importantly, observational studies demonstrate that the use of diuretics as opposed to ACE inhibitors are associated with faster progression to ESRD,⁴³ whereas β -blockers and ACE inhibitors demonstrate similar effects on the rate of renal progression.⁴⁴

There is lack of data available regarding the benefit of angiotensin receptor blockers, alone or in combination with ACE inhibitors in ADPKD.⁴⁵ There is significant variability in the level of blockade of the RAAS by ACE inhibitors and the additional use of angiotensin receptor blockers may maximize the blockade of the RAAS. The COOPERATE study randomly assigned 366 patients with nondiabetic kidney disease to either trandolapril, losartan, or a combination of the two and found a 61% decrease in the composite endpoint of doubling of serum creatinine, ESRD, or death in the combination group versus the other groups.⁴⁵

The PKD HALT network, a multicenter initiative funded by the National Institutes of Health, is currently investigating the role of dual blockade of the RAAS using lisinopril and telmisartan versus lisinopril alone in more than 1100 participants (HALT PKD trial). This trial includes those with chronic kidney disease types I, II, and III. The impact of dual blockade of the RAAS and the level of blood pressure control—120 to 130/70 to 80 mm Hg versus less than 110/75 mm Hg on total renal volume—is being evaluated in patients with chronic kidney disease I and II, whereas dual blockade of the RAAS is being evaluated in patients with CKD III with a composite endpoint of the time to a 50% reduction of baseline estimated glomerular filtration rate, ESRD, or death.

Kidney Pain in Autosomal Dominant Polycystic Kidney Disease

Kidney pain could be due to a variety of conditions such as chronic kidney pain, infections (cystic or parenchymal), nephrolithiasis, and cyst hemorrhage, and an accurate diagnosis is required before treatment. A thorough clinical history, physical examination, urinalysis and urine cultures, and imaging studies are usually sufficient to identify the cause of pain.

Chronic kidney pain is common and is associated with larger kidneys and increasing age. It can be unilateral or bilateral with varying intensity.¹ The presence of hematuria is possible, but painless hematuria is also common in ADPKD. Urine cultures are usually negative.

For mild pain, symptomatic relief with analgesics other than nonsteroidal anti-inflammatory drugs should be used. In cases of more severe and debilitating pain or occurrence of narcotic dependence, the possibility of intervention should be entertained. CT-guided cyst aspiration with or without sclerotherapy (with ethanol or tetracyclines) can be offered if only few large cysts are responsible for the pain.⁴⁶ Laparoscopic or open cyst reduction surgery is more complicated and is associated with more serious complications such as persistent postsurgical pain, leakage from the surgical site, ascites, and recurrent infections. It should be reserved for debilitating and refractory pain.⁴⁷ Infections have already been extensively discussed previously.

Cyst hemorrhage usually presents with sharp, acute pain without fever, but low-grade fever and leukocytosis can be present in some cases. Cyst hemorrhages can be confined to the cyst or communicate with the urinary (causing hematuria), perinephric, or retroperitoneal spaces. CT or MRI (especially when compared with previous studies) may confirm the diagnosis. Treatment is based on pain management. Prophylactic oral anti-biotherapy for a week to avoid infections could be considered.

Nephrolithiasis occurs in approximately 20% of patients with ADPKD. The most common type of kidney stones are composed of uric acid (>50%) and the remainder of calcium oxalate (40%).⁴⁸ They usually present as acute-onset episodes of flank pain with microscopic hematuria. The imaging study of choice should be CT. Medical management should consider abundant water intake (almost a gallon per day), low-salt diet, citrate supplements in case of hypocitraturia, and allopurinol in case of hyperuricosuria. Cystoscopy and/or extracorporeal shock wave therapy should be considered if kidney stones are less than 2 mm. Kidney stones larger than 2 mm, particularly if they are associated with infection and obstruction, may require open surgical removal.⁴⁸ Table 45-2 summarizes differential diagnoses and treatment of kidney pain in ADPKD.

Table 45-2 Differential Diagnosis and Treatment of Kidney Pain in Autosomal Dominant Polycystic Kidney Disease

	Pain Characteristics	Associated Features	U/A	Cultures	Imaging	Treatment
Cyst hemorrhage	Sudden onset, localized, unilateral, sharp, improves after few days	Usually afebrile, nausea/vomiting, hematuria possible	±/Hematuria, cultures negative	Negative	CT or MRI	Analgesics, bed rest and hydration, compression on affected side; if shock: transfusions
Pyelonephritis	Unilateral, progressive, diffuse ++	High-grade fever, nausea/vomiting, dysuria, sepsis	WBCs/pyuria, ± bacteria, ± hematuria	Urine positive, ± positive blood	Not indicated with positive cultures, CT or MRI	IV antibiotics with good urine concentration (4 wk), followed by PO treatment
Cyst infection	Unilateral, localized, subacute, sharp +++	Fever, nausea/vomiting	Usually bland	Urine negative, blood positive	CT or MRI, WBC tagging if uncertain	Cyst-penetrating antibiotics (4 wk minimum), longer recovery time
Nephrolithiasis	Unilateral, acute, sharp ++++, paroxysmal, renal colic, radiation to pelvis or groin	Usually afebrile unless infection, nausea/vomiting	Hematuria common, crystals (uric acid and/or calcium oxalate)	Usually negative unless infected stone	Spiral CT, stone protocol	IV hydration, analgesics, ureteroscopy, percutaneous nephrolithotomy, open surgery
Chronic renal pain	Diffuse, constant, variable intensity, positional in nature aggravated by inspiration, automobile, sudden impact	Afebrile	Usually bland, occasional hematuria	Negative	Usually negative	Analgesics, cyst aspiration ± sclerosis with ethanol or tetracyclines if few large cysts causing pain, cyst reduction

+++, moderate; ++, severe; CT, computed tomography; MRI, magnetic resonance imaging; WBCs, white blood cells.

Therapeutic Modalities to Slow Disease Progression in Autosomal Dominant Polycystic Kidney Disease

The Modification of Diet in Renal Disease study, evaluating the role of protein restriction in the course of renal disease in 222 ADPKD patients with a baseline glomerular filtration rate between 25 and 55 mL/min, did not demonstrate benefit. At present, dietary protein restriction to less than 0.8 g/kg/day is not recommended in patients with ADPKD. Other approaches such as alkali therapy,⁴⁹ amiloride,^{50,51} caffeine intake,⁵² and cyst drainage^{46,47} have been investigated in animal or in vitro models of PKD with evidence of benefit. There are, however, no data from randomized clinical trials on the efficacy of these agents. Better understanding of cellular and molecular mechanisms of cystogenesis has opened the way to new approaches to delay progression of ADPKD. Recently, testing for exciting new treatments has begun based on the understanding of the underlying pathophysiology of cyst growth in ADPKD as well as positive preclinical results in murine models of ADPKD.

Evidence suggests that increased intracellular cyclic adenosine monophosphate plays a significant role in proliferative and fluid secretion pathways in cyst formation and expansion in PKD.⁵³ The vasopressin V₂ receptor antagonist OPC-31260, which lowers renal epithelial cell intracellular cyclic adenosine monophosphate levels, has been evaluated in a transgenic model of PKD2 and demonstrated a significant decrease in renal and cyst enlargement and renal dysfunction. Renal cyclic adenosine monophosphate levels were decreased, with a decrease in cystic fluid collection.⁵⁴ Administration of the selective V₂ receptor antagonist tolvaptan (OPC-41061) also lowered renal cyclic adenosine monophosphate levels, decreased the severity of cyst formation, and resulted in lower kidney weights and cyst and fibrosis volumes in a model of autosomal recessive PKD, the PCK rat.⁵⁵

Phase IIA studies of tolvaptan in adult patients with ADPKD and normal kidney function confirmed a dose-dependent response with increasing urine output and decreasing urine osmolality in 11 patients. In addition, the safety and tolerability of four escalating doses of oral tolvaptan were established in 27 individuals who maintained 24-hour urine osmolality less than 300 mOsm with an average daily urine output of 6 L after 5 days of treatment.⁵⁶ Phase IIB and III trials investigating the safety and efficacy of tolvaptan therapy targeting urinary concentration are currently ongoing. Increased water intake could mimic the results obtained by blocking vasopressin and associated pathways. A 3.5-fold increase in water intake in PCK rats by using a 5% glucose solution was associated with a significant decrease (>60%) in renal expression of arginine vasopressin V₂ receptors, B-Raf, phosphorylated extracellular signal-regulated kinase, and proliferating cell nuclear antigen-positive renal cells. High water intake ultimately decreased the kidney-to-body weight ratio 28.0% and improved renal function.⁵⁷

Somatostatin C (octreotide) is a synthetic analogue of the natural hormone and has been successfully used in the treatment of multiple endocrine tumors.⁵⁸ Experimental data suggest that cyst fluid secretion in several animal models requires active chloride transport. Somatostatin C inhibits this phenomenon. The cyclic adenosine monophosphate pathway is also inhibited by somatostatin in one animal model of PKD.⁵⁹ In a pilot study comparing somatostatin with placebo

in patients with PKD, active therapy was associated with a smaller increase in cyst and total kidney volume after 6 months of treatment.⁶⁰

Polycystin-1 functions by inducing the formation of a complex with tuberlin and the Ser/Thr kinase mTOR thereby inhibiting mTOR activity. Rapamycin is an antiproliferative agent, which inhibits tubular epithelial cell proliferation through the mTOR pathway. Rapamycin reverses this inhibition and has been shown to inhibit cyst formation and renal failure in the Han:SPRD rat model of PKD.⁶¹ A clinical trial of rapamycin is currently ongoing in ADPKD patients.

The use of triptolide (the active diterpene in the traditional Chinese medicine Lei Gong Teng) in a murine model of ADPKD arrests cellular proliferation and attenuates overall cyst growth by induction of Ca²⁺ release through a polycystin 2-dependent mechanism.⁶² Potential uses of this agent are being tested in preclinical models of PKD.

In summary, multiple pathways, selectively targeted based on the cell signaling or trafficking abnormalities defined in transgenic animal models of PKD and cell culture systems of PKD epithelia, provide a range of therapeutic options. In addition to the systemic and general renal benefits obtained from agents that inhibit the RAAS, targeted therapies for high-risk ADPKD individuals will be available to optimize therapy early, before the loss of renal function.

The techniques of gene cloning, chromosomal localization, and genomic evaluation have more clearly elucidated the pathogenesis and treatment strategies of many of the inherited renal disorders. This chapter reviews a number of clinical disorders that have as their basis a defect in some transport or metabolic function of the renal tubular epithelium. Using this model of inherited disorders of renal tubular transport, one is able to define conditions in which single or multiple substances are lost, in which inorganic ions or organic solutes are overly excreted, and in which the whole body pool of these substances is diminished due to excessive urinary losses. Conversely, sometimes metabolites are stored to excess, with toxic effects. The basic genetic and pathophysiologic mechanisms underlying these transport and metabolic defects are detailed elsewhere.¹⁻⁵ The intent of this chapter is to focus on current therapeutic approaches.

AMINOACIDURIAS

The aminoacidurias may be specific to a single amino acid or to a group of amino acids whose structure and charge are similar.^{2,4} In recent years, virtually all amino acid transporters have been cloned.⁵ The technique of amino acid analysis of urine or plasma permits diagnosis of these disorders, particularly the measurement of urinary clearance or fractional excretion. Several of the aminoacidurias, such as iminoglycinuria in which excessive amounts of L-proline, hydroxy-L-proline, and glycine are found in the urine, are benign traits requiring no treatment.¹ In dicarboxylic aminoaciduria, there are no apparent clinical features and hence no recommended therapy.¹

Hartnup disease is an autosomal recessive disorder characterized by massive urinary losses and intestinal malabsorption of the neutral monoamino-monocarboxylic amino acids. Affected patients develop features of pellagra^{2,4} because of inability to synthesize minimal concentrations of nicotinamide as a

result of extensive bowel and urinary L-tryptophan losses. Thus, insufficient absorption and reabsorption of L-tryptophan results in niacin deficiency. Treatment consists of providing nicotinamide (40–150 mg/day) or an American diet containing leafy green vegetables. This effectively bypasses the need for tryptophan. With the provision of nicotinamide, the red scaly rash heals and neurologic problems improve.

Renal and urinary tract stones develop in cystinuria, an autosomal recessive disorder in which the poorly soluble disulfide amino acid is excreted into the urine in increased amounts.⁶ Cystinuria is a relatively frequent cause of nephrolithiasis, found in 1 in 12,000 persons worldwide. The initial goal of therapy is to decrease the urinary concentration of cystine below its solubility limit and is generally accomplished by a forced high fluid intake. Unfortunately, this form of therapy requires strenuous compliance, with frequent ingestion of fluids and nocturnal awakening to empty the bladder and drink additional fluids. Patients should also receive oral alkali therapy because the solubility of cystine is pH dependent (urinary solubility of cystine increases sharply at pH values greater than 7.5). A suggested dose is 650 mg of sodium bicarbonate every 6 to 8 hours.

Should these more conservative measures fail, the next line of therapy is the thiol-containing agents. Oral D-penicillamine (dimethylcystine), a mercaptan that undergoes an *in vivo* disulfide exchange reaction with cystine, causing urinary excretion of a more readily soluble penicillamine-cystine mixed disulfide. In parallel, the concentration of cystine in the urine of a cystinuric subject actually decreases.^{2,4} Treatment with oral D-penicillamine at 1 to 2 g/day in the adult and 30 mg/kg in the child is highly effective in decreasing urinary cystine excretion to less than 200 to 300 mg/day, but patient tolerance is poor and adverse effects are frequent.⁶ Serious adverse effects that result in discontinuance of the drug occur in 30% to 50% of patients and include skin rash, membranous or linear IgG antglomerular basement membrane antibody-induced

nephropathy, nausea, vomiting, impairment or loss of taste or smell, and pemphigus.¹

Because of these serious adverse effects, other disulfide compounds have been used. Indeed, D-penicillamine should probably not be a first-line drug of choice. Most experience has been gained with 2-mercaptopyrionylglycine (α -MPG, tiopronin), which is 1.5 times as effective as D-penicillamine in decreasing free cystine and in increasing the quantity of mixed disulfides appearing in the urine.⁶ Tiopronin also results in adverse effects, including nausea, vomiting, and rash, but far less frequently than D-penicillamine. Development of the nephrotic syndrome is rare. The final dose of tiopronin needed to reduce urinary cystine varies from 100 to 200 mg/day. Although patients may experience adverse effects, it is seldom necessary to discontinue therapy, and only 6% of patients receiving tiopronin because of D-penicillamine toxicity must stop taking it.^{2,4}

Surgery for staghorn calculi or obstructing stones can potentially be avoided by the use of extracorporeal shock wave lithotripsy.⁷ In ultrasonic lithotripsy, an ultrasound probe is passed up the ureter during cystoscopy; it is 97% effective in removing an obstructing calculus. Extracorporeal shock wave lithotripsy employs a totally external technique, with patients placed in a special bath, anesthetized, and then receiving thousands of precisely directed shock waves. The main drawbacks are hematuria, failure of stone passage, and mild to moderate obstruction and infection, although most patients pass the stone fragments with lesser symptoms of colic. Cystine stones are less effectively fragmented than are calcium oxalate stones.⁷

Hypercystinuria probably requires no treatment because patients do not excrete the same quantities of cystine as patients with classic cystinuria.⁷

GLYCOSURIAS

The renal glycosurias are a group of conditions in which excessive urinary excretion of glucose occurs in the absence of hyperglycemia. The glycosurias occur because of abnormal renal tubular reabsorption of glucose due to mutations in the two renal isoforms of the sodium-dependent glucose transporter. The clinical course of the primary renal glycosurias is benign because there is neither progressive renal deterioration nor serious metabolic derangement, and there is no specific therapy. It is important to distinguish the primary renal glycosurias from diabetes mellitus, which requires insulin or other hypoglycemic therapy.

CLASSIC PSEUDOHYPOALDOSTERONISM

Classic pseudohypoaldosteronism is a condition in which both renal tubular salt wasting and hyperkalemia are observed, despite normal renal and adrenal function.² The defect relates to abnormalities of the renal aldosterone or mineralocorticoid receptor, with an ultimate defect in the epithelial sodium channel.⁴ Salt wasting does not respond to exogenous mineralocorticoids alone, so sodium chloride supplements must be provided. This hyperkalemic state occurs in infancy, and 24-hour Na^+ and Cl^- losses are as high as 10 to 15 mEq/kg, despite hypovolemia and hyponatremia. The administration of gluco-

corticoids, deoxycorticosterone acetate, or fluorinated glucocorticoids (which have extensive mineralocorticoid activity) do essentially nothing to reverse hyponatremia and hyperkalemia because of defective epithelial sodium channel or mineralocorticoid receptor. The most effective therapy is supplemental sodium chloride, with the dose based on the magnitude of measured urinary losses (mEq/kg/24 hr).^{2,4} In infants, salt supplements normalize growth and correct serum Na^+ and Cl^- concentrations, despite the finding of persistently elevated plasma renin and aldosterone concentrations. A potassium-binding resin may be required to correct the concomitant hyperkalemia, and oral bicarbonate or citrate therapy is necessary to correct the acidosis. Patients can often have their salt supplements decreased or discontinued after infancy without effect, and they continue to grow at a normal rate.²

HEREDITARY PHOSPHATURIAS

Phosphorus is the most prevalent mineral anion found in bone (75%–85% of total body phosphate pool) and is also essential for numerous life processes.¹ Because phosphate is a key anion for important biologic systems, processes that affect the maintenance of phosphate homeostasis are important. The proximal tubule is the major site of regulation of phosphate homeostasis.² A number of clinically distinct phosphaturic syndromes have been defined,^{1,4} all of which result in excess renal phosphate wasting and hypophosphatemic osteomalacia. If these conditions present during childhood, the result is incomplete mineralization and the radiographic appearance of rickets, with bowing of the lower extremities. Because the fundamental pathogenic mechanisms of the major phosphaturic syndromes differ, their treatment is also distinctly different (Table 46-1).

Primary or X-Linked Hypophosphatemic Rickets

This X-linked dominant disorder is the most common of the phosphaturic syndromes and involves a double renal tubular defect: (1) failure of $\text{Na}^+/\text{PO}_4^{3-}$ cotransport across the brush border membrane of the proximal tubule and (2) reduction in the conversion of 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D_3 by proximal tubule cell mitochondria.^{2,4} A defective phosphate regulatory protein (PHEX) that fails to degrade fibroblast growth factor 23 is the cause of this condition.

The current recommendation regarding the most appropriate form of treatment is a combination of oral 1,25-dihydroxyvitamin D_3 in as low a dose as possible (5–50 ng/day) plus oral phosphate supplements (70 mg/kg/day).^{1,4,8} Although this therapy has been shown to improve calcium and phosphate retention, phosphate must be administered every 4 to 5 hours because the renal phosphate leak persists (see Table 46-1). Therapy is probably needed throughout the life of the patient. Not only will the rachitic growth plate lesion be improved but endosteal bone trabecular lesions will also improve, a change not apparent when using vitamin D_2 or D_3 alone. Oral phosphate can be administered as Joulie solution⁸ or as neutral phosphate.⁹ The latter is commercially available and far easier to use. This form of therapy should be given during childhood. Medical

Table 46-1 Features of Different Forms of Primary Hypophosphatemic Rickets

Condition	Pattern of Inheritance	Gene Defect	Associated Findings	Salient Clinical Features	Age Detected	Therapy
X-linked hypophosphatemic rickets (vitamin D dependent or familial)	X-linked dominant (rarely dominant or AR)	Defect in PHEX, a regulator of protein coded Xp22.1-22.2	Occasional parathyroid adenoma/hyperplasia	Bowing lower segment, short stature, no myopathy; more severe in males (lyon effect)	9-13 mo	Oral phosphate 70-100 mg/kg/day (4-5 times daily); oral 1,25-(OH) ₂ D ₃ 5-50 ng/kg/day
Hypophosphatemic nonrachitic bone disease	AD or sporadic	FGF23	Glycinuria	No radiographic evidence of rickets; slight short stature may develop late	3 yr to adult	Oral phosphate and vitamin D; 1,25-(OH) ₂ D ₃ may heal osteomalacia
Hereditary hypophosphatemic rickets and hypercalciuria	AR; consanguinity frequent	Unknown	High plasma 1,25-(OH) ₂ D ₃ ; increased intestinal calcium absorption, hypercalciuria, low urine cAMP	Rickets, short stature, osteomalacia, equal sex distribution	Early childhood	Oral phosphate (70-100 mg/kg/day)
Oncogenous rickets with phosphaturia	Sporadic or AD/AR	Presumed defect in phosphatonin activity; failure to degrade FGF23	Neurofibromatosis, polyostotic fibrous dysplasia, epidermal nevus syndrome	Rickets healed by removal of tumor where measured; serum 1,25-(OH) ₂ D ₃ values are usually low	Birth onward	Oral phosphate and 1,25-(OH) ₂ D ₃ reverse hypophosphatemia; surgery may be curative
Adult sporadic hypophosphatemic osteomalacia	Sporadic	Not relevant	Glycinuria	Severe bone pain, vertebral flattening, Looser-Milkman zones, severe myopathy/weakness	Adult	Oral phosphate and vitamin D (any form)

AD, autosomal dominant; AR, autosomal recessive; cAMP, cyclic adenosine monophosphate; FGF23, fibroblast growth factor 23; 1,25-(OH)₂D₃, 1,25-dihydroxyvitamin D₃; PHEX, phosphate-regulating gene on the X chromosome with homologies to endopeptidases.

noncompliance is a major problem, as are excessively loose stools due to oral sodium phosphate. Hydrochlorothiazide and amiloride may be used in some cases in which there appears to be resistance to the combination of vitamin D and phosphate supplementation in terms of calcium malabsorption and hypercalciuria.

No long-term studies have been reported that confirm the role of lifetime phosphorus supplementation in adults with this disorder. However, studies indicate that calcification of ligaments and joints (enthesopathy) can occur in untreated adult patients,¹⁰ suggesting the need for therapy during adult life. Severely affected adults who continue to have osteodystrophy, stress fractures, and dental caries require prolonged treatment, yet those who are asymptomatic may not always need to continue treatment. Normal pregnancies have been reported both in mothers treated with vitamin D/phosphate supplementation and in those not treated. The concomitant use of recombinant human growth hormone, as an adjunct to standard therapy, probably improves growth.

Autosomal Dominant Hypophosphatemic Rickets

Hypophosphatemic nonrachitic bone disease is an autosomal dominant or possibly sporadic disorder in which hypophosphatemia is milder than in X-linked hypophosphatemia and rickets is absent.^{1,4} Both the $T_m \text{ PO}_4$ /glomerular filtration rate in hypophosphatemic patients and serum 1,25-dihydroxycholecalciferol concentrations are normal. Therapy with vitamin D₂ and oral phosphate salts appears to improve bone mineralization; however, oral 1,25-dihydroxyvitamin D₃ can be used in place of vitamin D₂ or D₃.

Hereditary Hypophosphatemic Rickets with Hypercalciuria

This is a familial disorder that manifests as rickets, short stature, phosphaturia, hypercalciuria (8 mg/kg/24 hr), and augmented intestinal calcium and phosphate absorption.¹¹ Circulating 1,25-dihydroxyvitamin D₃ concentrations are two to five times normal compared with decreased concentrations in X-linked hypophosphatemic rickets and normal concentrations in hypophosphatemic bone disease. This disorder represents a renal phosphate leak that results in hypophosphatemia, which in turn stimulates 1,25-dihydroxyvitamin D₃ synthesis. Higher vitamin D metabolite concentrations lead to increased active intestinal calcium absorption, suppression of parathyroid hormone (PTH) secretion, and hypercalciuria. As 1,25-dihydroxyvitamin D₃ concentrations in plasma are elevated, vitamin D therapy is not indicated. Long-term oral phosphate alone reverses the biochemical features of this rare disorder.¹¹

MAGNESURIAS

Magnesium depletion is an uncommon mineral disorder and is frequently overlooked because it usually arises within a complex clinical setting. Renal magnesium wasting may be part of a primary inherited disorder (Gitelman's syndrome),^{12,13} a single defect in magnesium reabsorption,¹⁴ or associated with several other clinical disorders.^{2,4} Excessive urinary losses of magnesium can also be associated with diabetic ketoacidosis,

hyperaldosteronism, hypercalciuria (with concomitant use of loop diuretics), Gitelman's syndrome, and the use of several therapeutic agents such as cisplatin, aminoglycoside antibiotics, diuretics, and cyclosporine.⁴ Hereditary isolated renal magnesium wasting is due to defects in three genes: a Na⁺/K⁺-ATPase subunit (a routing defect) and paracellin,¹ a protein located on the tight junction,¹⁴ and transient receptor potential cation channels.¹⁵ Gitelman's syndrome is discussed later.

A predominant feature of magnesium deficiency is hypocalcemia related to altered parathyroid gland function. Hypomagnesemia alters end-organ (bone) responsiveness to PTH⁴ and hence contributes to hypocalcemia. Further, the provision of intravenous magnesium supplements to magnesium-deficient hypocalcemic patients has been shown to augment serum values of PTH.⁴ Magnesium may also be an important factor in the action and/or metabolism of vitamin D in that some hypomagnesemic patients respond to 1 α -vitamin D metabolites only after correction of serum magnesium values.^{3,4} Serum concentrations of 1,25-dihydroxyvitamin D₃ are decreased in many magnesium-depleted patients.⁴ Thus, the mineral abnormalities can include reduced serum concentrations of magnesium, calcium, 1,25-dihydroxyvitamin D₃, and PTH, all of which may be restored to normal by infusion or oral ingestion of magnesium. Therapy with magnesium oxide 1 to 5 g (50–250 mEq) in three divided doses daily causes the following changes: increased serum and urine magnesium and calcium, decreased serum phosphate, increased urine phosphate, and increased serum 1,25-dihydroxyvitamin D₃ and PTH.¹⁶ Although the doses of oral magnesium required vary from one patient to the next, improved magnesium homeostasis can usually be achieved. Magnesium should be taken three to four times daily as magnesium oxide or magnesium pyrrolidine carboxylate because urinary magnesium losses occur continuously, and patients who have magnesium wasting will constantly lose this divalent ion.

Infants who have hypomagnesemic tetany should receive 0.4 to 0.8 mg/kg of a 50% solution of magnesium sulfate either intramuscularly or intravenously. Intravenous magnesium should be infused slowly with monitoring, and calcium gluconate or lactate should be on hand to reverse dysrhythmias. Finally, renal magnesium wasting can occur in conjunction with varying degrees of renal insufficiency,¹⁶ and these patients may also require oral vitamin D analogues and calcium salts. A daily dose of 0.25 to 1.0 μ g of 1,25-dihydroxyvitamin D₃ may be needed as well as calcium lactate, carbonate, or acetate.

FANCONI SYNDROME

Fanconi syndrome is a generalized disorder of proximal tubule function that can occur either as a primary disorder or as secondary to a number of inherited conditions.^{1–4} Patients always show hyperexcretion of substances that are reabsorbed and diminished excretion of substances that are secreted.^{1–3,5} The manifestations of Fanconi syndrome often vary depending on the underlying disorder. Tubular dysfunction typically involves glycosuria, phosphaturia, generalized aminoaciduria, proteinuria, polyuria, and proximal renal tubular acidosis. Other substances frequently excreted in increased quantities include uric acid, sodium, potassium, magnesium, citrate, and proteins of molecular mass less than 45,000 kd.¹⁴ Because of

phosphaturia, hypophosphatemia, and sometimes renal insufficiency, various bone disorders may be found, including rickets, osteomalacia, osteoporosis, and osteitis fibrosa.¹⁷ Adult patients may have severe osteomalacia and may present with intense bone pain and muscle weakness.^{1-3,5} Symptomatic hypokalemia is manifested by muscle weakness, growth failure, dehydration, unexplained fevers due to volume depletion, and profound metabolic acidosis.¹⁷

Therapy of Fanconi syndrome depends on the underlying cause. Symptomatic therapy includes large doses of oral alkali (sodium bicarbonate, often as much as 10–15 mEq/kg/day), phosphate supplements given four to five times daily (Table 46-2), a vitamin D analogue (usually calcitriol), adequate water, and adequate sodium and potassium replacement to correct volume depletion and signs of hypokalemia. Indomethacin may reduce urine volume.¹⁷

Patients with infantile nephropathic cystinosis have specific therapeutic needs. Cystine deposition within the cornea leads to photophobia, which may be improved with dark glasses, wetting solutions, and the use of cysteamine eyedrops that can dissolve cystine deposits.¹⁷ The molecular defect in this disorder involves reduction in the rate of efflux of cystine, but not cysteine, from within a lysosomal compartment; the oxidized (-S-S-) form of this sulfur amino acid remains trapped, thus forming intralysosomal cystine crystals. The defective gene encodes the lysosomal cystine transporter (cystinosin) and represents a defect in the endocytic pathway.^{14,17} At least two cystine-depleting agents, cysteamine and pantethine (its precursor), can be used to deplete the lysosomes, creating mixed disulfides with cystine that are freely permeable across the lysosomal membrane. The reduced SH form is then free to exit the lysosome as well and thus intracellular cystine decreases.^{14,17} The results of the Collaborative Cysteamine Study indicated that 98 patients receiving cysteamine showed a real slowing of the progression to renal failure and improved linear growth compared with more than 100 historic control cystinotic subjects.¹⁸ A recent analysis of 88 patients followed for more than 10 years identified not only uremia but also hepatomegaly, splenomegaly, neurological disease, progressive ocular disease, and continuing poor growth despite a functioning renal allograft.¹⁸ These results suggest the need for continuing cysteamine therapy, but this is only now being addressed by clinical trials. The drug Cystagon (cysteamine bitartrate) in capsule form has been approved by the U.S. Food and Drug Administration for

use in patients with cystinosis at a daily dose of 1.3 g/m². Patient compliance should be ensured by measuring leukocyte cystine content on a scheduled basis.¹⁸

Because of glandular cystine crystal deposition, hypothyroidism is universal in cystinosis, and therefore low-dose thyroxine is needed to prevent the clinical features of this endocrinopathy.¹⁷ The dose of L-thyroxine is chosen by determining the amount needed to suppress thyroid-stimulating hormone levels to the normal range. Cystinotic patients have also been shown to lose massive amounts of carnitine and therefore have a deficiency of this acyl-transporting compound. Oral carnitine therapy may reverse muscle carnitine depletion and the histologic features of the deficiency.¹⁷ Finally, recall that cystinosis is a lifelong disorder with continuing cystine deposition. The long-term involvement of organs other than the kidney is only now being appreciated since long-term survivors of renal transplantation became available for study.¹⁹

Lowe syndrome is an X-linked disorder that presents with cataracts, glaucoma, growth impairment, hypotonia, severe mental retardation, and features of Fanconi syndrome. It is caused by defective inositol polyphosphate 5'-phosphatase activity, presumably involving the phosphatidylinositol signaling pathway.¹ Treatment is directed at correcting the metabolic derangements of Fanconi syndrome. Renal dysfunction begins with tubular dysfunction but can progress to chronic renal failure. Tubular dysfunction eventually diminishes because of the decline in glomerular filtration rate. Patients with this syndrome usually die of infection or renal insufficiency but have a lifelong need for ophthalmologic evaluations. Most patients are boys, although girls with Lowe syndrome have been described due to chromosomal translocations.^{1,4}

Patients with galactosemia, an autosomal recessive deficiency of galactose 1-phosphate uridylyltransferase, develop a Fanconi syndrome that is totally reversible when patients are maintained on a galactose- and lactose-free diet.¹ This diet is a lifelong necessity.

Tyrosinosis is due to an autosomal recessive defect in fumarylacetoacetate fumaryl hydrolase, with the accumulation of succinylacetone and succinylacetoacetate, which in turn leads to hepatomegaly, cirrhosis, and full-blown Fanconi syndrome.^{1,2} The disorder has a poor prognosis and usually results in death in children due to cirrhosis and/or hepatoblastomas. A low-tyrosine, low-phenylalanine diet can treat the Fanconi syndrome

Table 46-2 Phosphate Preparations for Therapy of Phosphaturic Syndromes and Fanconi Syndrome

Content	Constituents	Phosphate
K-Phos M.F.	Potassium acid phosphate, sodium acid phosphate	125.6 mg per tablet
K-Phos No. 2	Potassium acid phosphate, sodium acid phosphate	250 mg per tablet
K-Phos Neutral	Potassium acid phosphate, monobasic; sodium acid phosphate, monobasic/dibasic	250 mg per tablet
Neutra Phos	Potassium acid phosphate, monobasic; sodium acid phosphate, monobasic/dibasic	1 g/300 mL
Neutra Phos (capsules)	Potassium acid phosphate, monobasic; sodium acid phosphate, monobasic/dibasic	250 mg per capsule (dissolve in water)
Joulie solution*	Sodium phosphate, phosphoric acid	30.4 mg/mL

*Must be prepared by a pharmacist.

and prevent rickets but does not prevent cirrhosis. The definitive form of therapy is liver or liver-kidney transplantation.²⁰ Most authorities suggest liver-kidney transplantation.

Hereditary fructose intolerance is an autosomal recessive disorder caused by mutations in the aldolase B gene, resulting in decreased aldolase B activity in the liver, renal cortex, and small intestine and leading to accumulation of fructose 1-phosphate.^{1,4} Diagnostic clues to this condition include an aversion to sweets, a lack of dental caries, and hepatomegaly. Development of Fanconi syndrome is temporally related to exposure to fructose, and treatment is directed at assiduously avoiding this sugar in the diet. As in galactosemia, development of Fanconi syndrome may occur within a few minutes to hours after ingestion of fructose and patients may become gravely ill with profound acidosis. Patients generally quickly recognize the advantage of avoiding fructose-containing foods.

Fanconi syndrome can be seen in certain children with an as yet untyped glycogen storage disease that is associated with hepatomegaly, massive glycosuria, glucose and galactose intolerance, and a mutation in the glucose transporter GLUT-4.^{14,21} These patients are also profoundly growth retarded. Treatment consists of controlling the symptoms of Fanconi syndrome with sodium bicarbonate, phosphate, potassium chloride, and vitamin D, and patients tend to improve with age.

Wilson's disease is an autosomal recessive hepatocellular disorder of copper metabolism that presents with hepatomegaly and Fanconi syndrome. Copper deposits are noted in the brain, liver, and kidney.¹ Patients with Wilson's disease also have, in addition to proximal renal tubular acidosis, findings that can only be explained as distal renal tubular acidosis, and urinary calculi are common. Hypoparathyroidism has also been described in one patient with Wilson's disease, possibly related to copper deposits in the parathyroid gland.¹ Therapy for Wilson's disease consists of D-penicillamine, which can be

troublesome in some patients, as noted in the discussion on cystinuria. Whenever D-penicillamine cannot be used, triethylene tetramine dihydrochloride can be used without fear of the same allergic manifestations.⁴

When Fanconi syndrome appears in conjunction with the nephrotic syndrome, it is usually found in association with a familial pattern and focal segmental glomerulosclerosis. Tubular atrophy and interstitial fibrosis are prominent.¹ Treatment of this glomerulopathy is unsatisfactory, and features of Fanconi syndrome continue until renal failure ensues.

Finally, Fanconi syndrome is associated with mutations of the mitochondrial genome,²² particularly if the respiratory chain is affected. Treatment is symptomatic, as described previously.

BARTTER SYNDROME

Bartter syndrome is characterized by hyperplasia of the juxtaglomerular apparatus, increased circulating angiotensin II concentrations, normal blood pressure with diminished pressor response to infused angiotensin II, hyperaldosteronism, hypokalemic alkalosis, and vasopressin-resistant polyuria.^{2,4} This condition is heterogeneous, and most patients present in infancy or later childhood, although a presentation after the age of 40 has occurred.⁴ The inheritance pattern is sporadic or autosomal recessive.

Recent progress in molecular biology has clarified certain aspects of this syndrome (Table 46-3).^{14,23-25} The genetic mutations that underlie Bartter syndrome involve defects in (1) the luminal Na⁺/K⁺/2Cl⁻ cotransporter (NKCC2), (2) the outwardly directed K⁺ channel (ROMK), or (3) the Cl⁻ channel (ClCNKB). These transport proteins are all located in the thick ascending limb of the Henle's loop; NKCC2 and ROMK are in the luminal membrane and ClCNKB in the peritubular membrane.²⁵ Gitelman's syndrome is caused by a mutation in the

Table 46-3 Forms of Bartter Syndrome

Type	Defective Protein	Clinical Characteristics	Inheritance Mode	Location	Therapy
Bartter type I	Bumetamide-sensitive sodium-potassium-chloride cotransporter	APP, HMA, nephrocalcinosis	AR	TAL	KCl, indomethacin
Bartter type II	Potassium channel, ROMK1	APP, HMA, nephrocalcinosis	AR	TAL	KCl, indomethacin
Bartter syndrome	Calcium-sensing receptor	HMA, hypomagnesemia	AD	TAL	KCl, magnesium oxide
Bartter type III	Chloride channel kidney B	Growth retardation, hypercalciuria, HMA	AR	TAL	KCl, indomethacin
Bartter type IV	Barttin (regulates chloride channel kidney A and B)	APP, HMA, sensorineural deafness, developmental delay	AR contiguous gene deletion	TAL	KCl, indomethacin
Gitelman's syndrome	Thiazide-sensitive sodium-chloride cotransporter	HMA, hypocalciuria, hypomagnesemia, chondrocalcinosis (onset in late childhood or adolescence)	AR	Distal convoluted tubule	Magnesium oxide or Mg pyrrolidine (30 mmol/day)

APP, antenatal with polyhydramnios and prematurity; AR, autosomal recessive; HMA, hypokalemic metabolic alkalosis; ROMK, renal outer medulla potassium channel; TAL, thick ascending Henle's loop.

thiazide-sensitive Na^+/Cl^- cotransporter in the lumen of the distal convoluted tubule. Differences in the function of these four ion-transport systems help explain the clinical heterogeneity in Bartter and Gitelman's syndromes.

Children may present with growth failure as well as weakness, muscle cramps, polyuria, and abdominal pain; delayed or slowed mentation is seen in all children with Bartter syndrome. The laboratory features are also heterogeneous in that patients show variable degrees of increased urinary losses of potassium, sodium, chloride, magnesium, calcium, and kallikrein and increased production and excretion of prostaglandin E_2 .¹³ The differential diagnosis includes Fanconi syndrome, incomplete distal renal tubular acidosis, use of diuretics, abuse of laxatives, cyclical vomiting, chloride-deficient diets, and cystic fibrosis. Alkalosis is associated with administration of impermeable anions, mineralocorticoid excess, and primary renal magnesium wasting (Gitelman's syndrome).²⁵ Because of abnormalities in the concentration of prostaglandins in plasma and urine, it was once thought that the primary defect was one of prostaglandin metabolism⁴; this was before the roles of ion channels or transporters were understood.^{13,25} Elevated prostaglandin levels could potentially explain vasodilation, the lack of responsiveness to pressors, the inhibition of chloride transport in Henle's loop, and potassium hyperexcretion and metabolic alkalosis. However, prostaglandin inhibition does not always correct the defect in these patients.¹³ Recent studies suggest that at least five different pathogenetic mechanisms produce this syndrome.²⁴ Moreover, in disorders that mimic hereditary Bartter syndrome, such as bulimia, chronic diuretic abuse, and chloride-deficient formula-induced disease, the same plasma profile is evident.¹

Therapy of Bartter syndrome is problematic.^{4,24} Potassium supplementation is necessary, and large doses of potassium chloride may be required. Prostaglandin inhibitors have short-lived effects when used alone²⁴; indomethacin has been used most often. Prostaglandin inhibition is an adjunct therapy that limits the need for potassium chloride supplements.^{4,24}

In a subset of patients, the use of supplemental potassium chloride and treatment with a prostaglandin synthetase inhibitor may not fully correct hypokalemia, which should be the primary aim of therapy. In these cases, a potassium-sparing diuretic such as amiloride or triamterene in the usual doses can be useful.^{1,4} If constantly applied, these therapeutic approaches usually result in improved growth and development in children and improved symptoms in adult patients with Bartter syndrome.

Patients with Gitelman's syndrome have renal magnesium wasting, hypokalemia, metabolic alkalosis, and hypocalcemia.^{4,14,23} Some patients may have a tendency toward hypocalcemia,²³ and cramps may be common. If magnesium wasting is present, magnesium supplementation is clearly indicated. Supplementation with magnesium oxide or magnesium pyrrolidine carboxylate 30 mmol/day improves hypomagnesemia, sometimes corrects hypokalemia, and increases hypocalcemia.²³

LIDDLE SYNDROME

Liddle syndrome is a rare familial cause of hypokalemia associated with failure to thrive, sodium retention, hypertension, and suppressed plasma levels of renin and aldosterone.²⁷ The specific transport defect is located in the cytoplasmic

region of the β or γ subunit of the sodium channel or the amiloride-sensitive channel in the distal nephron segments.^{26,27} Sodium reabsorption is excessive even with dietary salt excess. Therapy is aimed at reducing dietary salt intake and the use of amiloride.²⁷

CHLORIDE SHUNT (GORDON'S) SYNDROME

The chloride shunt syndrome (type 2 pseudohypoaldosteronism) is almost a mirror image of Bartter syndrome. The principal metabolic derangement is a hyperkalemic, hyperchloremic metabolic acidosis.²⁸ The primary cause is a defect in WNK1 or WNK4 (serine/threonine kinases).⁴ Clinical variants include Gordon's syndrome and Spitzer-Weinstein syndrome,² with hyperkalemia, hyperchloremia, normal glomerular filtration rate, and hypertension. The hypertension is associated with low plasma aldosterone and plasma renin activity; blood pressure is often normal in children. Muscular weakness may be a presenting symptom of this disorder, and hypercalciuria is sometimes present.

A similar syndrome of metabolic acidosis with hyperkalemia is also associated with short stature and has been called Spitzer-Weinstein syndrome.^{29,30} Thiazide diuretics have been used in the management of both Gordon's syndrome and Spitzer-Weinstein syndrome, with varying results.

FAMILIAL MEDITERRANEAN FEVER

Familial Mediterranean fever (FMF) is a hereditary systemic disorder with recurrent bouts of polyserositis and fever. Mutations in the *MEFV* (Mediterranean fever) gene result in abnormal forms of the protein pyrin.³¹ This protein, localized mainly in neutrophils, functions to inhibit the chemotactic factor C5a. Unimpeded chemotaxis promotes the release of inflammatory cytokines and factors including C-reactive protein, fibrinogen, interleukin-6, interleukin-1, tumor necrosis factor α , and interleukin-8.^{31,32} The peritoneal fluids of FMF patients contain low levels of the inhibitor to C5a and interleukin-8.³³

Episodes last from 2 to 4 days with severe peritonitis, pleuritis, arthritis, and other serosal sites associated with a rash and high fever. Certain individuals develop amyloidosis and the nephrotic syndrome. This amyloid kidney can lead to chronic renal failure and hence is of interest to nephrologists.^{32,33}

The disease is far more common in people of Mediterranean origin with high carrier rates among Arabic, Turkish, Armenian, Ashkenazi Jewish, and Sephardic Jewish people, and especially Jewish people from North Africa. Many in the last group have a specific mutation of the *MEFV* gene that is associated with progression to renal failure and with more serious recurrent attacks of fever and serositis.³¹⁻³³

The therapeutic goal for FMF is to effectively protect against FMF attacks and FMF-related amyloidosis, and colchicine is the drug of choice (Table 46-4).³⁴ Its mode of action is to block activation of neutrophils by binding β -tubulin and producing β -tubulin-colchicine complexes. These actions result in inhibition of assembly of microtubules and mitotic spindle formation. Ultimately, colchicine moderates chemokines and prostanoids and inhibition of adhesion molecules in neutrophils and endothelial cells.^{32,34}

Table 46-4 Therapeutic Options in Familial Mediterranean Fever

Drug	Dose
Colchicine, PO	Children: 0.5–1.0 mg/day Adults: 1.0–2.0 mg/day
Colchicine, IV	1.0 mg/wk
Anti-TNF- α monoclonal antibodies	0.8 mg/kg/wk, IV infusion
Interferon alfa	3–10 million IU (variable), SC injection

TNF- α , tumor necrosis factor α .

The minimal dose in adults is 1.0 mg/day and 0.5 to 1 mg/day in children.^{34,35} Careful trials in children show that a dose of 0.07 mg/kg/day or 1.9 mg/m² in children younger than 5 years of age and 0.03 \pm 0.02 mg/kg/day or 1.16 mg/m² in older children is effective. The plasma half-life is prolonged in patients with liver or renal failure. The major side effects are gastrointestinal in nature; therefore, many patients are placed on lactose-free diets and with evaluation for *Helicobacter pylori* infection.^{31,34}

Children pose an especially vexing therapeutic challenge because overdose can be associated with massive organ failure.³⁶ A salutary effect of colchicine is improvement in height and weight velocity in children receiving prophylactic doses of this drug.³⁷

Approximately 10% to 15% of FMF patients fail to respond to colchicine prophylactic therapy. These patients pose a special problem, and several strategies are being explored. First, laboratories are trying to develop colchicine analogues with less toxicity and a more effective therapeutic profile.³⁴ Intravenous colchicine has been used to treat FMF patients unresponsive to the orally administered drug.³⁸ Patients were treated with weekly injections of 1 mg, and decreases occurred in the number and mean severity of abdominal attacks, the number of overall attacks, chest attacks, the erythrocyte sedimentation rate, and the number of analgesic tablets administered. Anti-tumor necrosis factor α monoclonal antibodies have also been used,^{39,40} especially in patients with protracted attacks. A dose of etanercept 0.8 mg/kg/week was used.⁴⁰ Some studies have also examined the role of interferon alfa as a therapeutic agent.⁴¹

The patients who appear to require the keenest attention to preventing attacks and the development of amyloid renal disease are those patients from North Africa who are homozygous for the M694V mutation of the *MEFV* gene.⁴² The risk of amyloidosis is greatest in males bearing polymorphism a/a in the *SAAI* gene.

FABRY'S DISEASE

Fabry's disease is a rare X-linked lysosomal storage disorder due to partial or complete deficiency of the lysosomal enzyme α -galactosidase. Although Fabry's disease mainly affects males and most female carriers are asymptomatic or have milder disease than males, some heterozygous females develop full-blown disease because of X-chromosomal inactivation.⁴³

The deficiency of α -galactosidase leads to accumulation of the glycosphingolipid globotriaosylceramide in visceral organs and vascular endothelium, which results in crises of pain, paresthesias of the hands and feet, and corneal and lenticular opacities. The skin shows characteristic lesions called *angiokeratomas*.⁴⁴ This cutaneous manifestation with acroparesthesia should strongly suggest Fabry's disease. Neuropathy is another prominent feature,⁴⁵ with accumulation of globotriaosylceramide in Schwann cells, dorsal root ganglia, and the central nervous system. Cardiac manifestations include premature coronary artery disease, myocardial infarctions, angina, and arrhythmias.^{45–47}

The nephrologic aspects include proteinuria, Maltese crosses on microscopy of the urine, and features of the Fanconi syndrome.⁴⁶ The nephrologist may also notice the angiokeratomas, which represent vasodilatation from lipid-laden vascular endothelial cells in a typical "bathing suit" distribution. Renal failure usually occurs by the fourth to fifth decades of life. The kidney is enlarged due to accumulation of globotriaosylceramide in every renal cell type, but especially in Henle's loop and distal tubule, with early loss of concentrating ability. A renal biopsy specimen usually reveals inclusion bodies in the cytoplasm with concentric lamellation that have an onion skin appearance under electron microscopy.^{46–48}

Therapy of Fabry's disease is directed at early diagnosis and enzyme replacement therapy.^{49,50} A major breakthrough is the cloning and development of agalsidase alfa and beta, which have now been infused into hundreds of patients around the world (Table 46-5). Although early results are encouraging, long-term follow-up is essential.⁵¹ In one study involving 201 patients and infusion for as long as 4.7 years, enzyme replacement therapy was associated with a decrease in serum creatinine.⁵² The slope of serum creatinine decrease was steep during the first year of therapy and then flattened. When enzyme replacement therapy was begun in childhood, salutary changes in neuropathy, anhidrosis, and the need for antineuropathic analgesics occurred.⁵⁰

The plethora of clinical trials has led to the formation of an international panel of physicians with expertise in Fabry's disease that can develop guidelines for the recognition, evaluation, and surveillance of disease-associated morbidities.⁵³ A Cochrane-type analysis has looked at agalsidase alfa (from a human cell line) and beta (from a Chinese hamster ovary cell line). Eleven trials can be analyzed. No direct head-to-head comparisons of the alfa and beta forms have been performed. Compared with placebo, enzyme replacement therapy has positive effects on the heart, kidneys, and central nervous system as well as the quality of life.⁵⁴ The major side effects of therapy are mild to moderate infusion reactions and the development of IgG antibodies against agalsidase alfa.⁵⁰

Table 46-5 Therapy of Fabry's Disease

Enzyme	Source	Dose of Infusion
Agalsidase- α	Human cell line	0.2 mg/kg (males); 1.0–2.0 mg/kg (females)
Agalsidase- β	Chinese hamster ovary cell line	0.2 mg/kg (males), 1.0–2.0 mg/kg (females)

Serial testing of cardiopulmonary exercise⁵⁵ revealed improvement after enzyme replacement therapy, but no change in coronary arterial microvasculature was found.⁵⁶ A placebo-controlled trial of agalsidase beta showed slowing of progression to primary clinical event (renal, cardiac, cerebrovascular, or death) in patients with advanced Fabry's disease on therapy.⁵⁷ Patients whose creatinine clearance was greater than 55 mL/min/1.73 m² had a greater treatment versus placebo than those with lower clearance values.⁵⁷ A dose of 1 mg/kg body weight was employed. A drawback to this therapy is an annual cost of US\$240,000, which makes lifelong therapy problematic.⁵⁸

Home infusion therapy with agalsidase alfa at 0.02 mg/kg in males and 1 to 2 mg/kg in females has been used successfully.⁵⁹ No infusion-related reaction, described in three of 30 patients, required hospitalization.

Alternative therapeutic strategies include inhibition of the multiple drug resistance protein 1 (MDR1) in a Fabry mouse model using cyclosporin A.⁶⁰ Cyclosporin A treatment depleted globotriaosylceramide from Fabry mouse liver. Other strategies include the development of chemical chaperones, chemicals that deplete sites of substrate storage, and stem-cell therapy.⁵⁸

At present, the U.S. Food and Drug Administration has approved only agalsidase beta, whereas both the alfa and beta forms have been approved in Europe.

The primary goal of this chapter is to discuss prospects for gene therapy in the kidney. We briefly review general concepts of gene therapy and vectors for this purpose. We discuss specific considerations unique to the kidney that affect gene therapy approaches to renal diseases, based on current data from clinical trials and studies in experimental renal diseases.

DEFINITION OF GENE THERAPY AND GENERAL CONSIDERATIONS

Gene therapy is defined as the delivery of DNA or RNA coding a particular sequence into targeted nongermline cells by vectors to provide beneficial effects by inducing or inhibiting synthesis of a particular protein(s). Gene therapy can provide correction of cellular dysfunction by expressing a gene, the addition of a new function for a cell by transferring exogenous genes, and inhibition of unfavorable cellular action by introducing counteracting genes. Gene therapy targeting germline cells is ethically prohibited.

General considerations in designing gene therapy are delivery, expression, and safety. Delivery refers to the ability to introduce the gene of interest where it needs to affect the disease process. Gene therapy approaches can be divided into *in vivo* and *ex vivo*. *In vivo* gene therapy uses either viral or nonviral vectors for gene delivery and is treated as a drug to be administered with or without a specific delivery system. Localized gene delivery can be used for systemic delivery of the product (e.g., skeletal muscle is an ideal organ for producing secretory proteins for systemic delivery). *Ex vivo* gene therapy refers to the genetic modification of cells or organs by gene transfer outside the body and subsequent placement of genetically engineered tissue into a patient. The source of cells may be from patients or be generic human or animal cells appropriately altered genetically. Xenotransplantation is an attractive target for *ex vivo* gene therapy if rejection can be surmounted. If universal donor cells could be developed, the cost of *ex vivo* gene therapy would decrease and its application would expand dramatically.

Expression of a particular gene must be controllable. Given that overexpression of a therapeutic protein may cause

harmful effects, regulation of transgene expression is an important issue to be considered. The issue of safety is an important problem not only for patients, but also for the population at large. Toxic effects of gene therapy include inflammation, injury, functional damage to the transduced organ, and induction of gene mutations that may cause cancer. These considerations must be examined in the context of the particular disease to be treated: its severity and clinical course, alternative treatment available, organs affected, and so forth. Consideration needs to be given to selecting patients at certain stages of disease, perhaps those with the worst prognosis, and to carefully weighing risks and benefits.

CONSIDERATIONS FOR APPLICATION TO RENAL DISEASE

The kidney is a complex organ whose function depends on its architecture, which is composed of glomeruli, tubules, vasculature, and interstitium. Consequently, it is not possible to introduce genes into all its various cell types by a single method. In principle, five routes to transfer genes by injection into the kidney exist whether by *ex vivo* or by *in vivo* methods: renal artery, renal vein, parenchyme, subcapsular region, and ureter in the retrograde direction.

VECTORS

Because excellent detailed articles exist on the vector for gene therapy, only a brief summary is provided. The advantage and disadvantage of various vector systems have been discussed extensively¹⁻³ and are subjects of intense ongoing investigation.

Viral Vectors

Retroviruses are well studied for *ex vivo* application because of their broad host range and their ability to give long-term expression through proviral integration into the host genome.

However, in vivo fragility and low titers limit in vivo applications, as does the requirement for cell division for DNA integration. In addition, human gene therapy trials using retroviral vector for X-linked severe combined immunodeficiency indicate that quasi-random integration of transgene can induce malignant transformation in transduced cells.⁴

Adenoviruses are DNA viruses that have a wide host range and survive robustly in the circulation. High titers of replication-deficient adenovirus can easily be generated, and the virus can infect nondividing cells. The duration of expression is largely limited by a T-cell response to low levels of adenoviral proteins and of the transgene itself produced in the transduced cells. The ideal vector would contain only the *cis* elements required for packaging, namely, the inverted terminal repeats and the packaging signal, and progress toward the construction of such a vector has been reported.⁵ However, these advances do not circumvent the antibody response to adenoviral proteins, which precludes secondary infection with the same serotype, although not with a different serotype.⁶ The nonspecific inflammatory response that can be produced even by empty vector may also limit the amount of adenovirus that can be delivered. However, adenoviral vectors have been used for treatment of cancer because of their efficiency of gene transfer and also because cellular toxicity and immunogenicity may enhance the antitumor effects.

Vectors based on recombinant adeno-associated virus (rAAV) have attracted much attention as potent gene delivery vehicles because of sustainable expression of the transgene and excellent preclinical safety.⁷ AAV vectors package and deliver an inactive single-stranded DNA genome that is converted into active double-stranded DNA in the nucleus. A new rAAV designed using the serotype 5 AAV inverted terminal repeat has enhanced gene expression.⁸ The AAV integrates at high frequency at a specific region on human chromosome 19 in a reaction that requires the AAV *rep* gene. After infection with helper viruses such as adenovirus or herpesvirus that provide factors necessary for replication, the virus can enter a lytic cycle. However, it appears that when rAAV is used as a gene delivery vehicle, most transgene expression results from extrachromosomal viral genomes that persist as double-stranded circular or linear episomes,⁹ which decreases the risk of insertional mutagenesis. rAAV has drawn attention because of the potential for gene targeting through homologous recombination, which allows efficient, high-fidelity, nonmutagenic gene repair in a host cell.⁷

Lentivirus-based vectors are used for gene delivery into nondividing cells.¹⁰ Vesicular stomatitis virus–pseudotyped lentiviral vectors can be delivered directly in vivo. Stable, long-term transgene expression has been observed without detectable pathologic consequence. Weak and localized but stable expression of transgene for 3 months was reported in the outer medulla and corticomedullary junction of the kidney after parenchymal or ureteral injections.¹¹

Nonviral Vectors

Nonviral vectors for gene delivery include naked DNA or DNA in combination with liposomes or with pegylated (polyethylene glycol-conjugated) nanoparticles with multiple components.¹² Hydrodynamic delivery of plasmid DNA has been reported with successful expression of the transgene in kidney and liver. Maruyama and colleagues¹³ reported that the rapid

injection of naked DNA with large volume of saline into the vena cava induced potent gene transfer into the liver and kidney. Electroporation after hydrodynamic delivery of plasmid, small DNA, or small RNA provides an efficient gene transfer into the kidney.¹⁴ To target cancer, pegylated nanoparticles with multiple components are the most promising nonviral vector for systemic delivery.¹⁵ Such vectors are relatively nontoxic and nonimmunogenic, but generally the transduction efficiency in vivo is less than with viral vectors and the duration of the gene expression is relatively short. Repeated administration may be needed.

RNA Interference

The discovery of RNA interference (RNAi) has changed the strategy of gene therapy. RNAi is an endogenous mechanism for posttranscriptional gene regulation. Therapeutic RNAi, initiated by the introduction of double-stranded RNA into the cell, leads to the sequence-specific destruction of endogenous RNA.¹⁶ Long endogenous or exogenous double-stranded RNAs are cleaved intracellularly by the protein Dicer, which contains RNase III domains, leading to the formation of small interfering RNAs (siRNAs) (21–23 nt long) with a symmetric 2 nt overhang at its 3' end and a 5' phosphate and 3' hydroxy group. One strand of the siRNA duplex, termed the guide strand, is incorporated into a nuclease-containing multiprotein complex called the RNA-induced silencing complex, whereas the second, passenger strand is released and degraded. Once incorporated into RNA-induced silencing complex, the guide strand guides this complex to the target mRNA and induces endonucleolytic cleavage. This cleavage leads to the rapid degradation of the entire mRNA molecule due to the generation of its unprotected RNA ends, whereas the RNA-induced silencing complex is recovered for further cleavage cycles.

Novel therapeutics using RNAi are being actively developed partly by learning lessons from the setbacks experienced with antisense oligonucleotides and conventional DNA vectors. Indeed, a number of biotech companies are actively working in this area to make RNAi-based drugs a reality. Phase I clinical trials have already been initiated for age-related macular degeneration, a vascular-proliferative disorder of the retina using siRNA for vascular endothelial growth factor or vascular endothelial growth factor receptor and for respiratory syncytial virus infection.

Viral vectors expressing siRNA that have been intensively investigated for application to in vivo gene therapy in animal models include lentivirus,¹⁷ adenovirus,¹⁸ AAV,¹⁹ and baculovirus.²⁰ Nonviral delivery of siRNAs or siRNA expression vectors has also been intensively studied. Chemical modifications, encapsulation of the siRNA in microparticles or liposomes, and/or binding siRNAs to particulate carriers have been developed to circumvent the shortcomings of the naked siRNAs. The goals of these approaches are (1) prolonged duration of the RNAi activity by stabilization, (2) improvement of the cellular tropism, (3) enhancement of the silencing activity, and/or (4) selective tissue delivery.

siRNAs are rather stable compared with single-stranded RNA in serum, but will still be degraded within a few hours due to the cleavage activity of an RNase. Therefore, the development of chemical modifications that make them resistant to RNase is the rational approach. These include the use

of boranophosphate²¹ and the phosphothioates 2'-deoxy, 2'-fluoro,²² and 2'-O-Me, but it has yet to be fully elucidated which modification best increases the stability.

Another approach to increase the plasma stability and/or direct the preferential uptake by the target cells is the use of envelope packaged siRNA. Various liposomes are reported to be efficient *in vivo*, including oligofectamine,²³ cationic 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP) liposomes,²⁴ neutral 1,2-dioleoyl-sn-glycero-3-phosphatidylcholine (DOPC) liposomes,²⁵ and gelatin.²⁶ Urban-Klein and colleagues²⁷ demonstrated that the noncovalent complexation of siRNAs with low molecular weight polyethylenimine efficiently stabilizes siRNAs and *in vivo* systemic delivery of the polyethylenimine-complexed siRNAs targeting HER2 reduced tumor growth.

Several attempts have been directed at realizing specific tissue tropism by simple delivery (e.g., intravenous injection). Song and colleagues²⁸ developed an antibody-conjugated siRNA technique. First, the authors constructed a conjugate composed of an antibody against a cell surface receptor and a basic cellular protein protamine, and then this conjugate was noncovalently linked to siRNAs targeting the gene of interest. They injected an antibody against human immunodeficiency virus envelope glycoprotein pg160-protamine conjugate mixed with siRNAs targeting c-Myc, transformed 3T3 cell double minute 2 (MDM2), and vascular endothelial growth factor intravenously as well as intratumorally in a xenograft tumor mouse model. As a result, significant tumor growth retardation was observed by targeting pg160-positive cells. In another attempt, polyethylene glycol strands were conjugated to the outer surface of a liposome, and specific antibodies attached to these polyethylene glycol strands, creating a pegylated immunoliposome.²⁹ The authors successfully delivered this siRNA expression vector to an implanted brain tumor across the blood-brain barrier and the tumor cell membrane by conjugating it with a monoclonal antibody to a transferrin receptor.

Recently it has been reported that siRNAs and short hairpin RNAs (shRNAs) have broad and complicated effects beyond the selective silencing of target genes when introduced into cells. This is of critical importance because siRNAs are currently being explored for their potential therapeutic use.

High sequence specificity is the major characteristic of RNAi. However, several reports raise questions about its specificity. Jackson and colleagues³⁰ report *in vitro* silencing of nontargeted genes containing as few as 11 contiguous nucleotides of identity to the siRNA. These results demonstrate that siRNAs may cross-react with targets of limited sequence similarity. There is no doubt that siRNAs have advantages over conventional antisense oligonucleotides in their sequence specificity, but these off-target effects must always be kept in mind when exploring RNAi in clinical applications.

Another nonspecific effect that deserves attention is the interferon response, which is the first line of defense system activated by double-stranded RNA derived from viral infection. Activation of interferon responses results not only in the up-regulation of many interferon-related genes but also in inhibition of cellular protein synthesis and induction of apoptosis.

Because siRNAs and shRNAs are artificial orthologues of microRNAs, siRNA- and shRNA-mediated RNAi share the components used for the endogenous microRNA-induced gene activation. Therefore, it is possible that the transfections of siRNA or shRNA, especially at high doses, would interfere with normal

cellular physiology that is mediated by micro-RNAs. Grimm and colleagues¹⁹ systematically investigated the long-term effect of the introduction of shRNA based on AAV type 8 in adult mice after intravenous infusion. An evaluation of 49 distinct AAV/shRNA vectors, unique in length and sequence and directed against six targets, showed that 36 resulted in dose-dependent liver injury, with 23 ultimately causing death. Morbidity was associated with the down-regulation of liver-derived microRNAs, indicating possible competition of microRNAs with shRNAs for limiting cellular factors, including the nuclear exportin-5. They also found that the risk of oversaturating endogenous small RNA pathways can be minimized by optimizing shRNA dose and sequence.

APPLICATION TO KIDNEY DISEASES

Kidney Transplantation

The transplant kidney is an ideal setting for gene therapy. After the kidney is harvested from the donor, *ex vivo* gene therapy can be easily performed on the kidney and the surplus vector can be flushed out before transplantation, which reduces the harmful effects from inappropriate delivery to other organs. Gene products could be delivered for four purposes: (1) to reduce ischemia/reperfusion injury, (2) to decrease organ antigenicity for acute rejection, (3) to induce tolerance or block the effector arm of the immune system for chronic rejection, and (4) to improve organ preservation.

Candidate genes (given individually or in combination) might include donor major histocompatibility complex class I or II molecules,^{31,32} cytotoxic T-lymphocyte antigen 4 immunoglobulin,³³⁻³⁶ interleukin (IL)-4, IL-10,³⁷ Fas ligand,³⁸ galectin,³⁹ adenoviral E3 gene, soluble tumor necrosis factor receptor, IL-1 receptor antagonist, adhesion molecules, transforming growth factor β (TGF- β),⁴⁰ hepatocyte growth factor (HGF),^{41,42} and catalase.⁴³ Inhibition of the following genes might provide beneficial effects: nuclear factor κ B (NF- κ B),⁴⁴ nitric oxide synthase,⁴⁵ and CD28.³⁶

Acute rejection occurs as a consequence of T-cell activation. In this process, the engagement of T-cell receptor and alloantigens presented by major histocompatibility complex molecules is essential, and the activation of costimulator signals, such as CD28 and B7, is also important. Tomasoni and colleagues³⁵ injected an adenoviral vector encoding the chimeric fusion protein, cytotoxic T-lymphocyte antigen 4 immunoglobulin, *ex vivo* into the artery of Brown Norway rat kidneys, which were then transplanted into Lewis rats. The rats that received cytotoxic T-lymphocyte antigen 4 immunoglobulin gene therapy had inhibited T-cell activation and prolonged survival by 50 days. Azuma and colleagues⁴⁴ investigated whether transfection of NF- κ B decoys into the donor kidney would prevent acute rejection and prolong graft survival. They introduced NF- κ B decoy DNA into the transplant kidney by microbubble-mediated gene transfer. The NF- κ B decoy improved renal function and histology of the transplant kidney by reducing expression of NF- κ B-regulated cytokines and adhesion molecules. In the early phase of kidney transplantation, when the transplant kidney is exposed to insults by ischemia/reperfusion, high doses of the immunosuppressant HGF may afford protection against acute kidney injury and may enhance tubular cell regeneration. Isaka and colleagues⁴² studied the renoprotective action of HGF gene transfer using

a model of porcine kidney transplantation after 10 minutes of warm ischemia injury. The harvested right kidney was transfected with *HGF* gene injected via the renal artery with hydropressure followed by electroporation. After removing the left kidney, the genetically modified kidney was transplanted. The warm ischemia induced tubular injury in the control kidney, followed by tubulointerstitial fibrosis, whereas HGF-transfected kidneys showed no initial tubular damage and little fibrosis at 6 months posttransplantation.

Short-term outcome of clinical transplantation has improved remarkably with the development of better immunosuppressants, but the long-term outcome of transplantation has not. Benigni and colleagues³⁶ applied rAAV for cytotoxic T-lymphocyte antigen 4 immunoglobulin gene transfer to protect major histocompatibility complex–mismatched renal allografts from chronic rejection. The expression of the transgene lasted for 90 days, renal function was preserved, and glomerulosclerosis and interstitial fibrosis were ameliorated.

Additional problems specific to xenotransplantation are hyperacute rejection and acute rejection of the transplanted kidney, which are caused by antibody against alpha-1,3-galactosidase and complement-mediated hyperacute rejections. Ex vivo gene transfer of H-transferase⁴⁶ and CD59 or decay-accelerating factor⁴⁷ before transplantation may be worthy of consideration.

Renal Cancer (Renal Cell Carcinoma)

The most challenging issue for gene therapy in cancer is that of metastatic disease. Because localized renal cell carcinoma is an indication for surgical treatment, advanced renal cell carcinoma has been a target of gene therapy and has been confirmed to be a considerable success. Most of the cases of gene therapy for renal cell carcinoma use immunotherapy, which strengthens the immunity against cancer-specific antigens. IL-2 is a cytokine with potent immunomodulatory activities including activation of T cells and natural killer cells. The administration of IL-2 protein results in significant clinical benefits for patients with renal cell carcinoma.⁴⁸ Despite producing beneficial effects with some durable remissions, recombinant IL-2 therapy is often limited by potential life-threatening side effects, including pulmonary edema, hypertension, anemia, and organ dysfunction resulting from capillary leak syndrome. An alternative approach to IL-2 cancer immunotherapy would be an effective delivery of small amounts of IL-2 directly to the tumor microenvironment by gene therapy. This can be approached by direct injection of IL-2 gene into tumor cells for local secretion or by ex vivo introduction of IL-2 gene to tumor cells in culture. Galanis and colleagues⁴⁹ reported the effects of direct injection of leuvestin (a cationic lipid mixture with a plasmid vector containing the human IL-2 gene) into the tumors. They treated 14 patients with renal cell carcinoma, and two patients responded partially with a reduction in the size of tumor and two had regression of the injected lesion by more than 25%. Schmidt-Wolf and colleagues⁵⁰ also reported IL-2 immunotherapy by ex vivo gene transfer of IL-2 gene to autologous natural killer–like T lymphocytes. This report did not identify the patients but treated one patient with advanced renal cell carcinoma and eight patients with colon cancer with multiple metastasis. Six patients remained in progression, and three patients showed no change with treatment, suggesting that it is somewhat effective in some cases. Ongoing clinical

trials for renal cell carcinoma are encouraging in that IL-2 gene therapy using nonviral vector systems can decrease the tumor burden.

Wittig and colleagues⁵¹ reported immunotherapy by therapeutic vaccination with IL-7 and granulocyte/macrophage colony–stimulating factor (GM-CSF) gene-transfected tumor cells. The genetically modified autologous tumor cells expressing IL-7 and GM-CSF were introduced in patients, and in consequence, they showed the capability of autologous expression–modified and –immunomodulated tumor cell vaccines to stimulate a strong immune response in some patients with metastatic cancer even in the presence of a large tumor. In Japan, GM-CSF gene therapy for renal cell carcinoma is in progress, and a case of regression was observed but no conclusive result is reported yet.⁵²

Glomerulonephritis and Renal Fibrosis

Gene therapy for experimental glomerulonephritis and interstitial fibrosis has been energetically tackled. For an effective molecular intervention, the choice of the target tissue or cells for gene transfer is crucial. Strategies for gene therapy can be divided into two categories: tissue- or organ-specific delivery and systemic delivery. It has been reported that growth factors and cytokines are involved in the progression of glomerular and tubulointerstitial diseases. Therefore, numerous DNA- or RNA-based biopharmaceuticals attempt to control disease progression by inhibiting these genes. The potential therapeutics include antisense oligonucleotides, decoys, ribozymes, DNazymes, and siRNA. In this case, the therapeutic gene has to be delivered to the specific tissue or organ, for example, mesangial cells in glomerular diseases or interstitial fibroblasts in tubulointerstitial diseases. Conversely, several somatic tissues, such as skeletal muscle, can be used to introduce the foreign gene if the transgene product is secreted in plasma.

Recent understanding of the molecular pathogenesis has led to the identification of new therapeutic targets. One of these targets is TGF- β , which plays an important role in the progression of glomerulosclerosis and interstitial fibrosis.⁵³ The introduction of antisense oligonucleotides,^{54,55} DNazyme,⁵⁶ or siRNA⁵⁷ against TGF- β into glomerular mesangial cells^{54,56,57} and interstitial fibroblasts⁵⁵ resulted in the suppression of TGF- β and of the consequent glomerular extracellular matrix expansion in rats with anti-Thy-1 glomerulonephritis and of the interstitial fibrosis in unilateral ureteral obstruction (UUO) (a model of acute tubulointerstitial fibrosis), respectively. Another target is early growth response gene 1 (*egr-1*), a transcription factor involved in mesangial cell proliferation and phenotypic alteration of myofibroblasts. The transfer of antisense oligonucleotides⁵⁸ and DNazyme⁵⁹ against *egr-1* prevented *egr-1* expression and eventually inhibited mesangial proliferation in anti-Thy-1 glomerulonephritis and interstitial phenotypic alteration in UUO rats, respectively.

Double-stranded oligonucleotides containing a *cis* binding element for a particular transcription factor can act as a decoy and inhibit transactivation of the particular promoter coding the *cis* element. E2F decoy inhibits cell proliferation by mimicking the *cis* element of the promoter regions of dihydrofolate reductase, *c-myc*, *cdc2* kinase, and proliferating cell nuclear antigen, whereas NF- κ B decoy suppresses inflammatory genes including IL-1, IL-6, IL-8, intracellular cell adhesion molecular 1, vascular cell adhesion molecule, and endothelial

leukocyte adhesion molecule. E2F decoy⁶⁰ and NF- κ B decoy⁶¹ successfully inhibit the mesangial proliferation and extracellular matrix expansion in experimental glomerulonephritis. The overexpression of inhibitory molecules in signal transduction has also been reported. The introduction of Smad-7 inhibited TGF- β action and suppressed renal fibrosis in the UUO model.^{62,63} The inhibition of NF- κ B by gene therapy of a truncated I κ B α , a dominant negative-type molecule, reduced renal fibrosis in a protein-overload model.⁶⁴

Skeletal muscle-targeted gene therapy for renal diseases is more practical and less invasive because it provides high efficiency and long-lasting gene expression compared with the kidney.⁶⁵ Inhibitory molecules against TGF- β were extensively studied for muscle-targeted gene therapy. The transduction of decorin,⁶⁶ a natural inhibitor against TGF- β , or the artificial soluble receptor for TGF- β ⁶⁷ in muscle cells led to the competitive inhibition against glomerular TGF- β , which resulted in the amelioration of glomerulosclerosis. Gene therapy of the artificial soluble receptor for platelet-derived growth factor B⁶⁸ also inhibited glomerulosclerosis in anti-Thy-1 glomerulonephritis. Electroporation-mediated gene transfer into skeletal muscle with the soluble form interferon gamma receptor successfully induced the interferon gamma/Fc protein in the serum and ameliorated murine lupus nephritis model.⁶⁹ Intravenous administration of adenoviral vector coding for the adrenomedullin gene significantly improves the renal histology of streptozotocin-induced diabetic rats.⁷⁰

HGF is a multifunctional cytokine that regulates mitosis, angiogenesis, morphogenesis, cell movement, and apoptosis.⁷¹ As HGF acts against TGF- β and recombinant HGF administration suppresses renal fibrosis in the UUO model,⁷² HGF gene therapy was examined in the UUO model. The transduction of HGF in the kidney suppressed renal fibrosis in the UUO model.^{73,74} The introduction of plasmid coding 7ND, a dominant-negative type antagonist against membrane cofactor protein 1, into the kidney⁷⁵ attenuated the interstitial fibrosis in a protein-overload proteinuria model. Intraparenchymal injection of adenoviral vector encoding IL-10 suppresses proteinuria of focal segmental glomerulosclerosis in a mouse model.⁷⁶

The therapeutic impact of siRNA or siRNA expression vectors targeting the kidney has been reported. For example, Hamar and colleagues⁷⁷ described the administration of siRNAs targeting Fas via the tail vein or renal vein of mice with ischemia-reperfusion injury. A single hydrodynamic injection of Fas siRNA decreased its mRNA and protein expression in the kidney fourfold. Kidneys from mice that received Fas siRNA 2 days earlier had less tubular damage and apoptosis. siRNA expression vector targeting Fas or caspase 8, transfected via the inferior vena cava⁷⁸ or targeting the C3 component of complement transfected via tail vein,²⁹ have also been reported to decrease ischemic-reperfusion injury. Kushibiki and colleagues²⁶ investigated the *in vivo* transfection efficiency of a plasmid DNA expressing TGF- β 1 receptor type II siRNA with various cationized gelatins of nonviral carriers and evaluated the antifibrotic effect on a mouse model of UUO. The complex of a plasmid DNA with a biodegradable cationized gelatin prevented DNase digestion, decreasing the molecular size and making the net charge of the complex positive, which led to facilitated and stable gene expression. The injection of the complex of the plasmid DNA expressing TGF- β 1 receptor type II siRNA and the cationized gelatin via the ureter of the UUO model mice led to the marked decrease in the TGF- β

receptor expression and the collagen content of mice kidney, and eventually suppressed the progression of renal interstitial fibrosis. Takabatake and colleagues⁵⁷ demonstrated that the injection of synthetic siRNAs or siRNA expression vector via the renal artery, followed by electroporation, could be an effective therapeutic approach to the glomeruli in which there is a central region of inflammatory response in the initiation and progression of various kidney diseases. RNAi targeting against TGF- β 1 significantly suppressed TGF- β 1 mRNA and protein expression, thereby ameliorating the progression of matrix expansion in experimental glomerulonephritis.

Genetically modified macrophage-like cells have been developed for the treatment of anti-glomerular basement membrane glomerulonephritis. Yokoo and colleagues⁷⁹ differentiated bone marrow cells into CD11b⁺CD18⁺ cells, which migrate into inflamed glomeruli. The genetically modified macrophage-like cells migrated into inflamed glomeruli in experimental anti-glomerular basement membrane antibody-induced glomerulonephritis and supplied the functional secretory protein, IL-1 receptor antagonist, into the inflamed glomeruli.⁸⁰ These results suggest that reconstitution of bone marrow for the continuous supply of anti-inflammatory cells may be a useful strategy for the treatment of chronic inflammation.

Renal Anemia

Erythropoietin (EPO), which is secreted from the kidney in response to hypoxia, is an essential stimulator of erythropoiesis. The shortage of EPO leads to anemia in most cases of advanced renal failure. EPO gene transcription is driven by a transcription factor, hypoxia inducible factor 2 α , in tubulointerstitial fibroblasts, which are the responsive cells in EPO production.

Gene therapy for renal anemia has been a challenge for 15 years. Recombinant human EPO is commercially available for clinical use. However, demand for successful gene therapy still remains because recombinant human EPO is relatively expensive, and the treatment must last a long time.

A variety of methods have been reported for experimental EPO gene therapy. The simplest method is injection of plasmid encoding the EPO gene into skeletal muscle followed by electroporation.⁸¹ Maruyama and colleagues⁸² treated experimental renal anemia with gene therapy and showed increases in hematocrit in uremic rats. Long-term EPO gene expression was also achieved using a lentiviral vector.⁸³ Adenovirus-mediated EPO gene transfer also succeeded in long-term EPO delivery from skeletal muscle.⁸⁴ Transplantation of genetically modified fibroblasts succeeded in long-term supply of the EPO gene.⁸⁵ Rinsch and colleagues⁸⁶ used homozygous EPO SV40 T antigen (EPO-Tagh) transgenic mice, which have a target disruption in the 5' untranslated region of the EPO gene that causes severe anemia by dramatically decreasing EPO expression. They demonstrated that the renal anemia of EPO-Tagh mice was corrected by implantation of encapsulated fibroblasts secreting EPO.

Inducible gene therapy of EPO by mifepristone administration has been reported.⁸⁷ Two plasmids encoding a gene switch responsive to mifepristone and an inducible transgene for EPO were introduced into skeletal muscle by electroporation. Intraperitoneal administration of mifepristone resulted in an increase in serum EPO, leading to an increase in hematocrit. A

recent development in EPO gene therapy is the use of an inducible gene responsive to the degree of hypoxia. Binley and colleagues⁸⁸ developed an oxygen-regulated gene therapy strategy by using an AAV vector carrying the EPO gene driven by the Oxford Biomedica hypoxia response element (OBHRE) promoter, which responds to hypoxia by binding of hypoxia inducible factor 1 α . They injected the AAV vector carrying OBHRE-EPO into hindlimb skeletal muscle of EPO-Tagh mice and observed an increase in the hematocrit from 20% to 50%. The hematocrit stabilized at normal levels and did not increase to the polycythemic range because the transactivation of OBHRE promoter was switched off by oxygenation of peripheral blood cells. The constant regulation persisted for at least 5 months. This result suggested that the OBHRE promoter gives rise to physiologically controlled regulation of EPO gene expression in an anemic mouse model. This approach for renal anemia may provide more physiologic and less expensive treatment than recombinant human EPO.

Meanwhile, human EPO gene therapy was reported from Israel. Lippin and colleagues⁸⁹ harvested subcutaneous dermal samples (dermal core, 30–35 \times 1.5–2.5 mm) from 13 patients. The EPO gene was transfected into the dermal core by adenoviral vector, and the transfected dermal core was implanted into the forearm of 10 patients. The EPO level was increased on day 1 and persisted for 14 days. The EPO level was decreased on day 14, coincident with infiltration of CD8 T cells into the dermal core. This first human trial of gene therapy with EPO was successful, and no adverse event was observed.

Hemodialysis Vascular Access

The number of patients with end-stage renal disease has been increasing worldwide and is expected to reach 210 million by 2010. More than 140 million will be treated with hemodialysis. Vascular access is critical for good hemodialysis treatment and the creation of a good native arteriovenous fistula is a key to successful dialysis because arteriovenous fistulas have a relative low rate of infection and thrombosis.⁹⁰ Venous stenosis followed by thrombosis is caused by neointimal hyperplasia and vascular remodeling. Therefore, the ideal therapy for vascular stenosis is likely to be an intervention to block both adverse remodeling and neointimal hyperplasia. Gene therapy for neointimal hyperplasia in AVF has been proposed.⁹¹ Inhibition of neointimal hyperplasia in experimental models has been achieved by gene therapy with endothelial nitric oxide synthase, cyclin-dependent kinase inhibitor p21^{KIP1}, GATA-6, GAX, HGF, and decoy of E2F.⁹² A phase II trial of E2F decoy is currently in progress in arteriovenous grafts.⁹⁰

Decisions for Management of High Blood Pressure: A Perspective

Lawrence R. Krakoff

CHAPTER CONTENTS

DECISION 1: WHAT IS HYPERTENSION AND WHO IS HYPERTENSIVE? 567

DECISION 2: WHICH BLOOD PRESSURES ARE MOST ACCURATE AND USEFUL FOR DIAGNOSIS AND TREATMENT? 568

DECISION 3: PREHYPERTENSION OR HIGH NORMAL PRESSURE? 569

DECISION 4: TREATMENT OF HYPERTENSION: SHOULD GOALS BE BASED ON BLOOD PRESSURE OR ON REVERSIBLE GLOBAL RISK OF FUTURE DISEASE? GUIDELINES COMPARED: IS THERE AGREEMENT? 570

DECISION 5: HOW SHOULD ELDERLY HYPERTENSIVE PATIENTS BE TREATED? 572

CONCLUSIONS 572

Treatment of hypertension is a most important way for primary care practitioners and medical subspecialists to preserve their patients' health. This is a daily activity in offices and clinics and a cornerstone for prevention of both cardiovascular disease (CVD) and end-stage renal disease. The evidence provided by the abundance of randomized clinical trials of antihypertensive therapy fully supports antihypertensive drug treatment and its widespread application for lowering blood pressure in those at risk. These trials, taken individually or in aggregate via meta-analysis, demonstrate that, for both middle-aged and elderly hypertensive individuals, antihypertensive drug therapy is highly and predictably effective for preventing fatal and nonfatal cerebrovascular disease (stroke) and cardiac disease (myocardial infarction and heart failure).¹ Progression of renal disease by antihypertensive drug therapy is also well documented.² Thus, there is no longer doubt that antihypertensive therapy is beneficial.

Are there any decisions to be made by those who treat hypertension? Have choices become unnecessary because evidence-based guidelines have eliminated or decreased decision making? Decisions or choices imply a lack of certainty and are not automatic (as is the case for computer algorithms). Decisions in medicine can be considered choices made in "ignorance," which, in this setting, means incomplete information rather than a total lack of relevant facts. Despite the wealth of information now available, significant gaps remain that require careful thought and analysis for decisions. The lessons and limitations of recent trials and research reveal these gaps. They expose areas where certainty should yield to best judgment, that is, decision making. This chapter focuses on the set of decisions (and areas of uncertainty) that I consider are most important at present (Box 48-1).

- Decision 1: What is hypertension and who is hypertensive?
- Decision 2: Which blood pressures are most accurate and useful for diagnosis and treatment? When should supplemental pressures, ambulatory monitoring, or home blood pressures be used?

- Decision 3: How should those with prehypertension or high-normal pressures be managed: by lifestyle improvement alone or by drug treatment?
- Decision 4: Treatment of hypertension: should goals be based on blood pressure or on reversible global risk of future disease? Guidelines compared: Is there agreement?
- Decision 5: How should elderly hypertensive patients be treated?

These five sets of decisions imply that the strategies and decisions related to initiating, maintaining, and changing antihypertensive therapy, although often thought to be quite simple, in reality are often highly complex. Both simple and complex decisions rely on a successful synthesis of the clinical characteristics of each patient with evidence from appropriate clinical trials, knowledge of pathophysiology and pharmacology, and good sense. This chapter focuses on the evidence and rationale for decisions linked to the five issues listed.

DECISION 1: WHAT IS HYPERTENSION AND WHO IS HYPERTENSIVE?

Hypertension can now be defined in several ways. Guidelines use specific cutoff points for classification: 140/90 mm Hg has been selected by most guideline committees.³⁻⁵ However, some suggest that any arterial pressure higher than that associated with the lowest epidemiologic risk of future cardiovascular problems (i.e., 120/80 mm Hg) should be considered hypertensive. A major problem with the latter definition is the lack of trial evidence to support it. A more useful definition is the baseline blood pressure that, when lowered by antihypertensive therapy in clinical trials, predicts benefit. This definition includes the results of trials enrolling patients with abundant target organ damage, diabetic nephropathy, or chronic renal disease in which antihypertensive drugs (angiotensin-converting enzyme inhibitors or angiotensin receptor blockers) were effective

Box 48-1 Factors to Be Assessed in Establishing Cardiovascular and Renal Risk Status

Related to Blood Pressure	Nonpressure Risk Factors	Target Organ Damage Pathology
Ambulatory and home blood pressures; for all ages, estimate of usual average pressures; consideration of abnormal diurnal pattern in selected patients	Best established: presence or absence of type 1 or 2 diabetes, history of smoking, lipid status (elevated LDL, low HDL cholesterol, metabolic syndrome cluster)	Cardiac: left ventricular enlargement, ischemia, previous MI or angina, abnormal stress test, impaired systolic function, arrhythmia
Age < 50 yr: diastolic pressure most important	Less well established but may be useful: plasma renin profile, triglyceride levels	Renal microalbuminuria or proteinuria, decreased GFR, increased creatinine
Age 50–60 yr: both systolic and diastolic pressures equally important	Suggested by recent research: C-reactive protein, fibrinogen, lipoprotein(a), homocysteine	Peripheral vascular: Ankle-arm index, claudication, arterial bruits, aortic aneurysm
Age > 60 yr: systolic pressure and pulse pressure are more important		Cerebrovascular: history of TIA or stroke, carotid bruit
Age > 85 yr: increased risk of lower pressures, orthostatic hypotension, and low diastolic pressure; J-curve issue		

GFR, glomerular filtration rate; HDL, high-density lipoprotein; LDL, low-density lipoprotein; MI, myocardial infarction; TIA, transient ischemic attack.

when baseline pressures were less than 140/90 mm Hg and goals of treatment were less than 130/80 mm Hg. Thus, the definition of hypertension becomes contextual, related to other risk predictors for a patient rather than limited to a single cutoff point. For some older patients, hypertension may need to be defined as systolic pressures higher than 160 mm Hg and goals for treatment set higher than 140/90 mm Hg.⁶ A context-based definition, related to likelihood of benefit from blood pressure lowering, can go higher or lower than the rigid 140 mm Hg systolic to benefit individuals within definable subgroups, but must be validated by trial evidence. Epidemiologic association between pressures higher than the optimal and risk that is not validated by therapeutic trials is a weak basis for clinical decisions.

Some suggest that hypertension is a high-risk state for CVD that is independent of high blood pressure. This implies that antihypertensive drug treatment might be beneficial for those with other risk factors and/or target organ damage irrespective of their baseline blood pressure.⁷ Trying to separate hypertension from high blood pressure creates semantic confusion and ignores the abundant evidence that the major therapeutic effect of antihypertensive drugs for the high-risk group is their ability to decrease pressure, even when pretreatment pressures are in the high-normal range. This is consistent with the context-based definition. Some drugs classed as antihypertensive, however, have other actions that are beneficial for selected populations. Thus, β -blockers for coronary heart disease or angiotensin receptor blockers for diabetic nephropathy have added unique value apart from decreasing pressure. Furthermore, the cardiovascular pathology often associated with hypertension may occur in those with normal pressures but other risk factors and unknown etiologies. Thus, an attempt to separate hypertension from high blood pressure is confusing and unnecessary.⁸

DECISION 2: WHICH BLOOD PRESSURES ARE MOST ACCURATE AND USEFUL FOR DIAGNOSIS AND TREATMENT?

The measurement of blood pressure made at a single visit in the highly contrived atmosphere of a busy medical practice is insufficient for a diagnosis of normal pressure, prehypertension, or hypertension. Screening or clinic blood pressures are often inaccurate and misleading, especially when they are either not clearly normal (<120/80 mm Hg) or very high (>180/110 mm Hg). It is now evident from many studies of ambulatory and home pressure measurement (supplemental pressures) that the average pressure is best related to risk. This average requires several measurements for confidence. The distribution of blood pressures in a population approaches a normal bell shape. The various cut points for blood pressure that have been used to divide high-normal from hypertensive are all on the upper part of the down slope of these distributions. This implies that a large fraction of those with high-normal pressures (or the prehypertensives) may be falsely labeled as hypertensive, for a small measurement error (5–10 mm). It is less likely that a patient with hypertension will be falsely classified as normal or prehypertensive, but this remains a worrisome possibility, as some with normal clinic pressures have increased supplemental pressures (i.e., masked hypertension) because the clinic measurements give a false-negative diagnosis.⁹ Only by accumulating enough measurements through supplemental pressures can an accurate classification be made for normal, prehypertension, or hypertension.

Ambulatory blood pressure monitoring has become a widespread and available technique as a result of its recognition for improved diagnostic accuracy. It is the gold standard for clinical diagnosis.^{10–14} Self-recorded home blood pressures may be nearly as useful.^{15,16} Home pressures can be

valuable for determining average pretreatment pressures and assessing treatment effects for adjusting antihypertensive medication.¹⁷

The systolic pressure is clearly a major determinant of risk in middle-aged and elderly populations,^{18,19} which is supported by results of clinical trials of antihypertensive therapy.²⁰ However, retrospective analysis of some databases has suggested that the simple arithmetic difference between systolic and diastolic pressures, the pulse pressure, may be a superior predictor of later CVD when compared with systolic pressure alone and that for equally high pulse pressures, a higher diastolic pressure confers less risk for older patients.²¹ In treating older patients, an excessive decrease in diastolic pressure may be as harmful as an adverse effect of an overzealous decrease in systolic pressure.²² However, reanalysis of age-related trends in the Framingham study indicates that for those younger than 50 years of age, diastolic pressure remains the better predictor of risk; between ages 50 and 59, both systolic and diastolic pressures are directly related to risk; and for ages older than 59 years, systolic and pulse pressures are the best predictors.²³ Thus, the age of the patient must be considered in determining whether the average systolic or diastolic pressure has the greatest clinical relevance. This is another example of a context-based definition. For the elderly, the risk of a low diastolic pressure needs greater emphasis for proper decisions in treatment.

DECISION 3: PREHYPERTENSION OR HIGH NORMAL PRESSURE?

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure Report 7 (JNC-7) provided a new classification for high arterial blood pressure: optimal blood pressure, prehypertension, and hypertension.³ The novel feature of this advisory was the introduction of the term *prehypertension* to identify those with blood pressure higher than the optimal level (120/80 mm Hg), but lower than the hypertensive range (140/90 mm Hg). This classification is based only on clinic measurements, omitting supplemental pressures to reclassify patients more precisely should false-positive or false-negative assessments occur due to inaccurate or misleading clinic measurements.⁹ Before the JNC-7, the term high-normal had been applied to those pressures near the hypertensive range, generally 130 to 139/80 to 89 mm Hg. The JNC-7 did not include an age-based classification. However, the rationale for recommending that *prehypertension* be used could be found in the high likelihood that those with this level of pressure in middle age would eventually become hypertensive as they age, as shown by the longitudinal Framingham study.²⁴ It is not surprising that retrospective assessments of population studies, such as the National Health and Nutrition Examination Survey, report that a large fraction (20%–30%) of the sample could be classified as prehypertensive.²⁵ The important factors contributing to the transition from prehypertension or high-normal pressure to hypertension, in addition to age, are the actual pressure level, overweight, and weight gain.²⁶ High salt intake may also contribute to this transition.²⁷ Increased C-reactive protein levels have also been identified as a predictor of future hypertension, but this finding may be related only to overweight.^{28,29}

Long-term follow-up has revealed that prehypertension is associated with eventual rates of CVD that are intermediate between those with optimal pressure at baseline and those that are hypertensives.³⁰ As a group, prehypertensives tend to be overweight and have serum lipid abnormalities and type 2 diabetes or the metabolic syndrome, but smoking is less frequently a factor. Many prehypertensive individuals have a cluster of cardiovascular risk factors with high-normal blood pressure alone in only a small fraction. A schematic comparison of this relationship for prehypertension, compared with established hypertension, is given in Figure 48-1. Some risk calculations attribute all future risk of CVD in those who are prehypertensive to factors other than the blood pressure.³¹ That conclusion clearly implies that interventions to decrease the risk should focus on lifestyle improvement through weight loss, improved nutrition, and increased exercise.

Is there any basis for treatments to lower blood pressure as a primary goal for management of prehypertension or should all attention be given to encouraging a favorable lifestyle that may have benefit whether or not pressure is lowered? What is the evidence to help clinicians make best decisions?

Many lifestyle interventions reduce blood pressure in short-term studies. Those best studied are weight loss, decreased diet salt with increased potassium, and increased exercise.³² Changing the source of diet protein from a meat-based source to soy lowers pressure.³³ The Dietary Approaches to Stop Hypertension trial diet, a diet high in potassium, fruits, and vegetables combined with low fat and restricted salt intake, has been given much attention in this regard. However, over 18 months, this strategy has a relatively small effect on blood pressure but does reduce the transition from prehypertension to hypertension.³⁴ Bear in mind, however, that this event (new hypertension) occurred when the clinic systolic pressure could increase as little as 1 mm Hg (from 139 to 140 mm Hg between visits), a very artificial and unstable definition. In a population survey of middle-aged women, there is no correlation between ingestion of a Dietary Approaches to Stop Hypertension-like diet and either hypertension or cardiovascular mortality after adjustment for other risk factors.³⁵

Do any lifestyle interventions impart a reduction in future CVD? Only diet salt reduction has been shown to cause a small, but significant, decrease in CVD events and mortality, in a combined analysis of two components from the Trial of Prevention of Hypertension. There was, over a 5- to 10-year follow-up period, a 25% decrease in relative risk of cardiovascular events and a 19% decrease in relative risk of death.³⁶ The absolute reductions were 1.5% for cardiovascular events and 0.3% for mortality. The numbers needed to treat, based on a 10-year follow-up with a 5% dropout rate per year, are 106 for one cardiovascular event and 528 for one death; these numbers are, however, compelling for an effective and safe population-based strategy.

There is a widespread consensus that the other lifestyle interventions, now favored by advisory groups, ought to be beneficial, yet no trial evidence has yet emerged to confirm this hope. Perhaps there should be more emphasis on a decrease in diet salt for those who are prehypertensive and equal emphasis on weight decrease and increased exercise for the entire population, regardless of their blood pressure, as those with optimal pressure may still be at risk due to overweight, lipid abnormalities, and high-normal blood glucose.

Figure 48-1 Comparison of the relationships between nonpressure risk factors and target organ damage in prehypertension or established hypertension (**A**) and high-normal blood pressure (**B**).

Many antihypertensive drugs lower pressure in hypertensive populations, and some appear to be beneficial in nonhypertensives who have abundant target organ damage (preexisting CVD) or diabetes. Candesartan, the angiotensin type I receptor blocker (ARB) decreased blood pressure significantly in a placebo-controlled, randomized trial of prehypertensives who were young with no CVD.³⁷ The design of the trial called for 2 years of active treatment combined with lifestyle advice followed by a 2-year phase in which the active drug was withdrawn and both groups were placed on placebo. In this second phase, a high fraction of those whose pressure had previously been lowered by the angiotensin receptor blocker returned to higher pressure levels and became hypertensive at nearly the same rate as those on placebo in both phases. There were too few CVD events in the trial for evidence that angiotensin receptor blocker treatment is effective for decreasing mortality or morbidity as a treatment for prehypertension or high-normal pressure.

What decisions should be made for the treatment of prehypertension? Should prehypertensives be treated differently from those with optimal pressure who are overweight or have other risk factors or should they be treated as if they already had hypertension? Should they be treated only for the risk factors that are present—obesity, lipid disorders, or high fasting glucose (prediabetes)—or by addition of antihypertensive drugs? Given the results of the Trial of Prevention of Hypertension follow-up observations, would a low-dose diuretic be the equivalent of low-salt diet for long-term benefit? Is the long-term risk of diabetes related to diuretics a concern?³⁸ Without better evidence, these decisions can be made as well with a coin toss or by theoretical reasoning so that the decision, for any given patient with prehypertension, is for each clinician to make. It is not yet time for guidelines to set the rules.

DECISION 4: TREATMENT OF HYPERTENSION: SHOULD GOALS BE BASED ON BLOOD PRESSURE OR ON REVERSIBLE GLOBAL RISK OF FUTURE DISEASE? GUIDELINES COMPARED: IS THERE AGREEMENT?

The factors that determine future cardiovascular disease for hypertensive patients can be divided into categories: (1) age alone, (2) average pressures, (3) non-pressure-related reversible risk factors, and (4) preexisting cardiovascular or renal pathology, that is, target organ damage such as left ventricular enlargement. For any given level of pressure, future risk of stroke, coronary heart disease, or renal failure varies over a wide range. However, the abundant evidence from clinical trials clearly supports drug treatment of established hypertension.

Guidelines for the diagnosis and treatment of hypertension emerged shortly after evidence from randomized clinical trials demonstrated the effectiveness of drug treatment for high blood pressure. The most recent advisory from the United States is JNC-7.³ Guidelines have also been issued from a combined effort by the European Society of Hypertension with the European Society of Cardiology⁴ and the British Hypertension Society.⁵ Although these three guidelines share many features, there are differences with regard to diagnostic categories and recommendations for treatment. Prehypertension is defined only in the JNC-7 recommendation, whereas the other two guidelines retain the term *high-normal blood pressure* for those with clinic measurements of 130 to 139/85 to 89 mm Hg. For stage 1 hypertension, clinic pressures of 140 to 159/90 to 100 mm Hg, the JNC-7 advises drug treatment for all and favors starting with a thiazide-type diuretic. The European Society of Hypertension with the European Society of Cardiology and British Hypertension Society take a more

restrained view using a global risk-based approach. For those with low risk and stage 1 hypertension, there is more emphasis on continued observation and patient preference. All guidelines recommend a favorable lifestyle change (smoking cessation, increased exercise, weight loss, and diet improvement) irrespective of the need for drug treatment.

For initiation of drug treatment, the British Hypertension Society guideline originally took age and ethnic status into account using the ABCD strategy. For those younger than 55 years and nonblack, initial treatment with either an angiotensin-converting enzyme inhibitor (A) or β -blocker (B) was initially suggested. For those 55 years and older and/or black, the recommended initial treatment is a calcium blocker (C) or a thiazide-type diuretic (D). Due to evidence that β -blockers are associated with increased incidence of diabetes and a lack of clear-cut effectiveness,³⁹ the B was dropped, resulting in the ACD strategy in a revision of the British Hypertension Society guideline.⁴⁰ The European Society of Hypertension with the European Society of Cardiology approach is less stringent in suggesting monotherapy with any selected class as the first step. Both age and risk status are included as bases for choice.

For definite hypertension, all three guidelines share the recognition that most patients will require two to three drugs for effective control (e.g., an angiotensin-converting enzyme inhibitor plus a diuretic or a calcium channel blocker). Goals for treatment are similar: lower than 140/90 for most patients and lower than 130/80 mm Hg for those with either diabetes or chronic renal disease. The guidelines also recommend drug treatment for definite hypertension from at least age 50 to age 80, due to the abundant trial evidence of this conclusion. For those older than 80 years of age, there is recognition that definitive trial evidence is lacking. The European Society of

Hypertension with the European Society of Cardiology and British Hypertension Society guidelines emphasize the need for individualization and recognize the risk of overtreatment and the need to screen for orthostatic hypotension in this age group to avoid syncope. Table 48-1 lists the main features for screening, classifying, and treatment for these three guidelines.

How should a clinician decide which guideline to use? Are the diagnosis and treatment of hypertension to be defined by national borders or are international standards more appropriate? One consideration for those nations with limited resources for health care is to favor the most cost-effective strategies with emphasis on high-risk groups for control of hypertension to minimize inefficient resource consumption.⁴¹ The risk-based approach to choice of treatment will decrease or withhold drug treatment for those with the combination of stage 1 or grade 1 hypertension and low-risk profiles represented by less than a 10% to 15% likelihood of CVD over the next 10 years. All those with higher stages or higher risk will be given drug treatment. This strategy would decrease the number needed to treat for benefit of individual patients and should be cost-effective, a necessity for nations with limited funds for health care. The JNC-7 imperative to treat all stage 1 hypertensives with drug treatment irrespective of their overall risk profiles may lead to overtreatment with no benefit for many (a high number needed to treat), excess cost, adverse effect (diuretics are still a problem in this regard), and dilution of the effort to find and effectively treat those with high risk due to higher blood pressure or presence of other risk factors and/or target organ damage.

I suggest that those who manage hypertension be aware that experts who write guidelines have differing opinions due to lack of evidence and that treating physicians tailor the

Table 48-1 Comparison of the Guidelines for Detection of Hypertension and Goals for Treatment

Initial Classification	JNC-7	ESH-ECS	BHS
Prehypertension	120–139/80–89	Not used	Not used
High normal	No longer used	A: 130–139/85–89	130–139/85–89
Hypertension	Stage 1: 140+/90+ to 159/100; stage 2: > 159/100	B: 140–179/90–109; C: $\geq 180/\geq 110$	Grade 1: 140–159/90–99 Grade 2: 160–179/100–109 Grade 3: $\geq 180/\geq 110$
Isolated systolic hypertension	$\geq 140/<90$	$\geq 140/<90$	Grade 1: 140–159/<90 Grade 2: $\geq 160/<90$
Goals for treatment	<140/90 nondiabetic <130/80 diabetes and chronic renal disease	<140/90 nondiabetic <130/80 diabetes	<140/85 nondiabetic <130/80 diabetes, renal disease, established cardiovascular disease
Initial treatment nondiabetics	Diuretic preferred	Any drug class	ACD* selection based on age and ethnic status (black-white)
Initial treatment diabetics	Two drugs, usually including ACEI or ARB	ACEI or ARB	Type I: ACE Type II: ARB

All blood pressures are given as mm Hg.

*AA, angiotensin-converting enzyme inhibitor for white patients and those younger than 55 years; CD, calcium blocker or diuretic for black or older patients.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; BHS, British Hypertension Society guidelines for hypertension management, 2004 (BHS-IV)^{5,40}; ESH-ECS, 2003 European Society of Hypertension–European Society of Cardiology guidelines for the management of arterial hypertension⁴; JNC-7, Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure.³

guidelines to the patient rather than force the patient to fit into a guideline. This is particularly the case for those with prehypertension or high-normal pressure or low-risk stage 1 or grade 1 hypertensive patients.

DECISION 5: HOW SHOULD ELDERLY HYPERTENSIVE PATIENTS BE TREATED?

In developed countries, a larger fraction now survives longer than 80 years of age, with many alive in the 85- to 100-year range. Epidemiologic surveys project that more than 90% in this age range will be hypertensive according to current criteria, most with isolated systolic hypertension.⁴² Antihypertensive drug treatment of hypertension in those as old as 80 years of age is effective for reduction in stroke and CVD and prevention of heart failure.²¹ The evidence is less convincing with those older than 85 years of age. Furthermore, the trials have largely recruited healthy older groups, yet many of the old-old have other diseases leading to frailty, diminished mobility, and, all too often, dementia. Low diastolic pressures often occur in the elderly that might decrease to levels near or below the threshold for coronary perfusion with antihypertensive treatment, leading to higher mortality due to lower treatment pressures, the J-curve phenomenon.²² Orthostatic hypotension is more likely in older patients, adding to risk of syncope and fractures.⁴³ Where then does antihypertensive drug treatment find its place in the complex balance of considerations for this group? Epidemiologic surveys of the very old suggest that those with the lowest blood pressure actually have the highest short-term mortality rates compared with those with higher (even hypertensive) pressures.^{44,45} A meta-analysis of old-old subgroups selected from reports of larger trials found that active treatment does decrease the rate of stroke, but increases overall mortality.⁴⁶ A pilot trial of active treatment compared with placebo in hypertensives 85 years of age and older, found a similar pattern: reduced stroke and higher mortality.⁴⁷ A larger trial (the Hypertension in the Very Elderly Trial) will investigate the effect of antihypertensive treatment in the old-old on cardiovascular event rates, dementia, and fractures.^{48,49} It is hoped that the results will be available in 2009.

The value of antihypertensive drug treatment in the old-old offers potential benefit and harm. This potential is conveyed in Figure 48-2, which portrays the likelihood of benefit versus harm in relation to age. Until additional trials coupled with careful observational studies are available, emphasis should be placed on thoughtful assessment of each individual patient to ponder reversible risk of cardiovascular disease, quality of life, likelihood of syncope (orthostatic hypotension) and patient's preferences. *Primum non nocere* should be balanced against the urge to write prescriptions in order to make the best decisions.

CONCLUSIONS

Physicians evaluate and treat patients one by one. The lessons learned from large epidemiologic and clinical trials need translation and individualized application for optimal decision making. It is recommended that physicians consider the views presented in this chapter to give attention to the

Figure 48-2 Schematic estimate of the relationship between benefit and harm of treatment of hypertension in relation to age. Based on trial evidence, benefit clearly exceeds harm when drug treatment is given to those 50 to 80 years of age and very likely for those between 40 and 50. With increasing frailty in the elderly, the presence of other diseases requiring medications, and the likelihood of drug interactions, the potential for harm increases and may cross the benefit line at ages 80 to 85.

following: (1) focus on the daily average pressure for diagnosis and treatment with recognition that age-based criteria for either systolic or diastolic pressure are relevant, (2) be aware of the limited or absent evidence of effective treatment of prehypertension or high-normal pressure, and (3) recognize that well-meaning guidelines differ among groups who are distant from the day-to-day challenges of patient care. Lowering blood pressure to compensate for other risk factors may be valuable in selected, but not all, cases.⁴ Treating systolic hypertension in the elderly and especially the old-old is a multifaceted challenge that should combine realistic goals for treatment with principles of geriatric medicine.

Decisions (choices made in ignorance) are built into the practice of preventive medicine. The current abundance of evidence combined with useful guidelines has reduced, but not eliminated, the ignorance, so that the best decisions will require knowledge, thought, and wisdom.

EFFECTS OF WEIGHT LOSS	577		

There is a continuum of risk between blood pressure and cardiovascular events. Although 27% of the U.S. adult population has hypertension and often receives some form of pharmacological therapy,¹ many fewer are counseled about, or actually implement, nonpharmacologic treatments. However, the greatest impact of nonpharmacologic treatments may actually be in the large group of individuals with prehypertension. Nonpharmacologic interventions involving dietary and lifestyle changes, such as weight loss, sodium restriction, and changes in dietary patterns, either alone or in combination, may decrease the incidence and prevalence of hypertension. Clinicians do not place sufficient emphasis on these interventions because patient acceptance and adherence are often low.

The treatment of hypertension has evolved over the past 40 years. Research has generated changes in strategies, approaches, treatment options, and effects of nonpharmacologic treatment. However, what has remained constant is the recognition that lifestyle modifications are a cornerstone of treatment. Although clinical trials of nonpharmacologic treatments have not had sufficient power to show differences in cardiovascular events, implementing these interventions can be supported from cardiovascular risk reduction associated with their blood pressure effects *per se*.

This chapter summarizes the results of studies that evaluate the effects of nonpharmacologic treatments in prehypertensives and hypertensives. A summary of systolic blood pressure changes that may be anticipated with the interventions is shown in Table 49-1.

EFFECTS OF DIETARY PATTERNS

A diet that replaces animal products with vegetable products decreases blood pressure. However, it is unrealistic to assume that vegetarian diets would be widely accepted. Features of a vegetarian diet have been identified (e.g., higher fiber, potassium, and magnesium content and decreased fat content) that may affect blood pressure. Although each of these individual nutrients is associated with decreased blood pressure, trials that have tested the effects of such individual nutrients have seen only small blood pressure changes. This may be due to each nutrient by itself having a small effect so that only when all are consumed together is a clinically significant effect observed.

The Dietary Approaches to Stop Hypertension (DASH) trial² was designed to identify a diet that decreases blood pressure and is also palatable and acceptable to the general population. Individuals with a diastolic blood pressure of 80 to 95 mm Hg and a systolic blood pressure less than 160 mm Hg were randomized to receive one of three intervention diets. Participants were provided with all their meals for an 11-week period. After a 3-week run-in period on a control diet, participants were randomized to either continue with the control diet or receive (1) a diet rich in fruits and vegetables (fruits and vegetables diet) but otherwise similar to the control diet in fat and carbohydrate content or (2) a diet that combined the increased fruits and vegetables of the fruits and vegetables diet with increased low-fat dairy products and overall decreased total and saturated fat and cholesterol (DASH diet). All diets had similar sodium content (approximately 3 g/day). The diets and feeding protocols were designed to prevent significant weight change.

Participants randomized to the DASH diet had a significant decrease in blood pressure. The fruits and vegetables diet produced an intermediate effect. The DASH diet decreased blood pressure by $-6/-3$ mm Hg. The response was greater in African Americans ($-7/-4$ mm Hg systolic/diastolic) than in whites ($-3/-0.5$ mm Hg) and those with hypertension benefited the most ($-12/-5$ mm Hg).³ By the end of the trial, 70% of participants who entered the study with hypertension had normal blood pressure ($<140/90$ mm Hg) if they ate the DASH diet compared with only 23% of those eating the control diet.⁴ The DASH diet was well accepted and self-reported adherence with the diet was more than 90%.

Other dietary patterns that build on the components of the DASH diet may also be beneficial for blood pressure in individuals with prehypertension and hypertension. Evidence supporting favorable effects of protein and unsaturated fat intake on blood pressure led to the Optimal Macronutrient Intake Trial to Prevent Heart Disease (OMNI-Heart).⁵ Three healthy dietary patterns were assessed: a carbohydrate-rich diet (similar to the DASH diet), a diet rich in protein (approximately one half from plant sources), and a diet rich in unsaturated fat (mostly mono-unsaturated fat). All the diets were enriched in vegetables, fiber, potassium, and other minerals, with decreased saturated fat and cholesterol. Participants consumed each of the

Table 49-1 Nonpharmacologic Treatments to Prevent and Manage Hypertension

Intervention	Approximate Systolic Blood Pressure Reduction (mm Hg)
Dietary patterns	
DASH	6–12
DASH with higher protein or monounsaturated fat intake	8–14
Individual micronutrients	
Potassium	4
Calcium	1
Magnesium	No change
Other dietary changes	
Restricting alcohol intake	3
Coffee consumption	+2
Cocoa consumption	1–3
Weight loss	5–20/10 kg
Exercise	7
Other lifestyle changes	
Smoking cessation	No change (short term)
Tai chi	No change
Transcendental meditation	3
Acupuncture	No change

DASH, Dietary Approaches to Stop Hypertension study.

diets for 6 weeks. Each diet significantly decreased blood pressure. However, the diets that substituted protein or unsaturated fat for carbohydrate (~10% of total calories) further decreased systolic blood pressure by as much as 4 mm Hg in hypertensive participants.

Each of these feeding studies was a short-term trial that assessed effects on blood pressure. Other epidemiologic studies have confirmed the favorable long-term effects of similar lifestyle modifications on cardiovascular disease outcomes. Modifying dietary fat intake for secondary prevention of coronary heart disease (CHD) was confirmed in the Lyon Diet Heart Study, which showed that a Mediterranean-type diet, enriched in linolenic acid but with decreased saturated fat, decreased CHD mortality by 70%.⁶ Two large cohort studies, the Nurses' Health Study (>75,000 women) and the Health Professionals' Follow-up Study (>38,000 men), indicated that risk of ischemic stroke was decreased by 31%⁷ and the risk of CHD was decreased by 20%⁸ among individuals consuming the highest quintile for daily intake of fruits and vegetables (approximately five to six servings per day). In other analyses from the Nurses' Health Study, a dietary pattern similar to that of the DASH diet was associated with a 24% decreased risk of CHD over a 12-year period.⁹ Higher fiber intake was associated with a 47% risk reduction for CHD events¹⁰ and higher whole-grain intake with a 43% decrease in ischemic stroke.¹¹

Thus, the DASH diet and similar dietary patterns studied in the OMNI-Heart Trial decrease blood pressure. Components of these dietary patterns are also associated with a decreased incidence of cardiovascular events. These findings provide abundant evidence that dietary patterns enriched in fruits and vegetables and low in saturated fat are an effective, well-tolerated, nonpharmacologic treatment for prehypertension and stage 1 hypertension.

EFFECTS OF INDIVIDUAL DIETARY MICRO- AND MACRONUTRIENTS

In an attempt to dissect the blood pressure effects of individual dietary nutrients, several studies have evaluated effects of mineral intake (i.e., potassium, calcium, and magnesium) and macronutrient intake (i.e., protein, carbohydrate, and fat).

Substantial evidence exists for an effect of higher potassium intake on blood pressure. A number of clinical trials and meta-analyses have confirmed that increased potassium intake is associated with lower blood pressure. Whelton and colleagues¹² showed that a net increase in potassium intake of 2 g/day (50 mmol/day) resulted in a significant decrease in blood pressure by $-4/-3$ mm Hg. Blood pressure effects in African Americans appear to be greater than those in whites.

Support for a small effect on blood pressure by increased calcium intake comes from a series of observational and interventional studies. Although increased calcium intake per se is associated with lower blood pressure, a meta-analysis of trials showed that the effects are modest, amounting to approximately 1 mm Hg or less for systolic and diastolic blood pressures.^{13,14} Similarly, although there is an association between increased magnesium intake and lower blood pressure, an analysis of 20 trials did not show a significant effect on blood pressure.¹⁵

Increased potassium, calcium, and magnesium intake may be achieved through individual supplements or food intake. However, the preferred strategy is to increase such micronutrient intake from foods rather than nutritional supplements because the former would also provide other nutrients. For example, adhering to the DASH dietary pattern provides intake of these micronutrients at or near recommended levels, approximately 4.7 g/day of potassium, 0.5 g/day of magnesium, and 1.25 g/day of calcium, based on 2100 kcal/day.

Dietary intake of macronutrients, that is, carbohydrate, protein, and fat, may also affect blood pressure. However, in general the effects are less certain and likely complex. Probably the most consistent evidence is an inverse relationship between blood pressure and protein intake (primarily from plant sources).¹⁶ However, in studies in which one macronutrient is altered, there is always a concomitant change in others, making it difficult to discern whether an effect is due to increases in one or decreases in another. In the OMNI-Heart Trial,⁵ a carbohydrate-rich diet similar to the DASH diet decreased blood pressure significantly, but partial substitution of carbohydrate with protein or monounsaturated fat further decreased blood pressure. Thus, these findings are consistent with the hypothesis that substituting carbohydrate with either protein or monounsaturated fat decreases blood pressure further. However, it is unclear whether this is mediated by the

increases in protein or unsaturated fat rather than decreases in carbohydrate intake.

EFFECTS OF DIETARY SODIUM RESTRICTION

Sodium restriction has been well documented to decrease blood pressure in normal and hypertensive individuals. Guidelines for the prevention and treatment of hypertension continue to advocate restriction of dietary sodium intake in the general population by limiting intake to no more than 2.3 g/day.¹⁷ A discussion of the evidence and recommendations for reduced sodium intake are detailed in Chapter 50.

EFFECTS OF OTHER DIETARY CHANGES

There is ample evidence showing a direct relationship between alcohol intake and blood pressure. Some evidence suggests that not only the amount but also the pattern of alcohol intake affects blood pressure. Binge drinking has acute effects on blood pressure compared with similar amounts consumed in a distributed manner.¹⁸ Although moderate alcohol intake is associated with favorable effects on CHD, this same relationship is not evident for the incidence of ischemic stroke. Possibly through its effects on blood pressure, increased alcohol intake is associated with higher risk.¹⁹ Decreasing excess alcohol intake decreases blood pressure. Results from a meta-analysis of 15 trials showed that decreasing alcohol intake by approximately 75% resulted in a significant decrease in blood pressure ($-3/-2$ mm Hg).²⁰

Coffee consumption has a complex relationship with blood pressure. Some evidence suggests a positive relationship, with intake of more than five cups per day associated with increased blood pressure ($+2/+1$ mm Hg).²¹ One study suggested a direct relationship between coffee intake and incident hypertension²²; another study showed a U-shaped relationship, with coffee abstainers and those with higher intake (more than six cups/day) having the lowest risk of hypertension.²³ However, studies of coffee intake have not adequately controlled for other lifestyle factors, such as stress, smoking, alcohol intake, and brewing methods that may produce more or less caffeine in the beverage. Coffee contains a mixture of substances that affect blood pressure. In a meta-analysis of studies evaluating coffee intake compared with caffeine per se, intake of caffeine tablets increased blood pressure by $+4/+2$ mm Hg, whereas coffee intake increased blood pressure by $+1/+0.5$ mm Hg.²⁴ In contrast, long-term green tea consumption has no significant short-term effects on blood pressure²⁵ but is associated with decreased risk of incident hypertension.²⁶

Recently there has been much interest in the effects of cocoa consumption on blood pressure and endothelial function. Several short-term studies have investigated the effects of cocoa consumption on blood pressure. In a meta-analysis of five trials, cocoa drinkers had a $-5/-3$ mm Hg decrease in blood pressure compared with control groups over a median of 2 weeks, with the greatest effects seen in younger hypertensive individuals.²⁵ Although these early results are intriguing, most studies are of short duration and conducted in an unblinded manner. At present, it is unclear whether long-term

increased cocoa consumption is effective in decreasing blood pressure. Because most forms of dietary cocoa are contained in high-fat or carbohydrate-rich foods, cocoa consumption should be approached with caution, with particular attention to calorie substitution for other calorie-dense portions of the typical diet.

EFFECTS OF WEIGHT LOSS

Weight loss as a lifestyle modification has long been advocated to decrease blood pressure and other cardiovascular risk factors. This has been explored in relationship to blood pressure in several recent trials.²⁷⁻³² In each, weight loss (particularly among obese participants) decreased blood pressure, prevented the development of hypertension, or potentiated the effects of antihypertensives.

The Trials of Hypertension Prevention phase I entailed an 18-month lifestyle modification in which individuals with high-normal blood pressure were randomized to weight loss, sodium restriction, or a control group.²⁹ Follow-up examinations (7 years after randomization) were conducted in 181 of the 208 participants studied at Johns Hopkins University.³⁰ During the original 18-month study, significant weight loss was achieved in the group randomized to the weight-loss intervention. This was associated with a significant decrease in blood pressure. However, after 7 years of follow-up, the weight-loss group did not differ from the other intervention groups in body weight or urinary sodium excretion. Despite this, the weight-loss group retained a decreased incidence of hypertension of 77%.

The Trials of Hypertension Prevention phase II study had a similar design but enrolled more patients and had 3 to 4 years of follow-up.^{28,31} The group randomized to weight loss (595 individuals with high-normal blood pressure who were 110%–165% of ideal body weight) had a 2-kg weight difference at 3 years of follow-up. This modest weight loss was associated with a 19% decreased risk of developing hypertension; those with a sustained 4.5-kg weight loss had a 65% decreased risk.

In a substudy of the Hypertension Optimal Treatment study, obese hypertensive patients were randomly assigned to receive a weight-loss intervention, including individual and group counseling, or no intervention.³² Those in the weight-loss group lost significantly more weight than the control group during the initial 6 months, but at 30 months of follow-up, there was no significant difference. Despite this, patients in the weight-loss group used fewer medications to achieve the same blood pressure.

These results show that weight-loss interventions may facilitate control of blood pressure and prevent the progression to hypertension or may control blood pressure with fewer antihypertensive medications, even without producing sustained weight loss.

EFFECTS OF EXERCISE

Exercise is frequently promoted as a tool to facilitate weight loss and decrease blood pressure. Indeed, exercise and weight loss together result in lower blood pressure than either alone.³³ The mechanisms that mediate decreasing of blood pressure

with exercise likely include effects on the sympathetic nervous system, renin-angiotensin system, and endothelial function. These effects appear to be independent of changes in weight or body composition.

Several studies have evaluated the effects of moderate-intensity aerobic exercise or resistance training on blood pressure. Among individuals with high-normal or stage 1 hypertension, aerobic exercise decreases blood pressure significantly, although the effects tend to be smaller than those seen with moderate sodium restriction.³⁴ Among postmenopausal women³⁵ or elderly individuals,³⁶ low- to moderate-intensity aerobic exercise (e.g., walking) significantly decreases blood pressure. Among postmenopausal women, increased frequency of moderate physical activity is associated with a 30% decreased risk of mortality over 7 years.³⁷

Meta-analyses have compared the effects of walking, aerobic exercise, and resistance exercise on blood pressure. One may conclude that regular aerobic exercise produces the greatest reduction in blood pressure ($-7/-6$ mm Hg)^{38,39} compared with walking ($-3/-2$ mm Hg)⁴⁰ or resistance exercise ($-3/-3$ mm Hg).⁴¹

Thus, the optimal exercise program for decreasing blood pressure should include moderate-intensity aerobic exercise three to five times per week for 30 to 60 minutes per session. Resistance exercise has limited effects on blood pressure. There is no apparent age- or sex-related difference in the response to exercise. Weight loss is facilitated by exercise programs that expend 1255 to 2090 kJ/day. Exercise intensity and duration should be appropriate to the individual's abilities and concomitant medical conditions. In some cases, an assessment of cardiovascular risk may be appropriate before participation in a regular exercise program. As with most lifestyle modifications, the greatest effects on blood pressure occur in individuals with high-normal or stages 1 to 2 hypertension.

EFFECTS OF OTHER LIFESTYLE CHANGES

Smoking cessation clearly decreases cardiovascular risk. However, its effects on blood pressure are uncertain. Indeed, several studies have shown that former smokers have a significant risk of developing hypertension with longer duration of smoking cessation. Among former smokers who quit for more than 3 years, the relative risk of hypertension was 3.5.⁴² Much of this increased risk of hypertension may relate to the weight gain that frequently occurs after smoking cessation.^{43,44} Smoking is also associated with diffuse vascular changes including increased vascular stiffness and pulse wave velocity. Unlike the increasing risk of hypertension among former smokers, more than 10 years of smoking cessation reverses these vascular changes.⁴⁵

Complementary and alternative medicine techniques to decrease blood pressure have been evaluated, although limitations and biases are present in many studies. In a systematic review of the health outcomes of tai chi, there appears to be some physiologic and psychological benefits.⁴⁶ However, specific studies of effects of tai chi on blood pressure have shown no benefit. In a study that directly compared tai chi with resistance training among healthy elderly participants over a 12-month period, tai chi had no significant effect on blood pressure.⁴⁷

Stress reduction through transcendental meditation (TM) has varied effects on blood pressure. Results of a meta-analysis of randomized trials of TM revealed no con-

vincing evidence of an effect of TM on blood pressure, with significant concerns about study methodologies and potential author bias. However, in a study of hypertensive African Americans, TM for 20 minutes twice daily decreased blood pressure $-3/-5$ mm Hg over 12 months.⁴⁸ A randomized trial of TM compared with health education in patients with CHD showed significant benefits in blood pressure ($-3/-2$ mm Hg) and insulin resistance over a 16-week period.⁴⁹ In a study of long-term follow-up of participants in trials of TM and other behavioral stress-reducing interventions, the TM group had a 23% decrease in all-cause mortality and a 30% decrease in cardiovascular mortality.⁵⁰ Thus, stress-reducing interventions such as TM may have beneficial effects among individuals with hypertension, but good-quality evidence is lacking.

Small studies and anecdotal evidence initially supported an effect of acupuncture on blood pressure in hypertensive patients.⁵¹ However, the results of a randomized, controlled trial of acupuncture has now debunked that purported effect. The Stop Hypertension with Acupuncture Research Program study enrolled 192 participants with untreated hypertension, randomized to individualized or standardized acupuncture compared with sham acupuncture.⁵² After a 10-week period, there was no significant difference between those receiving acupuncture compared with the sham control subjects. Thus, use of acupuncture to decrease blood pressure likely offers no significant clinical benefit.

EFFECTS OF COMBINED DIETARY AND NONPHARMACOLOGIC INTERVENTIONS

Although clinical trials have often studied the effects of single dietary or lifestyle interventions on blood pressure, guidelines and recommendations advocate combining multiple interventions. Those studies that have carefully evaluated such comprehensive lifestyle modifications have shown significant favorable effects on blood pressure.

The PREMIER study assessed the blood pressure effects of implementing all the major lifestyle modifications. This randomized trial was designed to assess the effects of multiple established lifestyle recommendations with or without the addition of the DASH diet.⁵³ Participants with prehypertension and stage 1 hypertension were studied. Compared with a control group that received advice about adopting such lifestyle changes, both groups that received the multiple behavioral interventions experienced significant weight loss, improved fitness, and decreased sodium intake, whereas the group that received counseling on the DASH diet also increased fruit, vegetable, and dairy intake over the 6 months of study. When compared with the advice-only group, the overall change in systolic blood pressure from the combined interventions including the DASH diet was -4 mm Hg. The prevalence of hypertension was decreased from 38% to 12% among those following the behavioral intervention that included the DASH diet. No participants had blood pressure less than 120/80 mm Hg at baseline, but this number increased to 35% in the group that received counseling on the DASH diet. More than 90% of study participants were followed for as long as 18 months to see whether the recommended lifestyle changes persisted and to assess their clinical effects. Blood pressure remained lower in the groups that re-

ceived the multiple behavioral interventions with or without the DASH diet. The odds ratio for developing hypertension at 18 months was decreased by 23% among those following the DASH diet (see Table 49-2).⁵⁴

This same approach has been applied to individuals with treated hypertension. In a study of overweight hypertensive patients taking a single antihypertensive medication, participants were randomized to a control group or to a group that received a weight-reducing version of the DASH diet with sodium restriction and a supervised moderate-intensity exercise program.⁵⁵ After 9 weeks, those in the intervention group had significant reductions in 24-hour ambulatory blood pres-

sure (−10/−5 mm Hg), weight (−5 kg), and cholesterol (−25 mg/dL).

The Trial of Nonpharmacologic Interventions in the Elderly (TONE) studied hypertensive patients between 60 and 80 years of age who were treated with one antihypertensive medication.²⁷ Overweight patients were randomized to either sodium restriction (<1.8 g/day), weight loss (at least 10 lb), combined weight loss and decreased sodium intake, or usual care, whereas normal-weight patients were assigned to sodium reduction or usual care. Those in the weight-loss group lost an average of 8 to 10 lb. Thirty-eight percent of those in the sodium-reduction group decreased their

Table 49-2 Following the Dietary Approaches to Stop Hypertension (DASH) Diet

Food Group	Daily Servings (Except as Noted)	Serving Sizes	Examples and Notes	Significance of Each Food Group to the DASH Eating Plan
Grain and grain products	7–8	1 slice bread 1 oz dry cereal* ½ cup cooked rice, pasta, or cereal	Whole wheat bread, English muffin, pita bread, bagel, cereals, grits, oatmeal, crackers, unsalted pretzels, popcorn	Major sources of energy and fiber
Vegetables	4–5	1 cup raw leafy vegetable ½ cup cooked vegetable 6 oz vegetable juice	Tomatoes, potatoes, carrots, green peas, squash, broccoli, turnip greens, collards, kale, spinach, artichokes, green beans, lima beans, sweet potatoes	Rich sources of potassium, magnesium, and fiber
Fruits	4–5	6 oz fruit juice 1 medium fruit ¼ cup dried fruit ½ cup fresh, frozen, or canned fruit	Apricots, bananas, dates, grapes, oranges, orange juice, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, prunes, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Low-fat or fat-free dairy foods	2–3	8 oz skim milk 1 cup yogurt 1½ oz cheese	Fat-free (skim) or low-fat (1%) milk, fat-free or low-fat buttermilk, fat-free or low-fat regular or frozen yogurt, low-fat and fat-free cheese	Major sources of calcium and protein
Meats, poultry, and fish	≤2	3 oz cooked meats, poultry, or fish	Select only lean; trim away visible fats; broil, roast, or boil instead of frying; remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and dry beans	4–5 per week	⅓ cup or 1½ oz nuts 2 tbsp or ½ oz seeds ½ cup cooked dry beans	Almonds, filberts, mixed nuts, peanuts, walnuts, sunflower seeds, kidney beans, lentils, peas	Rich sources of energy, magnesium, potassium, protein, and fiber
Fats and oils†	2–3	1 tsp soft margarine 1 tbsp low-fat mayonnaise 2 tbsp light salad dressing 1 tsp vegetable oil	Soft margarine, low-fat mayonnaise, light salad dressing, vegetable oil (such as olive, corn, canola, and safflower)	DASH has 27% of calories as fat, including that in or added to foods

*Equals ½ to 1¼ cups, depending on cereal type. Check the product’s nutrition label.

†Fat content changes serving counts for fats and oils; for example, 1 tbsp of regular salad dressing equals one serving; 1 tbsp of a low-fat dressing equals ½ serving; 1 tbsp of a fat-free dressing equals 0 servings.

The Dietary Approaches to Stop Hypertension (DASH) eating plan is based on a calorie intake of 2000 calories per day. The number of daily servings in a food group may vary based on the caloric needs of the individual.

From Facts about the DASH Diet (NIH publication 01-4082), Bethesda, MD: NHLBI Health Information Center, May 2001.

sodium intake to less than 1.8 g/day. After 30 months, 30% were off antihypertensive medications. The need for antihypertensive medications was decreased by 31% with sodium restriction, by 36% with weight loss, and by 53% with the combination of both.

CONCLUSION AND RECOMMENDATIONS

There is ample evidence showing favorable blood pressure effects with consumption of low-fat diets enriched in fruits and vegetables such as the DASH diet, sodium restriction, weight-loss interventions, restricting alcohol intake, and increased aerobic exercise. There is some evidence of favorable effects with relaxation techniques such as TM. There are no clear blood pressure benefits from restricting coffee intake and smoking cessation, although these and other lifestyle changes may have benefits for cardiovascular health that extend beyond blood pressure control.

The results of these studies have broad applicability. Although lifestyle modifications and nonpharmacologic treatments are difficult to sustain, a population-wide decrease in blood pressure to the same extent as was observed with the DASH diet would reduce the incidence of CHD by 15% and stroke by 27%.¹⁷ The long-term effects on blood pressure of weight-loss interventions, with or without aerobic exercise, provide a strong case to continue advocating for obese individuals to receive weight management counseling. A secondary benefit of these lifestyle changes (2–3 kg weight loss) also includes a decreased incidence of type 2 diabetes mellitus, particularly in those with impaired glucose tolerance.⁵⁶

The foods that comprise the DASH diet are readily available. The DASH diet is not expensive, but eating the DASH diet requires attention to food groups, caloric requirements, and the calorie content of foods (Table 49-2). The servings of fruits and vegetables (8–10 daily) are approximately twice the typical daily consumption of four servings by U.S. adults. Likewise, the three servings of dairy products are twice the typical daily U.S. consumption.⁵⁷ More detailed summaries of the findings of the DASH studies and some menus that employ the DASH diet have been published for lay audiences.^{58,59}

Results from studies of lifestyle and dietary modifications are relevant to the care of patients with prehypertension and hypertension.⁶⁰ However, it is important to keep in mind a few points that have not been addressed:

1. Most studies have involved only short-term intervention periods. In some cases, it is not known whether such blood pressure changes are sustained over longer periods of time.
2. Some studies of dietary patterns provided foods to study participants and therefore facilitated adherence to the diet. When such dietary patterns are replicated in real life and individuals are responsible for purchasing and preparing their own foods, it is not known what level of adherence to the dietary pattern is necessary to produce the same effect.
3. Studies of dietary patterns did not assess the effects of individual components of the diets. Thus, one cannot conclude that specific food items and/or nutrients (e.g., potassium, magnesium, carbohydrate) produce the effects of the dietary pattern. It is very likely that an interaction of effects

from the various dietary constituents is responsible for the favorable effects.

4. Lifestyle changes have greater blood pressure effects in patients with hypertension than in those with prehypertension. However, individuals with higher levels of blood pressure (e.g., stage 2 hypertension) will likely require adjunctive therapy (i.e., antihypertensive medications) to fully control blood pressure.
5. The DASH dietary pattern is enriched in potassium, magnesium, and protein, which should be limited in patients with kidney disease. Therefore, this dietary pattern should be implemented with caution in such patients.

Patients can implement lifestyle modifications and nonpharmacologic treatments on their own. Such interventions involve minimal risk, may have a positive impact on quality of life, and may also be less expensive than antihypertensive medications. The long-term beneficial effects of eating a dietary pattern such as the DASH diet have been demonstrated. Clearly, the role of lifestyle modifications has been affirmed in both the prevention and treatment of hypertension.

DIETARY APPROACHES TO STOP HYPERTENSION (DASH) DIET	585		

Cardiovascular diseases (CVDs) are the leading cause of mortality, morbidity, and disability worldwide.¹ Although CVDs are proportionally more relevant in developed countries, currently 70% of the total number of cardiovascular deaths occurs in developing countries. Globally, high blood pressure causes 7 million premature deaths per year.¹ In particular, hypertension affects approximately 1 billion individuals.² The burden of hypertension-related diseases is likely to increase as the population ages.³ Overall, high blood pressure is the most important and independent risk factor for myocardial infarction, heart failure, stroke, and kidney disease. Accordingly, prevention and treatment of hypertension are increasingly regarded as a priority in both developed and developing countries.

Nonpharmacologic interventions, also termed lifestyle modifications, represent an essential approach to the primary prevention of high blood pressure and an important component of the treatment of hypertension. These lifestyle modifications are effective in decreasing blood pressure, increasing the efficacy of pharmacologic therapies, and decreasing the global risk of CVD. In this chapter, I evaluate the appropriateness of recommendations at a population level regarding the reduction of dietary salt intake, the different approaches to intervention needed to implement a successful strategy to prevent hypertension in developing and developed countries, and the recommendations to individuals to reduce dietary salt intake for the overall management of hypertension.

DEFINITIONS

Publications refer to sodium intake as either mass or millimolar amounts of sodium or mass of sodium chloride (salt) (1 g of sodium chloride = 17.1 millimolar amounts of sodium or 393.4 mg of sodium). In this chapter, the word *salt* is used to refer to sodium and sodium chloride intake. The term *reduction in dietary salt intake* implies the reduction in total sodium intake from all dietary sources including, for example, additives such as monosodium glutamate and preservatives.

EFFECT OF DECREASING DIETARY SALT INTAKE ON BLOOD PRESSURE AND CARDIOVASCULAR DISEASE

Animal studies, ecologic analyses, epidemiologic investigations, and clinical trials support a relationship between salt intake and blood pressure. The amount of dietary salt is an important determinant of blood pressure levels and of hypertension risk in both individuals and populations. This relationship is direct and progressive without an apparent threshold. Thus, the reduction in dietary salt intake is one of the most important and effective lifestyle modifications to decrease blood pressure and control hypertension.^{4,5}

The importance of salt intake in determining blood pressure and the incidence of hypertension is well established. Furthermore, randomized, controlled clinical trials of moderate reductions in salt intake show a dose-dependent cause-and-effect relationship and a lack of threshold effect within usual levels of salt intake.⁶ The effect is independent of age, sex, ethnic origin, baseline blood pressure, and body mass. Prospective studies^{7–10} with one exception¹¹ also indicate that higher salt intake predicts the incidence of cardiovascular events. Finally, participants in randomized clinical trials of long-term moderate reduction in salt intake (e.g., ~2.5 g of salt reduction) show a 30% reduction in cardiovascular events 10 to 15 years later.¹²

That habitual salt intake could be associated with blood pressure levels was suggested several millennia ago, in the history of humankind, after the transition from food gathering to food producing with the addition of salt to preserve food and the consequent shift to a high-salt diet.¹³

More than 50 randomized clinical trials support a role for decreasing salt intake in the prevention and management of high blood pressure. In the largest of these trials, the Dietary Approaches to Stop Hypertension (DASH) trial,¹⁴ salt reduction alone from a high to a low level was associated with a decrease in blood pressure of 8.3/4.4 mm Hg (systolic/diastolic) among hypertensive individuals and 5.6/2.8 mm Hg among

normotensive individuals. Moreover, the combination of this amount of salt reduction and the DASH diet further decreased blood pressure by 11.5/5.7 mm Hg and 7.1/3.7 mm Hg, respectively, among those with and without hypertension. In subgroup analyses, significant effects of salt intake reduction on blood pressure levels were present in both genders and all racial and age groups, although they were more marked among African Americans, women, and those older than 45 years of age.¹⁵

Pooled estimates from meta-analyses of clinical trials on the effects of salt intake reduction on blood pressure levels indicate a decrease in blood pressure of 7.1/3.9 mm Hg in hypertensive individuals and 3.6/1.7 mm Hg in normotensive individuals per 100 mmol reduction of 24-hour urinary sodium excretion (~6 g of salt per day). For example, He and MacGregor¹⁶ estimated blood pressure decreases of 5.0/2.7 mm Hg in hypertensives and 2.0/1.0 in normotensives for a median reduction in urinary sodium of 78 mmol/day. In the latest published meta-analysis of 40 randomized trials, an average decrease in urinary sodium excretion of 77 mmol/day was associated with a decrease in blood pressure levels of 2.5/2.0 mm Hg.¹⁷ Blood pressure response was significantly greater in hypertensive than normotensive individuals (systolic: -5.2 vs. -1.3 mm Hg; diastolic: -3.7 vs. -1.1 mm Hg). Accordingly, findings from randomized clinical trials support a role for decreasing dietary salt intake in the primary prevention and management of hypertension.^{18,19}

The response of blood pressure to dietary changes in salt intake, as to other environmental stimuli, may vary between individuals. This phenomenon has been termed salt sensitivity,²⁰ and it is likely to be due to the degree of response of the renin-angiotensin system.^{21,22} The weaker the response of this system is to a change in sodium intake, the greater the response of the blood pressure will be. This phenomenon explains why the blood pressure-lowering effect of salt intake reduction is greater in hypertensive individuals, the elderly, and low-renin black populations. These groups are all characterized by weaker responses of the renin-angiotensin system to changes in the amount of salt ingested, showing a greater blood pressure decrease as a result of a decrease in dietary salt intake. Indeed, although a significant decrease in blood pressure induced by decreased salt intake has been observed in children and adolescents as well,²³ this response increases with age and is greatest in the elderly.²⁴ Furthermore, the blood pressure decrease observed in the elderly as a result of a dietary salt reduction may decrease the need for antihypertensive medication.²⁵ These observations are relevant to the prevention of hypertension-related diseases in developed countries, where the majority of strokes occur in the elderly and individuals with blood pressure levels below the treatment threshold for hypertension.²⁶ Nevertheless, several antihypertensive drugs blocking the renin-angiotensin system (e.g., angiotensin-converting enzyme inhibitors, β -blockers, angiotensin II receptor antagonists, and renin inhibitors) have an additive effect on blood pressure reduction in those patients already on a reduced salt diet²⁷ (see later).

Furthermore, people of black African origin show a greater blood pressure response when dietary salt intake is decreased.^{14,22,28} For example, the efficacy of a moderate decrease in salt intake has recently been tested in two short-term trials in both urban and rural areas of West Africa (Nigeria and Ghana), where the prevalence of hypertension is increasing.^{29,30} In both studies, a moderate decrease in salt intake was associated with a

significant decrease in blood pressure. In areas such as sub-Saharan Africa, the prevalence of hypertension is increasing, the health care resources are scarce, and thus the identification of people with hypertension is still haphazard. The effectiveness of a decrease in salt intake at a population level might prove extremely important for policy makers.

Given the overwhelming evidence of the efficacy of decreasing dietary salt intake in the prevention and management of hypertension, the debate is currently based on issues regarding the long-term outcome benefits and thereafter the appropriateness of a population-wide strategy to reduce dietary salt intake. The major benefit of salt reduction is the lowering of blood pressure. It has been argued that the blood pressure decrease realistically achievable at a population level (i.e., 1–3 mm Hg in systolic blood pressure) is small, not clinically significant, and with long-term benefits remaining unclear.³¹ However, a meta-analysis of 61 prospective studies estimated that even a decrease of 2 mm Hg in systolic blood pressure would determine a 10% decrease in stroke mortality and a 7% decrease in mortality from coronary heart disease or other cardiovascular causes, meaning a large number of premature deaths and disabilities would be avoided.³² Other results corroborate these estimates and suggest that the benefits of such a small decrease in blood pressure, induced by reducing dietary salt intake, in the population would be almost immediate.¹⁶ Finally, recent evidence from randomized clinical trials suggests a 30% decrease in CVD mortality after a moderate decrease in salt intake.¹³ Moreover, although the principal benefit of decreasing dietary salt intake is a decrease in blood pressure, it is not the only one. There is a large body of evidence that supports other benefits: regression of left ventricular hypertrophy, reduction in proteinuria and glomerular hyperfiltration, reduction in bone mineral loss with age and osteoporosis, protection against stomach cancer, stroke, asthma attacks, and possibly cataracts.³³

In light of the present evidence, decreasing dietary salt intake appears a plausible population-wide recommendation for the prevention and treatment of hypertension.^{4,5} A decrease in dietary salt intake to no more than 6 g/day (2.3 g or <100 mmol of sodium) represents a reasonable goal at a population level given the current dietary patterns of high levels of salt intake worldwide. However, this decrease will be feasible in Western societies only if efforts are made by the food industry, manufacturers, and restaurants to decrease the amount of salt added to processed food.³⁴ In fact, in these societies, a large proportion of salt intake (75%–80%) comes from processed food and bread.³⁵ On the contrary, in developing countries where the prevalence of hypertension continues to increase, more traditional health promotion strategies would be applicable and nutritional education might have an important effect in these settings.^{26,30,36} In the next sections, the issues pertaining to the implementation of public health strategies to reduce dietary salt intake in both developed and developing countries are more specifically addressed.

PUBLIC HEALTH STRATEGIES TO REDUCE SALT INTAKE IN DEVELOPED COUNTRIES

In developed countries, the estimated prevalence of hypertension is, on average, 28% in North America (Canada and the United States) and 44% in Western Europe.³⁷ Community-based intervention trials to decrease blood pressure by means

of decreasing dietary salt intake are scanty. For example, a community-based intervention trial in Portugal over 2 years involved a whole town receiving a health education program to reduce salt intake, while another town was not given any advice and was used as a control.³⁸ The average blood pressure decreased by 3.6/5.0 mm Hg at 1 year and 5.0/5.1 mm Hg at 2 years in the former. In developed countries, the majority of an individual's salt intake is not added by the person but is already present in foods. Indeed, given that 75% to 80% of salt intake comes from salt added to bread and processed foods,³⁵ a population-wide strategy involving the food industry would be more effective in the long term. The North Karelia Project is a meaningful example to support this concept. The program was launched in 1972 in Finland to prevent noncommunicable diseases and, primarily, to decrease the mortality and morbidity from CVDs.³⁹ The interventions implemented during this trial were extensive: collaborations with the community, health services, and food industry were added to a mass media campaign. The results have been outstanding. Over 25 years, the age-adjusted mortality rate from CVDs among men aged 25 to 64 years decreased by 73%. These results clearly show that a comprehensive and collaborative program involving the food industry and health and community services is essential to successfully implement strategies of primary prevention of CVDs in developed countries.

A complementary approach to lower salt intake in developed countries may reside in the use of salt substitutes. The American Heart Association recommends the use of non-chloride salts of sodium because they do not increase blood pressure.⁴⁰

In summary, in developed countries, comprehensive population strategies to reduce the average levels of salt intake are required. The expected benefits of a modest decrease in blood pressure across the whole population would be significant, especially on stroke, coronary heart disease, and all other cardiovascular conditions for which high blood pressure is a causative risk factor. The benefits would be greater in the elderly because they have a much higher stroke incidence (greater absolute risk); additionally, in this age group, most strokes occur at blood pressure levels not always requiring drug therapy (more stroke events attributable to the effect of blood pressure).

PUBLIC HEALTH STRATEGIES TO REDUCE SALT INTAKE IN DEVELOPING COUNTRIES

In developing countries, noncommunicable diseases are increasingly becoming an important threat to the health of populations.¹ Worldwide, stroke is second only to ischemic heart disease as a cause of death, and most of these deaths occur in developing countries.⁴¹ For example, data from Tanzania suggest a high burden of stroke comparable with that observed in developed countries.⁴² Likewise, in areas such as sub-Saharan Africa, the prevalence of hypertension is elevated and comparable with figures from developed regions.^{2,36} Thus, preventing the impending epidemic of CVDs in these countries is critical as they are facing a rapid demographic change and already experiencing a double burden of disease, that is, communicable and noncommunicable. In the 30-year period from 2000 to 2030, the population of elderly persons is projected to double in many sub-Saharan African countries.

Salt consumption in developing countries is becoming more common as urbanization increases. However, interventions to decrease salt intake at a population level have not been extensively studied in these countries. The population approach to reduce salt consumption is particularly relevant in developing countries due to the cost-effectiveness of these measures.⁴³ Furthermore, in countries of sub-Saharan Africa where effective health care provision for chronic diseases is haphazard, a population strategy to limit salt consumption might prove extremely effective. It can be predicted that the same decrease in salt intake obtained with a behavioral intervention will be more effective in black African origin populations than in white populations due to the higher salt sensitivity of people of black African origin and because most of the salt ingested is added to food by the consumer, whereas processed food is used relatively rarely compared with in developed countries.²⁶ Two short-term trials in sub-Saharan Africa have confirmed that simple, cost-effective, and culturally adapted behavioral and educational interventions to decrease blood pressure can be successfully implemented.^{29,30} Concerns about population-wide strategies to limit salt consumption in developing countries pertain to the perceived risk of counteracting worldwide policies directed at the prevention of iodine deficiency disorders through universal salt iodination. There is therefore an urgent need to consider alternative vehicles for the deliveries of iodine to populations.

In summary, in developing countries, which are experiencing an increasing burden of CVDs, multiple risk factor interventions and community-based programs of primary prevention should be encouraged. In particular, public health measures to promote dietary changes such as reduction in salt intake should be strongly recommended given that the prevalence of hypertension is likely to increase in these countries.

IMPORTANCE OF DIETARY PATTERNS

Diet plays a major role in the regulation of blood pressure and is one of the most important determinants of blood pressure levels in both individuals and populations. There are large variations in dietary patterns across populations that are likely to account for a considerable part of the observed differences in mean blood pressure levels, with populations consuming mostly plant-based diets having lower blood pressure than populations in industrialized countries. Additionally, even within industrialized countries, individuals consuming diets with increased intakes of fruits and vegetables and decreased intake of saturated fats tend to have, on average, lower blood pressure than individuals following more typical Western diets.⁴⁴

DIETARY APPROACHES TO STOP HYPERTENSION (DASH) DIET

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure⁴ and a recent scientific statement from the American Heart Association⁵ emphasize the importance of adopting a dietary regimen resembling the so-called DASH diet as one

major lifestyle modification to prevent and treat hypertension. The DASH dietary plan provides large intakes of fruits, vegetables, and low-fat dairy products; comprises whole grains, poultry, fish, and nuts; and has limited amounts of red meat, sweets, and sugar-containing beverages. Thus, compared with habitual diets of Western societies, the DASH dietary pattern provides higher intake of potassium, magnesium, calcium, fiber, and proteins and lower intake of total fat, saturated fat, and cholesterol.⁴⁵ The blood pressure–lowering effect of this diet is the result of the combined effects of these nutrients when consumed together in food rather than of the specific effect of a single nutrient. Indeed, the DASH trial was designed to test the effects on blood pressure of a change in dietary patterns rather than the effects of a change in a single nutrient, as generally tested in previous trials.⁴⁶ This trial was an 11-week feeding program including 459 adults with ($N = 133$) and without ($N = 326$) hypertension. For 3 weeks, participants followed a control diet that was low in fruits, vegetables, and dairy products. Then, for the next 8 weeks, participants were randomly allocated to three groups and each group was fed a different diet. One group was fed the same control diet, the second group a diet richer in fruits and vegetables but similar to the control diet for other nutrients, and the third group was fed the DASH diet, which is a diet rich in fruits and vegetables, low-fat or fat-free dairy products, and reduced saturated and total fat content—in other words, a high potassium, magnesium, calcium, fiber, and protein diet. The salt intake was held constant in the three groups. Overall, findings indicated a gradient in the decrease in blood pressure among the diets. The DASH diet significantly decreased blood pressure by 5.5/3.0 mm Hg, and the fruits and vegetables diet significantly decreased blood pressure by 2.8/1.1 mm Hg compared with the control diet. Among subjects with hypertension, the blood pressure decreases in the DASH diet group were more marked. Further subgroup analyses showed significant effects of the DASH diet in all major subgroups (e.g., sex, race, age, body mass index), although the effects were more marked among African Americans than in whites.⁴⁷

In 2001, findings from a further trial in the same population testing the effects of the DASH diet in combination with decreased salt intake were published.¹⁴ A total of 412 participants were randomly allocated to two dietary regimens, one following a control diet representative of the average diet in the United States and one following the DASH diet. Within these two dietary regimens, participants were randomly assigned to three decreasing levels of salt consumption, defined as high (~9 g of salt or 150 mmol or 3.5 g of sodium per day, reflecting typical consumption in the United States), intermediate (<6 g of salt or 100 mmol or 2.3 g of sodium per day, reflecting the upper limit of the current recommendations), and low (<3 g of salt or 50 mmol or 1.6 g of sodium per day). Each feeding period lasted 30 consecutive days. Overall, findings indicate that (1) the DASH diet lowers blood pressure independently of the level of salt intake; (2) the blood pressure–lowering effect of a decrease in salt intake occurs by decreasing the salt intake even to levels below the currently recommended limit (i.e., <6 g/day); (3) the effects of salt intake reduction are observed in all major subgroups; (4) greater lowering effects on blood pressure may derive from the combination of the two interventions than from adopting either the DASH diet or low-salt diet individually. In fact, the difference in systolic blood pressure between the DASH low-salt group and the control high-salt group was a substantial decrease of 7.1 mm Hg in participants

without hypertension and 11.5 mm Hg in participants with hypertension. The last finding resembles the effect of a single-drug therapy in hypertensive individuals. Thus, the combination of the DASH diet and decreased salt intake represents an alternative to drug therapy for individuals with mild hypertension and willing to comply with long-term dietary changes.

More recently, findings from the Optimal Macronutrient Intake Trial to Prevent Heart Disease (OmniHeart) have extended the observations derived from the DASH trial.⁴⁸

ASSESSMENT OF HYPERTENSIVE PATIENTS

All hypertensive patients should have a thorough history and physical examination, but need only a limited number of routine investigations. It is beyond the scope of this chapter to discuss every detail of the clinical evaluation, but it is important to consider and document the following: the causes of secondary hypertension, contributory factors, complications of hypertension, CVD risk factors to allow the assessment of CVD risk, and contraindications to specific drugs. Routine investigation must include urine strip test for protein and blood, serum creatinine and electrolytes, blood glucose (ideally fasted), lipid profile (ideally fasted), and an electrocardiogram. A case should be made for the inclusion of 24-hour urinary collections for sodium, potassium, and creatinine to assess levels of sodium (salt) and potassium intake, given that more than 95% of the ingested salt and more than 80% of the ingested potassium are excreted in the urine daily. Chest radiograph, urine microscopy and culture, and an echocardiogram are not required routinely. An echocardiogram is valuable to confirm or refute the presence of target organ damage. When the clinical evaluation or results of these simple investigations suggest a need for further investigation, it may be best to refer for specialist advice if the additional investigations needed are difficult to arrange from general practice.

PRIMARY PREVENTION OF HYPERTENSION

Current approaches to the prevention of adverse cardiovascular sequelae due to hypertension are unsatisfactory because they require prolonged drug therapy for a large proportion of the adult population. Moreover, this strategy does not reduce the risk of treated hypertensive patients compared with that of the normotensive population.⁴⁹ A population strategy is therefore necessary to (1) prevent the increase in blood pressure with age and therefore decrease the prevalence of hypertension, (2) reduce the need for antihypertensive drug therapy, and (3) reduce CVD burden.

The following lifestyle modifications for the primary prevention of hypertension are consistent with those recently outlined by the U.S. National High BP Education Program and the British Hypertension Society: (1) maintain normal body weight for adults (e.g., body mass index 20–25 kg/m²), (2) decrease dietary salt intake to less than 6 g/day (<100 mmol or <2.4 g of sodium per day), (3) engage in regular aerobic physical activity such as brisk walking (30 minutes per day, most days of the week), (4) limit alcohol consumption to no more than three units

per day in men and no more than two units per day in women, (5) consume a diet rich in fruits and vegetables (e.g., at least five portions per day), and (6) consume a diet with reduced saturated and total fat content.

LIFESTYLE CHANGES IN ESTABLISHED HYPERTENSION

Recent controlled trials⁵ have confirmed that lifestyle changes can lower blood pressure. Clear verbal and written advice on lifestyle measures and moderate decrease in dietary salt intake in particular (Box 50-1) should be provided for all hypertensive patients and also those with high-normal blood pressure or a strong family history. Effective lifestyle modification may lower blood pressure as much as a single blood pressure-lowering drug.¹⁴ Combinations of two or more lifestyle modifications can achieve even better results. Lifestyle interventions reduce the need for drug therapy, can enhance the antihypertensive effects of drugs, reduce the need for multiple drug regimens, and can favorably influence overall CVD risk. Conversely, failure to adopt these measures may attenuate the response to antihypertensive drugs.

In patients with grade 1 (mild) hypertension, but no cardiovascular complications or target organ damage, the response to these measures should be observed during the first 4 to 6 months of evaluation. When drug therapy has to be introduced more urgently, for example, in patients with grade 3 (severe) hypertension, lifestyle measures should be instituted along with drug treatment. The initiation of drug treatment should never be delayed unnecessarily, especially in patients at higher levels of risk.

Weight reduction by calorie restriction is appropriate for the majority of hypertensive patients because most are overweight.⁵⁰ The blood pressure-lowering effect of weight reduction may be

enhanced by a decrease in salt intake.¹⁹ Salt reduction from an average of 10 to 5 g (5 g is ~1 teaspoon) daily lowers blood pressure by approximately 5/2 mm Hg, with greater blood pressure decreases in the elderly and in those with higher initial blood pressure levels. These effects are additive to the blood pressure-lowering effect of a healthy diet. As indicated earlier, all hypertensive patients should have clear verbal and written advice to reduce salt intake to less than 6 g/day (<100 mmol/day) (see Box 50-1). This will be achieved more effectively through dedicated sessions held by well-trained nurses or other health professionals outside the clinical consultation. In suitable cases, online resources aimed at increasing education and awareness about the salt content of food and how to read food labels and make an informed choice should be used. Many will already have stopped adding salt at the table and even when cooking, but few are aware of the large amount of salt in processed foods, such as bread (one slice contains on average of ~0.5 g of salt), some breakfast cereals, prepared meals, and flavor enhancers such as stock cubes or manufactured sauces. Patients and those who cook for patients should be provided with specific written advice.

THE NATIONAL INSTITUTE FOR CLINICAL EXCELLENCE-BRITISH HYPERTENSION SOCIETY ALGORITHM

Hypertension control remains suboptimal in the United Kingdom and around the world.³⁷ Most people require more than one drug to control blood pressure, and yet the majority of treated hypertensive patients continue to receive monotherapy.³⁷ The National Institute for Clinical Excellence and the British Hypertension Society have recently jointly published a treatment algorithm (ACD) designed to encourage improved blood pressure control (Fig. 50-1). The theory underpinning the ACD algorithm is that hypertension

Box 50-1 Practical Advice for Patients on How to Reduce Dietary Salt Intake

Target daily salt intake should not exceed 6 g/day

1. Never Add Salt to a Meal

Do Not

Use rock salt or sea salt
Add sauces

Instead

Use pepper, garlic, lemon, and herbs.

2. Do Not Add Salt When Cooking

Do Not

Use stock cubes, gravy browning, soy sauce, salted dry fish, curry powders, and prepared mustards

Instead

Try other flavorings: any herbs, spices, lemon or lime, vinegar, onions, garlic, ginger, and chilies.

3. Avoid Manufactured or Processed Foods with Added Salt

Food Labeling

Salt is sodium chloride. At present, most food labels only report sodium as grams per 100 g of food. To convert to salt, multiply by 2.5.

1 g of sodium per 100 g of food is the equivalent to the saltiness of seawater.

Beware

Most breads, many cereals
Ready-made soups and meals, processed meats, pizzas, Chinese take out

Ideally

Only choose food items with no more than 0.3 g of sodium per 100 g of food.

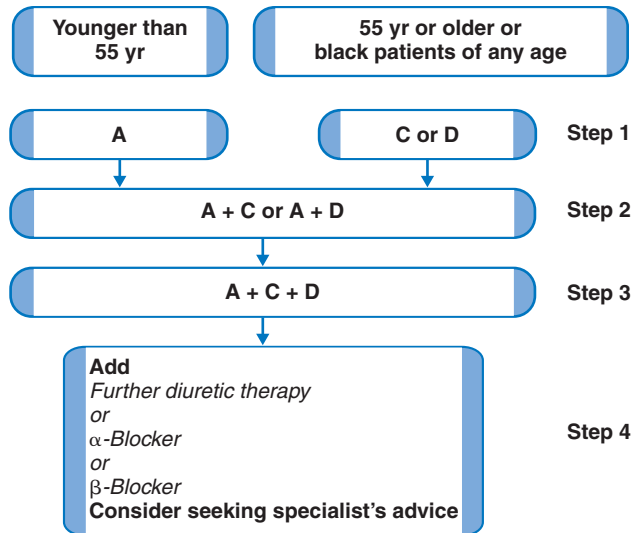

Figure 50-1 National Institute for Clinical Excellence–British Hypertension Society algorithm for the pharmacologic management of hypertension. A, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers; C, calcium channel blockers; D, diuretics.

can be broadly classified as high renin or low renin and is, therefore, best initially treated by one of two categories of antihypertensive drug, that is, those that inhibit (angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, renin inhibitors, or β -blockers) and those that do not inhibit (calcium channel blockers or diuretics) the renin-angiotensin system. Renin profiling studies have demonstrated that younger people (younger than 55 years) and whites tend to have higher renin levels relative to older people (older than 55 years) or the black population (of African descent). Thus, the drugs that reduce blood pressure at least in part by suppressing the renin-angiotensin system at one point or another are generally more effective as initial blood pressure–lowering therapy in younger white patients. In contrast, calcium channel blockers and diuretics are less effective as initial blood pressure–lowering therapy in these patients and are better used as first-line treatment in older whites or the black population of any age.⁵¹ The detailed analysis of this algorithm is beyond the scope of this chapter. However, it is important to consider the use of a moderate dietary salt reduction in the overall therapeutic framework. A moderate reduction in dietary salt intake is effective in lowering blood pressure on its own but is also additive to pharmacologic treatment and can be as effective as a low-dose thiazide diuretic. Furthermore, based on the underlying principles informing the ACD algorithm, a moderate decrease in dietary salt intake can be added to the algorithm, emphasizing its additive blood pressure–lowering effect to drug classes that predominantly block the renin-angiotensin system (such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, renin inhibitors, β -blockers), with less predicted additive effect to thiazide and thiazide-like diuretics, dihydropyridine calcium channel blockers, and α -blockers (Fig. 50-2). Furthermore, a moderate decrease in dietary salt intake is more effective in low renin hypertension as seen in people of black African origin, in the elderly, and in many cases of type 2 diabetes and metabolic

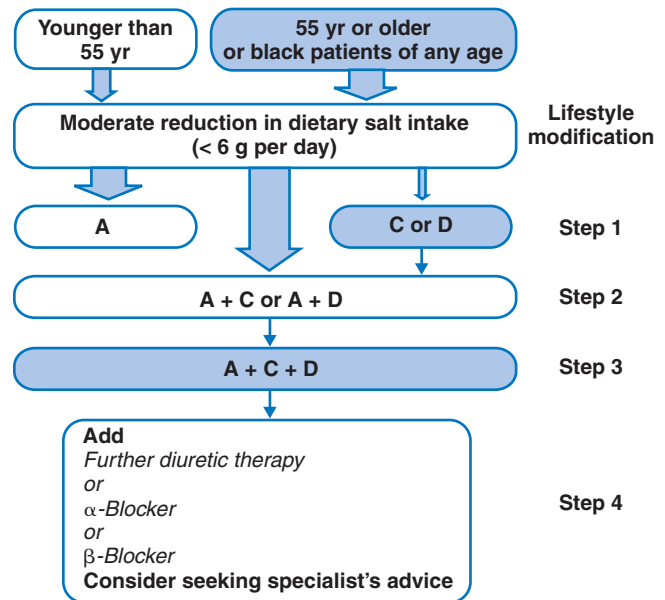

Figure 50-2 Modified National Institute for Clinical Excellence–British Hypertension Society algorithm with the inclusion of a moderate reduction in dietary salt intake as lifestyle modification step. syndrome whether or not associated with hyperfiltration or microalbuminuria.

CONCLUSIONS

Extensive and consistent evidence provides the scientific basis for clinical and public health strategies directed at long-term lifestyle modifications to prevent and reduce the burden of disease related to high blood pressure in both individuals and populations. In the clinical setting, a comprehensive lifestyle intervention, including a moderate reduction in dietary salt intake, represents a cost-effective therapeutic option among nonhypertensive individuals with above-optimal blood pressure levels as well as among hypertensive individuals who are not receiving medication therapy but who comply with long-term lifestyle changes. In addition, a moderate decrease in dietary salt intake is an essential adjuvant therapy in hypertensive individuals who are already pharmacologically treated. In the public health arena, there is an urgent need to develop and implement population-wide strategies aimed at substantial societal changes to tackle the current epidemic of hypertension in both developed and developing countries. However, these changes will be realistic only if collaborative initiatives are implemented at multiple levels: government, manufacturers, health care providers, researchers, and the general public.³⁴ In the clinical setting, there is the need to provide specific and targeted advice on how to effectively reduce dietary salt intake and to provide support to patients to sustain the decreases by monitoring compliance through regular assessment of salt intake with 24-hour urine collections.

CONCLUSIONS AND TREATMENT

ALGORITHM 596

The original large-scale trials that established the benefit of lowering blood pressure (BP) in reducing cardiovascular mortality in uncomplicated hypertension were based largely on the use of β -blockers and diuretics. Until recently both have remained first-line treatments. However, since the last edition of this book, the situation has changed. The role of β -blockers has been questioned because of growing evidence of adverse metabolic effects (such as glucose intolerance) and recognition that β -blockers may be inferior to other first-line treatments in reducing the risk of stroke. These conclusions are controversial; moreover, newer β -blockers may redress these concerns. Yet thiazide diuretics retain their position as an excellent, inexpensive first-line therapy. Debate continues as to whether they are superior to other first-line options, such as angiotensin-converting enzyme (ACE) inhibitors. Diuretic therapy for patients with normal renal function is usually based on thiazides. Loop diuretics are not effective antihypertensive therapy because of their short duration of action and the postdiuretic renal salt retention that occurs unless they are given two or three times daily with restriction of dietary salt intake; however, they are used to control fluid retention and hypertension and in patients with renal failure who are refractory to thiazides.

RANDOMIZED TRIALS OF DIURETIC OR β -BLOCKER TREATMENT AGAINST PLACEBO

Although the place of β -blockers as first-line therapy has recently been called into question,¹ the original studies established that these drugs lower BP and reduce the risk of

stroke. The results of randomized trials comparing diuretics or β -blockers with placebo are discussed extensively in the meta-analysis and review by Psaty and colleagues.² The 18 trials identified included 48,220 patients followed for an average of 5 years. The earlier trials were conducted mainly in middle-aged adults given higher doses of diuretics or β -blockers, whereas trials from the late 1980s were mainly in older adults given lower doses. High-dose diuretics, low-dose diuretics, and β -blockers *all* reduced the risk of stroke, with relative risks (RR) in the meta-analysis of 0.49, 0.66, and 0.71, respectively. The risk of coronary artery disease (CAD) was reduced in the low-dose diuretic trials (RR, 0.72), but not in the high-dose diuretic trials or in the β -blocker trials. These results are surprising in view of the proven benefits of β -blockers in secondary prevention of CAD. It is not clear if this difference in the rate of coronary events is due to differences in the patient groups included in these trials or to real biologic differences in these therapies, including their metabolic side effects (see “Adverse Effects of Diuretics and β -Blockers” in this chapter). Cardiovascular mortality was significantly reduced with high-dose and low-dose diuretic therapy, but not with β -blockers. There was a trend toward reduced overall mortality for all therapies, but in no case did this reach statistical significance.

In a 22-year follow-up of hypertensive men identified and treated in the 1970s, a significant excess of deaths due to cardiovascular disease and stroke has been shown, despite apparently adequate control of their BP.³ This suggests that even patients adequately treated with current therapies do not return to the cardiovascular risk of the general population. An overview and meta-analysis of drug treatment of hypertension concluded that even over the short term (a few years),

effective treatment of hypertension reduces the risk of stroke in treated patients by almost exactly the amount expected from epidemiologic studies.⁴ However, the reduction in risk of CAD, although clinically and statistically significant, is less than might have been expected from the observed fall in BP. It has been suggested that this failure of predominantly diuretic-based treatments to reverse the increased mortality associated with hypertension may be due to the adverse metabolic effects of diuretics.⁵ Hypertension often occurs in the setting of the *metabolic syndrome*, which is associated with a number of risk factors for cardiovascular disease, such as insulin resistance, glucose intolerance, hypertriglyceridemia, and central obesity, which are not addressed by lowering BP alone.

RANDOMIZED TRIALS OF DIURETICS OR β -BLOCKERS AGAINST OTHER ANTIHYPERTENSIVE TREATMENTS

General agreement concerning the benefits of treatment of hypertension in middle-aged and elderly persons now exists. Further placebo-controlled trials are probably no longer ethically justified. Therefore, recent trials have compared one therapy with another.

The established dogma has been that β -blockers, diuretics, ACE inhibitors, and calcium channel blockers (CCBs) are equally effective in lowering BP. The choice of therapy should be tailored to the individual patient according to the side effect profile and the specific indications or contraindications of one other agent. Thiazides and β -blockers have often been used as first-line treatment because of their low cost. However, two recent developments have questioned this approach.

First, a large meta-analysis of trials comparing β -blockers with other therapies published in the *Lancet* in 2005¹ concluded that β -blockers were associated with an increased risk of stroke of approximately 16% (although β -blockers did reduce the risk when compared with placebo). There was a non-significant trend toward increased mortality. The authors argued that β -blockers could no longer be recommended as first-line treatment for hypertension in the absence of other specific indications, such as secondary prevention of CAD. They suggested possible reasons for this difference, including the adverse metabolic and hemodynamic effects of β -blockers. Most antihypertensive agents act by decreasing systemic vascular resistance (SVR). However, β -blockers can increase SVR by allowing unopposed activation of vascular smooth muscle α -adrenergic receptors. They can also reduce cardiac output. Newer vasodilating β -blockers have been developed to address these concerns, although outcome data for these β -blockers are limited.

These new findings remain controversial. A subsequent meta-analysis of the β -blocker trials subdivided them into those involving younger or older (>60 years) patients. The authors concluded that the increased risk of stroke with β -blocker therapy only applied to the older age group.⁶ This result may be explained by differences in the underlying pathophysiology in the two groups, with hypertension in younger patients believed to be due to an increase in cardiac output (*hyperdynamic circulation*), whereas hypertension in the elderly is due to an increase in SVR. The guidelines have begun

to change. In 2004, The British Hypertension Society did not recommend β -blockers as first-line therapy for uncomplicated hypertension, because of the risk of developing diabetes.⁷ Moreover, the Canadian Hypertension Education Program recommends that β -blockers should only be first line treatment in patients younger than 60 years of age,⁸ in accordance with the meta-analysis referred to previously.

Unlike β -blockers, thiazide diuretics have retained their position as recommended first-line therapy for hypertension. In the second major recent development, it was suggested that thiazides may actually be superior to other first-line therapies. This finding derives from the ALLHAT study, which compared a thiazide diuretic (chlorthalidone) with either an ACE inhibitor (lisinopril), a CCB (amlodopine), or an α -adrenoreceptor blocker.⁹ The last arm of the study was halted early due to an increase in the risk of heart failure. When compared with the ACE inhibitor or the CCB, the thiazide diuretic had a better outcome in heart failure (vs. amlodopine) and stroke (vs. lisinopril). The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High BP now recommends thiazides as first-line treatment for uncomplicated hypertension.¹⁰ However, this view has been challenged,¹¹ and it was not endorsed in the 2003 guidelines issued jointly by the European Society of Hypertension and the European Society of Cardiology.¹²

ADVERSE EFFECTS OF DIURETICS AND β -BLOCKERS

Hypokalemia

Thiazide diuretics reduce serum potassium concentration in a dose-dependent fashion. In the Multiple Risk Factor Intervention Trial, in a subgroup of patients with abnormal electrocardiograms at baseline, there was an increase in the risk of death due to CAD in those patients randomized to high-dose thiazide diuretics.¹³ However, in patients with normal electrocardiograms, there was a lower mortality in this group. In the Systolic Hypertension in the Elderly Program (SHEP) trial, patients randomized to diuretics had significantly lower serum potassium levels than those on placebo (average reduction, 0.36 mmol/L), and significantly more of them were clearly hypokalemic (7.2% vs. 1%).¹⁴ Hypokalemic patients had higher event rates, similar to those seen in patients on placebo. A case-control study reported that patients on high-dose diuretics were at increased risk of cardiac arrest.¹⁵ The lowest risk of all was in patients taking thiazides in combination with a potassium-sparing diuretic. A recent meta-analysis of trials involving thiazide diuretics also suggested that an inverse relationship exists between hypokalemia and hyperglycemia,¹⁶ providing an additional mechanism for the association of thiazide usage with the development of glucose intolerance and diabetes.

It is clearly important to measure serum potassium in patients taking thiazide diuretics and, if necessary, to correct hypokalemia. However, the increasing use of treatment combinations to lower BP with agents such as ACE inhibitors, which can raise serum potassium concentrations, and the low doses of thiazides currently recommended, make hypokalemia with thiazide diuretic treatment less common. This can be

easily prevented by combined therapy with a thiazide and a distal-acting potassium-sparing diuretic.

Dyslipidemia

Diuretics cause modest adverse changes in serum lipids in short-term studies. A meta-analysis concluded that thiazides caused a significant increase in total and low-density lipoprotein cholesterol but no change in high-density lipoprotein cholesterol.¹⁷ These changes were more marked in patients on higher doses of diuretic. However, in longer-term studies these effects do not persist beyond about 1 year.^{18,19} In the Treatment Of Mild Hypertension Study (TOMHS), no difference was seen in serum lipids between the placebo and diuretic groups after the first year.¹⁸ In the Multicentre Isradipine Diuretic Atherosclerosis Study (MIDAS), the difference in lipids noted in the first year between patients treated with thiazides or CCBs disappeared by the third year. The ALLHAT study reported that after 4 years of treatment thiazide diuretics increased total cholesterol when compared with an ACE inhibitor or a CCB,⁹ although this did not translate into any worsening of outcome. A longer follow-up period may be required to evaluate this potentially adverse, but small, metabolic effect of diuretics.

The effects of both thiazides and β -blockers on serum lipids appear small and of little clinical significance.²⁰ The widespread use of statins in hypertensive patients may counteract any detrimental effect of a small rise in serum lipids. Carvedilol, a newer third-generation β -blocker, does not cause significant changes in serum cholesterol.²¹

Insulin Resistance/Diabetes

Diuretics and β -blockers can impair glucose tolerance. The ALLHAT study⁹ reported an increased incidence of diabetes in the group taking a thiazide diuretic compared with either lisinopril or amlodipine. However, this did not translate into any observed worsening of outcomes over the 8 years of the study. Hyperglycemia has been related to hypokalemia in patients taking diuretics.¹⁶ Other studies have not detected any increase in diabetes in patients on thiazides.^{22,23}

One prospective study of middle-aged patients found no increased risk of diabetes with thiazide diuretics, CCBs, or ACE inhibitors,²² but a 28% increased risk in patients taking β -blockers. However, because the study was not randomized, differences in patient selection for these drug classes cannot be ruled out. An increased risk of diabetes with β -blockers compared with other antihypertensives may be due to the protective effects of ACE inhibitors²⁴ and CCBs²⁵ rather than to any adverse effects of β -blockers.

Suggested mechanisms of β -blocker-induced diabetes include systemic vasoconstriction with reduced tissue glucose uptake, impaired insulin secretion from the pancreas, weight gain, and increased hepatic gluconeogenesis (for review, see Sarafidis and Bakris²⁶). In the United Kingdom Prospective Diabetes Study (UKPDS 38), diabetic patients randomized to a β -blocker-based regimen had as much cardiovascular disease protection as those receiving ACE inhibitors, perhaps reflecting the high incidence of CAD in the diabetic population and the protective effects of β -blockers.²⁷ Carvedilol, a newer vasodilating and antioxidant β -blocker, has shown promise that may translate into additional benefit. In a controlled trial (GEMINI) involving diabetic hypertensive patients random-

ized to carvedilol or metoprolol, with similar control of BP, carvedilol was associated with better insulin sensitivity.²⁸ Longer-term trials are required to see if this translates into better morbidity and mortality outcomes.

A recent "network meta-analysis" examined the risk of diabetes associated with antihypertensive drugs.²⁹ Only angiotensin receptor blockers were associated with a significantly reduced risk of developing diabetes, and only diuretics with a significantly increased risk. However, the numbers of new diabetics were small, and the absolute differences in the incidence of new-onset diabetes were less than 5%. Thus, this may only be a factor in high-risk groups such as the obese.

Hyperuricemia

Diuretics raise serum urate levels by decreasing renal secretion and increasing reabsorption. Gout is one of the few contraindications to thiazide therapy. Hyperuricemia per se is associated with cardiovascular disease.³⁰ However, in the Framingham cohort urate level was not found to be a significant predictor once allowance had been made for other risk factors.³¹ Urate production may be toxic, perhaps through the generation of free radicals,³² but the association with CV risk may not be causal.³¹ Among patients in the SHEP trial,³³ the baseline serum urate level did predict subsequent events. Relative risk for the highest versus the lowest quintile of serum urate was only 1.32. Baseline urate levels did not affect the demonstrable benefits of active treatment in this trial. However, treatment with a thiazide increased serum urate by a median of 0.06 mmol/L. After dividing patients into two groups according to the increase in serum urate level, those with a small change in serum urate (<0.06 mmol/L) had a highly significant reduction in event rates on treatment, whereas those with a larger increase in urate had no decrease in event rates on active treatment.

These data suggest that patients' cardiovascular risk can be stratified according to their serum urate response to thiazides. However, there is no direct evidence that the increases in urate observed in patients taking thiazides are harmful per se. Moreover, thiazides have similar effects to β -blockers and ACE inhibitors (which do not affect serum urate) on the risk of cardiac death.

Sexual Dysfunction

A high incidence of impotence was reported in the Medical Research Council trial of mild hypertension, leading to the withdrawal of 12.6% of male patients in the diuretic arm, compared with 6.3% in the β -blocker arm and 1.3% in the placebo arm.³⁴ The incidence of this adverse effect seems to be lower in more recent trials, although whether this relates to the lower doses of diuretics used or the older patients studied in more recent trials is not clear. A review of trials involving β -blockers found overall a small increased risk of sexual dysfunction and fatigue, with no increased risk of depressive symptoms (another side effect previously associated with β -blockers).³⁵

The incidence of sexual dysfunction is increased in men with hypertension, whether they are on treatment or not. The incidence of complete erectile dysfunction was 15% in those with treated hypertension and 14% in those with untreated hypertension in a population sample of American men in whom the overall incidence of impotence was 9.6%.³⁶ A post

hoc subanalysis of patients in trials of sildenafil who were taking antihypertensives concluded that sildenafil was as effective in these patients as in those not on antihypertensives and was no more likely to cause adverse effects.³⁷ Whether antihypertensive treatment causes sexual dysfunction in women is less clear, although most investigators have reported no significant problems. Prisant and colleagues³⁸ concluded that only high-dose diuretics consistently cause sexual dysfunction.

Increased Risk of Cancer

An association of diuretic use with renal or colonic cancers has been noted.³⁹ Case-control studies have suggested an increased risk of renal cell carcinoma. However, the largest of these studies found that the excess risk associated with being hypertensive was larger than that associated with any drug exposure. The risk associated with diuretics disappeared once adjusted for the risk associated with hypertension itself.⁴⁰ A more recent case-control study of women with breast cancer reported an association with both hypertension and diuretic usage.⁴¹ However, this was most pronounced in women with a high body mass index (a recognized risk factor), perhaps indicating that the link may be more with shared metabolic risk factors in hypertension and cancer (including diet), rather than any causal relationship.

No clinical trial of diuretics and β -blockers has demonstrated an increased risk of cancer in treated patients, although, because most trials are followed up for less than 5 years and many patients take antihypertensive medication for decades, this issue is still an open question. In a cohort of hypertensive men treated for longer than 2 decades with therapy based on these agents, there was no increase in cancer mortality.³ At present, the proven benefit of BP reduction outweighs the unproven, and rather poorly defined, risk of cancer.

Effects on Bone

Thiazide diuretics reduce urinary calcium excretion and are thought to reduce postmenopausal bone loss. Numerous case-control studies have demonstrated a reduction in risk of fractures in patients taking thiazides.⁴² Hypertension itself has been suggested as a risk factor for bone mineral loss⁴³ (and is also associated with renal stone disease). A recent randomized, controlled trial demonstrated that thiazides slow cortical bone loss in postmenopausal women, although the effect was small⁴⁴; a recent extension to this trial has shown that the effect persists for at least 4 years.⁴⁵

Studies in mice have suggested that β -blockers can increase bone mass,⁴⁶ but human studies have failed to show any significant association; at present β -blockers are not indicated for the treatment of osteoporosis.⁴⁷

Chronic Obstructive Pulmonary Disease and Bronchospasm

β -Blockers have traditionally been withheld from patients with chronic obstructive pulmonary disease (COPD) because of the risk of provoking bronchospasm by blocking β_2 -adrenergic receptors in the lung, even with more selective β_1 -blockers. However, a Cochrane database systematic review of trials comparing cardioselective (β_1 -adrenergic receptor-specific) β -blockers with

placebo found no adverse respiratory effects and concluded that these drugs need not be withheld in COPD patients who have a valid indication for β -blocker therapy, such as CAD or heart failure.⁴⁸

DIURETIC AND β -BLOCKER USE IN SPECIFIC GROUPS OF PATIENTS

Elderly Patients

The evidence for the benefits of drug treatment of isolated systolic hypertension in elderly patients is now very strong.^{14,49,50} The most dramatic reductions are in risk of stroke, both ischemic and hemorrhagic,⁵¹ but there are also reductions in the risk of CAD and heart failure. Elderly patients also benefit from the treatment of diastolic hypertension.⁵² There is still some uncertainty about the treatment of patients over age 80, although a subgroup meta-analysis of patients over this age included in the trials of the past 20 years concluded that they too can benefit from treatment.⁵³ Thiazide diuretics are well tolerated in the elderly and are of proven effectiveness.⁵² A systematic review of the risk of falls in elderly patients on antihypertensive drugs found a modestly increased risk with diuretics (odds ratio, 1.08) and non-significant differences for β -blockers (perhaps surprisingly) and other classes of antihypertensive drugs.⁵⁴ However, none of the studies was randomized and the effects were small. The presence or absence of postural hypotension should always be determined in elderly patients before commencing antihypertensive therapy.

Because of their high absolute risk of stroke and cardiovascular events, elderly patients have much to gain from effective BP control. In older patients, a low-dose thiazide is the preferred treatment. An appropriate second or additional treatment is a CCB. β -Blockers seem to be less well tolerated by older patients; because they are apparently less effective in preventing stroke in older age groups, they should probably be avoided, unless there is a specific indication (e.g., angina or post-myocardial infarction [MI]).⁵⁵

Black Patients

There is considerable evidence that black people have higher rates of hypertension.⁵⁶ They also have higher risks of stroke and renal failure, although (at least in the UK) not of CAD.⁵⁷ Black patients are more likely to have salt-sensitive hypertension and are less likely to have high renin levels.⁵⁸ Hypertensive black men have a larger BP response to hydrochlorothiazide than to propranolol, whereas there is no significant difference in responses in white men.⁵⁹ Studies have usually found that black patients respond well to diuretics¹⁹ but require higher doses of ACE inhibitors to achieve a given level of BP control. A trial from South Africa⁶⁰ concluded that in black patients, CCBs were more effective as monotherapy than either diuretics or ACE inhibitors; however, these patients were younger than those in most other published studies. A systematic review of hypertension treatment in blacks has concluded that β -blockers are less efficacious than either diuretics or CCBs. However, there is no difference in outcome if BP is lowered to the same level by using combinations of drugs that contain a β -blocker.⁶¹ Current UK and U.S. guide-

lines recommend using thiazides as the preferred treatment in black patients.

Patients with Cardiovascular Disease

In patients who have suffered an MI, prescription of a β -blocker reduces mortality by approximately 20%.⁶² This also applies to diabetic patients.⁶³ ACE inhibitors also benefit this group of patients. Many patients should be taking both drugs, as well as aspirin.⁶⁴ The Heart Outcomes Prevention Evaluation (HOPE) study showed that the ACE inhibitor ramipril reduced the risk of death, MI, and stroke, each by approximately 20% in patients at high vascular risk.⁶⁵ Although 80% of patients in this trial had previously suffered an MI, only 40% were on a β -blocker. Patients in the HOPE study had acceptable control of BP at study entry, and the investigators concluded that the effects of ACE inhibition were not due to BP reduction; this has been vigorously challenged.

Although there is clear evidence for the use of β -blockers in patients who have suffered an MI, the evidence is less good for the use of these agents in patients with hypertension and stable CAD but no history of a major cardiac event. Although β -blockers are an effective treatment for the symptoms of angina, as with other antianginals, outcome data are lacking. In the INVEST trial, which looked specifically at patients with hypertension and CAD, no significant difference was observed between either a verapamil/trandolapril-based or atenolol/hydrochlorothiazide-based strategy,²⁵ suggesting that treatment of BP per se may be more important than the choice of antihypertensive agent.

In the PROGRESS perindopril-based trial of secondary prevention of stroke, a lower risk of subsequent stroke was recorded among actively treated patients, although subgroup analysis found that only those treated with both an ACE inhibitor and a thiazide diuretic had significant benefit.⁶⁶ As previously mentioned, β -blockers are not thought to be suitable first-line agents in the prevention of stroke.

Patients with Heart Failure

β -Blockers are negatively inotropic and can worsen or precipitate heart failure, especially at high doses. For this reason, heart failure was long considered a contraindication to β -blocker therapy. However, trials have shown that closely supervised β -blocker treatment is associated with reduced mortality in patients with moderate^{67,68} and severe heart failure. This is partly due to a reduction in the incidence of sudden death. Trials have used the cardioselective β -blockers bisoprolol and metoprolol and the nonselective $\alpha\beta$ -blocker carvedilol. It remains unclear whether these have the same benefit. A head-to-head comparison showed a greater improvement in left ventricular ejection fraction with carvedilol but a greater increase in exercise capacity with metoprolol.⁶⁸ A more recent study compared nebivolol (another vasodilating β -blocker) with placebo in patients over age 70 and found a reduction in all-cause mortality.⁶⁹ Further trials are needed to establish whether newer β -blockers are superior to older agents.

The most appropriate strategy, based on currently published data, is to treat with both ACE inhibitors and β -blockers, if tolerated, and to aim for a BP target of 130/70 mm Hg or less.

Diuretics can be added to control fluid retention, although there is no evidence that this alters outcome.

Patients with Left Ventricular Hypertrophy

Left ventricular hypertrophy (LVH) is an independent risk factor for cardiovascular events and sudden cardiac death.⁷⁰ Patients with hypertension often have LVH. In the Framingham Heart Study of persons older than age 40, less than 1% had an ECG suggesting LVH, but 15.5% of men and 21% of women had LVH on echocardiography.⁷⁰ Some of the newer antihypertensives may be better at inducing regression of LVH than diuretics or β -blockers. A meta-analysis of randomized studies concluded that ACE inhibitors are more effective at reducing LVH than β -blockers, CCBs, or diuretics.⁷¹ However, direct head-to-head trial evidence suggests that diuretics are as effective as other drugs in inducing regression of LVH, although β -blockers seem less effective. In the LIFE study of patients with diabetes and hypertension (with echocardiographic evidence of LVH), losartan reduced cardiovascular morbidity and mortality compared with atenolol.⁷² In the Veterans Study,⁷³ hydrochlorothiazide was at least as effective as any other drug in reversing LVH. In the TOMHS trial, diuretic treatment was superior to any other drug.⁷⁴

Patients with Hypertension in Pregnancy

The treatment of hypertension in pregnancy is an especially difficult area. There remains disagreement as to the most appropriate treatment strategy (see Chapter 41). β -Blockers have been widely used in treating hypertension in pregnancy, particularly in the United States. A Cochrane review of trials of β -blockers for the treatment of mild-to-moderate hypertension in pregnancy concluded that although β -blockers lower BP when compared with placebo, no benefit to either the mother or baby has been demonstrated. In addition, the authors found a trend toward small-for-gestational-age infants and no advantages over other established drugs such as methyldopa.⁷⁵

Diuretics have not been widely used in pregnancy-associated hypertension because of concerns about contraction of the circulating volume. However, they can be safely continued during pregnancy in those taking them for hypertension before conception.⁷⁶

Patients with Chronic Kidney Disease

The goal of treatment in patients with hypertension and chronic kidney disease (CKD) is twofold: first, to reduce the rate of decline of renal function, and, second, to reduce mortality from cardiovascular disease (for which CKD is a significant and independent risk factor). Generally, very few studies have examined the treatment of hypertension in CKD patients. Guidelines extrapolate data from studies on patients with normal renal function.

In patients with significant proteinuria, ACE inhibitors are generally thought to be the agents of choice,⁷⁷ particularly in diabetic patients with renal disease.⁷⁸ A meta-analysis reported that regimens containing ACE inhibitors are more effective in slowing the progression of renal disease than those without, but for the subset of patients with proteinuria less

than 0.5 g/day, no definite advantage of ACE inhibitors is evident.⁷⁹ This is probably because the rate of decline of renal function in patients with minimal proteinuria is very slow.

A recent meta-analysis of trials published in 2005 challenged this view, concluding that in patients with proteinuric CKD, ACE inhibitors provide only a very small benefit in comparison with other drug classes, and that any additional benefits observed in placebo-controlled trials are due only to a greater reduction in BP rather than any class-specific effect.⁸⁰ This view remains controversial, but it does highlight the paucity of data on the treatment of hypertension in CKD and the need on more trials to determine which agents should be first-line. In support of this, UKPDS 38 found no differences between patients randomized to captopril or atenolol as their first antihypertensive agent, again suggesting that tight control of BP is much more important than the agent used to achieve it.²⁷

In practice, patients with renal disease often require multiple drugs for BP control. In the REIN follow-up study, 77% of patients required antihypertensives in addition to ramipril to keep their diastolic BP below 90 mm Hg.⁸¹ The majority of patients are currently undertreated. For dialysis patients, adjustment of circulating volume is a key nonpharmacologic factor in BP control. Water-soluble β -blockers such as atenolol can accumulate in renal failure; doses should be reduced. This recommendation does not apply to lipid-soluble drugs such as metoprolol. In addition, β -blockers can worsen hyperkalemia by causing a shift of potassium from the intracellular to extracellular compartment. In a subset analysis of the ALLHAT study in patients with CKD Stage 3 (glomerular filtration rate, 30–59 mL/min), thiazide diuretics appeared equivalent to either ACE inhibitors or CCBs in reducing the rate of decline of renal function.⁹ For more advanced stages of CKD, thiazides are less effective natriuretic agents, and loop diuretics are more commonly used.

Patients Outside the Developed World

The vast majority of patients in trials of hypertension have come from Western Europe, North America, Australia, and New Zealand. One major exception is the Sys-China trial, which demonstrated significant benefits for stroke risk and reduced mortality when older Chinese patients with isolated systolic hypertension were treated.⁸² The Global Burden of Disease Study attempted to look at premature mortality and disability worldwide. This study found that in 1990 ischemic heart disease was the fifth leading cause of disability-adjusted life years lost and that cerebrovascular disease was the sixth leading cause.⁸³ Projections for 2020 are that cardiovascular disease will be the leading cause of disability-adjusted life years lost and cerebrovascular disease will be the fourth leading cause.⁸⁴ The overall burden of cerebrovascular and cardiovascular disease worldwide is projected to almost double by 2020 from what it was in 1990, with the biggest increase occurring in the developing world.

Evidence from Africa indicates that urbanization leads to a significant increase in the incidence of hypertension.⁸⁵ Very high age-adjusted rates of stroke are seen in sub-Saharan Africa.⁸⁶ Because other cardiovascular risk factors are largely absent in this population, these high rates have been attributed to untreated hypertension. The countries of Eastern Europe are also suffering an epidemic of cardiovascular disease.^{87,88} Clearly, a great need exists for effective and inexpensive treatment of hypertension in these populations. In view of their low cost and documented effectiveness, thiazides and

β -blockers are the drugs of choice, although outcome trials in these populations are urgently needed. Sadly, a World Health Organization study of 10,000 patients with either CAD or cerebrovascular disease in middle- to low-income countries found that many modifiable cardiovascular risk factors were still not being addressed.⁸⁹

CONCLUSIONS AND TREATMENT ALGORITHM

Several epidemiologic studies in Europe and the United States have shown that many patients known to be hypertensive have poorly controlled BP, either because they are not on treatment or because their treatment is inadequate.⁹⁰ These findings have been confirmed in a study of 24-hour BP control.⁹¹ It is becoming increasingly clear that a significant proportion of all patients requiring treatment for hypertension need a combination of drugs to bring their BP down to a desirable level.⁵⁵ At present, guidelines from the British Hypertension Society and the US Joint National Committee on Prevention, Detection, Evaluation and Treatment of High BP recommend thiazide diuretics as first-line agents for the treatment of hypertension. The latter committee goes further, currently recommending thiazides over other agents in the absence of any other specific indications. β -Blockers have lost their place as first-line treatment because of more recent concerns over metabolic side effects and possibly reduced efficacy in reducing stroke, particularly in an aging population. This view has been endorsed by a recent Cochrane systematic review.⁹² Perhaps with time, newer vasodilating β -blockers may be shown to address these concerns. In certain cases, such as secondary prevention of CAD and heart failure, β -blockers are still indicated as first-line antihypertensive therapy.

A low starting dose of a thiazide diuretic or β -blocker (e.g., hydrochlorothiazide 12.5 mg, bendrofluzide 1.25 mg, or atenolol 25 mg) should always be used initially. If after 4 weeks the BP is not adequately controlled, these doses can be doubled. Little further gain in BP control is seen by increasing doses beyond these levels, and there is also good evidence that more adverse side effects will occur.⁹³ Patients receiving diuretics should have their serum potassium level checked within the first month of treatment and at least annually thereafter. Significant hypokalemia is not common on low-dose thiazide diuretics; its occurrence should raise the possibility of an underlying endocrine abnormality such as primary aldosteronism. Patients who become hypokalemic should have the serum potassium level corrected. No clear evidence exists on whether oral potassium supplementation or the addition of a potassium-sparing diuretic is the better way to do this, although both have been shown to be effective.⁹⁴ Our practice is to add amiloride or spironolactone (the latter may be more beneficial in patients with CKD or heart failure⁹⁵).

Patients in whom BP control is still poor after 3 months of treatment require a change of therapy. In practice, most patients need a combination of antihypertensive drugs to reach their target BP.⁵⁵ Monotherapy is rarely successful. We recommend adding another agent sooner rather than later and before the maximum dose of the starting agent has been reached.

Some of the commonly used diuretics and β -blockers in hypertension are listed in Tables 51-1 and 51-2. An algorithm for the use of diuretics or β -blockers in the treatment of hypertension is shown in Figure 51-1.

Table 51-1 Diuretics for the Treatment of Hypertension

	Initial Daily Dose (mg)	Maximum Daily Dose (mg)
Hydrochlorothiazide	12.5	50
Bendroflumethiazide	1.25	5
Chlorthalidone	25	50
Trichloromethiazide	2	4
Amiloride	5	10
Spironolactone	25	100

Table 51-2 β -Blockers for the Treatment of Hypertension*

	Initial Dose	Maximum Dose
Atenolol	25 mg once daily	100 mg once daily
Metoprolol [†]	50 mg once daily	100 mg twice daily
Propranolol [†]	40 mg twice daily	80 mg three times daily
Bisoprolol	2.5 mg once daily	10 mg once daily
Carvedilol [†]	12.5 mg once daily	25 mg twice daily
Nebivolol	2.5 mg once daily	10 mg once daily

*Low doses of β -blockers are appropriate for the treatment of hypertension, as discussed in the text. Higher doses (if tolerated) are of proven benefit in the treatment of heart failure and should be employed in this situation.

[†]A sustained-release preparation is available for once-daily dosing.

**Figure 51-1** Algorithm for the use of thiazides or β -blockers in the treatment of hypertension.

RENIN-ANGIOTENSIN SYSTEM BLOCKADE AND THE NATURAL HISTORY OF RENAL INJURY	605	OPTIMIZATION OF RENIN SYSTEM BLOCKADE	607

When pharmacologic interruption of the renin-angiotensin system first became possible through the development of angiotensin-converting enzyme (ACE) inhibitors, even the wildest enthusiast could not have predicted the evolution of this field.^{1,2} Agents that block the renin system were thought by many at that time to hold promise only in a small patient population, those with hypertension associated with elevated plasma renin activity. This group of patients is important, because it includes those with accelerated hypertension and those in whom hypertension tends to be difficult to treat, but these processes are relatively uncommon. This class of drug was therefore perceived to occupy an important but rather small niche.

That niche has grown and, indeed, continues to grow. The introduction of ACE inhibitors was marked by early success in patients with extremely high blood pressure (BP) resistant to the effects of triple-drug regimens. A series of studies over the past two decades has identified a much broader range of efficacy for ACE inhibitors, indicating that these drugs are also remarkably helpful in patients with advanced heart failure, those with a large anterior myocardial infarction, and those at risk of diabetic nephropathy, other forms of nephropathy, and (in the HOPE study) the consequences of atherosclerosis.² ACE inhibitors have gradually emerged, therefore, as the leading class for the treatment not only of those complicated patients initially described, but also of the patient with mild-to-moderate essential hypertension who is free of any identifiable target organ damage and who is at rather low risk. Although this chapter lies in a section entitled Management of Essential Hypertension, and there are separate and relevant chapters on drug dosing and renal failure, prevention of progressive renal failure, cardiovascular complications, control of cardiovascular risk factors in hypertension, and individualization of pharmacologic therapy, as well as on management of diabetic nephropathy, IgA nephropathy, and other forms of

glomerulonephritis, and clinical trials in nephrology and hypertension—with inevitable overlap—it is necessary to touch on many of these subjects in this chapter. Because the drugs are not the subject of any other individual chapter, greater emphasis will be given to their pharmacology and to their handling in patients who have lost kidney function.

Despite their remarkable record of success, it is important to recognize that ACE inhibition was not the product of a planned pharmacologic approach, but rather was an accidental byproduct of snake venom toxicology. A pharmacologist examining the renin cascade would first have chosen two alternative points as candidates for blockade.³ In principle, blockade of a system is most effective at the rate-limiting step: in the renin cascade, the interaction between renin and its substrate, angiotensinogen. Renin inhibitors were developed and were efficacious, but poor bioavailability and cost of synthesis brought development programs to a halt for more than a decade. With the development of aliskiren, the first clinically approved renin inhibitor, we have a new tool, as is discussed under Pharmacology of Direct Renin Inhibition in this chapter. Blockade at the level of the angiotensin II receptor is also attractive, especially if non-ACE-dependent pathways for angiotensin II generation exist. Evidence for such pathways (especially in the kidney) in the intact human is growing,³ which makes blockade of the renin system at the level of the angiotensin II receptor an important therapeutic step.

Another factor shapes use of these agents. The angiotensin II antagonists are products of imidazole chemistry, and imidazole derivatives have a wide range of pharmacologic activity.⁴ Thus, no one could have anticipated how remarkably well tolerated this class of agents is. In study after study, AT₁ receptor blockers compare favorably with placebo in frequency of adverse reactions,^{1,5} a statement that could never have been made about antihypertensive agents in the past.

PHARMACOLOGY OF THE ACE INHIBITORS

Angiotensin-converting enzyme is a widely distributed zinc metalloproteinase that represents the final enzymatic step in the lysis of angiotensin I to produce angiotensin II. There are three main ACE isoforms: somatic ACE, plasma ACE, and testicular ACE. Somatic ACE is attached to the cell membrane and has an extracellular region that consists of two homologous domains,^{6,7} each of which contains an active catalytic site. Testicular ACE, conversely, has only one catalytically active site. Plasma ACE is thought to be derived from the somatic ACE but lacks the transmembrane domain and intracellular portion. Like somatic ACE, plasma ACE contains two active sites. The presence of two catalytic sites in somatic ACE, each capable of converting angiotensin I to angiotensin II and displaying different kinetics, has raised the interesting possibility that ACE inhibitors could differ in their affinity for the two sites. The C-terminal site accounts for approximately 75% of total ACE⁷ and is largely responsible for the conversion of angiotensin I to angiotensin II. It has been suggested that the N-terminal site has greater responsibility for the metabolism of other peptide substrates.⁸

ACE inhibitors interact differently with ACE-active sites, depending on their structure.^{9,10} Lisinopril, for example, shows affinity for only one binding site on both somatic and testicular ACE, suggesting that it binds only the C-terminal active site of ACE. Conversely, cilazaprilat has affinity for the two binding sites on somatic ACE. These findings suggest that the two active sites of somatic ACE have different structural requirements. Although of interest, at the moment there are no compelling data to indicate a functional or therapeutic implication for these findings.

ACE generally functions as a carboxyl-dipeptide hydrolase, which includes many substrates, not only angiotensin I and bradykinin, but also a wide range of peptides, including enkephalins, substance P, and the beta chain of insulin.¹¹ Clearly there are consequences to the broad range of peptide substrates degraded by ACE for the specificity of ACE inhibitor function. A number of studies in animal models, not yet supported by information from studies in humans, have suggested that bradykinin might play a role in the tissue-sparing effects of ACE inhibitors. Conversely, it is thought that the same mechanism might underlie the cough so often induced by ACE inhibitors, which represents their main drawback.¹¹

The first early effective ACE inhibitor, captopril, is a sulfhydryl-containing compound, which is relatively rapid in onset and short acting.¹¹ Thereafter, all of the ACE inhibitors that have been developed are longer-acting and, with the exception of lisinopril and captopril, undergo metabolic conversion into an active diacid form. There is no evidence that this conversion is ever rate-limiting. The ACE inhibitors are structurally heterogeneous in both their primary binding sites to the ACE receptor and in the side chains capable of binding ACE. The sulfhydryl group in captopril was replaced by a carboxyl group in most of the remaining ACE inhibitors, with the exception of a phosphinyl group in fosinopril. Although there are a number of claims that these substitutions have functional significance—for example, the reduced frequency of cough claimed for fosinopril and free-radical scavenging for the sulfhydryl group on captopril—in fact,

Table 52-1 Clinical Pharmacology of ACE Inhibitors

Drug	Elimination Route	Serum Half-life (hr)	Effect of Food	Protein Binding (%)
Benazepril	Renal, some biliary	10–11	None	>95
Captopril	Renal, as disulfides	<2	Reduced	25–30
Enalapril	Renal	11	None	50
Fosinopril	Renal = hepatic	11	None	95
Lisinopril	Renal	13	None	10
Moexipril	Renal, some biliary	2–9	Reduced	50
Perindopril	Renal	7	None	60
Quinapril	Renal > hepatic	2	Reduced	97
Ramipril	Renal	13–17	Reduced	73
Trandolapril	Renal > hepatic	16–24	None	80–94

clinically meaningful difference remains to be proved. Indeed, beyond the frequency of dosing and handling of these agents in the patient with renal failure, there are few persuasive differences.

For all of the ACE inhibitors, with the exception of fosinopril and trandolapril, the diazo-form is excreted primarily via renal clearance, involving both filtration and tubular secretion.^{11,12} In the case of fosinopril and trandolapril, excretion is more balanced, and hepatic excretion rises with a reduction in renal function (Table 52-1).

Although there are many claims that ACE inhibitors differ in functionally important ways, such as tissue penetration and action on endothelial function, in fact the available evidence for such differences is not persuasive; neither is there clear evidence that these differences have therapeutic implications. Most of the impetus for such claims has come from industry. Quantitatively important differences in duration of action and in metabolism have implications for use in the patient with renal failure.

PHARMACOLOGY OF THE ANGIOTENSIN RECEPTOR BLOCKERS

The first antagonists to angiotensin II and its receptor were peptide analogs of angiotensin II, developed as a byproduct of analyses of the structural requirements for binding of angiotensin II to its receptor and the synthesis of many structural analogs of angiotensin II.^{1,5} The most widely studied angiotensin receptor blocker (ARB), saralasin, is an octapeptide that differs from angiotensin II in structure at the eighth amino acid, where alanine is the residue, and at the first amino acid, where

sarcosine—an amino acid that does not occur in mammals—was employed to slow the degradation of the molecule. Because saralasin could only be given intravenously, was a partial agonist, and was very expensive to manufacture, it never developed a major role in therapy or diagnostics.

In 1982, an unanticipated advance was made through the application of high throughput screening in the laboratory of Takeda in Japan.¹³ They identified a series of imidazole derivatives that bound specifically to the angiotensin II receptor. Structure action work at Dupont Laboratories led to the development of losartan, the first of a new class of nonpeptide, clinically effective ARBs.¹⁴ Most of the antihypertensive action of losartan in vivo involves conversion of the parent compound to EXP-3174, the carboxylic acid metabolite of losartan.¹⁵ Further structural modifications led to the identification of valsartan, irbesartan, candesartan, and telmisartan.⁵ All are biphenyl tetrazoles. Investigators at SmithKline Beecham pursued an alternative pathway from the original Takeda compound to produce eprosartan, which is a nonbiphenyl, nontetrazole compound.¹⁶

One clear difference among the available agents involves structure. All of the currently marketed AT₁ receptor antagonists, with the exception of eprosartan, are biphenyl tetrazoles.^{4,5} Eprosartan also differs from all of the other marketed drugs in its interaction with the AT₁ receptor. Eprosartan is a pure competitive antagonist, the action of which is surmountable by sufficiently high angiotensin II concentration.¹⁷ Valsartan, irbesartan, candesartan, telmisartan, and the active metabolite of losartan, EXP-3174, all show noncompetitive kinetics, which suggests a nonequilibrium relation to the receptor.¹⁸ When the binding is sufficiently tight, equilibrium conditions required to show competitive antagonism are not in place, and the kinetics become insurmountable. In the case of losartan, the parent molecule is a weak competitive antagonist, and virtually all of the blockade after the first several hours depends on the 15% that is converted to a much more potent nonequilibrium antagonist, EXP-3174. One clinically relevant byproduct of the tight binding is the very long duration of action of the nonequilibrium ARBs. The half-life in plasma poorly predicts the duration of the blockade because of the long sojourn of the blocker on the receptor.

The available angiotensin II receptor blockers differ from one another in their oral bioavailability, metabolism, and elimination.^{1,5} Candesartan cilexetil is a true prodrug, the active agent being candesartan, which is freed from the complex during passage through the gut wall. Losartan is an active agent, a very weak competitive antagonist, with an active metabolite (EXP-3174) that is substantially more potent and long acting. Bioavailability ranges from approximately 25% for valsartan to 80% for irbesartan (Table 52-2). The absorption of neither candesartan nor irbesartan is influenced by food, whereas valsartan and losartan do show interference with absorption by food. With the exception of candesartan, which has a 60% renal route of elimination, for most of the agents the primary excretion is biliary (see Table 52-2). Only one of the agents, losartan, has a tubular action that leads to increased uric acid excretion.

The angiotensin II receptors are divided into AT₁ and AT₂ subtypes, characterized both pharmacologically and by cloning. All of the clinically important, well-defined actions of angiotensin on the kidney are mediated via the AT₁ receptor. Studies in animal models where AT₂ receptor

Table 52-2 Clinical Pharmacology of Angiotensin Receptor Blockers

Drug	Elimination Route	Effect of Food	Protein Binding (%)	Uricosuric
Candesartan	Renal (60%)	No	99	No
Eprosartan	Biliary (70%)	No	90	No
Irbesartan	Biliary (99%)	No	90	No
Losartan	Biliary (90%)	Yes	98	Yes
EXP-3174	Renal (50%)	—	99	Yes
Telmisartan	Biliary (99%)	No	99	No
Valsartan	Biliary (70%)	Yes	95	No

competitive antagonists are available has suggested that the renal actions supported by the AT₂ receptor are opposite to those of the AT₁ receptor, including vasodilation, natriuresis, and growth inhibition.¹⁹ The AT₂ receptor is prominent during embryogenesis, in the kidney and elsewhere, but becomes rapidly and progressively more sparse after birth. Any discussion of the role played by the AT₂ receptor in humans is speculative, because there are no direct data available from studies in humans. Species difference in the contribution of the renin-angiotensin system to renal control mechanisms is discussed in Renal Actions of Renin-Angiotensin System Blockers in this chapter, and may well be relevant. For example, there is a single AT₁ receptor and responsible gene in humans and two AT₁ receptor isoforms in the rat.²⁰

PHARMACOLOGY OF DIRECT RENIN INHIBITION

Although renin inhibition has long been recognized as a preferred site for blockade of the renin-angiotensin system because renin is the rate-limiting step in the cascade, until recently the development of renin inhibitors has been limited by poor bioavailability, limited efficacy, and substantial cost.²¹⁻²³ The aid of molecular modeling and x-ray structure analysis has brought about significant improvement in the design of potent and selective inhibitors of renin. The result has been the development of aliskiren, the first orally effective direct renin inhibitor approved for use in humans. Significant improvement in binding has resulted from the recognition of compounds that optimize the interaction of the molecule with elements of the active site. Although aliskiren has limited bioavailability, with some 2% to 3% of an oral dose being absorbed, its affinity for the receptor is profound, with an IC₅₀ of 0.6 nmol/L. Thus, the limited plasma concentrations achieved are more than adequate to produce complete inhibition of renin.

The importance of the direct renin inhibitor has been enhanced by the recent recognition of a functional role for prorenin at the tissue level in the pathogenesis of a number of clinical problems. Data are available, for example, to indicate that prorenin acting on a special renin receptor found in the

glomerular mesangium and in arteries contributes to the pathogenesis of diabetic nephropathy and retinopathy.²⁴⁻²⁵

Aliskiren is very long acting, with a half-life of approximately 40 hours after ingestion, and is extremely hypophilic.²¹⁻²³

The usual doses employed in humans, 150 and 300 mg, are well tolerated and appear to be largely free of important adverse effects. Frequent diarrhea limits the use of doses of 600 mg or more.

Although the BP effects of aliskiren are similar to the responses to ACE inhibitors and ARBs in double-blind studies,²¹⁻²³ there is evidence at the tissue level that aliskiren may have effects that go beyond what can be achieved with an ACE inhibitor or an ARB.²⁶ These effects include an especially prominent influence on the kidney.²⁶

RENAL ACTIONS OF RENIN-ANGIOTENSIN SYSTEM BLOCKERS

The renal response to blocking the renin-angiotensin system with any of the three classes of blocker that have been studied depends on three factors. The first is the actions of angiotensin II on the kidney in the setting of the study. Thus, for example, salt intake is a major determinant of the response to blocking the renin system, because salt intake influences the production and action of angiotensin II on the kidney. Second, the completeness of blockade induced by the agent is a crucial factor. In many studies, a somewhat arbitrary dose of a blocker has been employed, often much less than the optimal dose for blockade. The third major factor involves additional actions of the pharmacologic agent employed. Achieving an overall synthesis of the data is further complicated by the important species differences both in the renin-angiotensin system pathways and in the additional effects of the agents used to block the system.²⁰ Moreover, in protocols performed in animals, anesthesia is often used, which further modifies both the state of the renin-angiotensin system and the condition of the kidney.²¹

Shortly after the first ACE inhibitor, the peptide teprotide, became available, studies in dogs and rabbits made it clear that when the renin system was activated by a low-salt diet, the administration of the ACE inhibitor would lead to striking and consistent renal vasodilation and natriuresis, with little or no change in glomerular filtration rate.³ In studies performed in trained animals that could be studied without anesthesia, it became apparent that the responses were much smaller when the animals were studied on a high-salt diet to suppress the renin-angiotensin system. The angiotensin II receptor blocker available at that time, saralasin, was a partial agonist with substantial angiotensin-like activity—especially when the dose was pushed. When used properly, saralasin revealed a qualitatively similar, albeit smaller, renal vasodilator response as that seen with the ACE inhibitor. Essentially identical findings were found with teprotide, captopril, and saralasin in humans.²⁷

The striking influence of salt intake on the renal vasodilator response to ACE inhibition, recognized early, supported a dominant role for the angiotensin II mechanism.²⁰ If the renal vasodilator response induced by ACE inhibitors in humans included a substantial component due to bradykinin, prostaglandins, nitric oxide, or some other vasodilator pathway, several conclusions follow. First, if alternative vasodilator

pathways were engaged, the vasodilation should have been associated with blunting of the renal vascular response to angiotensin II. Conversely, if the vasodilator response reflected a reduction in angiotensin II formation, enhancement of the renal vascular response to angiotensin II would be expected. Because such enhancement was found, it seemed likely that the other vasodilator pathways were less important.

A second consequence would have been that the renal vasodilator response to renin inhibition would have been substantially less than the response to ACE inhibition. In fact, in humans the renal vasodilator response to two renin inhibitors exceeded expectations from earlier experience with ACE inhibition.³ Because of the notorious risk of employing historical controls, a coded, double-blind study was performed in which volunteers received an ACE inhibitor, a renin inhibitor, or placebo during the same week. The response was unambiguous: Renin inhibition induced a substantially larger renal vasodilator response than did ACE inhibition. That left no room for ACE inhibition-induced activation of renal vasodilator pathways, but did not provide an explanation for why the response to renin inhibition was substantially larger. In this case, the angiotensin II receptor blocker provided a “tie breaker.” If the renin inhibitor indeed operated via the renin-angiotensin system cascade, one would anticipate a similar or larger renal vasodilator response to the angiotensin II antagonist in studies performed with an identical protocol. This is precisely what was found. Three angiotensin II receptor blockers—eprosartan, irbesartan, and candesartan—induced a renal vasodilator response that matched or slightly exceeded the response to renin inhibition in healthy humans in balance on a low-salt diet.²⁰ All of the studies were performed at the top of the relationship between drug dose and renal vascular response.

From this observation, a series of conclusions is reasonable. The renal hemodynamic response to ACE inhibition has systematically underestimated the contribution of angiotensin II to renal vascular tone in humans. The effectiveness of renin inhibition suggests that this response represents interruption of primarily renin-dependent but non-ACE-dependent pathways, probably involving chymase. From quantitative considerations—response to ACE inhibition was 90 to 100 mL/min/1.73 m² in this model as opposed to the 140 to 150 mL/min/1.73 m² induced by renin inhibition or angiotensin II receptor blockers—it follows that 30% to 40% of angiotensin-dependent renal vascular tone reflects angiotensin generated via a non-ACE-dependent pathway.³ That percentage is higher when the renin system is suppressed by a high-salt diet in healthy humans.²²

In more recent studies in an identical model, aliskiren has led to a response substantially larger than ever seen with an ACE inhibitor or an ARB, averaging at peak dose approximately 200 mL/min/1.73m².²⁶ Given the specificity of renin inhibition, it is unlikely that a nonrenin pathway is involved. A more likely explanation is that the direct renin inhibitor is also interfering with pathways involving prorenin.^{24,25}

Several important species differences merit discussion.²⁰ The first involves pathways for non-ACE generation. In humans and other primates the enzyme chymase has a single substrate, angiotensin I, and a single product, angiotensin II. Indeed, it should have been called *angiotensin-converting enzyme*, but that name was subsumed for another enzyme in the 1950s. The primate separated from other mammals in

phylogeny millions of years ago. Since that time, there have been ample opportunities for shifts in metabolic pathways. In the rat and rabbit, chymase does not have angiotensin I as its substrate, but rather has angiotensin II as its substrate and degradation products of angiotensin II as its product. Thus, the action of chymase in humans and in small animals is opposite. One would anticipate that ACE inhibitors and angiotensin II receptor blockers would have similar actions. In these small creatures, they do.

A second major species-dependent difference involves the mechanism by which ACE inhibition influences the renal blood supply. In rats and dogs, considerable evidence indicates that bradykinin and other vasodilator pathways make a substantial contribution to the renal vasodilator response to ACE inhibition. Conversely, in the rabbit and humans, available evidence suggests that the dominant action, by far, involves a reduction in angiotensin II production with little evidence of activation of these alternative pathways.²⁸ The biochemical explanation underlying these differences is not yet available.

RENIN-ANGIOTENSIN SYSTEM BLOCKADE AND THE NATURAL HISTORY OF RENAL INJURY

Opinion will vary as to the first observation that pointed to a specific renal action of ACE inhibitors, especially their potential for preserving renal function. One can argue that this was first recognized in 1979, in a description of maintenance of renal function with BP control during captopril treatment of two patients with unequivocal scleroderma renal crisis.²⁴ Because this process is characterized by a rapidly progressive downhill course, with no exceptions in the literature, it was clear that something special had happened. The outcome did raise debate on whether it was BP control, which was improved with ACE inhibition, that led to improvement of the renal course or whether ACE inhibition offered other renal protective qualities.

In 1985, studies in animal models and in patients with proteinuria led to the first discussion of the possibility that ACE inhibition might be renal protective and to discussions of a possible ambitious therapeutic trial in patients with type 1 diabetes mellitus. The decision to focus on the patient with type 1 diabetes mellitus had nothing to do with the special role of ACE inhibitor therapy in diabetes, but rather recognized that these patients represent a very attractive target for establishing a principle. The disease course is relatively predictable based on renal function and level of proteinuria; the patient population is relatively homogeneous and young, so that the natural history of nephropathy is less likely to be complicated by cardiovascular events. Thus, one could isolate a specific renal influence and thereby establish a principle. In part because the study was planned as a collaboration between a corporate sponsor and the National Institutes of Health, several years were required before the study was launched, and the data did not become available until late 1993.²⁷ During that time, a large literature had accrued both in animal models and in humans, reported as a meta-analysis of 100 clinical studies performed during that time. With the 1993 publication, policy changed; for the first time, a regulatory agency approved a drug for a specific renal protective indication. Since that time, studies on ACE inhibition have been extended to studies in patients with type 2 diabetes mellitus and nondiabetic renal disease.²⁶

What of the ARBs? Until recently, their potential utility in preventing the progression of renal disease was a construct. The outcome predicted depended on whether one thought that non-ACE angiotensin II generation (in which case, the ARBs would be better) or the non-angiotensin-dependent actions of ACE inhibition (in which case, the ACE inhibitors would be better) was quantitatively important. In 2001, three studies appeared in a single issue of the *New England Journal of Medicine*.^{27,29–32} In patients with type 2 diabetes mellitus and nephropathy, both irbesartan and losartan reduced the frequency of progression to a renal endpoint—doubling serum creatinine, need for dialysis, or death—by approximately 20%. The study in which irbesartan was employed included three limbs: irbesartan in one limb, placebo add-on in the second limb, and amlodipine add-on in the third limb. Amlodipine proved to be essentially identical to placebo. Perhaps the most exciting finding was in the third study, in which two doses of irbesartan were employed in patients with type 2 diabetes mellitus and microalbuminuria to assess the frequency with which the patients would move on to frank proteinuria.³¹ The results were extraordinarily striking. The 150-mg irbesartan dose reduced the frequency of progression from about 15% to about 10%. An increase in the irbesartan dose to 300 mg reduced the frequency of progression further, to about 5%. Overall, at the highest dose, the protective effect was a 70% reduction, much the largest reduction in risk induced by blockade of the renin-angiotensin system in any clinical condition. The important message seems to be that it is better, indeed far better, to treat early.

RENIN SYSTEM BLOCKADE AND NEPHROPATHY: WHY DO THE NEWSPAPERS SAY THERE IS A CONTROVERSY?

Recently, the special role of the renin-angiotensin system in determining the progression of renal disease was called into question. The first challenge came from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),³³ and the second came from a recent meta-analysis on this subject.³⁴ The third challenge arose from an epidemiological study in Canada. In the last study, they claimed not only that ACE inhibitors were not protective, but moreover that they may have contributed to the development of end-stage renal disease (ESRD).³⁵ Here we discuss each in turn.³⁶

ALLHAT was not designed specifically to address the issue of kidney disease, but with the massive number of patients enrolled, in fact it is the largest study on diabetes yet reported. Had nephrologists designed such a study, surely they would have insisted on better renal evaluation, measurement of proteinuria, and more regular follow-up. However, it must be accepted that the likelihood that the investigators missed ESRD is small. ALLHAT found that patients who were treated with the ACE inhibitor lisinopril did not show the anticipated protection from renal injury. Patients who were treated with a diuretic did as well as lisinopril-treated patients. The authors of a report emphasized their failure to confirm the value of renin system blockade: The premise, not stated, was that the earlier studies were “wrong” and that ALLHAT—presumably by virtue of the fact that it was big—provided the correct answer.

But, did it? One of the fundamentals of therapeutics is dose.³⁷ Each of the major clinical trials that led to approval used

a very substantial dose of the ACE inhibitor or the ARB. Indeed, in one of these important studies, the experimental design involved identifying the relationship between dose and response. Whereas 150 mg/day of irbesartan was effective, it was substantially less effective than 300 mg/day of irbesartan.³¹

In ALLHAT, they initiated lisinopril treatment with a daily dose of 10 mg. Few would choose to use 10 mg of lisinopril in the average patient. Experts do not hesitate to titrate upward. Conversely, the physicians involved in ALLHAT were often reluctant to update drug dose. Information on which drug dose the patient received was not given in the original article but has appeared recently in response to a letter to the editor.^{38,39} More than 50% of the patients randomly assigned to lisinopril either were taking no ACE inhibitor or had remained at the lowest dosage level in year 1, year 3, and year 5. Only a little more than one third received the top dose. From this study, we can conclude firmly only that an inadequate dose of ACE inhibitor is not better than other antihypertensive agents. Surely, if we did not already know that, we at least so suspected.

The second source of confusion and one that received substantial attention in the lay press is a recent meta-analysis³⁴ that concluded that there was little or no advantage to renin-system blockade in preventing nephropathy. In view of the fact that the meta-analysis involved more than 73,000 patients who were culled from 127 studies, they were confident that their conclusion was correct. Thus, the predecessors must have been wrong.

The large studies that led to regulatory approval shared a number of features. All were big enough to have the necessary power. In each the dose of drug was adequate to the task. Finally, in each, follow-up was sufficiently long that an endpoint could be achieved. A useful meta-analysis would have required that all three criteria be met. Regretfully, this meta-analysis did not. Adding small, poor studies to large, excellent studies does not improve the information yield. The problems of many of the studies were that the drug doses were too low and follow-up was too short.

The third challenge to a contribution of the renin system to ESRD came from an epidemiologic study in Canada. The authors, using a database that provides information on clinically relevant events, concluded not only that ACE inhibition did not protect patients from ESRD, but that in fact ACE inhibition promoted ESRD.³⁵ The authors treated the groups as though the individual patients were randomly assigned to drug therapy. Nowhere in their article does it indicate the possibility that patients who were at greater risk for ESRD received captopril and other ACE inhibitors preferentially because of that risk. Proteinuria is an important driving force in clinical decision making, and proteinuria was not listed in their database. By the early to the mid-1980s, there was already substantial interest in the possibility that ACE inhibition might improve the natural history of renal disease.⁴⁰

For all of these reasons, the use of the term *controversial* is inappropriate.

USE OF THESE AGENTS IN THE PATIENT WITH RENAL FAILURE

ACE inhibitors are used in the patient who has lost renal excretory function for two reasons: to control hypertension and to retard the progression of renal injury. There is much less clinical experience with the ARBs, but the goal of their use is the

same, and preliminary data indicate that their efficacy is probably similar to that of ACE inhibitors. ACE inhibitors are effective antihypertensive agents in most patients with renal insufficiency, but their use is complicated by their tendency to increase azotemia in certain patients. This is especially likely to occur in the patient who has been treated aggressively with restriction of salt intake or diuretic therapy, and their use may be difficult to manage in the patient who is already very azotemic. Too often physicians are tempted to discontinue ACE inhibitor therapy because of an abrupt rise in serum creatinine during initiation of treatment.¹¹ Whenever possible, generally when the patient is free of symptoms of azotemia, it is worthwhile to maintain ACE inhibitor therapy. In the Collaborative Study Group Trial of captopril in patients with type 1 diabetes mellitus, the patients who were already azotemic at baseline showed the greatest benefit from captopril treatment,²⁵ and most showed increased azotemia during initial therapy.

In such patients, it is important to be aware of the possibility of drug accumulation during treatment because of renal excretion.¹² Although not entirely predictable, in general, dosage modification is not required with the use of fosinopril, trandolapril, or quinipril. With the use of perindopril, benazepril, enalapril, lisinopril, and ramipril, a 50% to 75% reduction in dose is recommended. In the case of captopril, the dose should be reduced by 50% to 75% and administered only once daily.

In general, the principles for the use of ARBs are the same, although only candesartan is more than 50% excreted by the kidney, and there is little information to suggest that dose adjustment is crucial in the patient with renal failure for any of these agents.⁵

Another consideration in the use of drugs that block the renin-angiotensin system in the patient with renal failure involves potential hyperkalemia.^{11,12} The patient at greatest risk has diabetes mellitus, mild to moderate azotemia, and evidence of hyporeninemic hypoaldosteronism, such as a high baseline serum potassium concentration. In addition, often evidence of metabolic acidosis that is more severe than expected for the degree of renal failure is present. Such patients should be treated cautiously and seen within 48 hours of beginning ACE inhibitor therapy for repeat serum potassium and creatinine measurement because they can develop a life-threatening rise in serum potassium. The use of cyclooxygenase inhibitors in such patients can precipitate hyporeninemic hypoaldosteronism; patients should be cautioned about their use.

For reasons that are not entirely clear, the ARBs appear to cause less hyperkalemia than do ACE inhibitors.^{1,5,41} Because a close correlation was found between the uricosuric effect and kaliuretic effect when losartan was used, it was initially believed that the potassium effect of losartan reflected a tubular action rather than angiotensin receptor blockade. This explanation has been called into question by the recent observation that valsartan, which has no tubular action, also appears to spare potassium.²⁹ In the patient in whom hyperkalemia is an important threat, the uses of one of these two ARBs in place of an ACE inhibitor should be considered.

Goal BP for such patients is the subject of substantial debate, remains controversial, and is addressed in greater detail elsewhere. Most advisory groups now recommend a goal of less than 130/80 mm Hg in patients at risk of progression to ESRD, and it will not be surprising to find groups recommending systolic BPs of 120 mm Hg or lower—if only we can find a way to get down to those BP levels.

ALDOSTERONE ANTAGONISTS

The first aldosterone antagonist, spironolactone, was introduced in 1959, well before ACE inhibitors were developed. The agent, a 17-spirolactone steroid, was an unanticipated byproduct of progesterone chemistry and pharmacology. It was quickly shown to be a specific competitive antagonist of aldosterone at the receptor level and was developed as a potassium-sparing diuretic. Because of a substantial frequency of side effects, it was of limited therapeutic interest until about 10 years ago when interest in a specific interruption of aldosterone production or action began to grow, arising from three major sources. The first involves a series of studies in the heart and kidney that indicated that aldosterone leads to substantial fibrosis and tissue injury via a mechanism that could be interrupted by an aldosterone antagonist.⁴²⁻⁴⁴ Indeed, in some studies, a substantial portion of the tissue sparing provided by ACE inhibition involved reduction in plasma aldosterone concentration.

The second line of investigation leading to renewed interest in blockade of aldosterone effects was the RALES Trial in patients with advanced heart failure. In this study, the addition of spironolactone in very low doses—averaging 25 mg a day—reduced cardiovascular event rate by a striking 30%.⁴⁵ Because the doses were very low, the agent was well tolerated, but the doses are probably too low to have a major influence on BP or electrolyte homeostasis. Thus, another mechanism must be sought.

The third reason for a renewal of interest in aldosterone antagonists as a therapeutic area involved the development of a new aldosterone antagonist, eplerenone, which is much better tolerated than spironolactone. Eplerenone doses producing a substantial influence on BP and electrolyte homeostasis, comparable to the top of the spironolactone dose-response (believed to be about 150 mg daily) had little or no effect on libido, gynecomastia, or breast pain and tenderness.

Epstein and colleagues recently reported compelling results in a study with eplerenone in patients with type 2 diabetes mellitus.⁴⁶ The 268 patients enrolled were randomized into three equal-sized groups, each of which was maintained on enalapril, 20 mg/day. In one third a placebo was added for 12 weeks; in a second group eplerenone was added at 50 mg/day; in a third group eplerenone was added at 100 mg/day. By week 12, proteinuria was reduced by 7.4% in the placebo group, by 41% in the eplerenone 50 mg group, and by 48.4% in the eplerenone 100 mg group. The frequency of hyperkalemia was not different in any of the three treatment groups. These striking results suggest that we should be more involved in blocking aldosterone in such patients. DelVecchio and co-workers⁴⁷ recently reviewed eight small studies in patients with proteinuria treated with an aldosterone antagonist. Results in all studies are in striking accord of those of Epstein and colleagues.

MECHANISMS AND PHARMACOLOGY OF ALDOSTERONE ANTAGONISTS

Although until recently most attention had focused on the distal tubules in the nephron, in fact aldosterone receptors are found in many tissues. Spironolactone acts as a competitive inhibitor of aldosterone binding to its receptor. Spironolactone is extensively metabolized in humans, and at least some of the metabolites—

especially canrenone—have anti-aldosterone activities, but the dominant effect appears to be due to the parent compound.

In part because it was developed in the 1950s, the pharmacokinetics of spironolactone have not been well worked out. Concomitant food intake enhances bioavailability by increasing the absorption of spironolactone and decreasing the first-pass effect.^{48,49} A gradual onset of diuretic action is seen, requiring 3 days to reach its maximum, and the diuretic response persists for 2 or 3 days.⁴⁹ It is unlikely that the tissue-sparing effect involves sodium or potassium handling, and little is known about the kinetics of that action.

The most troubling adverse effect of spironolactone has been gynecomastia. This adverse effect is dose sensitive. In a systematic comparison of spironolactone doses of 100, 200, and 400 mg/day, the 200- and 400-mg/day doses were associated with a striking increase of gynecomastia and no greater antihypertensive effect than that associated with 100 mg/day.^{50,51} In general, spironolactone has much more often been used in combination with a thiazide diuretic, as much for the potassium-sparing effect as for the primary diuretic action.

The adverse effect of greatest concern is hyperkalemia. The risk of hyperkalemia was found to be greatly increased in patients with renal insufficiency and in those in whom there was simultaneous exposure to potassium supplements.^{49,50} In one large survey, 8.6% of patients taking spironolactone developed hyperkalemia. The frequency was only 2.8% in those with a normal blood urea nitrogen in that study and rose to 42.1% in those in whom blood urea nitrogen exceeded 50 mg/dL.³⁸

At least in part because of the interaction between azotemia and hyperkalemia, few studies have been performed in patients with renal failure. Glomerular filtration rate has been shown to be stable over 3 months of spironolactone therapy.⁵²

Substantially less has been published on eplerenone, which is not yet marketed for hypertension. Presumably many of the issues addressed in this review will become available in the medical literature before long.

OPTIMIZATION OF RENIN SYSTEM BLOCKADE

It is now about three decades since the introduction of renin-system blockade with the advent of the ACE inhibitor captopril. The first two decades or so involved large studies designed to ascertain when blocking the renin system provided benefit. The past several years have seen a shift in emphasis to address the issue of optimization of renin system blockade. The addition of aldosterone antagonists to an ACE inhibitor or ARB represents one approach to doing so. The use of combinations of ACE inhibitors and ARBs represents a second approach. Although there have been dozens of reports on such combinations in the patient with proteinuria, the literature is not very useful, because the issue of dose has not been addressed directly.⁵³

As an alternative, very high-dose ARBs have received recent attention.⁵⁴ These studies take advantage of the fact that angiotensin receptor blockers are so well tolerated that very high doses can be employed. In fact, there is a very clear benefit to using very high doses of ARBs in the patient with proteinuria. The drugs employed have included irbesartan (to 900 mg), valsartan (to 640 mg), and candesartan (to 96 mg).

Renin inhibition clearly will join these three other approaches to optimization of treatment. We have a lot of work to do. The next 10 years should prove to be very interesting.

Acknowledgments

I am grateful to Ms. Diana Capone for her assistance in the preparation and submission of this chapter.

Studies Examining the Effect of Calcium Channel Blockers on the Development of Kidney Disease	613		
Studies Comparing Calcium Channel Blockers to Blockers of the Renin-Angiotensin-Aldosterone System on Progression of Kidney Disease	614		

Calcium channel blockers (CCBs) were developed in the 1960s, introduced for clinical practice in the 1980s, and are widely used for the treatment of hypertension, angina, and cardiac arrhythmias. They are structurally heterogeneous but share the universal property of blocking the transmembrane flow of calcium ions through voltage-derived channels (L-type channels) in vascular and nonvascular smooth muscle.¹ Blockade of these channels results in smooth muscle relaxation, decreased peripheral vascular resistance, dilation of coronary arteries, and a decrease in myocardial contractility.

CLINICAL PHARMACOLOGY

Calcium channel blockers can be divided into two classes based on differences in structure and function: dihydropyridines and nondihydropyridines. Dihydropyridines block L-type channels relatively selectively in peripheral vascular tissue and act primarily by dilating resistance vessels. Nondihydropyridines block L-type channels in both vascular and cardiac tissue and therefore affect cardiac function and the atrioventricular (AV) node in addition to causing vasodilation. They decrease heart rate and prevent reflex tachycardia. Only nondihydropyridine agents decrease glomerular protein and albumin sieving and decrease renal protein excretion.¹

Most CCBs currently in use are dihydropyridines. In the United States, commercially available dihydropyridines include amlodipine, felodipine, isradipine, nicardipine, nifedipine, nimodipine, nisoldipine, and nitrendipine. The two nondihydropyridines are verapamil, a phenylalkylamine, and diltiazem, a benzothiazepine (Table 53-1). Barnidipine, lacidipine, lercanidipine, and manidipine, all dihydropyridines, are not commercially available in the United States. Nimodipine, a dihydropyridine, is approved for use as a cerebral vasodilator but not for hypertension.

The newer agents and formulations of most CCBs have a relatively long half-life and time to peak effect, either because the intrinsic half-life is long, as in the case of amlodipine, or because drug delivery has been manipulated. Immediate-release, relatively short-acting preparations of diltiazem, verapamil, nifedipine, and nicardipine are also available. Diltiazem, nicardipine, and verapamil are available in intravenous formulations. Because of the potential risks of short-acting agents, only the long-acting preparations are recommended for use in hypertension, although the short-acting nondihydropyridine agents can be used to decrease AV nodal conduction in arrhythmias or atrial tachycardia.

Calcium channel blockers are primarily metabolized in the liver. Dose adjustment generally is not required even in end-stage renal disease (ESRD),² although there have been reports of toxicity with long-acting verapamil in patients with ESRD.^{3,4}

Clinical studies of CCBs in hypertensive patients have examined their use in four settings: controlling hypertension, reducing cardiovascular morbidity and mortality, preventing progression of kidney disease, and treating hypertension associated with ESRD.

EFFICACY IN TREATMENT FOR ESSENTIAL HYPERTENSION

In short-term studies single-agent therapy with CCBs yields results at lowering of blood pressure (BP) similar to those seen with other antihypertensive agents. In the VA cooperative study, hypertensive patients were randomized to placebo or one of six agents as monotherapy. Those randomized to diltiazem had the highest rate of success compared to those given hydrochlorothiazide, atenolol, captopril, clonidine, or

Table 53-1 Calcium Channel Blockers: Recommended Doses for Hypertension

	U.S. Trade Name	Half-life (hr) (Normal/ESRD)	Dosage	Comment
Amlodipine	Norvasc	35–50/50	Initial: 2.5 mg/day Maintenance: 2.5–10 mg/day	Dihydropyridine Combinations with benazepril and atorvastatin available Dosage adjustment for liver disease
Barnidipine		24/24		Dihydropyridine Not in use in the U.S.
Diltiazem	Dilacor, Cardizem, Cartia, Tiazac	2–8/2–8	Initial: 120–180 mg/day Maintenance: 120–360 mg/day	Benzothiazepine Greater potential than dihydropyridines to cause AV nodal dysfunction and impaired LV function Dosage adjustment for liver disease Comes in long-acting (CD, XR, LA) formulations for once-daily dosing
Felodipine	Plendil	10–14/21	5–10 mg/day	Dihydropyridine; combination with enalapril available
Isradipine	Dynacirc	2–5/10–12	Initial: 5 mg/day Maintenance: 5–10 mg/day	Dihydropyridine Comes in long-acting (CR) formulation
Lacidipine		12/12		Dihydropyridine Not in use in the U.S.
Lercanidipine		8–10/8–10		Dihydropyridine. Not in use in the U.S.
Manidipine		4–6/4–6		Dihydropyridine Not in use in the U.S.
Nicardipine	Cardene	5/5–8	Initial: 60 mg/day Maintenance: 60–120 mg/day IV: 1–15 mg/hr	Dihydropyridine Comes in long-acting (SR) preparations Can be given parenterally as continuous infusion in malignant hypertension
Nifedipine	Adalat, Procardia	4–6/6–8	Initial: 30–60 mg SR/day Maintenance: 30–90 mg SR/day	Dihydropyridine Comes in long-acting (CC, XL) preparations
Nimodipine	Nimotop	1–3/20–24	60 mg q4h for 21 days	Dihydropyridine Not approved for hypertension Used to treat neurological deficits due to cerebral artery spasm in patients with subarachnoid hemorrhage
Nisoldipine	Sular	6–8/7–10	Initial: 20 mg/day Maintenance: 10–40 mg/day	Dihydropyridine Dosage adjustment for liver disease
Nitrendipine		4–6/4–6	Initial: 10 mg/day Maintenance: 10–40 mg/day	Dihydropyridine
Verapamil	Calan, Covera, Isoptin, Verelan	3–7/3–7	180–480 mg/day	Phenylalkylamine Greater potential than dihydropyridines to cause AV nodal dysfunction or LV dysfunction Comes in long-acting (SR, HS, PM) preparations Combination with trandolapril available

AV, atrioventricular; LV, ventricular.

prazosin.⁵ In the Treatment Of Mild Hypertension Study (TOMHS), amlodipine was as effective as chlorthalidone, acebutolol, doxazosin, or enalapril in hypertensive men and women.⁶ In the German HANE study, nitrendipine was equivalent in BP lowering to hydrochlorothiazide, atenolol, or enalapril.⁷

PREVENTION OF CARDIOVASCULAR MORBIDITY AND MORTALITY

Table 53-2 lists the major prospective, randomized clinical trials in which cardiovascular outcomes were compared in hypertensive patients randomly assigned to receive a CCB or to another antihypertensive agent. In general, CCBs are as, or marginally less, effective than other agents, particularly when they are prescribed as sole agents. In the FACET study (Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial), hypertensive diabetics were randomly assigned to receive fosinopril or amlodipine; the rate of cardiovascular morbidity and mortal events was greater in the amlodipine group.⁸ In the Verapamil in Hypertension and Atherosclerosis Study (VHAS), there was no difference in outcome between patients randomly assigned to receive verapamil or a diuretic.⁹ In the STOP-2 trial, elderly patients with hypertension were randomly assigned to a calcium channel blocker (isradipine or felodipine), an angiotensin-converting enzyme (ACE) inhibitor, or conventional therapy with diuretics and β -blockers. CCBs were equivalent to ACE inhibitors and conventional therapies in preventing most cardiovascular morbidity, but were inferior to ACE

inhibitors in preventing congestive heart failure or myocardial infarction (MI).¹⁰ In the Intervention as a Goal in Hypertension Treatment (INSIGHT) trial, in patients randomly assigned to long-acting nifedipine, a trend was seen toward a lower risk of stroke compared to those receiving a diuretic, but the risk of fatal MI, congestive heart failure, or any cardiovascular mortality was significantly increased.¹¹ In the Appropriate Blood Pressure Control in Diabetes (ABCD) trial, subjects with diabetes and hypertension were randomly assigned to receive nisoldipine or enalapril. The study was stopped prematurely because of an increase in the risk of nonfatal MI in the nisoldipine group.¹² However, there was no significant difference in overall mortality, and the original assessment of relative risk was lowered when additional patient safety data became available.¹³ In the Multicenter Isradipine Diuretic Atherosclerosis Study (MIDAS), patients were randomly assigned to isradipine or hydrochlorothiazide.¹⁴ Some adverse cardiovascular effects, such as the development of angina, occurred more commonly in the isradipine group. In the huge Antihypertensive and Lipid Lowering treatment to prevent Heart Attack Trial (ALLHAT), patients were randomly assigned to amlodipine, a diuretic, or an ACE inhibitor. The primary endpoints of fatal coronary disease or nonfatal MI did not differ in the amlodipine-treated group, but patients receiving amlodipine were significantly more likely to have heart failure than the diuretic-treated group.¹⁵ In the Controlled ONset Verapamil INvestigation of Cardiovascular Endpoints (CONVINCE) trial, patients were randomly assigned to extended-release verapamil or a β -blocker/hydrochlorothiazide combination; most cardiovascular endpoints were equivalent in the two

Table 53-2 Summary of Studies of Calcium Channel Blockers in Prevention of Cardiovascular Disease in Hypertensive Patients

Study and Reference	Patients (N)	Drugs Studied	CV Morbidity*	CV Mortality*	Stroke*
FACET ⁸	380	Amlodipine vs. ACE inhibitor		2.04 (1.05–3.84)	2.56 (0.81–8.33)
VHAS ⁹	498	Verapamil vs. diuretic	Lower event rate		
STOP-2 ¹⁰	6614	Isradipine/felodipine vs. diuretic/ β -blocker vs. ACE inhibitor	0.99 (0.87–1.12)	0.97 (0.80–1.17)	0.88 (0.73–1.06)
INSIGHT ¹¹	6321	Nifedipine vs. diuretic	1.11 (0.90–1.36)	3.22 (1.18–8.80)	0.87 (0.61–1.26)
ABCD ¹²	470	Nisoldipine vs. ACE inhibitor	3.3 (1.5–7.1)	NS	
MIDAS ¹⁴	883	Isradipine vs. diuretic	1.78 (0.94–3.38)		2.00 (0.50–7.93)
ALLHAT ¹⁵	33,357	Amlodipine vs. diuretic	0.98 (0.90–1.07)		
CONVINCE ¹⁶	8241	Verapamil vs. β -blocker vs. diuretic		1.08 (0.93–1.26)	1.15 (0.90–1.48)
VALUE ¹⁷	15,245	Amlodipine vs. ARB		1.04 (0.90–1.16)	0.98 (0.72–1.19)
IDNT ¹⁹	1715	Amlodipine vs. ARB	1.11 (0.91–1.35)	0.74 (0.48–1.12)	0.64 (0.35–1.19)
CAMELOT ²⁰	1991	Amlodipine vs. ACE inhibitor	0.81 (0.63–1.04)	1.07 (0.31–3.70)	0.76 (0.26–2.20)
SYSTEUR ²²	4695	Nitrendipine vs. placebo	0.69 (0.55–0.86)	0.73 (0.52–1.02)	0.58 (0.40–0.83)
NORDIL ²³	10,881	Diltiazem vs. β -blocker	1.04 (0.91–1.18)	1.11 (0.87–1.43)	0.80 (0.65–0.99)
INVEST ²⁵	22,576	Verapamil vs. β -blocker	1.03 (0.93–1.14)	0.98 (0.90–1.07)	0.89 (0.70–1.12)
ASCOT ²⁶	19,257	Amlodipine vs. β -blocker		0.89 (0.81–0.99)	0.77 (0.66–0.99)

*Data presented are for relative risk of those randomized to calcium channel blockade (95% confidence intervals). ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CV, cardiovascular.

groups, but there was a higher risk of hemorrhage in the verapamil group.¹⁶ In the NICS-EH (National Intervention Cooperative Study in Elderly Hypertensives; nifedipine vs. diuretic), the CAMELOT (Comparison of Amlodipine vs Enalapril to Limit Occurrences of Thrombosis; amlodipine vs. enalapril), the VALUE (Valsartan Antihypertensive Long-term Use Evaluation trial; amlodipine vs. valsartan), and the IDNT (Irbesartan Diabetic Nephropathy Trial; irbesartan vs. amlodipine), cardiovascular events were similar in CCB-treated groups and comparison groups.^{17–20} In a recent meta-analysis of more than 150,000 patients in 29 trials,²¹ comparing therapies based on different categories of antihypertensive drugs, CCB-based therapy was superior to placebo in preventing stroke and coronary heart disease and inferior to diuretic/ β -blocker therapy and ACE inhibitor therapy in preventing heart failure.

On the other hand, a number of clinical trials have shown improved cardiovascular outcomes in patients randomly assigned to CCBs, especially in prevention of cerebrovascular disease. In the SYST-EUR study, elderly patients with hypertension were randomly assigned to nitrendipine or placebo; ACE inhibitors and diuretics were added to both groups to decrease the systolic BP equivalently. The risk of cardiovascular events and stroke was lower in the nitrendipine group.²² In the Nordic Diltiazem (NORDIL) study, patients were randomly assigned to diltiazem or to a β -blocker and diuretic; there was a lower risk of stroke in the diltiazem group.²³ A large meta-analysis of more than 100,000 patients in 13 trials demonstrated a 10% lower risk of stroke in patients randomly assigned to CCBs; this benefit was greatest with dihydropyridines.²⁴

A number of studies support the use of CCBs in prevention of cardiovascular disease when these agents are used in combination with other antihypertensive agents to achieve low BP targets. In the International Verapamil-Trandolapril Study (INVEST), patients were randomly assigned to verapamil or a β -blocker; an ACE inhibitor and diuretic were added to both groups to achieve JNC-VI blood pressure targets; the verapamil- and β -blocker-treated groups had similar outcomes.²⁵ In the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT), patients were randomized to amlodipine with the subsequent addition of an ACE inhibitor, or to a β -blocker with the subsequent addition of a diuretic. Patients randomly assigned to the amlodipine/ACE inhibitor arm had lower rates of cardiovascular morbidity and all-cause mortality.²⁶ Finally, in the Hypertension Optimal Treatment (HOT) trial, patients with hypertension were randomized to three different diastolic BP goals, from less than 80 mm Hg to 90 mm Hg. Felodipine was given to every patient; other agents were added to reach the specific BP target. Patients whose diastolic BP fell below 85 mm Hg benefited from the use of a CCB; this effect was greater in diabetics.²⁷

The rate of cardiovascular effects in the HOT trial was lower than reported in previous studies; along with the other studies discussed here, this suggests that CCBs do improve cardiovascular outcomes, but this effect is greatest when low BP targets are achieved and CCBs are used in conjunction with other agents, especially ACE inhibitors. The question of which combination of antihypertensive therapy is optimal will hopefully be addressed by the Avoiding Cardiovascular events through COMbination Therapy

in Patients Living with Systolic Hypertension (ACCOMPLISH) trial,²⁸ which randomizes 11,000 hypertensive patients to an ACE inhibitor/diuretic (benazepril/hydrochlorothiazide) versus ACE inhibitor/calcium channel blocker (benazepril/amlodipine) combination. Study results should be available by 2009.

PREVENTION OF PROGRESSION OF CHRONIC KIDNEY DISEASE

Calcium channel blockers modulate the progression of chronic kidney disease (CKD) by a number of mechanisms, including alterations in renal hemodynamics and renal growth, and by direct effects on the production and/or responses to cytokines, growth factors, and vasoconstrictor substances by glomerular or tubular cells. CCBs tend to have a protective effect on renal progression in experimental models, but the results are inconsistent. Explanations for these divergent findings are not always apparent; findings have been attributed to differences in the animal model, the drug or dose administered, variability in systemic or intraglomerular pressure, and other factors. A detailed discussion of these data is beyond the scope of this chapter; the reader is referred to some recent comprehensive reviews.^{29–32}

The effects of CCBs on progression of renal disease in humans has been examined in several randomized, prospective clinical trials. A discussion of these trials follows, divided into three categories: (1) studies examining the development of renal disease in hypertensive patients with normal renal function, (2) studies in patients with CKD in which CCBs were compared to drugs that block the renin-angiotensin-aldosterone system, and (3) studies in patients with CKD in which CCBs were added to drugs that block the renin-angiotensin-aldosterone system.

Studies Examining the Effect of Calcium Channel Blockers on the Development of Kidney Disease

The ALLHAT study excluded patients with a serum creatinine level above 2.0 mg/dL. There was no difference in the incidence of either a 50% decrease in the glomerular filtration rate (GFR) or the development of ESRD in patients who were randomly assigned to chlorthalidone, amlodipine, or lisinopril.³³

The BEergamo NEphrologic Diabetic Complications Trial (BENEDICT)³⁴ randomly assigned hypertensive diabetics with normal kidney function and normoalbuminuria to the ACE inhibitor trandolapril, long-acting verapamil, a combination of the two, or placebo, with additional agents given to reduce BP to less than 130/80 mm Hg. The group receiving ACE inhibitors had a significantly lower risk of microalbuminuria, even when the BP was not controlled to the target range.

A meta-analysis of 16 trials of the effect of various antihypertensive agents on the development of diabetic nephropathy, defined as the development of microalbuminuria, in diabetic patients with normoalbuminuria, showed that there was a 42% lower risk of development of microalbuminuria in patients given ACE inhibitors rather than CCBs in clinical trials. The effect of CCBs compared to β -blockers or other

antihypertensive agents on the development of renal disease was not examined.³⁵

Studies Comparing Calcium Channel Blockers to Blockers of the Renin-Angiotensin-Aldosterone System on Progression of Kidney Disease

Most comparison studies evaluating the progression of renal disease have compared CCBs to ACE inhibitors. Zucchelli and colleagues studied 121 patients with hypertension and CKD³⁶; patients were observed for 1 year on standard therapy and then randomly assigned to captopril or long-acting nifedipine. The mean BP dropped by more than 20 mm Hg in both groups; mean protein excretion did not significantly decline, and the rate of renal functional decline was slowed significantly, but was similar in both groups. The study concluded that ACE inhibitors and CCBs have similar renal protective effects when hypertension is aggressively treated.

Velussi and colleagues³⁷ studied 44 patients with hypertension and type 2 diabetes mellitus; they had microalbuminuria or no proteinuria and all had normal renal function. They were randomly assigned to the ACE inhibitor cilazapril or to amlodipine. Blood pressure was lowered aggressively. The GFR stabilized after an initial decline, and protein excretion declined comparably in both groups. In another relatively small study, Bakris and colleagues³⁸ compared treatment with diltiazem or verapamil to the ACE inhibitor lisinopril or the β -blocker atenolol in 52 patients with type 2 diabetes mellitus and diabetic nephropathy. The decline of the creatinine clearance was modest and similar in patients receiving lisinopril or one of the CCBs, and proteinuria was reduced similarly by all three agents.

The dihydropyridine CCB nisoldipine was compared to the ACE inhibitor enalapril, examining its effects on the rate of change in creatinine clearance in 470 hypertensive diabetic subjects, in the ABCD trial.¹² The study was stopped prematurely because of an increase in nonfatal MI in the nisoldipine group. The renal endpoint data were subsequently analyzed, and there was little difference between the two groups. The enalapril-treated patients had an initial decline in proteinuria, but there was no difference in proteinuria, or in progression of proteinuria, between the groups by the end of the study; changes in renal function were equivalent.

The Modification of Diet in Renal Disease (MDRD) study examined the effect of a low BP target on progression of nondiabetic CKD.³⁹ Post hoc subset analysis suggested that African Americans with hypertensive nephropathy specifically benefited from a low BP target, but the number of subjects was insufficient. The African American Study of Kidney Disease and Hypertension (AASK) was launched to address this question.⁴⁰ Participants were 1094 African Americans with hypertension and presumed nephrosclerosis, with GFR between 20 and 63 mL/min/1.73 m². Subjects were randomized to a usual (102–107 mm Hg) or low (92 mm Hg) mean BP goal and to one of three antihypertensive agents as preferred therapy: the β -blocker metoprolol, the ACE inhibitor ramipril, or amlodipine. Additional agents were used to attain the target BP. The primary endpoint of the study was the rate of change in GFR. The amlodipine intervention was discontinued prematurely because of an apparent increase in the rate of decline of the GFR in proteinuric patients randomized to this group. A final analysis failed to confirm a significant difference in the rate of

decline in GFR. However, significantly more subjects assigned to the amlodipine group had a reduction in GFR of at least 50%, developed ESRD, or died during the study compared to the subjects assigned to ramipril, and the risk of development of new-onset glucose intolerance was more common in subjects assigned to amlodipine.⁴⁰ There were no significant differences in the rate of decline in GFR between those randomly assigned to the ACE inhibitor or the β -blocker, or between those randomized to the normal or low BP goal.

In the Irbesartan Diabetic Nephropathy Trial (IDNT), Lewis and colleagues examined the BP-independent capacity of the angiotensin receptor blocker irbesartan and amlodipine to slow progression of kidney disease in patients with type 2 diabetes mellitus and nephropathy.¹⁹ Subjects were randomly assigned to receive irbesartan, amlodipine, or placebo, and BP was treated aggressively in all groups to an average value of 142/77 mm Hg. The risk of reaching the primary endpoint (doubling of serum creatinine, development of ESRD, or death) was reduced by 23% in patients receiving irbesartan compared to those receiving amlodipine or placebo. Primary outcomes were not significantly different in patients receiving amlodipine and placebo (the “placebo arm” were receiving diuretics, β -blockers, and other agents and had similar BPs as the other groups). The risk of doubling of serum creatinine was 37% lower in the irbesartan group, whose urine protein excretion was also substantially lower.

Studies in Which Calcium Channel Blockers Were Combined with Blockers of the Renin-Angiotensin-Aldosterone System to Prevent Progression of Kidney Disease

Bakris and colleagues⁴¹ randomly assigned 37 patients with hypertension and diabetic nephropathy to receive the ACE inhibitor trandolapril, the CCB verapamil, or both drugs in combination. Blood pressure was reduced in all three groups to less than 140/90 mm Hg; virtually all patients needed the addition of a diuretic to achieve this goal. Protein excretion was reduced somewhat in the verapamil group and to a greater extent in the trandolapril group, but to the greatest extent (a drop of 62%) in the group receiving combination therapy.

The Ramipril Efficacy in Nephropathy (REIN) Study⁴² randomized patients with nondiabetic CKD (GFR 20–70 mL/min, >1 g proteinuria/24 hr) to either the ACE inhibitor ramipril or to placebo. Antihypertensive agents, including CCBs, were given to lower the diastolic BP to less than 90 mm Hg. Patients randomly assigned to ramipril had significant decreases in proteinuria and in the rate of decrease of GFR. In a subsequent report Ruggenenti and colleagues described a subset of 117 patients in the study given CCBs.⁴³ Subjects in the placebo group (not receiving an ACE inhibitor) who received a CCB had an increase in protein excretion and a more rapid decline in the GFR. However, if the BP was well controlled or if the patients received an ACE inhibitor, proteinuria declined and renal progression was slowed.

A similar outcome was observed in patients with type 2 diabetes mellitus in the Reduction of Endpoints in NIDDM (RENAAL) trial,⁴⁴ which enrolled 1500 patients with type 2 diabetes and nephropathy and randomly assigned them to receive the angiotensin receptor blocker losartan or placebo; BP was treated to a goal BP of 140/90 mm Hg or less; subjects

received other antihypertensive agents to achieve this goal. Losartan administration reduced the number of patients who doubled their serum creatinine level or reached ESRD, compared to the patients who received placebo. More than 85% of patients in both arms received CCBs, and more than 60%

received dihydropyridine CCBs. This study showed that simultaneous therapy with CCBs does not detract from the beneficial effects of losartan.

Table 53-3 summarizes clinical trials examining the effects of CCBs on the progression of CKD.

Table 53-3 Summary of Long-term Randomized Clinical Trials Examining the Effects of Calcium Channel Blockers on Progression of Chronic Kidney Disease

Ref.	Renal Disease	Patients (N)	Duration	Drugs	Effect on Proteinuria	Effect on GFR Decline
ABCD ¹²	Hypertensive NIDDM	470	5 yr	Nisoldipine vs. enalapril	No change	Stable in patients with microalbuminuria Annual rate of decline 5–6 mL/min in patients with overt albuminuria
ALLHAT ¹⁵	Hypertensives with serum creatinine < 2.0 mg/dL	33,357	6 yr	Amlodipine vs. chlorthalidone vs. lisinopril	Not measured	No differences between groups in decline of GFR
IDNT ¹⁹	NIDDM with nephropathy	1715	2.6 yr	Amlodipine vs. irbesartan vs. placebo	Declined by 6%, similar to placebo, inferior to losartan	Decline similar to placebo, inferior to irbesartan
BENEDICT ³⁴	Hypertensives with normal GFR	1204	3.6 yr	Verapamil vs. trandolapril vs. combination	Lower rate of microalbuminuria in trandolapril groups	Not measured
Zucchelli et al ³⁶	Nondiabetic	121	3 yr	Nifedipine vs. captopril	Declined if MAP < 100 mm Hg	50% reduction in rate of decline compared to baseline
Velussi et al ³⁷	NIDDM	44	3 yr	Amlodipine vs. cilazapril	Declined	Annual rate of decline 2 mL/min
Bakris et al ³⁸	Hypertensive NIDDM	52	63 mo	Diltiazem or verapamil vs. lisinopril vs. atenolol	Decreased	Annual rate of decline 1.44 mL/min on CCBs
AASK ⁴⁰	African-Americans with hypertensive nephrosclerosis	653	3 yr	Amlodipine vs. ramipril	Increased	Annual rate of decline 3.22 mL/min for all Faster with baseline proteinuria or GFR < 40 mL/min
Bakris ⁴¹	NIDDM with nephropathy	37	1 yr	Verapamil vs. trandolapril vs. combination	Declined by 27% on verapamil alone, 62% on combination therapy	GFR unchanged
REIN ⁴³	Nondiabetic nephropathies	117	18 mo	Various dihydropyridines ± ramipril	Increased by 20%, but not in patients on ACE inhibitor and good BP control	30% faster than non-CCBs, but not in patients on ACE inhibitors with good BP control
RENAAL ⁴⁴	NIDDM with nephropathy	1513	3.4 yr	Various CCBs ± losartan	No adverse impact on beneficial response to ARB	No adverse impact on beneficial response to ARB

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blockers; BP, blood pressure; CCBs, calcium channel blockers; GFR, glomerular filtration rate; MAP, mean arterial pressure; NIDDM, non-insulin-dependent diabetes mellitus.

USE IN END-STAGE RENAL DISEASE AND RENAL TRANSPLANTATION

Hypertension is prevalent in ESRD requiring dialysis. More than 70% of these patients receive antihypertensive therapy.⁴⁵ See Chapter 60 for a detailed discussion of therapy of dialysis-associated hypertension. CCBs are commonly used in this population because of the lack of efficacy of diuretics as urine output declines, as well as the toxicity of angiotensin-aldosterone blockers as renal function declines and hyperkalemia becomes problematic. The United States Renal Data System (USRDS) Dialysis Morbidity and Mortality Study (DMMS) Wave 2 reported that CCBs were by far the most commonly prescribed class of antihypertensive agent in a cohort of almost 3000 hemodialysis patients.⁴⁶ Of these, 54% were prescribed a dihydropyridine agent and 18% a nondihydropyridine agent; CCBs were used more than twice as often as ACE inhibitors, which were the next most commonly used drug class.⁴⁶ In a survey from 2003, CCBs were used in 61% of patients; they were still the most common class of antihypertensive agent used.⁴⁷

Very little data is available on cardiovascular outcomes in patients prescribed one or another class of antihypertensive agent, and such data that exists is observational or retrospective. In the USRDS DMMS study, the use of both dihydropyridine and nondihydropyridine CCBs was associated with a lower risk of all-cause mortality and cardiovascular mortality.²¹ This conflicts with the findings of an earlier study,⁴⁸ which observed that hemodialysis patients prescribed β -blockers had a mortality advantage over those prescribed CCBs. In contradiction, Kestenbaum and colleagues⁴⁹ reported that the prescription of a CCB in a prospective cohort study of 4000 hemodialysis patients was associated with decreased overall and cardiovascular mortality, even when adjusted for other comorbidities. In this study, 25% of patients used ACE inhibitors and none used angiotensin receptor blockers. Kestenbaum's observations were confirmed in a smaller prospective observational study of 188 hemodialysis patients; patients taking CCBs had a significantly lower mortality rate after adjustment for age and smoking status.⁵⁰ In the Dialysis Outcomes and Practice Patterns Study (DOPPS), in 2500 U.S. patients with arteriovenous grafts and fistulae for dialysis access, the use of CCBs for hypertension was associated with an improved arteriovenous graft patency rate.⁴⁷

The dose of dihydropyridine CCBs does not need to be changed in patients with chronic kidney failure or those treated with dialysis. Although the recommended dose of nondihydropyridine agents is also unchanged in chronic kidney failure,² there have been case reports^{3,4} of dangerous junctional bradycardias in patients with ESRD treated with long-acting verapamil.

Hypertension complicating renal transplant is discussed in Chapter 59. Many centers avoid renin-angiotensin-aldosterone blockers out of concern that they may exacerbate azotemia with concomitant calcineurin inhibitor therapy and may delay a diagnosis of rejection if azotemia is attributed to their use. Consequently, CCBs are widely prescribed. In a series of more than 600 hypertensive renal transplant recipients, CCBs were prescribed to more than 40% of subjects.⁵¹

In the 1990s, when cyclosporine-based immunosuppression was used extensively, CCBs, especially dihydropyridines, were recommended as the agents of choice in renal transplant

patients because of their ability to reverse cyclosporine-induced vasoconstriction.⁵² Calcium channel blockers also were reputed to be mildly immunosuppressive, because of the relationship between intracellular calcium levels and T cell activation. In a study over a 2-year period of 154 renal transplant recipients receiving cyclosporine who were randomly assigned to receive nifedipine or the ACE inhibitor lisinopril, patients treated with nifedipine had BPs equal to those treated with lisinopril, but a lower serum creatinine level. It is possible that the worse renal function in the lisinopril group was due to renal hemodynamic effects.⁵³ A meta-analysis of 21 studies showed no clear evidence that CCBs had independent effects on preventing renal transplant rejection.⁵⁴ However, a report of an observational cohort of more than 600 hypertensive renal transplant recipients concluded that patients prescribed a CCB for hypertension had a reduced renal graft survival and a higher mortality.⁵¹ In a recent study of 60 renal transplant patients prospectively randomized to amlodipine or the angiotensin receptor blocker losartan,⁵⁵ BP control and renal function were equivalent at 1 year after transplant. This study reported that amlodipine use was often associated with edema.

The controversy over whether renin-angiotensin-aldosterone blockers or CCBs are optimal for transplant hypertension may have been resolved by a study of 200 French renal transplant recipients randomly assigned to amlodipine, the ACE inhibitor enalapril, or a combination of enalapril and amlodipine.⁵⁶ There was a higher degree of BP control in the combination group. The creatinine clearance was lowest in the enalapril group and was unchanged in the combination group, suggesting that amlodipine mitigated adverse renal hemodynamic changes due to the ACE inhibitor. This study suggests that combination therapy with a CCB may be ideal for this population.

Dihydropyridine CCBs have no significant drug interactions with immunosuppressive agents used in renal transplantation. Verapamil and diltiazem decrease the clearance of cyclosporine and, to a lesser extent, tacrolimus and may contribute to high plasma levels of cyclosporine and tacrolimus unless the dose is decreased.²

SAFETY

Short-acting CCBs were anecdotally linked to a number of serious acute cardiovascular morbid events beginning in the 1980s. This was especially true for nifedipine administered sublingually for severe hypertension, perhaps because of reflex activation of the adrenergic system induced by sudden changes in BP. The use of short-acting CCBs for the treatment of hypertension is not recommended and has largely been abandoned.³⁰ In addition, a series of observational studies has described an increased risk of cardiovascular morbidity associated with the use of CCBs; for example, the Nurses Health Study of more than 14,000 women reported that those taking a CCB had an increased risk of death or MI.⁵⁷ A meta-analysis of 16 observational trials noted a dose-dependent link between nifedipine and cardiovascular mortality. Most of these studies included a large group of heterogeneous patients, and the choice of antihypertensive agent was not controlled. Differences in patient characteristics may explain the different outcomes. For example, in the Nurses Health Study, CCBs were more likely to be used in women with underlying heart disease. In addition,

a number of studies did not differentiate between long-acting and the more risky short-acting CCBs.

A few population-based studies in the 1990s reported a higher risk of cancer and gastrointestinal bleeding in patients taking CCBs.^{58,59} However, this observation was subsequently refuted by other observational studies, and a subcommittee of the World Health Organization and the International Society of Hypertension that formally reviewed the issue found no relationship between the use of CCBs and the risk of cancer or bleeding.⁶⁰

Calcium channel blockers generally are not associated with drug-drug interactions, aside from the obvious ones—for example, hypotension when combined with another antihypertensive agent or AV nodal dysfunction when diltiazem or verapamil are combined with a β -blocker or digoxin. An important exception is with the nondihydropyridine agents verapamil and diltiazem, which inhibit hepatic oxidation of statins, cyclosporine, carbamazepine, and quinidine, thereby increasing their blood levels.²

Most adverse effects associated with CCBs are relatively minor. They include dose-dependent dizziness, hypotension, and tachycardia with dihydropyridines and bradycardia and AV nodal dysfunction with nondihydropyridines. The most common side effect is peripheral edema, which is attributed to greater arteriolar than venular dilation that increases intracapillary pressure.⁶¹ More common with dihydropyridines, this effect is dose dependent,⁶¹ and is reduced if the treatment is combined with an ACE inhibitor.⁶² Symptoms of gastrointestinal reflux and constipation² are more common with CCB use.

CONCLUSIONS

Calcium channel blockers are effective and generally well tolerated antihypertensive agents. Their long duration of action and favorable adverse effect profile are benefits, and they are very widely prescribed. In observational studies, 30% to 40% of patients with hypertension are prescribed a CCB,⁶³ and the prevalence of their use is increasing.⁶⁴

When used as monotherapy, CCBs seem to be equal or superior to agents of other classes in decreasing BP. Although data is not completely consistent, when used as monotherapy, they are no better, and may be worse, than alternative agents, especially β -blockers, ACE inhibitors, and diuretics, in decreasing cardiovascular morbidity and mortality, with the possible exception of the beneficial effect of dihydropyridine agents on decreasing the risk of stroke. However, they do effectively decrease cardiovascular morbidity when used in combination with other agents, such as ACE inhibitors, while aggressive BP goals are targeted.

Calcium channel blockers as monotherapy probably do not increase the risk of developing renal disease in nondiabetic hypertensive subjects, but may be inferior to agents blocking the renin-angiotensin-aldosterone system, especially ACE inhibitors, in preventing the development of renal disease in diabetics. When used as initial therapy or as monotherapy, dihydropyridine CCBs seem to be inferior to ACE inhibitors and angiotensin receptor blockers in preventing progression of kidney disease, especially in diabetics. Most studies have been done with dihydropyridine CCBs. Data is scantier with nondihydropyridine CCBs, and it is possible that nondihydropyridine agents may be as protective as

renin-angiotensin-aldosterone blockers. When used in combination with ACE inhibitors or angiotensin receptor blockers, CCBs do not detract from the renal protective actions of these agents and might have an additive beneficial effect on decreasing the rate of progression of kidney disease if they further lower the BP.

Calcium channel blockers are widely used in patients with ESRD. There is evidence that they may be associated with a survival benefit, but most of this data comes from studies with low rates of use of ACE inhibitors or angiotensin receptor blockers. CCBs are effective in renal transplant recipients as antihypertensive agents, especially with the concomitant use of cyclosporine. They do not seem to have an independent effect on renal transplant function.

In summary, CCBs for patients with uncomplicated hypertension may be used as initial therapy or monotherapy, or added therapy to achieve a BP target of less than 140/90 mm Hg. They should not be used as initial therapy or monotherapy in patients at increased risk for cardiovascular disease, in those with renal disease or diabetes, or in those who are at risk for renal disease progression. They can be selected as second-, third-, or fourth-line agents to achieve a BP target of less than 130/80 mm Hg. Their widespread use continues because it is difficult to achieve a low BP target without them.

Individualization of Pharmacologic Therapy

Norman M. Kaplan

CHAPTER CONTENTS

COMPELLING INDICATIONS	620
AVOIDANCE OF DIABETES	620
THE FALL OF β -BLOCKERS	622

THE RISE OF ALDOSTERONE RECEPTOR BLOCKERS	622
CONCLUSION	622

All of the nondrug and drug therapies described in the preceding chapters can reduce the cardiovascular and renal consequences of hypertension.¹ Most, if not all, of this benefit derives from their ability to lower the blood pressure (BP).²

Faced with this large number of possible choices, what should the prudent practitioner do? In this age of evidence-based medicine, the number of choices can be reduced by deletion of modalities that have been shown to have no benefit (e.g., acupuncture) or that have not yet been tested for meaningful outcomes (e.g., direct renin inhibitors). Even so, there are many choices and they need to be carefully adapted to each patient. This is *individualized therapy*.

To be sure, all drugs approved for use in the treatment of hypertension will, in moderate doses, lower elevated BP by approximately 10% in about two thirds of patients. This uniformity of response is inherent in the approval process: Each drug must have been shown to lower BP significantly when compared to placebo and to have an efficacy equal to other antihypertensive drugs. Doses are chosen to provide significant but not excessive lowering of BP so that patients will tolerate them and achieve a demonstrable effect.

When comparisons between various antihypertensive drugs are made, they almost always demonstrate similar antihypertensive efficacy.³ However, individual patients show considerable differences in their response to one drug or another. Some of this variability can be accounted for by patient characteristics, including age and race, which in turn could be mediated by differences in activity of the renin-angiotensin system. In a Veterans Administration cooperative 1-year trial, 1292 men were randomly given one of six drugs from each major class; overall, and in the black patients, the calcium channel blocker (CCB) was most effective, but the angiotensin-converting enzyme (ACE) inhibitor was best in younger whites.⁴ Similarly, in a randomized, crossover trial of elderly patients with isolated systolic hypertension given a representative of four major classes (ACE inhibitor, β -blocker, CCB, and diuretic) each for 1 month, diuretics or CCBs were more effective than β -blockers or ACE inhibitors.⁵ In a similarly designed trial of younger patients with combined systolic and diastolic hypertension, the ACE inhibitor or β -blocker was more effective than the CCB or diuretic.⁶

A general pattern emerges from these various comparative trials.⁷ Younger and white patients, who have higher renin levels, respond better to drugs that work in large part by blocking

the renin-angiotensin system. Conversely, older and black patients, who tend to have lower renin levels, respond better to diuretics and CCBs, which work in ways independent of initial renin levels. As portrayed in the algorithm presented by the British Hypertension Society (Fig. 54-1),⁸ this separation can be used to decide on the first choice. However, the U.S. Seventh Joint National Committee algorithm recommends a low-dose thiazide diuretic for initial therapy for almost all patients.⁹

In clinical practice, the decision for first drug is less relevant now that two or more drugs are generally used to adequately control BP in most patients to below 140/90 mm Hg.^{10,11} This is even more the case for higher-risk patients, including those with diabetes or chronic renal disease who have been found to do better with BP below 130/80 mm Hg.¹

Fortunately all members of the major classes of drugs except CCBs are marketed with a low-dose thiazide diuretic. Therefore, the choice could easily be the diuretic first, followed by a combination of a diuretic plus a renin-angiotensin inhibitor (i.e., β -blocker, ACE inhibitor, or angiotensin receptor blocker [ARB]).

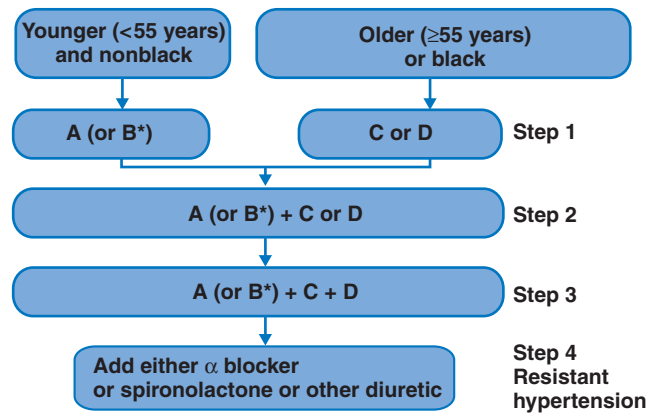

Combinations of a CCB, in particular the now generic amlodipine, with either an ACE inhibitor or an ARB will become more widely marketed and may logically be used, along with a diuretic, for the third level of therapy.

COMPELLING INDICATIONS

Most hypertensive patients have one or more coexisting conditions for which one class of antihypertensive drugs is either indicated or contraindicated (Table 54-1). Even though overall and cardiovascular mortality is similar with equal degrees of BP reduction by any drug, it is logical to choose an antihypertensive agent that has been shown to also improve a coexisting condition. Examples that have been strongly documented include β -blockers and ACE inhibitors post-myocardial infarction¹² and either ACE inhibitors or ARBs with heavy proteinuria.¹³

AVOIDANCE OF DIABETES

As obesity grows, the need to avoid diabetes increases. Antihypertensives differ in their propensity to provoke diabetes.¹⁴ High doses of diuretic and β -blockers are the worst; ACE

A: ACE inhibitor or angiotensin receptor blocker
 B: β blocker
 C: Calcium channel blocker
 D: Diuretic (thiazide and thiazide-like)

*Combination therapy involving B and D may induce more new onset diabetes compared with other combination therapies

Figure 54-1 An algorithm for initial and subsequent choices of antihypertensive therapy. (Modified from Williams B, Poulter NR, Brown MJ, et al: British Hypertension Society guidelines for hypertension management, 2004 [BHS-IV]: Summary. *BMJ* 2004;238:634–640.)

Table 54-1 Guidelines for Selecting Drug Treatment of Hypertension

Class of Drug	Compelling Indications	Possible Indications	Compelling Contraindications	Possible Contraindications
Diuretics	Heart failure Elderly patients Systolic hypertension	Diabetes	Gout	Dyslipidemia
β -Blockers	Angina After myocardial infarction Tachyarrhythmias	Heart failure Pregnancy Diabetes	Asthma and COPD Heart block	Dyslipidemia Athletes and physically active patients Peripheral vascular disease
ACE inhibitors or angiotensin receptor blockers	Heart failure Left ventricular dysfunction After myocardial infarction Diabetic nephropathy		Pregnancy Hyperkalemia Bilateral renal artery stenosis	
Calcium channel blockers	Angina Elderly patients Systolic hypertension	Peripheral vascular disease	Heart block	Congestive heart failure
α -Blockers	Prostatic hypertrophy	Glucose intolerance Dyslipidemia		Orthostatic hypotension

From Guidelines Subcommittee: 1999 World Health Organization—International Society of Hypertension guidelines for the management of hypertension. *J Hypertens* 1999;17:151.

inhibitors and ARBs are the best. Part of the difference may relate to the length of time that patients have been exposed to the metabolic influences of the various agents. However, there is a measurable influence of the various agents on insulin sensitivity, so these differences are almost certainly real. Therefore, an obese patient with a family history of diabetes and a

borderline elevated blood sugar level should be given an ACE inhibitor or an ARB.

If the results of two ongoing trials comparing the ARB telmisartan to an ACE inhibitor confirm the experimental and limited clinical evidence of this drug's significant PPAR gamma agonist activity, telmisartan may become the ARB of choice.¹⁵

THE FALL OF β -BLOCKERS

A meta-analysis on the degree of *primary* prevention of heart attacks and stroke by the various classes of antihypertensives¹⁶ corroborates a previous warning about the lesser effectiveness of β -blockers.¹⁷ The degree of protection against heart attack was the same with β -blockers as with other drugs, but there was a 16% higher incidence of stroke with β -blockers.

This lesser protection against stroke has been attributed to a lesser fall in central BP with β -blockers despite equal efficacy on peripheral BP. The adverse effects on lipids and insulin sensitivity may also be involved.

β -Blockers are vital for *secondary* protection, but they should not be used in the absence of a compelling indication (see Table 54-1).

THE RISE OF ALDOSTERONE RECEPTOR BLOCKERS

In the British Hypertension Society algorithm (see Fig. 54-1), spironolactone is shown as a fourth choice, to be added to those who are not controlled on three drugs.⁸ This later positioning may rapidly change as the efficacy and safety of low doses of spironolactone are increasingly recognized.¹⁸ In the study by Chapman and colleagues,¹⁸ as well as in most other recently published studies, spironolactone has been used primarily in resistant patients. However, there is a good reason to use it much earlier, particularly since a potassium-sparing agent is useful to prevent diuretic-induced potassium wastage, which, in turn, has been closely correlated with worsening of glucose tolerance.¹⁹

Both currently available aldosterone antagonists, spironolactone and eplerenone, are now generic. This will save the patient money but will prevent effective marketing of the agents by pharmaceutical companies, so physicians may not use them as often as they should. When an aldosterone antagonist is added to an ACE inhibitor or ARB in patients with any degree of renal impairment, close monitoring of serum potassium is needed to identify hyperkalemia.

CONCLUSION

More than 50 years after the advent of effective oral antihypertensive drugs, more choices are available, but they are often not provided in the most effective and least bothersome manner. The principles of individualization reviewed in this chapter should be useful guidelines to do better.

CONCLUSIONS	633

The term *hypertensive emergency* covers many clinical situations, with the degree of urgency determined by either the severity or acuteness of onset of blood pressure (BP) elevation or the presence of a critical underlying medical condition (e.g., acute aortic dissection) when even modest degrees of BP elevation may require immediate treatment.

True hypertensive "emergencies" (Box 55-1) require lowering of BP within minutes. The drug employed should act immediately and be predictably effective. In contrast, more gradual lowering of BP, over 30 minutes to hours, is appropriate in treating medical "urgencies" (Box 55-2). Rapidly acting drugs requiring intra-arterial monitoring are not necessary.

Rapid lowering of BP greatly increases the risk of unwanted adverse effects that can exceed benefits, particularly in the elderly and in patients in whom urgent treatment is not needed. Patients with severe, but asymptomatic, BP elevations usually do not require urgent therapy to lower BP.

NATURAL HISTORY OF UNTREATED SEVERE HYPERTENSION

Accelerated or Malignant Hypertension

The classic hypertensive crisis of accelerated or malignant hypertension is characterized by severe elevation of arterial pressure (usually with diastolic pressure > 140 mm Hg) and vascular

damage manifested by retinal hemorrhages and exudates.¹ The term accelerated signifies the absence, and malignant the presence, of papilledema. The pathogenesis, management, and prognosis of accelerated and malignant hypertension are similar.²

The syndrome usually occurs as an accelerated phase of preexisting hypertension.³ Severe and inadequately treated essential hypertension, particularly in smokers,² is the most common antecedent. Renovascular and renal parenchymal disorders, as well as primary hyperaldosteronism, are also associated with hypertensive crises.⁴

Why some individuals with hypertension proceed to an accelerated phase is not clear. A vicious cycle has been postulated whereby vascular damage from severe hypertension causes renal ischemia, which stimulates renin secretion and angiotensin-mediated vasoconstriction, which in turn worsens renal ischemia and further activates the renin-angiotensin system.³ Elevations of plasma renin activity and serum aldosterone concentration are commonly found. Moreover, angiotensin-converting enzyme (ACE) inhibitors usually lower BP.²

Hypertensive Encephalopathy

Hypertensive encephalopathy is characterized by a reversible alteration in neurological function during a severe or abrupt BP elevation. Manifestations include headache, altered mental status, visual impairment, nausea, and seizures.⁵ Focal neurological signs can occur.⁵ Although frequently a complication of

 Scleroderma renal crisis

malignant hypertension, hypertensive encephalopathy can result from an acute, albeit less severe, BP elevation from other causes, such as acute glomerulonephritis, preeclampsia, clonidine withdrawal, cocaine, or monoamine oxidase (MAO) inhibitor/tyramine interaction. The risk of encephalopathy or hemorrhage may be present at relatively modest BP elevation in patients without preexisting hypertension who lack protective vascular thickening.

Encephalopathy is ascribed by some to cerebral ischemia as a result of luminal narrowing and spasm² and even occlusion⁵ and by others to a breakdown (or failure) of autoregulation at high systemic pressures, leading to localized hyperperfusion and edema.^{5,6} Cerebral edema is a constant finding.² Pathologic findings suggest that both may occur because patients can have cerebral microinfarctions, petechial hemorrhages, and edema.²

Magnetic resonance imaging or computed tomography of the brains of patients with hypertensive encephalopathy show white matter edema in the posterior regions of the cerebral hemispheres, brain stem, or cerebellum.⁷ This disorder, named *reversible posterior leukoencephalopathy*, can occur without severe BP elevation.⁸ It has been associated with preeclampsia, hemolytic uremic syndrome, and drugs such as erythropoietin, tacrolimus, and interferon- α .⁸ It requires urgent BP lowering. Radiologic recovery occurs within days; complete clinical recovery, within weeks.

TREATMENT OF HYPERTENSIVE EMERGENCIES

General Considerations

Two initial decisions that must be made are how quickly and by how much to lower BP. Normalization of BP can cause

complications that are sometimes irreversible, particularly in patients with cerebrovascular or coronary artery disease. Unintended hypotension exaggerates this risk. Therefore, rapid normalization of BP should not generally be the goal of acute management.

The choice of antihypertensive agents should take into consideration the following factors.

Age

Elderly patients are at greater risk for adverse effects of acute BP lowering. Known or occult coronary and cerebrovascular disease, together with reduced autoregulatory capacity, predispose to hypoperfusion as BP is lowered. Often an increased sensitivity to the pharmacologic effect of drugs is present; this should prompt the use of lower doses, selection of a higher target BP, and careful monitoring in elderly patients.

Volume Status

Severe hypertension, particularly in the malignant phase, is often accompanied by vasoconstriction that reduces the intravascular volume.^{2,9} This volume constriction may be exaggerated by nausea, vomiting, reduced oral intake, or prior use of diuretics. Potent vasodilators can cause a precipitous fall in BP in patients with reduced vascular volume that may require 1 to 2 L of crystalloid infusion initially. Therefore, diuretics should usually be withheld until sodium retention induced by administration of a vasodilator is evident. In contrast, patients with volume overload, such as hypertension associated with left ventricular failure, renal parenchymal disease, acute glomerulonephritis, or iatrogenic volume overload, require diuretics.

Concurrent Antihypertensive Treatment

Antihypertensive medications taken before presentation may have blocked compensatory mechanisms sufficiently to lead to a drastic reduction in BP in response to the drug given acutely. Therefore, short-acting parenteral drugs should be considered.

Duration of Hypertension

Autoregulation of cerebral blood flow is impaired in chronic hypertension.¹⁰ Therefore, rapid normalization of BP can produce cerebral ischemia. Localized areas of ischemia may occur in malignant hypertension. Thus, cerebral ischemia can occur at a BP level that is close to normal, even in the absence of large-vessel cerebrovascular disease.

Underlying Medical Conditions

As described in *Drugs for Hypertensive Emergencies* in this chapter, central nervous system depressant drugs such as clonidine, methyldopa, and reserpine should be avoided in patients requiring neurological monitoring. Drugs that increase myocardial oxygen consumption or cardiac contractility should be avoided in patients with myocardial ischemia or dissecting aortic aneurysm. Other specific examples are considered later in this chapter.

Oral Versus Parenteral Agents

Oral agents are not always safer than those administered parenterally. Oral captopril and short-acting nifedipine can lower BP precipitously, whereas agents with short

half-lives that are infused intravenously can be titrated more accurately.

Predictability of Response

A universally effective agent should be employed in true emergencies. Intravenous nitroprusside and labetalol are more predictably effective than enalaprilat, which is effective in only about 60% of hypertensive urgencies.^{11,12} An ACE inhibitor seems better suited in hypertensive urgencies, in which the initial BP response can help to predict the response to subsequent treatment with an oral ACE inhibitor or an angiotensin receptor blocker (ARB). ACE inhibitors have a unique therapeutic advantage in hypertensive urgencies associated with congestive heart failure.

Cost

Treatment with oral labetalol, captopril, or other agents that do not require intra-arterial monitoring in an intensive care unit reduces costs. Agents such as nitroprusside should be reserved for true emergencies.

Drugs for Hypertensive Emergencies

Drugs for the treatment of hypertensive emergencies are outlined in Table 55-1.

Sodium Nitroprusside

Sodium nitroprusside provides rapid onset and offset of action, ease of titration, and almost universal effectiveness. It is an arterial and venous dilator that reduces myocardial oxygen requirement and is highly suitable for patients with coronary artery disease. Adverse effects are attributed to both the rapidity of BP lowering and toxic effects. The risk of unintended hypotension mandates intra-arterial monitoring in an intensive care unit. Computer-controlled infusion facilitates BP control.¹³

Thiocyanate toxicity causes blurred vision, tinnitus, confusion, and seizures. It occurs only rarely at infusion rates below 3 $\mu\text{g}/\text{kg}/\text{min}$ for up to 72 hours, except in patients with renal insufficiency. Blood thiocyanate levels should be monitored during high-dose or prolonged treatment. Cyanide accumulation can occur when the infusion rate is above 2 $\mu\text{g}/\text{kg}/\text{min}$, and concern about undiagnosed and hazardous cyanide toxicity has been raised.¹⁴ Thiosulfate infusion (150–200 mg/kg over 15 minutes) can prevent or treat cyanide toxicity.^{15,16} However, because the frequency of cyanide toxicity is unclear and because thiosulfate infusion can cause thiocyanate accumulation, particularly in patients with reduced renal function, the use of prophylactic thiosulfate infusion remains controversial.

Labetalol

Labetalol, a combination α - and β -receptor blocker, is usually effective, can be given intravenously for a rapid onset, has a sustained effect, is of low toxicity, and does not require intra-arterial monitoring. However, the use of large initial boluses (1–2 mg/kg) has been associated with precipitous falls in BP.² An initial bolus of 10 to 20 mg or an infusion of 1 to 2 mg/min can lower blood pressure within 15 minutes.² If an initial bolus does not lower blood pressure, repeat boluses of 20 to 40 mg can be administered at 10-minute intervals, up to a maximum cumulative dose of 300 mg.

Labetalol reduces peripheral resistance without reflex stimulation of cardiac output. Because of its β -blocking effect, it can cause deterioration in patients with preexisting left ventricular dysfunction.² It is useful in the treatment of hyperadrenergic states, including hypertension after coronary artery bypass graft (CABG), and clonidine withdrawal.² However, in patients with pheochromocytoma, it is generally preferable to first establish α -blockade and then add a β -blocker because of the risk of a paradoxical pressor response associated with β -blockade.

Diazoxide

Diazoxide is an arterial vasodilator. It fell into disfavor because of reports of precipitous falls in BP resulting in cerebral and coronary complications after administration of 300 mg as a rapid bolus.² However, the use of repeated smaller (e.g., 50 mg) boluses or a continuous infusion appears safer.²

Diazoxide is almost universally effective. Its sustained effect obviates the need for minute-to-minute monitoring once BP reduction has been achieved. A precipitous fall in BP is unlikely to occur beyond 5 minutes after administration, enabling repeated boluses to be given as frequently as every 5 to 10 minutes.² The sustained action is undesirable when BP lowering may cause clinical deterioration.

Because of reflex increases in cardiac rate, contractility, and output, diazoxide should not be used in patients with coronary disease or dissecting aneurysm. Adjunctive treatment with a diuretic and sympatholytic agent is generally required. The drug may cause hyperglycemia by inhibiting insulin release. Monitoring of blood glucose is advisable.²

Nitroglycerin

Intravenous nitroglycerin reduces BP, afterload, left ventricular filling pressures, and myocardial oxygen consumption. For an equivalent degree of BP reduction, it reduces myocardial oxygen consumption more and preserves coronary perfusion better than nitroprusside. Thus, it is favored for coronary insufficiency.¹⁶ It is also suitable in treating perioperative hypertension, including that following CABG.¹⁶ Nitroprusside is more effective in patients with severe hypertension.

Phentolamine

Phentolamine is a nonselective α -adrenergic blocker. It is most effective in situations of catecholamine excess, such as pheochromocytoma. It can be useful in diagnosing a pheochromocytoma but can lower BP precipitously. A test dose of 0.5 to 1 mg infused in 1 minute is generally advised, followed by infusion at 1 mg/min or more. The absence of a dramatic response virtually rules out the diagnosis.

Trimethaphan Camsylate

Trimethaphan is a rapidly acting, titratable, ganglionic blocking agent. It is rarely used because of adverse effects resulting from autonomic blockade and rare unpredictable reactions that include respiratory arrest. Because it impairs pupillary reflexes, it is contraindicated in patients requiring neurological monitoring. Its use requires intra-arterial monitoring of BP in an intensive care unit. It is more difficult to achieve stable BP with trimethaphan than with nitroprusside.

Its use has been generally limited to the following special situations: (1) hypertension associated with dissecting aortic aneurysm, for which blockade of a sympathetically mediated increase in ejection velocity is advantageous; (2) nitroprusside

Table 55-1 Drugs for the Treatment of Hypertensive Emergencies or Urgencies

	Method of Administration	Dosage Range	Precautions and Initial Dose or Interval	Onset	Duration	Adverse Effects
Direct Vasodilators						
Sodium nitroprusside*	IV infusion	0.3–0.5 $\mu\text{g}/\text{kg}/\text{min}$	0.5–10 $\mu\text{g}/\text{kg}/\text{min}$	Immediate	2–3 min	Shield infusate from light Thionate toxicity
Diazoxide	IV bolus	50–100 mg	50–100 mg at 5- to 10-min intervals to maximum 600 mg	1–2 min	3–15 hr	Hypotension: hyperglycemia, fluid retention, reflex tachycardia
Hydralazine	IV infusion IV bolus IM	10 mg/min 10 mg 10–25 mg	10–30 min 10–50 mg at 10- to 20-min intervals 10–50 mg at 20- to 30-min intervals	5–10 min 10–20 min	2–6 hr 2–6 hr	Reflex tachycardia
Nitroglycerin	IV infusion	5 $\mu\text{g}/\text{min}$	5–100 $\mu\text{g}/\text{min}$	2–3 min	3–5 min	Tachyphylaxis
ACE Inhibitors						
Captopril	Oral	6.25–50 mg	12.5–50 mg at 30- to 45-min intervals	10–15 min	2–6 hr	Hypotension; renal failure (if bilateral renal artery stenosis)
Enalaprilat	IV bolus	0.625 mg	0.625–2.5 mg	10–15 min	2–6 hr	Hypotension; renal failure (if bilateral renal artery stenosis)
Dopamine Antagonist						
Fenoldopam	IV infusion	0.03–0.1 $\mu\text{g}/\text{kg}/\text{min}$	0.1–1.6 $\mu\text{g}/\text{kg}/\text{min}$	5 min	15 min	Increased intraocular pressure

Continued

Table 55-1 Drugs for the Treatment of Hypertensive Emergencies or Urgencies—cont'd

	Method of Administration	Dosage Range	Precautions and Initial Dose or Interval	Onset	Duration	Adverse Effects
α-Adrenergic Blockers						
Phentolamine	IV infusion	0.5–1 mg bolus or 1 mg/min	1–5 mg/min	1–2 min	15–60 min	Hypotension; tachycardia
Labetalol	IV bolus IV infusion	10–20 mg 0.5 mg/min	20–80 mg at 5- to 10-min intervals 0.5–2 mg/min	5 min 5–30 min	2–6 hr 2–6 hr	Hypotension
Prazosin	Oral	1 mg	1–2 mg at 1-hr intervals	15–60 min	2–6 hr	Hypotension
Calcium Channel Blocker						
Nicardipine	IV infusion	5 mg/hr	5–15 mg/hr	5–20 min	1–4 hr	Tachycardia, headache
Ganglionic Blocker						
Trimethaphan	IV infusion	0.5 mg/min	0.5–5 mg/min	1–5 min	5–10 min	Urine retention, ileus; respiratory arrest
Sympatholytic Agents						
Clonidine	Oral	0.1–0.2 mg	0.05–0.1 mg	1–2 hr	8–12 hr	Drowsiness
Methyldopa	IV	250 mg	250–500 mg at 4- to 8-hr intervals	1–2 hr	8–12 hr	Drowsiness

*Preferred drug for true emergency.

resistance or toxicity; and (3) absence of alternative effective therapy.

New Agents

Fenoldopam

Fenoldopam is a vasodilator, a dopamine (D₁) receptor agonist that increases cardiac output, heart rate, and renal sodium excretion and preserves glomerular filtration rate.^{17,18} Its antihypertensive effect is comparable to that of nitroprusside, but is slower in onset.¹⁷ The dose can be titrated every 15 minutes. In comparison to nitroprusside, fenoldopam offers the advantages of lack of toxicity, a lower likelihood of hypotension, and lack of need for intra-arterial BP monitoring or shielding of the infusion line from light.¹⁹

Fenoldopam can substitute for nitroprusside in most hypertensive urgencies. The most common adverse effects are headache and increase in heart rate.¹⁹ Because fenoldopam increases intraocular pressure, it is contraindicated in patients with glaucoma.

Urapidil

Urapidil is a combination α_1 -adrenergic blocker and central serotonin antagonist at 5HT_{1A} receptors that prevents reflex tachycardia.²⁰ Urapidil lowers BP in hypertensive urgencies, although the onset of effect and time to BP target is slower than with nitroprusside.²¹ It requires further study.

Drugs for Hypertensive Urgencies

ACE Inhibitors

Captopril is most effective in patients with an activated renin-angiotensin system, such as those with accelerated or malignant hypertension, scleroderma, and other forms of renal vasculitis.² The antihypertensive response is exacerbated by volume depletion,² which can lead to hypotension requiring aggressive intravenous fluid replacement. Conversely, the BP response is small or absent in volume-expanded patients. The acute BP response is usually predictive of the chronic response. Thus, nonresponders can be switched to a different class of drug (Fig. 55-1). Patients with elevated plasma renin activity are much more likely to respond than patients with lower renin activity.²² Enalaprilat is the bioactive form of the prodrug enalapril that acts within 5 minutes when given intravenously.²³ Doses higher than 0.625 mg increase the duration, but not the magnitude, of the initial response.^{9,23} However, because enalaprilat is not universally effective, it is generally not a preferred drug in the treatment of true emergencies.

Direct Vasodilators

Intravenous hydralazine has been used for rapid reduction of BP in urgent situations, particularly preeclampsia. However, in a true emergency, more universally effective agents are preferable. Minoxidil may be effective within 4 hours of oral administration at doses of 5 to 20 mg. However, marked sodium retention and tachycardia require the addition of a diuretic and adrenergic blocker and discourage its more widespread use. Sympathetically mediated increases in cardiac contractility and heart rate associated with both of these drugs contraindicate their use in patients with coronary insufficiency or dissecting aortic aneurysm. Isosorbide dinitrate, given either

by sublingual or aerosol route, is an alternative to intravenous agents.²⁴

Calcium Channel Blockers

Nifedipine

Short-acting nifedipine causes a rapid fall in BP that can cause coronary or cerebrovascular events, even at a “normal” BP.²⁵ Consequently, its use in hypertensive urgencies is no longer recommended, particularly in elderly patients and those with suspected coronary or cerebrovascular disease. Reflex sympathetic discharge and tachycardia are the basis for contraindications to its use in patients with coronary insufficiency or dissecting aortic aneurysm. The use of nondihydropyridine calcium channel blockers in hypertensive emergencies is less well studied.

Nicardipine

Nicardipine is a dihydropyridine calcium channel blocker. A continuous infusion of nicardipine requires fewer dose adjustments, is associated with fewer adverse effects, and appears equally effective to nitroprusside.^{26,27} The infusion rate can be increased at 5- to 15-minute intervals. The mean time to response is 12 minutes.²⁸ It is selective for vascular tissue and actually increases cardiac output.²⁸ It causes less headache and tachycardia than nitroprusside.²⁸

Adrenergic Blocking Agents

Labetalol

Intravenous labetalol can be used in hypertensive urgencies. Oral labetalol, at doses of 100 to 400 mg, can lower BP within 1 to 3 hours.² A second dose can be administered after 3 to 4 hours.

Other β -Receptor Blockers

Intravenous propranolol, metoprolol, and esmolol have little acute BP-lowering effect but minimize reflex cardiac stimulation. They are useful in combination with vasodilators such as nitroprusside, in patients with acute aortic dissection or coronary insufficiency, and in combination with phentolamine in patients with pheochromocytoma.

Sympatholytic Agents

Clonidine lowers BP with a maximal response within 2 to 4 hours and little risk of a precipitous fall. However, the acute response and dosage do not predict the long-term response. Prolonged treatment with clonidine causes bothersome adverse effects (i.e., drowsiness, dry mouth, impotence, and constipation).

MANAGEMENT OF SPECIFIC CONDITIONS

Table 55-2 lists recommended agents.

Accelerated or Malignant Hypertension

Unless complicated by encephalopathy, symptomatic coronary insufficiency, or severe congestive heart failure, malignant hypertension is a medical urgency that does not require intravenous drugs, such as nitroprusside. A target diastolic BP of 100 to 110 mm Hg or higher is recommended during the first 24 to 48 hours of treatment. When time allows, the

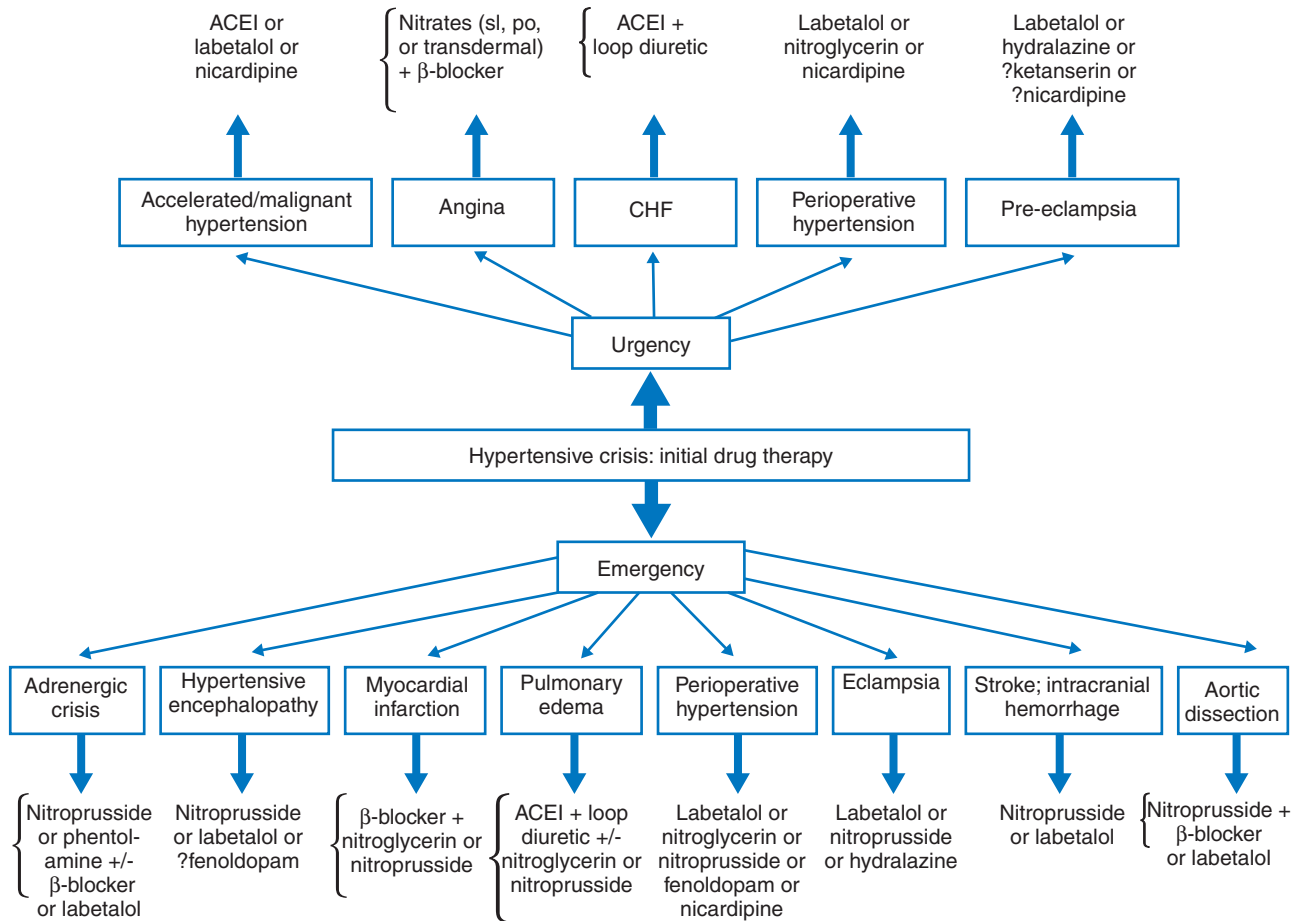

Figure 55-1 Algorithm for approach to treatment of hypertensive crises. ACE, angiotensin-converting enzyme.

response to a rapidly acting ACE inhibitor such as oral captopril or intravenous enalaprilat can provide useful diagnostic and therapeutic information. A different agent should be given if there is no response within 30 minutes.

Hypertensive Encephalopathy

The risk of imminent brain damage necessitates rapid lowering of BP. Treatment ameliorates the signs and symptoms of encephalopathy rapidly,⁵ but if BP falls below the autoregulatory limit, cerebral ischemia can worsen.²⁹ Therefore, drugs with a rapid offset of effect, such as nitroprusside, are recommended. If the neurological status deteriorates, the BP should be allowed to rise and other diagnoses, such as cerebrovascular accident, head injury, or other cerebral pathologic processes, should be considered as a contributory factor.

The mean BP in patients known to be hypertensive should generally be reduced during the first hour by a maximum of 20%, or to a diastolic BP of 100 to 110 mm Hg, although even higher target BPs may be advisable in selected patients. In previously normotensive patients, rapid normalization of BP is less hazardous.

Cerebrovascular Accident

Blood pressure elevation commonly accompanies thrombotic stroke.³⁰ Increased sympathetic tone and intracranial pressure may contribute. Whether BP elevation has the beneficial

effect of increasing flow through partially occluded, stenotic, or collateral vessels or a harmful effect by aggravating local edema formation is hotly debated.

Although there is agreement that mild BP elevation during an acute thrombotic stroke should not be treated, the need to treat acute and severe BP elevation is more controversial. An acute fall in BP might reduce cerebral blood flow and exacerbate the neurological deficit, particularly in the elderly, in which cerebral autoregulation is impaired. A recent meta-analysis of 32 trials concluded that there is still inadequate evidence to evaluate the effect of BP lowering on outcome.³¹ Recent guidelines for management of hypertension in acute stroke are presented in Table 55-3.³² Patients in whom thrombolytic therapy has been given or is being considered require intervention if systolic BP is higher than 180 mm Hg, or diastolic pressure is higher than 110 mm Hg.³²

Antihypertensive treatment in patients with hemorrhagic infarction after thrombotic stroke should follow the preceding guidelines. Stroke due to hypertensive hemorrhage may be treated more aggressively. However, this requires careful differentiation between hemorrhagic stroke and hemorrhagic infarction after thrombotic stroke.

Subarachnoid Hemorrhage

The best management of hypertension during subarachnoid hemorrhage is controversial. An abrupt reduction in BP might prevent rebleeding and reduce edema but could reduce cerebral

Table 55-2 Drugs of Choice

	Drugs	Relative Contraindications
Hypertensive encephalopathy	Nitroprusside, labetalol IV	Centrally acting sympatholytic agents
Malignant hypertension	ACE inhibitor, labetalol IV, clonidine, ? fenoldopam	
Hypertension associated with:		
Intracranial hemorrhage	Nitroprusside, labetalol IV	Diazoxide, nifedipine
Stroke	Nitroprusside, labetalol IV	Diazoxide, nifedipine
Left ventricular failure		
Pulmonary edema	ACE inhibitor + loop diuretic ± nitroprusside or nitroglycerin	β-Blocker, verapamil
Congestive heart failure	ACE inhibitor + loop diuretic	β-Blocker, verapamil
Coronary insufficiency		
Acute myocardial infarction	Nitroglycerin ± β-blocker Nitroprusside ± β-blocker	Diazoxide, hydralazine
Unstable angina	Nitrates (sublingual, oral, or transdermal) ± β-blocker, or as for myocardial infarction	Diazoxide, hydralazine
Adrenergic crisis	Nitroprusside, phentolamine ± β-blocker, ? IV labetalol	β-Blocker monotherapy
Dissecting aortic aneurysm	Nitroprusside + β-blocker; labetalol	Diazoxide, hydralazine, nifedipine
Perioperative hypertension	Nitroprusside, nitroglycerin, labetalol; fenoldopam, nicardipine	

Adapted from Mann SJ, Atlas SA: Hypertensive emergencies. In Laragh JH, Brenner BM (eds): Hypertension: Pathophysiology, Diagnosis and Management, 2nd ed. New York: Raven Press, 1995, pp 3009–3022.

perfusion, particularly in patients with chronic hypertension or increased intracranial pressure. Although mortality and re-bleeding are higher in patients presenting with a systolic pressure exceeding 160 mm Hg,³³ the effect of BP lowering on mortality is uncertain.

It seems reasonable to treat acutely and severely elevated BP with rapidly acting and easily titratable drugs. However, there is less evidence of benefit in patients with mildly elevated BP, or those with chronic hypertension. Nimodipine improves neurological outcome, likely by reducing cerebral vasospasm.³⁴ However, nicardipine, although also reducing vasospasm, does not affect the long-term outcome.³⁵ Treatment according to the guidelines for hypertension after stroke (see Table 55-3) is recommended, although definitive studies do not exist.

Hypertension Associated with Left Ventricular Failure

Left ventricular failure increases catecholamines and angiotensin II. The resultant elevation of peripheral vascular resistance can impair left ventricular performance. Consequently, vasodilators, including nitrates and ACE inhibitors, can improve cardiac output dramatically.

Acute pulmonary edema generally requires parenteral therapy. Either nitroglycerin or nitroprusside can be used initially, although nitroprusside is more effective. Administration of

oral captopril or intravenous enalaprilat, often with a loop diuretic, assists weaning from parenteral therapy.

Hypertension Associated with Myocardial Infarction or Coronary Ischemia

The goal of acute antihypertensive therapy is to reduce myocardial oxygen demand and increase myocardial blood supply. Intravenous nitroglycerin is ideal because it reduces myocardial oxygen consumption more than nitroprusside and sustains regional blood flow distal to a stenosis. β-Blockers generally have little acute antihypertensive effect but can reduce heart rate and oxygen consumption. The combined effects of β-blockers and nitrates are advantageous. The use of short-acting nifedipine can aggravate ischemia and is contraindicated.

Dissecting Aortic Aneurysm

Acute BP reduction reduces the distending forces on the damaged aorta. However, arterial vasodilators, such as hydralazine, diazoxide, and nifedipine, which cause a reflex increase in the rate and velocity of left ventricular ejection, are contraindicated because they can increase endothelial shear force. Nitroprusside combined with a β-blocker has replaced trimethaphan as the treatment of choice for immediate reduction in

Table 55-3 Approach to Elevated Blood Pressure in Acute Ischemic Stroke: AHA and American Stroke Association Guidelines

Blood Pressure	Intervention
Not Eligible for Thrombolytic Therapy	
SBP < 220 mm Hg or DBP < 120 mm Hg	Observe unless other indications for urgent BP lowering
SBP > 220 mm Hg or DBP 121–140 mm Hg	Labetalol 10–20 mg IV; repeat or double q10min (max dose 300 mg) OR nicardipine 5 mg/hr IV infusion; titrate by 2.5 mg/hr q5min (max 15 mg/hr) Aim for 10%–15% BP reduction
DBP > 140 mm Hg	Nitroprusside, starting with 0.5 mg/kg/min infusion Aim for 10%–15% BP reduction
Blood Pressure	Intervention
Eligible for Thrombolytic Therapy	
Pretreatment	
SBP > 185 mm Hg or DBP > 110 mm Hg	Labetalol 10–20 mg IV, may repeat 1 time; nitropaste 1–2 inches
During/After Treatment	
1. BP monitoring	Monitor q15min for 2 hr, then q30min for 6 hr, then q1h for 16 hr
2. DBP > 140 mm Hg	Nitroprusside, as above
3. SBP > 230 mm Hg or DBP 121–140 mm Hg	Labetalol as above, or 10-mg bolus followed by drip at 2–8 mg/min If ineffective, consider nitroprusside OR nicardipine as above
4. SBP 180–230 mm Hg or DBP 105–120 mm Hg	Labetalol as above, or 10-mg bolus followed by drip at 2–8 mg/min

DBP, diastolic blood pressure; SBP, systolic blood pressure
Adapted from Adams H, Adams R, del Zoppo G, Goldstein LB: Guidelines for the early management of patients with ischemic stroke. 2005 Guidelines Update. A scientific statement from the Stroke Council of the American Heart Association/American Stroke Association. *Stroke* 2005;36:916–921.

BP. Thereafter, intravenous labetalol can serve as a bridge to oral α - plus β -blockade.

Adrenergic Crises

Increased catecholamine and sympathetic tone mediate the acute hypertension complicating clonidine withdrawal, pheochromocytoma, cocaine abuse, MAO inhibitor/tyramine interaction, and use of sympathomimetics such as phenyl-

propranolamine. Acute BP elevation is largely due to α -mediated vasoconstriction.

Although the use of phentolamine is logical, nitroprusside is equally effective and more familiar. However, if adjunctive therapy with β -blockers is indicated (e.g., because of severe tachycardia or ventricular ectopy), establishment of α -blockade (with phentolamine or perhaps prazosin) should be accomplished first. β -Blockade, in the absence of prior α -blockade, can produce an undesired pressor effect due to unopposed α tone and loss of β -mediated vasodilation. Intravenous labetalol appears effective, but further experience with its use in pheochromocytoma is needed. If time allows, oral clonidine is an effective alternative for hypertension caused by clonidine withdrawal.

Preeclampsia

Hypertensive crises near the end of pregnancy are traditionally treated with parenteral hydralazine or labetalol. A recent trial found intravenous hydralazine and intravenous labetalol to be equally effective.³⁶ Magnesium sulfate can also lower BP but is indicated specifically to prevent convulsions.

Recent trials have examined the role of newer agents. Although the selective serotonin (5HT_{2A})-receptor antagonist ketanserin is as effective as hydralazine³⁷ and nicardipine is as effective as labetalol,³⁸ their roles in clinical practice remain to be established.

Postoperative Hypertension

Postoperative hypertension is characterized by increased sympathetic tone and vascular resistance. Pain and overhydration contribute to blood pressure elevation. Nonspecific vasodilators, including intravenous nitroglycerin and nitroprusside, are effective,³⁹ but nitroglycerin is preferred after CABG. Isradipine,⁴⁰ nicardipine,⁴¹ fenoldopam^{17,19} and, in patients with preserved left ventricular function, labetalol⁴² provide alternatives. Fenoldopam used after CABG achieves BP control as rapidly as nitroprusside.²⁸ After carotid endarterectomy, nicardipine controls BP elevation within 10 minutes in most patients.⁴³ Nicardipine resembles labetalol in its rapid onset and slow offset of action, and is an alternative to labetalol, particularly in patients in whom a β -blocker is contraindicated.

Postoperative hypertension is often a consequence of overzealous hydration, in which case an intravenous loop diuretic merits consideration.

Renal Failure

First and foremost in treatment of hypertension in the setting of renal failure is the need to increase sodium excretion. Furosemide doses up to 80 to 240 mg are required in those unresponsive to thiazides. Adding a thiazide diuretic such as metolazone to a loop diuretic further promotes sodium excretion and lowers BP. Aggressive volume control often increases serum creatinine. If it is not extreme, it is not a contraindication to continued diuretic therapy.

The renin-angiotensin system frequently contributes to hypertension in patients with renal failure. Thus, ACE inhibitors or ARBs are usually effective. Excretion of ACE inhibitors is reduced in renal insufficiency, and dosage should be reduced, with the exception of fosinopril. Dosage and excretion of ARBs is not altered in renal insufficiency. Combining an ACE

inhibitor with an ARB is less effective than combining either agent with a drug from a different class. Other agents, including calcium channel blockers, β -blockers, and α -blockers, are also effective, but studies provide little guidance as to which to choose. Erythropoietin can precipitate hypertensive crisis, especially if the hematocrit rises abruptly; phlebotomy has been reported to be helpful in management.⁴⁴

The majority of patients requiring hemodialysis have hypertension.⁴⁵ All classes of antihypertensive agents except diuretics can lower BP,⁴⁶ but hypertension remains uncontrolled in 62%.⁴⁶ Prominent reasons for this include failure to achieve dry weight, interdialytic weight gain, inadequate medication, and withholding of medication before dialysis.⁴⁶ If hypotension during dialysis prevents attainment of dry weight, withholding of antihypertensive agents such as ACE inhibitors, calcium channel blockers, or α -blockers on the day of dialysis can be helpful. For further discussion, see Chapter 60.

The blood levels of renally excreted agents such as atenolol persist longer in patients with renal failure, and lower dosage is usually sufficient.⁴⁷ Because atenolol is dialyzable, it should be given after dialysis.⁴⁷

“Severe” Hypertension

Severe hypertension usually does not constitute an emergency or urgency. If a patient presents with a BP of 180–220/110–130 mm Hg but is asymptomatic, without retinal hemorrhages or exudates or renal insufficiency, prescription of oral agents with close follow-up is appropriate.

The low probability of controlling severe hypertension with a single agent provides a rationale for ACE inhibitor/diuretic and ARB/diuretic combinations. A diuretic should nearly always be a component of any multidrug regimen. Failure to control hypertension is frequently due to inadequate diuretic dosage. Addition of a potassium-sparing diuretic such as spironolactone, eplerenone, or amiloride or, in patients with renal insufficiency, substitution of a loop diuretic, can enhance control of BP and blood volume.

CONCLUSIONS

Hypertensive “crises” can be viewed as a spectrum, from non-urgent, to urgent, to truly emergent. Most instances of severe but asymptomatic hypertension need not be treated urgently unless required by underlying conditions. Hypertensive urgencies can be treated with oral or intravenous agents, whereas true emergencies require short-acting intravenous agents such as sodium nitroprusside. The treatment of accelerated or malignant hypertension is usually sufficiently urgent to preclude the use of agents that can help identify pathogenetic mechanisms and guide subsequent treatment (see Fig. 55-1). Therapeutic restraint, particularly in patients with severe but asymptomatic BP elevation, is required to avoid complications from unnecessary and overzealous lowering of BP.

SMOKING AND HYPERTENSION	638	Homocysteine	640
DIABETES IN PATIENTS WITH HYPERTENSION	639	C-Reactive Protein	640

Hypertension is a major contributor to cardiovascular disease (CVD). Whereas some CVD endpoints, such as encephalopathy, hemorrhagic stroke, and acute renal failure, may be directly attributable to elevated blood pressure (BP), the most common consequence of chronic hypertension is progressive atherosclerosis. Hypertension plays a significant and independent role in atherogenesis, but its impact is greatly exaggerated by the presence of other risk factors. It seems that there is a threshold of BP required for the development of atherosclerosis. Lesions do not appear in normally low-pressure vascular beds, such as the pulmonary vasculature, but do appear in patients with pulmonary hypertension. Veins do not develop atherosclerosis until they are utilized as grafts in the systemic circulation. Animal experiments demonstrate that the development of atherosclerosis can be altered by manipulation of BP.^{1,2}

In the Framingham Heart Study, the risk of ischemic heart disease over a 10-year period was greatly influenced by other risk factors, as shown in Figure 56-1.^{3,4} The presence of other CVD risk factors is important for other reasons: (1) they influence the decision to treat, how aggressively to treat, and with what agents; (2) they affect the response to hypertension therapy; and (3) they influence the expected benefit on CVD endpoints (Box 56-1).

INFLUENCE OF DYSLIPIDEMIAS

A synergistic interaction between the risk for CVD events, systolic BP, and low-density lipoprotein (LDL) cholesterol has been shown. High-density lipoprotein (HDL) cholesterol enhances the removal of oxidized LDL from the tissues. An inverse relationship exists between HDL cholesterol and systolic BP.^{5,6} The interaction of LDL and HDL cholesterol and BP is shown in Figure 56-2. Several large randomized trials in patients with and without preexisting CVD have demonstrated conclusively that lowering of LDL cholesterol substantially reduces the risk of myocardial infarction (MI) and coronary events.⁶⁻¹⁰ Although epidemiologic observations have not detected a relationship between LDL and stroke, post hoc analysis has concluded that lowering LDL cholesterol also apparently lowers stroke incidence.¹¹ Women, minorities, diabetic

patients, and the elderly have been underrepresented in these trials. Three prominent primary prevention trials are the Helsinki Heart Study,¹² the West of Scotland Coronary Prevention Study (WOSCOPS),⁹ and the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS).¹³

The upper age limit for enrollment in the Helsinki Heart Study¹² was 55 years. The baseline LDL cholesterol averaged 270 mg/dL. This study demonstrated a 34% reduction in combined CVD events with the fibric acid derivative gemfibrozil. WOSCOPS was also limited to middle-aged men, with an upper age limit of 64 years and mean baseline LDL cholesterol of 272 mg/dL. This study also demonstrated a reduction of combined coronary events, CVD death, nonfatal MI, and all cardiovascular deaths by nearly one third, using pravastatin as the lipid-lowering intervention. The AFCAPS/TexCAPS included a lower risk but more representative population: the average age was 58 years, but 21% were older than age 65, 15% were women, 3% blacks, and 7% Hispanics. The average LDL cholesterol at baseline was 150 mg/dL. Treatment with lovastatin reduced the risk of coronary events, MI, and revascularization, but the number of participants in the subgroups was too small to allow definitive conclusions.

Three major secondary prevention trials established the benefit of lipid-lowering therapy in patients with known CVD. Although these studies also focused primarily on middle-aged men, they included women and patients older than age 65; they also included patients with LDL cholesterol from the high-normal range (110 mg/dL) and the very high range (232 mg/dL). The Scandinavian Simvastatin Survival Study (4S) included patients with established CVD and LDL cholesterol of 174 to 232 mg/dL (average, 188 mg/dL), of whom 19% were women and 23% were older than age 65.⁷ In this study, simvastatin resulted in a significant reduction in total mortality, coronary events, CVD deaths, revascularization procedures, and strokes. The Cholesterol And Recurrent Events (CARE) trial included post-MI patients with LDL cholesterol of 116 to 174 mg/dL (mean, 139 mg/dL), of whom 14% were women and 31% were older than age 65. In this study, treatment with pravastatin resulted in a 24% risk reduction of fatal coronary events and nonfatal MI and a 25% reduction in the need for revascularization.^{10,14} The Long-term

Figure 56-1 Estimated risk of ischemic heart disease over 10 years according to various combinations of risk factors for men and women. HDL, high-density lipoprotein; LVH, left ventricular hypertrophy. (From Anderson KM, Wilson PWF, Odell PM, et al: An updated coronary risk profile. Statement for health professionals. *Circulation* 1991;83:357–363.)

Box 56-1 Cardiovascular Risk Factors That May Interact with Hypertension

Major Risk Factors	Emerging Risk Factors
High LDL cholesterol (>130 mg/dL)	High lipoprotein (a) level
Low HDL cholesterol (<40 mg/dL)	High homocysteine level
Cigarette smoking	High-sensitivity CRP
Diabetes mellitus	Prothrombotic factors
Physical activity	Proinflammatory factors
Obesity	Impaired fasting glucose
	Subclinical atherosclerosis
	High uric acid
	Vascular calcification

CRP, C-reactive protein; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Intervention with Pravastatin in Ischemic Disease (LIPID) study included patients with a broad range of serum cholesterol levels (155–271 mg/dL).¹⁵ Average LDL at baseline was 150 mg/dL. Of the patients in this study, 17% were women and 39% were older than age 65. This study also demonstrated that treatment with pravastatin reduced the risk of major cardiovascular events, including stroke, by about 25%.

In a recent meta-analysis, LaRosa and colleagues¹⁶ examined the data from the five large trials that used statins as the lipid-lowering intervention (i.e., 4S, WOSCOPS, CARE, AFCAPS/TexCAPS, LIPID), with primary focus on risk reduction in women and the elderly. Collectively, these trials included 30,817 patients, of whom 13% were women and 29% were older than age 65. The overall proportional risk reduction for major cardiovascular events was similar in men and women, in younger and older patients, and in patients with or without hypertension. However, the effect on coronary deaths remained unclear. Overall, only two of the studies (4S and LIPID) showed significant reduction in coronary deaths, whereas the subgroups of women and the elderly were too small for definitive conclusions.

Figure 56-2 Relative risk of ischemic heart disease according to high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL), and systolic blood pressure in the Framingham Study. All subjects were men ages 50 to 70 years. (From Gordon T, Kannel WB, Castelli WP, et al: Lipoproteins, cardiovascular disease, and death: The Framingham Study. *Arch Intern Med* 1981;252:1123–1131.)

More recent studies have shed light on the optimal level of LDL cholesterol according to the risk of the patient. The lipid-lowering trial ALLHAT randomized 10,000 patients with hypertension and mild LDL cholesterol elevation to pravastatin or placebo. Unfortunately, during the course of the trial more than 25% of the control patients received therapy with other statins. The end result was a small difference in LDL cholesterol of 11%, which resulted in a nonsignificant 9% reduction on fatal/nonfatal MI.¹⁷ In a recent meta-analysis, Cannon and colleagues¹⁸ presented four recently published clinical trials comparing moderate to aggressive LDL cholesterol reduction with statin therapy (Table 56-1). Two studies addressed high-risk patients with stable coronary artery disease (CAD),^{19,20}

Table 56-1 Summary of Major Features of Intensive Versus Moderate Lipid-Lowering Trials

Trial	Enrollment	Population Studied	Treatments	LDL Achieved	Duration of Follow-up	Result
Secondary Prevention in Stable Patients						
TNT	10,001	History of MI or angina and coronary revascularization, LDL-C 130–250 mg/dL	Atorvastatin 10 mg vs. 80 mg	101 vs. 77 mg/dL	Median 4.9 years	HR 0.78 for major cardiac events ($P < .001$)
IDEAL	8888	History of MI meeting national guideline recommendations for cholesterol lowering	Simvastatin 20 mg vs. atorvastatin 80 mg	104 mg/dL vs. 81 mg/dL	Median 4.8 years	HR 0.89 death/MI/cardiac arrest ($P = .07$)
Secondary Prevention Following Acute Coronary Syndrome						
A to Z	4497	Acute coronary syndrome	Simvastatin placebo/20 mg vs. 40/80 mg	81 mg/dL vs. 66 mg/dL	Median 2.0 years	HR 0.89 for CV death/MI/stroke/ACS ($P = .14$)
PROVE IT—TIMI 22	4162	Acute coronary syndrome	Pravastatin 40 mg vs. Atorvastatin 80 mg	95 mg/dL vs. 62 mg/dL	Median 2.0 years	HR 0.84 for death/MI/UA/revascularization/stroke ($P = .005$)

A to Z, Aggrastat to Zocor; ACS, acute coronary syndrome; CV, cardiovascular; IDEAL, Incremental Decrease in End Points Through Aggressive Lipid Lowering; LDL-C, LDL cholesterol; MI, myocardial infarction; PROVE IT, Pravastatin or Atorvastatin Evaluation and Infection Therapy; TNT, Treating to New Targets; UA, unstable angina.

From Cannon CP, Steinberg BA, Murphy SA, et al: Meta-analysis of cardiovascular outcomes trials comparing intensive versus moderate statin therapy. *J Am Coll Cardiol* 2006;48:438–445.

and two studies addressed patients with acute coronary syndrome.^{21,22} These studies demonstrated that lower LDL cholesterol is better. The revised guidelines currently recommend LDL of less than 70 mg/dL in very high-risk patients. Whether there is benefit at even lower levels has not been yet established. These results are applicable to hypertensive and normotensive high-risk patients.

Role of Low HDL Cholesterol

Considerable epidemiologic data demonstrate that low HDL cholesterol is a major risk factor for CVD and stroke.^{23–26} Low HDL cholesterol is the most common lipid abnormality in men with CVD in the United States. Furthermore, low HDL cholesterol better distinguishes populations with CAD from those without. The Veterans Administration High-density lipoprotein cholesterol Intervention Trial (VA-HIT) established substantial benefits of interventions to raise low HDL cholesterol. The VA-HIT included 2531 men with known CAD, low HDL cholesterol, and fairly normal LDL cholesterol. Approximately 45% were also hypertensive. Patients were randomized to receive gemfibrozil (600 mg bid) or placebo. At baseline, the average total cholesterol was 175 mg/dL, triglycerides 162 mg/dL, LDL cholesterol 111 mg/dL, and HDL cholesterol 32 mg/dL. After 1 year of treatment and throughout the study, therapy with gemfibrozil reduced triglycerides by 31% and increased HDL cholesterol by 6%. No change in LDL cholesterol or total cholesterol was noted.

Over a median follow-up of 5.1 years, gemfibrozil therapy resulted in a significant 22% reduction in the primary endpoint of nonfatal MI and CVD death and a 31% reduction in atherothrombotic strokes.²⁷ Further extensive analysis of the data demonstrated that the reduction in the primary endpoint was significantly related with on-therapy changes in HDL cholesterol but not LDL cholesterol or triglycerides.²⁸ The benefits observed were similar among all subgroups analyzed, including hypertensive and diabetic patients. Thus, this study established for the first time that raising HDL cholesterol in patients with CVD and no other major lipid abnormality is beneficial. This was true even though the change in HDL cholesterol was only 6%.

Greater increases in HDL cholesterol can be achieved with niacin. Increases of up to 30% have been noted with daily doses of 3 g. However, several problems have limited the widespread use of niacin. Short-acting preparations need to be administered three times a day with food and/or aspirin to avoid flushing and gastrointestinal symptoms. Slow-release preparations are well tolerated but are associated with substantial hepatotoxicity.²⁹ A recently developed intermediate-release niacin (Niaspan) given at night with a snack is well tolerated and is devoid of hepatotoxicity. Changes in lipid profile noted with this intermediate-release preparation are similar to those seen with short-acting niacin and include up to 30% increase in HDL cholesterol, 15% reduction in triglycerides, 20% reduction in LDL cholesterol, and 28% reduction in lipoprotein (a) [Lp(a)]. These lipid improvements may

confer substantial improvements in CVD outcomes, particularly when combined with a statin.³⁰

More than 30 years ago, the Coronary Drug Project examined the effect of niacin on prevention of CVD.³¹ Over a 6.2-year follow-up, the study demonstrated that niacin-treated patients experienced 26% fewer MIs and 24% fewer strokes; need for cardiovascular surgery was reduced by 47%. After 15 years of follow-up the study still continued to show 11% lower total mortality in the niacin-treated patients ($P < .0004$).³² Interest in HDL continued unabated; the recently developed cholesteryl ester transfer protein (CETP) inhibitors entered clinical testing. The first to be evaluated extensively in humans was torcetrapib, whose use has been associated with substantial increases in HDL. Torcetrapib was evaluated in recent trials, of which the largest is the ILLUSTRATE.³³ Patients were treated with atorvastatin 10 to 40 mg as needed to reduce LDL cholesterol to close to 100 mg/dL. After 4 to 6 weeks of therapy, patients were randomized to either continue atorvastatin or to have 60 mg of torcetrapib added to the regimen. The primary endpoint for the study was average reduction in atheroma volume as measured by intravascular ultrasound. After 2 years of treatment, torcetrapib resulted in a 58% increase in HDL cholesterol and a further 12% reduction in LDL cholesterol, but no change in atheroma volume was noted. Overall adverse events were more frequent in the torcetrapib group. Systolic BP increased on average by 4.6 mm Hg, and a trend toward an increase in cardiovascular events was noted. The study was terminated prematurely and torcetrapib withdrawn from further testing. The future of CETP inhibitors remains uncertain.

Cholesterol and Blood Pressure Regulation

Therapy with a statin attenuates the onset and progression of hypertension and renal disease in Dahl salt-sensitive rats.³⁴ More recent data demonstrate a similar effect of long-term treatment with lovastatin in spontaneously hypertensive rats.³⁵ The mechanism by which statin therapy attenuates the development of hypertension may not be directly related to lipid lowering. Treatment shifts the relation between renal perfusion pressure and sodium excretion toward a lower BP. This effect has been attributed to the ability of statins to prevent vascular hypertrophy, thus improving pressure natriuresis. The effect of statins is largely related to their ability to inhibit synthesis of mevalonate, a precursor of isoprenoids,³⁶ and not to reduction of LDL cholesterol. A review of the literature suggests that a reduction of plasma cholesterol in humans is associated with a significant 3 to 5 mm Hg reduction in diastolic BP.³⁷ Statin therapy resulted in the greatest reduction of BP, and patients with the highest cholesterol benefited the most. In the Brighella Heart Study, more than 1500 hyperlipidemic patients were randomly treated with either a statin or other lipid-lowering therapy (fibrates or cholestyramine) for 5 years.³⁸ Changes in lipid profile and BP were assessed every 6 months. Lipid lowering was associated with a significant reduction of both systolic and diastolic BP (10–15 mm Hg) only among hypertensive patients in the higher two quartiles. There was only a weak correlation between changes in total cholesterol and blood pressure ($R = 0.16, P < 0.044$).

Glorioso and colleagues³⁹ conducted a double-blind, crossover study of patients with untreated hypertension and

hypercholesterolemia. Participants were randomly assigned to either pravastatin or placebo. Pravastatin resulted in a significant reduction of systolic, diastolic, and pulse pressure and blunted the cold pressor response. This study also found that the effect of statin therapy on BP was largely independent of the effects on LDL and total cholesterol.

More impressive data have been published recently from studies using 24-hour ambulatory blood pressure measurements. This more reliable methodology for assessment of BP changes has less variability, higher reproducibility, and no placebo effect compared to standard BP measurements. The four such studies suggest that statin therapy can reduce BP by an average of 6–7/5–6 mm Hg, particularly in patients in whom hypertension is not well controlled.^{40–43}

These data strongly suggest that treatment of hyperlipidemic hypertensive patients with a statin may result in better regulation of BP. The most plausible mechanism is a vasodilatory effect due to improvement in endothelial dysfunction. Increased cholesterol contributes to reduced arterial compliance⁴⁴ and increased BP. Reduction in cholesterol with statins can therefore contribute to improved arterial compliance and BP regulation and also may contribute to up-regulation of nitric oxide.⁴⁵

SMOKING AND HYPERTENSION

Epidemiologic data indicate that smoking and hypertension are additive major CVD risk factors. Approximately 30% of the U.S. population and 35% of hypertensive patients smoke.⁴⁶ The relative risk for death attributable to hypertension in participants in the Medical Research Council (MRC) Hypertension Trial was 1.9 for men smokers and 1.7 for women smokers, as opposed to 1.3 and 1.2 in nonsmoking men and women, respectively. The acute short-term effects of smoking on BP are related to nicotine, carbon monoxide, and other constituents of tobacco smoke. Heart rate and BP increase within 1 minute of smoking and rise about 30% during the first 10 minutes. The effects of nicotine are maintained for several minutes after smoking has ceased. The half-life of nicotine is more than 2 hours. Thus, heavy smokers may maintain elevated heart rates and BPs for most of their waking hours.⁴⁷ Several studies have suggested that infrequent and moderate smokers may have lower BP than nonsmokers.⁴⁸ However, in most of these studies, patients abstained from smoking before BP determination. The lower BP found in smokers persists after adjustments are made for body weight.⁴⁸ A recent study examined the effect of smoking cessation on BP and the incidence of hypertension in 8170 healthy male employees of a steel manufacturing company.⁴⁹ Mildly hypertensive patients were excluded from this analysis. Adjustments were made for baseline age, body mass index, cigarette smoking, alcohol consumption, exercise, family history of hypertension, systolic BP, and change in body mass index over the follow-up period of 4 years. The adjusted relative risks of hypertension in those who had quit smoking for less than 1 year, 1 to 3 years, and more than 3 years were 0.6, 1.5, and 3.5, respectively, compared with nonsmokers. The trends were similar among those who lost or gained weight during the follow-up period. The mechanism by which long-term smoking lowers BP or prevents hypertension and by which smoking cessation increases the frequency of hypertension is not clear,

but it should not distract from the well-known harmful effects of cigarette smoking.

Cigarette smoking increases the risk of MI, ischemic heart disease, sudden death, stroke, and peripheral arterial disease; worsens outcomes after percutaneous vascular procedures and bypass surgery; and worsens complications of hypertension.⁵⁰

Cigarette smokers may not derive the expected benefits from hypertension control. In the MRC trial β -blocker therapy in smokers was less effective in preventing strokes than thiazide diuretics.⁵¹ In the Heart Attack Primary Prevention in Hypertension (HAPPHY) trial, β -blockers failed to improve coronary morbidity in smokers.⁵² It is important, therefore, to inform patients of the importance of smoking cessation and encourage them to stop smoking at every visit. Smoking cessation is an important intervention in reducing CVD risk in patients with hypertension. Use of various smoking deterrents may be helpful. Pharmacotherapy for smoking cessation is a cost-effective intervention and it should be offered to all consenting smokers.

DIABETES IN PATIENTS WITH HYPERTENSION

Diabetes and hypertension commonly coexist. In the United States, more than 60% of diabetics have hypertension and approximately 20% of hypertensives have diabetes.⁵³ Diabetics are two to three times more likely to have hypertension than nondiabetics. The incidence is even higher among African Americans. Diabetes is the most common cause of end-stage renal disease and a major contributor to CVD.⁵⁴ Even mild elevations of BP in diabetics increase the risk of CVD and renal disease dramatically. It is therefore of the utmost importance to control both BP and blood glucose tightly in diabetics with hypertension.

Aggressive treatment of BP in diabetics has been largely ignored, although it may confer greater reduction of CVD events than glycemic control. The goal for BP reduction has been set at lower levels in diabetics, mostly because studies have shown continued benefit with lower BP. The Appropriate Blood Pressure Control in Diabetes (ABCD)⁵⁵ and the Hypertension Optimal Treatment (HOT)⁵⁶ trials indicated that aggressive reduction of diastolic BP to below 80 mm Hg provides greater reduction in CVD events. Similarly, the UK Prospective Diabetes Study (UKPDS) demonstrated that tight control of BP had greater impact on CVD events than tight glycemic control.⁵⁷ The impact on CVD events included a 44% reduction in strokes, a 24% reduction in diabetes-associated endpoints, and a 32% reduction in deaths. For every 10-mm Hg reduction in systolic BP, there was an associated risk reduction of 12% for any complication related to diabetes.⁵⁸ For these reasons, the recommended target BP in patients with diabetes is lower than 130/80 mm Hg. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers provide better vascular and renal protection, although most patients require combinations of three to four drugs to achieve target BP control.

The UKPDS study compared the effects of intensive blood glucose control with conventional treatment on microvascular and macrovascular complications of diabetes over 10 years in more than 4000 patients.^{59,60} Average glycosylated hemoglobin (HbA_{1c}) was reduced to 7% in the intensively treated group and

to 7.9% in the conventional group. This difference resulted in a 12% reduction in diabetes-related endpoints, a 10% reduction in deaths, and a 25% reduction in microvascular complications. There was minimal reduction in macrovascular disease. For every 1% reduction in HbA_{1c}, there was a 21% reduction in any endpoint related to diabetes, a 21% reduction in deaths, a 14% reduction in MIs, and a 37% reduction in microvascular complications. There was no threshold for any of the endpoints.

These observations suggest that aggressive glycemic and BP control is important in patients with diabetes and hypertension.

Whether lower levels of BP and HbA_{1c} confer better benefits for prevention of cardiovascular outcomes in diabetics has not been yet defined. The Action to Control Cardiovascular Risk in Diabetes (ACCORD), an ongoing study, targets HbA_{1c} less than 6.0% and systolic BP lower than 120 mm Hg as compared to recommended levels, in 10,000 patients with type 2 diabetes mellitus. Recently the glycemic arm of the study was discontinued prematurely because an interim analysis showed increased mortality and cardiovascular morbidity in patients randomized to tight glycemic control.

DIET, WEIGHT LOSS, AND EXERCISE IN PATIENTS WITH HYPERTENSION

Epidemiologic studies have consistently shown a substantial correlation between hypertension, excess body weight, and physical inactivity. Although all three variables are independently associated with increased CVD risk,^{61–63} their coexistence increases the risk for complications cumulatively. Guidelines for the management of hypertension recommend lifestyle changes for non-pharmacologic treatment of hypertension.^{61,64} Dietary changes are effective even without weight loss. The DASH study showed that a combination diet of fruits and vegetables low in saturated fats reduces BP in patients in the high-normal BP range. This diet was more effective in African Americans and in patients with established hypertension.⁶⁵ There is roughly a 1-mm Hg reduction in diastolic BP for every kilogram of weight loss in obese subjects. The World Health Organization/International Society of Hypertension guidelines recommend at least 5 kg of weight loss to induce BP reduction.⁶⁴

Numerous observational studies have shown an inverse relationship between physical activity and BP.^{66,67} We identified 12 prospective, randomized trials completed in the past 10 years.⁶⁸ Significant reduction in resting BP was reported with aerobic exercise in 10 of these studies. The average BP reduction was 8.7/7.0 mm Hg in the exercise group, compared with 3.8/1.3 mm Hg in the controls despite body weight remaining unchanged. An important observation is that low- to moderate-intensity exercise may be more effective in lowering BP than high-intensity exercise. Exercise appears safe and effective in improving hypertension in treated patients with severe hypertension and left ventricular hypertrophy. In a study of 46 African Americans with severe hypertension, we found that regular aerobic exercise for 30 to 60 minutes at least three times per week resulted in significant reduction of BP despite a decrease in antihypertensive medication of 30% to 40%. The body weight in the exercise and control groups and the BP in the controls remained unchanged at 32 weeks.⁶⁸ Blumenthal and colleagues⁶⁹ studied 134 patients with stage 1 hypertension. They compared the effect of aerobic exercise alone with weight management, including exercise. Aerobic exercise was more effective and reduced BP by 7/5 mm Hg.

These data indicate that diet, weight reduction, and exercise can reduce BP independently. However, reductions are modest. A combination can be more effective. Their feasibility and application in clinical practice remains to be demonstrated.

EMERGING CARDIOVASCULAR RISK FACTORS

New CVD risk factors have emerged in recent years. These have been associated with a high risk for coronary atherosclerosis, CVD complications, and cardiac death. These new risk factors include Lp(a), homocysteine, inflammatory markers, high triglycerides, coronary calcifications, high uric acid, and others. Extensive coverage of these risk factors is beyond the scope of this chapter. In general, clinical associations have been well established with all these factors, but interventional data conclusively demonstrating benefit is lacking in most instances. Figure 56-3 demonstrates the relative predictive value of many of these emerging risk factors derived from the Women's Health Study.

Lipoprotein (a)

Lipoprotein (a) resembles LDL but contains a highly glycosylated protein, apolipoprotein A. Elevated Lp(a) has been associated with CAD in most but not all studies. Some studies suggest gender differences in the prognostic significance of Lp(a). In a large cohort study, 4967 men and 4968 women free of atherosclerosis were followed for up to 14 years. There was a significant increase in the adjusted hazards ratio for CAD with increased Lp(a) (1.9 for women, 1.6 for men), but the association with cerebrovascular disease was less certain.⁷⁰ Lp(a) can be reduced significantly with niacin (up to 30% reduction), but the clinical importance of such an intervention has not been demonstrated.

Homocysteine

Homocysteinemia is an independent predictor of CAD, MI, and peripheral vascular disease. One recent study examined the association of homocysteine levels with recurrent events in 110 young patients (<56 years old) who had suffered a prior MI. Over a 7-year follow-up, patients with normal homocysteine levels had significantly fewer combined events

Figure 56-3 Multivariable-adjusted relative risks of cardiovascular disease according to levels of high-sensitivity C-reactive protein (hs-CRP) and categories of low-density lipoprotein cholesterol (LDL-C). hs-CRP levels add prognostic information at all levels of LDL-C and at all levels of the Framingham Risk Score. (From Willerson JT, Ridker PM: Inflammation as a cardiovascular factor. *Circulation* 2004; 109[Suppl]:II2-II10.)

Figure 56-4 Prognostic value of various cardiovascular biomarkers in healthy women in the Women's Health Study. The combination of high-sensitivity CRP with the total cholesterol:high-density lipoprotein cholesterol (TC:HDL-C) ratio provided a stronger predictor than either CRP or TC:HDL-C alone. Relative risks and 95% confidence interval (CI) are shown for individuals in the top versus the bottom quartile for each factor. sICAM-1 indicates soluble intracellular adhesion molecule-1; and sVCAM-1, soluble vascular adhesion molecule-1. Top versus the bottom quartile, after adjustment for age and smoking. (From Willerson JT, Ridker PM: Inflammation as a cardiovascular factor. *Circulation* 2004; 109[Suppl]:II2-II10.)

(26% vs. 72%), lower mortality (1.6% vs. 6%), lower morbidity (14% vs. 36%), and less need for revascularization (18% vs. 48%).⁷¹ Other studies, however, failed to demonstrate any benefit with drug therapy to reduce homocysteine. Definite interventional data with treatment to reduce homocysteine (vitamin B₆, vitamin B₁₂, or folic acid) is lacking. Similar deficiencies exist for all other emerging CVD risk factors.

C-Reactive Protein

Low-grade inflammation occurs in the vasculature in response to injury, lipid oxidation, and perhaps infection. All cardiovascular risk factors, including hypertension, diabetes, and smoking, are amplified by mild modification and oxidation of LDL cholesterol. Oxidation of LDL leads to inflammation, recruitment of monocytes, and production of

inflammatory markers that initiate the atherosclerotic process. Observational and experimental data have consistently shown a strong association between inflammatory markers and risk of cardiovascular events. Of all markers of inflammation the most reliable, reproducible, and widely available marker is currently high-sensitivity C-reactive protein (hs-CRP). It has been shown in many large trials to be a strong predictor of MI and stroke. Among 28,263 apparently healthy postmenopausal women⁷² monitored prospectively in the Women's Health Study, hs-CRP was the strongest predictor of cardiovascular events, outperforming homocysteine, LP(a), and LDL cholesterol (Fig. 56-4; see also Fig. 56-3). CRP is drastically reduced with good management of high cholesterol and treatment of hypertension.

		CONCLUSIONS AND RECOMMENDATIONS	655

The effects of medical treatment on the control of blood pressure (BP) and on stabilization or improvement of renal function in trials of patients with renovascular disease have been reviewed comprehensively.¹⁻⁷ The indications for, and expected outcomes from, angioplasty and surgery for renal artery stenosis are reviewed in Chapter 58.

Renal artery stenosis (RAS) is defined as a narrowing of one or both renal arteries or their branches (usually by more than 70% to 80% to be functionally significant).⁸ It can be caused by either malformation of the renal arteries, the most common type being fibromuscular dysplasia, or by atherosclerotic disease. These two conditions occur in different settings and have distinct clinical consequences and treatment. However, atherosclerosis is about three times more common. In the Medicare population the incidence of clinically manifest atherosclerotic RAS is 0.5% overall and 5.5% in those with chronic kidney disease (CKD).⁹ This value undoubtedly underestimates the true incidence of RAS because patients are often asymptomatic (approximately 7% in one community-based screening study).¹⁰ Interest in this diagnosis is spurred by the belief that hemodynamically significant RAS is a major cause of hypertension and CKD in affected patients. However, although RAS is common, the prevalence of *renovascular hypertension*, defined as hypertension caused by RAS, is unknown. No test reliably identifies hypertension that is improved or cured after correction of RAS.

Fibromuscular dysplasia is rarely associated with kidney failure, but impaired renal function is common in patients with atherosclerotic disease. The term *ischemic nephropathy* is often applied to individuals with atherosclerotic RAS and abnormal kidney function. However, in the absence of complete occlusion, there is little evidence that stenosis of the main renal artery actually causes renal failure or that renal ischemia causes progressive loss of renal function. Therefore, this condition is better referred to as *azotemic renovascular disease*. Regardless of whether hypertension and CKD are a direct

consequence of the renovascular lesion, it is important to diagnose atherosclerotic RAS because clinical outcomes are significantly worse in such patients. It is essential to understand the natural history of untreated subjects and the underlying pathophysiology to plan for rational therapy.

NATURAL HISTORY OF UNTREATED PATIENTS

Fibromuscular dysplasia has numerous subtypes. The most common is medial fibroplasia, which is not normally progressive. Thus, the aim of therapy is to improve or cure hypertension rather than to prevent azotemic renovascular disease. Approximately half of carefully selected patients may be cured of hypertension by percutaneous transluminal renal angioplasty (PTRA) or reconstructive surgery.¹¹ In contrast, cure of hypertension after correction of RAS due to atherosclerosis occurs in less than 20% of patients.¹² Studies with duplex ultrasound measurements over 5 years reported progression of atherosclerotic RAS in more than one third of patients and complete occlusion in 3% to 15%.¹³ Contemporary studies indicate that less than 10% to 15% of patients with RAS treated medically develop intractable hypertension, progressive renal insufficiency, or total arterial occlusion.¹³⁻¹⁵ In fact, in contrast to early studies, which suggested that RAS was a frequent cause of end-stage renal disease (ESRD), patients with untreated RAS often have stable kidney function for many years; progression to ESRD is relatively uncommon.¹⁶ Numerous observational studies^{1,2} have shown that, after intervention with PTRA and stenting (PTRA-S) or reconstructive surgery, approximately 25% of patients have a worthwhile improvement in glomerular filtration rate (GFR) matched by a reduction in serum creatinine concentration and blood urea nitrogen (BUN), approximately 50% have a stable GFR, and approximately 20% have a deterioration in GFR. Outcomes in

the three small prospective, randomized studies reported to date were inconclusive. In the Dutch Renal Artery Stenosis Intervention Cooperative (DRASTIC) trial, the largest study, the creatinine clearance was unchanged at 1 year both in patients treated medically and in those who were revascularized.¹⁴ A recent comprehensive review of published series and trials concluded that available evidence fails to demonstrate that revascularization or medical therapy is the treatment of choice for atherosclerotic RAS.⁵ Weak data suggest that mortality and cardiovascular event rates are similar for medically treated and revascularized patients. There is also a trend toward lower BP with angioplasty in patients with bilateral disease. However, this trend is based on very few patients, the data are more than 10 years old, and medical therapy has evolved significantly in that time. No study to date has compared aggressive medical therapy with revascularization. All of the studies in the review suffer from serious methodologic weakness. One observation that continues to drive clinical practice is that some patients appear to benefit either because of improvement in BP control or in kidney function. However, others deteriorate, either because of—or despite—the intervention. Published studies fail to adequately assess adverse events associated with revascularization.

These considerations give rise to the following suggestions regarding the choice of medical therapy or intervention:

1. Medical therapy is appropriate for patients with fibromuscular disease because it is not progressive and does not lead to significant loss of renal function. On the other hand, rates of cure of hypertension after intervention are high, and complications of PTRAS (such as atheroembolism) are quite uncommon. Therefore, most patients with troublesome hypertension are offered an intervention, but this can be preceded by a prolonged trial of medical therapy.
2. Few patients with atherosclerotic RAS will benefit from intervention (see Chapter 58). It is reasonable to use medical therapy alone for atherosclerotic RAS, regardless of the level of kidney function, the presence of resistant hypertension, or episodes of congestive heart failure.
3. Whether or not an intervention is performed, all patients with RAS require intensive medical therapy to reduce the risk of adverse cardiovascular and renal events. This includes tight control of BP, administration of an antiplatelet agent, and treatment of any associated dyslipidemia, diabetes, or CKD.
4. In patients with resistant hypertension and atherosclerotic RAS, revascularization may be associated with a reduction in the number of medications needed to control BP, but almost all patients will continue to require some antihypertensive medications.
5. The small risk of progression to ESRD in patients with RAS is not predictably reduced by intervention. Nevertheless, it is reasonable to offer intervention to patients with progressive renal insufficiency and bilateral high-grade stenosis or high-grade unilateral stenosis to a solitary functioning kidney. Revascularization is unlikely to improve kidney function if the kidney distal to the stenosis is less than 7 to 8 cm in length or if the patient has impaired function in the setting of unilateral RAS. A renal biopsy in selected patients may help predict the response to revascularization.

PATHOPHYSIOLOGIC BASIS FOR THERAPY

Animal models provide some insight into what may be anticipated from medical therapy. The two-kidney, one-clip (2K,1C) Goldblatt rat model of unilateral RAS is characterized by an early rise in BP and plasma renin activity. Hypertension initially is entirely dependent on angiotensin II. It can be rapidly restored to normal by an angiotensin converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB). After 2 to 12 months, the BP increases further, and many rats perish from malignant hypertension. The remainder develop normal-renin hypertension complicated by vascular and renal damage. At this stage, acute administration of an ACE inhibitor or ARB does little to the BP. However, prolonged administration over 3 days can restore BP to a nearly normal level.¹⁷

The one-kidney, one-clip (1K,1C) Goldblatt model of bilateral RAS or stenosis of a single or dominant kidney is characterized by an early rise in BP. The plasma renin activity increases only if fluid retention is prevented. The hypertension depends on the combined effects of salt intake and angiotensin II.¹⁸

Human renovascular disease usually has components of both models. Therefore, therapy directed at an overactive renin-angiotensin system on the one hand, and inappropriate renal salt and water retention on the other, is usually required for full control of hypertension, but carries risks of adverse changes in renal function, as described in Chapter 52.

The role of angiotensin II in maintaining BP and renal hemodynamics in Goldblatt hypertension has been studied with the use of ARBs and ACE inhibitors.^{18–20} As shown in Figure 57-1, compared with spontaneously hypertensive rats, an ACE inhibitor causes a larger fall in mean arterial pressure in 2K,1C Goldblatt rats.^{19,20} The GFR and excretion of fluid and sodium ions increase with the ACE inhibitor in the contralateral kidney, but decrease in the postclipped kidney. There is an increase in renal blood flow (RBF) at the contralateral kidney but variable changes at the poststenotic kidney, according to how the BP falls. The filtration fraction falls quite sharply.

The renal microvessels downstream from a functionally significant RAS are under two dominant influences (Fig. 57-2). One is renal autoregulation—vasodilation, especially of the afferent but also of the efferent arterioles—that maintains RBF. The second is the release of renin from the juxtaglomerular cells in the afferent arteriole in response to decreased stretch and decreased sodium chloride delivery to the macula densa²¹ (see Fig. 57-2). The ensuing increase in the generation of angiotensin I from angiotensinogen, and the action of ACE, increase the interstitial generation of angiotensin II in the kidney. Angiotensin II acts on angiotensin type 1 (AT₁) receptors to preferentially constrict the efferent arterioles, thereby maintaining a reasonable pressure for ultrafiltration at the glomerular capillaries despite a fall in mean arterial pressure. Therefore, an ACE inhibitor or an ARB may prevent an increase in efferent arteriolar resistance, leading to a fall in the pressure for ultrafiltration with a consequent fall in the GFR. However, RBF may be maintained because of a reduction in overall renal vascular resistance. These effects have been confirmed in studies of split renal function in patients with unilateral RAS.^{22,23}

A recent study compared responses to an ACE inhibitor and an ARB in 1K,1C Goldblatt hypertensive rats.²⁴ Both lowered

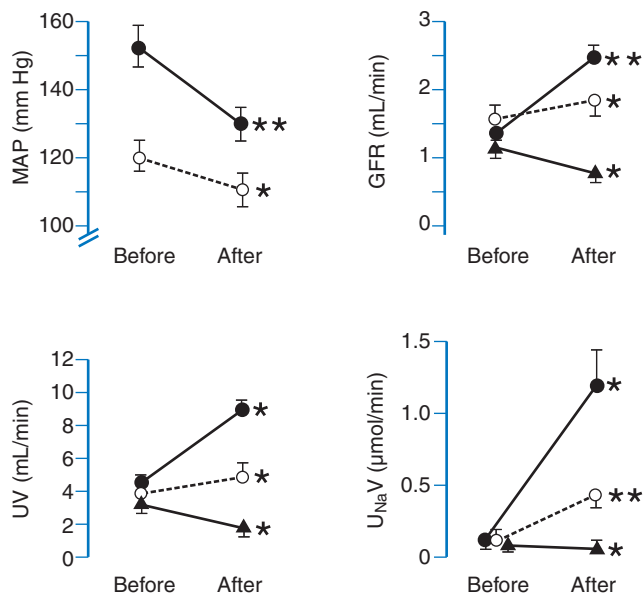

Figure 57-1 Mean \pm SEM values for mean arterial pressure (MAP), renal excretion of fluid and sodium (UV, $U_{Na}V$), and glomerular filtration rate (GFR) in anesthetized rats. Data are shown for spontaneously hypertensive rats (open symbols and broken lines) and for rats with Goldblatt two-kidney, one-clip hypertension (solid symbols and lines) for the contralateral kidney (solid circles); and postclipped kidney (solid triangles). Each panel shows values before and after administration of an angiotensin converting enzyme inhibitor, compared to before * $P < .05$; ** $P < .01$. (Drawn from data from Huang WC, Ploth DW, Bell PD, et al: Bilateral renal function responses to converting enzyme inhibitor (SQ 20,881) in two-kidney, one clip Goldblatt hypertensive rats. Hypertension 1981;3:285–293.)

the BP similarly, but the fall in GFR was greater with the ACE inhibitor, perhaps due to accumulation of bradykinin and its effects on the bradykinin type 2 receptor. A current study has contrasted the acute effects of an ACE inhibitor (enalaprilat) with an ARB (candesartan) in rats with early 2K,1C hypertension.²⁵ Whereas the ACE inhibitor reduced renal cortical blood flow and oxygen tension and actually increased the renal vascular resistance, the ARB did not cause these perturbations. Of interest was the finding that blockade of angiotensin type 2 (AT_2) receptors produced effects similar to those of the ACE inhibitor on renal hemodynamics and oxygenation. The authors concluded that angiotensin II can have a paradoxical effect by its action on AT_2 receptors in the poststenotic kidney, maintaining blood flow and oxygenation. Further analysis in this model demonstrated that these beneficial effects of AT_2 receptors in the postclipped kidney are due to generation of nitric oxide from nitric oxide synthase. Although these results have yet to be confirmed clinically, they suggest the possibility of some advantage of ARBs over ACE inhibitors in patients with renovascular disease who experience a reduction in GFR during treatment.

Calcium channel blockers (CCBs) administered to animals with angiotensin-induced hypertension reduce BP and renal vascular resistance substantially. However, in contrast to ACE inhibitors and ARBs, CCBs increase the GFR.²⁶ This is attributed to a preferential effect on vasodilation of afferent—rather than efferent—arterioles because of selective distribution of voltage-gated calcium channels to the afferent arteriole²⁷ (see Fig. 57-2). These effects of CCBs have been confirmed in studies of split renal function in patients with renovascular hypertension.²²

ACE inhibitors and CCBs should have contrasting effects on glomerular hemodynamics in the clipped kidney. Two studies compared therapy with ACE inhibitors and CCBs in Goldblatt hypertensive rats over 5 to 6 weeks.^{28,29} ACE inhibitor

Figure 57-2 Diagrammatic representation of factors affecting the pressure for ultrafiltration (P_{UF}) in the glomerulus downstream from a functional renal artery stenosis. Autoregulation leads to vasodilation of the afferent and efferent arterioles. Afferent arteriolar vasodilation is further enhanced by a calcium antagonist (CA). Renin release from the afferent arteriole acts on angiotensinogen (A_0) to form angiotensin I, which, after action by angiotensin-converting enzyme (ACE), forms angiotensin II. Angiotensin II preferentially constricts the efferent arteriole. ACE inhibitors or angiotensin receptor blockers prevent these effects of angiotensin II on type 1 receptors and reduce the P_{UF} .

therapy prevented glomerular hypertrophy and glomerular sclerosis in the contralateral kidney, whereas CCB therapy worsened these changes.²⁸ Only the ACE inhibitor reduced proteinuria from the clipped kidney.²⁹ Interestingly, the CCB worsened the lesions in the clipped kidney to the same extent as the ACE inhibitor.²⁹ These data suggest the possibility of a trade-off: ACE inhibitor therapy may reduce the GFR, and perhaps enhance irreversible atrophy in the poststenotic kidney, but may improve function in the contralateral kidney through better antihypertensive action, better control of glomerular capillary hypertension, and prevention of the fibrotic and sclerotic effects of angiotensin II. The role of ARBs and CCBs in therapy is not yet clear.

Further insight into potential therapeutic differences between ACE inhibitors and ARBs on the one hand, and vasodilators or CCBs on the other, comes from longer-term studies. In the 2K,1C model, both minoxidil, a vasodilator, and enalapril, an ACE inhibitor, compared with no treatment, reduced the BP, although the ACE inhibitor was more effective (Fig. 57-3). After 1 year, the postclipped kidney of the ACE inhibitor-treated rats was atrophic and had no residual function, but that of the minoxidil-treated rats that survived retained some residual GFR. This led to the concept of *pharmacologic nephrectomy* with ACE inhibitors.³⁰ This adverse effect of ACE inhibitors was, however, offset by two benefits. First, there was a significant increase in the GFR of the contralateral kidney with the ACE inhibitor, but not with the vasodilator. This resulted in an overall GFR of animals treated with an ACE inhibitor that was better preserved than those treated with minoxidil. Second, the 1-year survival was 15% in untreated rats, 48% in minoxidil-treated rats, and 84% in ACE inhibitor-treated rats. This study poses very elegantly the clinical dilemma: can a loss of GFR, with potential structural atrophy of the postclipped kidney during ACE inhibitor therapy, be considered a reasonable trade-off for improved function of the contralateral kidney, overall better BP control, and better cardiovascular survival? These issues are discussed in this chapter in the context of data from human subjects with renovascular disease (see “Specific Agents,” in this chapter).

Clinical studies have shown that there is a critical level of vascular occlusion beyond which the RBF and GFR fall with any further reduction in BP because the renal perfusion pressure is below autoregulatory limits.^{31,32} Revascularization can restore the ability of such kidneys to tolerate a reduction of BP to normal levels. The report of the Joint National Commission (JNC)³³ explicitly recognizes the potential for BP reduction to slow renal disease progression. It sets reduced goals (<130/75 mm Hg) for BP reduction in azotemic patients with proteinuria. However, a reduction of systemic pressures in patients with critical renal artery stenosis can cause a sharp fall in GFR, regardless of the type of antihypertensive agent used. Hence, chronic azotemic renovascular disease must be considered before vigorous BP reduction to low target goals is undertaken in patients with renal disease.

Atherosclerotic Renal Artery Stenosis, Comorbidities, and Clinical Outcomes

Atherosclerotic RAS is closely associated with hypertension, CKD, and vascular disease in other beds, including coronary artery disease, cerebrovascular disease, and peripheral vascular disease. Kalra and colleagues⁹ performed a retrospective analysis of patients with renal vascular disease in the U.S. Medicare population using a random sample of Medicare patients without RAS as controls. Results shown in Table 57-1 demonstrate a markedly greater prevalence and relative risk of CKD and other vascular disease in patients with RAS. Somewhat surprising, several other conditions thought to be highly associated with atherosclerotic RAS were in fact not more common than in controls. Thus, although quite prevalent, both congestive heart failure and diabetes mellitus had relative risks of 1 or less in patients with RAS after adjusting for other known risk factors and comorbidities.

Patients with RAS have worse outcomes from cardiovascular disease. In a large group of patients in whom renal arteriography was performed at the time of cardiac catheterization,

Figure 57-3 Mean \pm SEM values for mean arterial pressure (MAP) and glomerular filtration rate (GFR) in the contralateral (CL) and postclipped (PC) kidneys, the weight of the PC kidney, and number of animals surviving for control (Cont), and two-kidney, one-clip Goldblatt hypertensive rats given for 1 year either no treatment (NT), a vasodilator (minoxidil, M), or an angiotensin-converting enzyme inhibitor (enalapril, E). (Drawn from data by Jackson B, Franze L, Sumithran E, Johnston CI: Pharmacologic nephrectomy with chronic angiotensin converting enzyme inhibitor treatment in renovascular hypertension in the rat. *J Lab Clin Med* 1990;115:21–27.)

Table 57-1 Prevalence and Relative Risk of Hypertension, Chronic Kidney Disease, Other Vascular Disease, Congestive Heart Failure, and Diabetes in Medicare Patients with Atherosclerotic RAS

Comorbid Condition	No RAS N = 1,085,250 (%)	With RAS N = 5875 (%)	Adjusted Odds Ratio	P Value
Hypertension	53.4	90.8	4.31 (3.93–4.73)	<.0001
Chronic kidney disease	2.3	24.6	4.61 (4.27–4.98)	<.0001
Coronary artery disease	24.9	66.8	2.45 (2.30–2.61)	<.0001
CVA or TIA	12.0	36.9	1.58 (1.49–1.67)	<.0001
Peripheral vascular disease	12.7	56.0	3.96 (3.74–4.20)	<.0001
Aortic aneurysm	0.5	6.4	3.38 (3.00–3.81)	<.0001
Congestive heart failure	13.6	37.6	1.01 (0.94–1.07)	.9
Diabetes mellitus	17.9	32.5	0.89 (0.84–0.95)	.0001

CVA, cerebrovascular accident; TIA, transient ischemic attack

Adjusted odds ratio was calculated using a multiple logistic regression model that included multiple variables, including all those shown in the first column. Data from Kalra PA, Guo H, Kausz AT, et al: Atherosclerotic renovascular disease in United States patients aged 67 years or older: Risk factors, revascularization, and prognosis. *Kidney Int* 2005;68:293–301.

those with RAS had a much higher incidence of adverse cardiovascular events.³⁴ Furthermore, there was a direct correlation between the degree of stenosis and survival. Patients with renal artery narrowings greater than 95% had only about a 40% 4-year survival, as compared to 80% in those with normal arteries. These findings were independent of whether the patients underwent revascularization. In a cohort of almost 900 patients older than age 65 followed prospectively, the presence of RAS detected by duplex ultrasonography was associated with 1.96 (95% confidence interval, 1.00–3.83; *P* = .05) increased risk of an adverse coronary event after adjusting for demographics, prevalent cardiovascular disease, and traditional cardiovascular risk factors. The explanation for the increased risk of cardiovascular events in RAS is uncertain but may relate to concomitant atherosclerosis in other vascular beds.^{35–41} Alternatively, neuroendocrine systems activated by renal ischemia may lead to deleterious cardiovascular and renal outcomes. Angiotensin II has direct adverse effects on multiple tissues^{42–50} that may persist even when BP is controlled.⁵¹ Renal dysfunction itself is associated with increased rates of cardiovascular events^{52–55} and cardiovascular mortality.^{56,57} This is particularly true for patients with RAS.^{58,59} Renal ischemia may lead to neuroendocrine activation, hypertension, and renal insufficiency, which may accelerate atherosclerosis and promote thrombosis, renal dysfunction, and left ventricular hypertrophy. These may hasten the onset of congestive heart failure, myocardial infarction, stroke, progressive renal insufficiency, and ultimately death. Therefore, clinical outcomes may depend on the extent to which specific pathways, such as the renin-angiotensin-aldosterone system, are interrupted, and on preserving kidney function, which requires drug therapy and sometimes intervention.

Treatment has the following aims: (1) to control BP to recommended targets, (2) to improve or preserve kidney function, and (3) to treat common comorbidities and prevent adverse cardiovascular events.

OUTCOMES AND GOALS OF MEDICAL THERAPY

Three controlled trials and many observational trials have compared the outcomes of patients treated medically with those treated by intervention.^{5,6,14,60} In contrast, no controlled trials have examined specific medical therapies for renovascular disease. Consequently, the optimal medical management of patients with RAS has not been established. Nevertheless, extrapolations of data from other populations suggest that standard medical interventions should produce significant reductions in cardiovascular event rates. By analogy to patients with vascular disease in other beds, medical therapy should include BP control to standard targets with a regimen that includes an agent that inhibits the renin-angiotensin-aldosterone system if tolerated. Cholesterol management to the low target recommended for patients with vascular disease, antiplatelet therapy, tight glycemic control in diabetic patients, smoking cessation, and treatment of the complications of CKD, including anemia and secondary hyperparathyroidism, are recommended.

Hypertension

The optimal target BP for patients with RAS has not been established. However, by extension from other populations, a BP of no more than 140/90 mm Hg is suggested for patients without other comorbidities, and no more than 130/80 mm Hg for those with diabetes, or with CKD and proteinuria above 1 g/day.

Three groups performed controlled trials in which patients were randomized to receive medical therapy or intervention with PTRAs.^{14,60} Blood pressure was measured with automated devices. Each group concluded that patients randomized to intervention had a similar reduction in BP as those randomized to medical therapy, although those receiving the intervention required on average about one less antihypertensive drug.^{14,60} Apparently, modern antihypertensive drug therapy

given under protocol conditions is effective in controlling hypertension in the majority of patients with renovascular disease. These trials were relatively short-term (6–12 months). They provide no compelling evidence for intervention to control BP. However, it has yet to be determined whether these conclusions will hold over a longer period, whether reductions in BP achieved by medical therapy versus revascularization are equally effective in preventing adverse cardiovascular and renal events, and whether the choice of antihypertensive agent will influence the outcome.

Specific Agents

No controlled trials have been performed in patients with renovascular disease comparing classes of antihypertensive agents.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Three groups measured the BP of patients with renovascular hypertension during steady-state treatment with an ACE inhibitor and compared it with BP recorded after intervention by PTRR or reconstructive surgery.⁶¹ There was a close correlation between the systolic and diastolic BP achieved by these two forms of treatment. This implies that medical therapy with an ACE inhibitor is generally as effective in controlling hypertension as interventions. When these agents are given to patients with essential hypertension, they normally increase the GFR and block the sodium and fluid retention that normally accompanies a fall in BP. On the other hand, they can cause a sharp fall in GFR in some patients with chronic renal failure due to polycystic kidney disease⁶² or nephrosclerosis⁶³ when given with salt-depleting therapy. When given to patients with renovascular hypertension, they can reduce the GFR in the poststenotic kidney.^{22,64–67} There may be unacceptable worsening of azotemia if these drugs are given to patients with bilateral RAS or stenosis of a single or dominant kidney. Although many cases of acute renal failure have been reported, the risk is relatively low; renal function usually returns to baseline with cessation of the inciting drug. In patients with hypertension and CKD with or without RAS, a sharp fall in BP produced by any antihypertensive drug may be associated with a significant decline in GFR, at least in the first few weeks or months of treatment.^{31,68} Even the effects of angiotensin II on enhancing efferent arteriolar resistance cannot maintain the pressure for ultrafiltration of the glomerular capillaries in the presence of a tight stenosis and a sharp fall in arterial pressure.

Van de Ven and colleagues⁶⁹ studied 108 patients at high risk for renovascular disease. All patients received a 2-week course of ACE inhibitor therapy. This increased the serum creatinine level by more than 20% in all 52 patients with severe bilateral RAS when volume retention was prevented by diuretic therapy. These authors proposed that a reversible increase in serum creatinine could be used as a safe clinical test for bilateral renovascular disease. These interesting results also show that caution is needed when using ACE inhibitors in patients with bilateral RAS and azotemia, especially during diuretic therapy.

Long-term studies over 6 to 24 months in a small number of patients with renovascular disease have shown that ACE inhibitor therapy is effective in reducing or normalizing BP and does not lead (in the group as a whole) to a progressive deterioration in renal function or to a decrease in size of the

poststenotic kidney.^{70,71} In a worldwide study of 269 patients treated with captopril, 40% were azotemic before therapy; a similar fraction had either a solitary kidney or advanced bilateral renovascular disease.⁷² Even within this latter group, clinically significant renal failure during captopril therapy developed in only 12%. Overall, there was good control of BP.

In another study, 75 patients with renovascular hypertension were randomized to triple therapy (hydrochlorothiazide, β -blocker, and hydralazine) or to an ACE inhibitor and a diuretic. Antihypertensive control was clearly better in the group given an ACE inhibitor plus diuretic; some 80% of this group maintained their GFR over a mean follow-up period of 7.5 months. However, 10 patients—mostly with very high-grade RAS—had a deterioration of renal function.⁷³

In a 4-year study of patients with renovascular hypertension, Losito and colleagues⁷⁴ found a cumulative survival of only 60%. Cerebrovascular and cardiovascular disease caused 92% of these deaths. A multivariate analysis identified treatment with ACE inhibitors as the only factor associated with significantly better survival. Their observational data highlights once more the dilemma facing physicians using medical therapy for renovascular disease. Do the benefits from better control of hypertension and prevention of associated cardiovascular disease with ACE inhibitors or ARBs outweigh the possibility of a reduction in the GFR of the poststenotic kidney?

An important issue is whether a reduction in the GFR of a poststenotic kidney during long-term ACE inhibitor treatment for RAS leads to irreversible renal atrophy, as in the animal model.³⁰ In a study of split renal function in six patients with RAS, Miyamori and colleagues⁷⁵ reported the individual kidney responses to 1 week and 1 year of captopril therapy (Fig. 57-4). After 1 week, the GFR of the poststenotic kidney was reduced, but renal plasma flow to the two kidneys was maintained or increased. These changes remained stable over 1 year. This study is reassuring because it shows that progressive loss of GFR leading to renal atrophy is quite unlikely in RAS patients treated with ACE inhibitors. However, this conclusion may not hold for patients with high-grade RAS.

Another potentially important consideration is the effects of renin-angiotensin-aldosterone system blockade on the nonstenotic kidney in patients with unilateral RAS. Clinical and experimental data in patients with hypertension and CKD from other causes suggest that ACE inhibitors and ARBs often improve renal outcomes, and these data may be relevant to effects on the nonstenotic kidney in patients with unilateral RAS. Theoretically, reducing the glomerular pressure with these drugs should be associated with better preservation of structure and function in the nonstenotic kidney and, therefore, equivalent or better long-term preservation of total kidney function. The use of ACE inhibitors and ARBs in hypertension is discussed in Chapter 52.

Diuretics

Renovascular disease is a high-renin state. It has been considered resistant to diuretic therapy. However, there are good reasons for selecting a diuretic with dietary salt restriction as a first-line therapy for many patients. The poststenotic kidney has sharply reduced perfusion pressure, which is a powerful stimulus for salt and water retention. The contralateral kidney, although perfused at high pressure, is under the influence of unusually high levels of circulating angiotensin II and aldoste-

Figure 57-4 Mean \pm SEM values from four patients with unilateral renal artery stenosis studied (a) before, (b) 1 week after, and (c) 1 year after starting therapy with captopril. Using split renal function for glomerular filtration rate and effective renal plasma flow, data were obtained for the overall function (Total) and individual functions in the nonstenotic (NS) and stenotic (S) kidneys. Compared with before * $P < .05$. (After Miyamori I, Yasuhara S, Takeda Y, et al: Effects of converting enzyme inhibition on split renal function in renovascular hypertension. *Hypertension* 1986;8:415–421.)

rone. Its pressure natriuresis mechanism is also reset to favor salt retention. Moreover, the contralateral kidney may be damaged by nephrosclerosis or may develop a stenosis of its artery, which will leave no normal kidney to regulate salt balance. Severe and unpredictable episodes of primary renal salt and fluid retention can occur, leading to overflow flash pulmonary edema.⁷⁶ Diuretics and salt restriction enhance the antihypertensive response to all other medical therapies, except perhaps CCBs. For these reasons, dietary salt should be restricted and a diuretic used at an early stage in most treatment regimens. Because diuretics cause a further stimulation of plasma renin activity, with enhancement of angiotensin II and aldosterone, additional measures to combat renin secretion or inhibit its effects are usually necessary. Renin secretion can be inhibited by a β -blocker, and the effects of angiotensin II and aldosterone blunted by an ACE inhibitor, ARB, spironolactone, or eplerenone.

Dietary salt restriction and diuretics have little effect on the GFR of normal subjects.⁷⁷ However, in patients with renal disease and hypertension, such treatment often reduces the GFR—at least initially.⁷⁸ Therefore, some increase in serum creatinine and BUN after initiating diuretic therapy should be anticipated. Diuretic therapy for hypertension is discussed in Chapter 51.

β -Blockers

β -Blockers are most effective in patients with high-renin hypertension. Thus, these are a rational treatment for renovascular hypertension. Moreover, β -blockers inhibit renin secretion powerfully,⁷⁹ so it is rational to combine β -blockers with diuretics to prevent the further rise in plasma renin activity that would otherwise occur. β -Blockers are strongly indicated in patients with angina or with prior myocardial infarction. β -Blocker therapy for hypertension is discussed in Chapter 51.

Central Agents and α -Blockers

Central agents such as clonidine, or peripheral α - and β -blockers such as labetalol or carvedilol, are effective in hypertension that is associated with increased sympathetic drive. During renovascular or renal parenchymal hypertension, there is increased neural input from the affected kidney, which engages a central sympathetic drive that maintains the hypertension.⁸⁰ Therefore, the use of these agents is rational, and usually effective as adjunctive treatment for more severe forms of renovascular disease. Comparison of the short-term response to clonidine and an ACE inhibitor in patients with renovascular disease shows that both agents reduce the BP, although the ACE inhibitor is more effective.⁶⁴ However, the ACE inhibitor reduces the GFR in the poststenotic kidney, whereas this remains stable with clonidine.

Calcium Channel Blockers

Calcium channel blockers reverse the hypertension and renal vasoconstriction associated with prolonged angiotensin II infusion and selectively vasodilate the afferent arteriole.²⁶ They should, therefore, be ideal for patients with renovascular disease by controlling hypertension without compromising GFR in the poststenotic kidney, which is prevented from barotrauma by the upstream stenosis. Moreover, they have mild natriuretic actions and can blunt the aldosterone response to angiotensin II.⁸¹ Their role in treatment is not yet clear. The effects of CCBs seen in animal models are confirmed in acute studies of patients with renovascular disease. In studies of patients with RAS⁶⁵ or post-renal transplant stenosis,⁶⁶ the GFR in the poststenotic kidney is reduced by ACE inhibitors but unchanged by CCBs. During longer-term studies in patients with unilateral RAS, both ACE inhibitors and CCBs reduce the blood pressure and increase the RBF in the contralateral kidney.²² The total GFR is not affected significantly by either treatment, but the GFR of the poststenotic kidney is reduced by 54% during ACE inhibitor therapy, compared to only 21% during CCB therapy. Hence, there can be a relative sparing of the GFR of the poststenotic kidney with a CCB. Therefore, CCBs are indicated in patients with renovascular hypertension when renal function is already compromised or has been unacceptably reduced by an ACE inhibitor or ARB. Moreover, CCBs can be used in azotemia without modification of the dosage. Further study is needed on the role of CCBs in long-term management of patients with renovascular disease. CCB therapy for hypertension is discussed in Chapter 53.

Renal Function

In general, trials that have compared an intervention by PTRAs alone or combined with stenting (PTRAs-S) with medical therapy have failed to show statistically significant differences in renal function at follow-up.^{1,2} On the other hand, case series⁸²

describe patients with global renal ischemia and progressive renal impairment in whom renal function is stabilized or improved after PTRAS, suggesting that patients with documented progression of renal insufficiency may benefit from revascularization. In a large case series of patients with RAS and elevated levels of serum creatinine who underwent surgical revascularization and were followed for at least 3 years, 25% had an improvement in kidney function, it was unchanged in about half, and 20% experienced a significant worsening in function. Without a control group for comparison, it is unclear how patients would have fared if they had been treated medically. However, improvements in kidney function are rarely seen in medically treated patients. Nevertheless, for the group as a whole, there was little net benefit of revascularization on kidney function.

To date, only one controlled trial, by van Jaarsveld and colleagues,¹⁴ has compared the renal function of patients randomized to medical therapy or PTRAS, examining approximately 100 patients over 1 year. At completion there were no differences in creatinine clearance between the two groups, leading to the conclusion that there was no clear benefit of PTRAS over medical therapy. However, closer inspection highlights problems with this study that make it difficult to interpret. Some 44% of the patients randomized to medical therapy were subsequently referred for PTRAS during the 1 year of study because they were felt not to have responded adequately to medical therapy. These crossover patients were nevertheless analyzed with the medical treatment group, thereby very seriously confounding the interpretation of the results. Of concern, 12% of patients in the medical treatment group suffered complete occlusion of a renal artery, and twice as many suffered a significant decline in renal function, as indicated by a doubling of serum creatinine level or a need for hemodialysis. This trial included patients with refractory hypertension and an RAS of more than 50%. Recent studies show clearly that a narrowing of 75% to 80% is required to produce renovascular disease.⁸ Thus, many patients in this study may not have had functional renovascular disease and therefore could not have benefited from therapy. However, similar outcomes for renal function after treatment with medical therapy or interventions lead to the conclusion that medical therapy is an acceptable choice for patients with RAS and CKD, at least in the short term. Medical therapy is less expensive and less likely to produce serious short-term adverse effects, such as atheroembolic disease or contrast nephropathy.⁶⁰

Many patients with RAS have renal insufficiency that may progress over time. Elevation in serum creatinine is a relatively insensitive marker for reductions in GFR in elderly patients. A formula such as the one derived from the Modification of Diet in Renal Disease (MDRD) study should be used to estimate GFR more accurately in affected patients. If renal functional impairment is present, practitioners should follow the guidelines established by the National Kidney Foundation Kidney Disease Quality Initiatives (DOQI). Treatment of hypertension, diabetes, and lipid disorders are specifically addressed elsewhere in this chapter. Dietary modifications and vitamin supplements, as outlined in the DOQI guidelines, may be needed as GFR declines. Anemia commonly develops as renal disease progresses, even before the need for renal replacement therapy. This should be treated with erythropoietin or a related analogue when the hemoglobin falls below approximately 11 g/dL.⁸³ Many patients also require either oral or parenteral iron supplements once therapy with erythropoietin is initiated.

COMMON COMORBIDITIES AND ADVERSE CARDIOVASCULAR EVENTS

Dyslipidemia

Data suggest that therapy that reduces low-density lipoprotein (LDL) cholesterol reduces total mortality, cardiovascular mortality, major cardiovascular events, and strokes in persons with established coronary artery disease. No specific evidence exists for treatment of LDL cholesterol in patients with RAS. However, according to the established guidelines, RAS should be considered a coronary artery disease equivalent for cardiovascular risk. Therefore, as in patients with established coronary artery disease, an LDL cholesterol below 70 mg/dL is the goal of therapy.^{84,85} This goal should be accompanied by therapeutic lifestyle changes, including diet and exercise. However, if these measures fail, patients should be started on one or more lipid-lowering medications, including statins, nicotinic acids, or fibrates (see Chapters 56 and 63).

Diabetes Mellitus

Of the patients with atherosclerotic RAS, approximately 20% to 30% will have diabetes, predominantly type 2 diabetes. In addition to controlling BP to a lower target than recommended in hypertensive patients without diabetes, evidence-based guidelines regarding glucose control should be followed (see Chapter 28). Clear evidence suggests that tight glucose control to an HbA_{1c} of less than 7% is associated with reductions in microvascular and macrovascular complications in both type 1 and type 2 diabetes.^{86,87} Additionally, medical nutrition therapy, multidisciplinary foot care (particularly for patients with peripheral vascular disease), eye care to prevent and treat diabetic retinopathy, and physical activity are recommended.

Smoking

Smoking is common among patients with RAS. Cessation is an important, but underemphasized, component of therapy for these patients. Smoking triggers vascular spasm, reduces the anti-ischemic and antihypertensive effects of β -blockers, and increases mortality after acute myocardial infarction. Smoking may accelerate the course of RAS by promotion of atherosclerosis and cholesterol emboli. Smoking worsens atherosclerotic disease in normotensive, nondiabetic, elderly patients with normal GFR. This is associated with a lower renal plasma flow, which likely results from ischemic nephropathy.⁸⁸ Smoking cessation reduces progression of vascular disease and the rates of reinfarction and death within 1 year after quitting. Unfortunately, many patients who quit smoking relapse within 6 to 12 months. Practitioners treating patients with RAS should adopt an aggressive approach to encourage and assist patients in smoking cessation (see Chapter 56).

Antiplatelet Agents

The long-term use of aspirin in patients with hypertension and those who have had a myocardial infarction is associated with a significant reduction in subsequent cardiovascular events and mortality.⁸⁹ In a meta-analysis of randomized, controlled trials in patients 1 week to 7 years after a myocardial infarction, those receiving aspirin experienced a 13% reduction in mortality, a

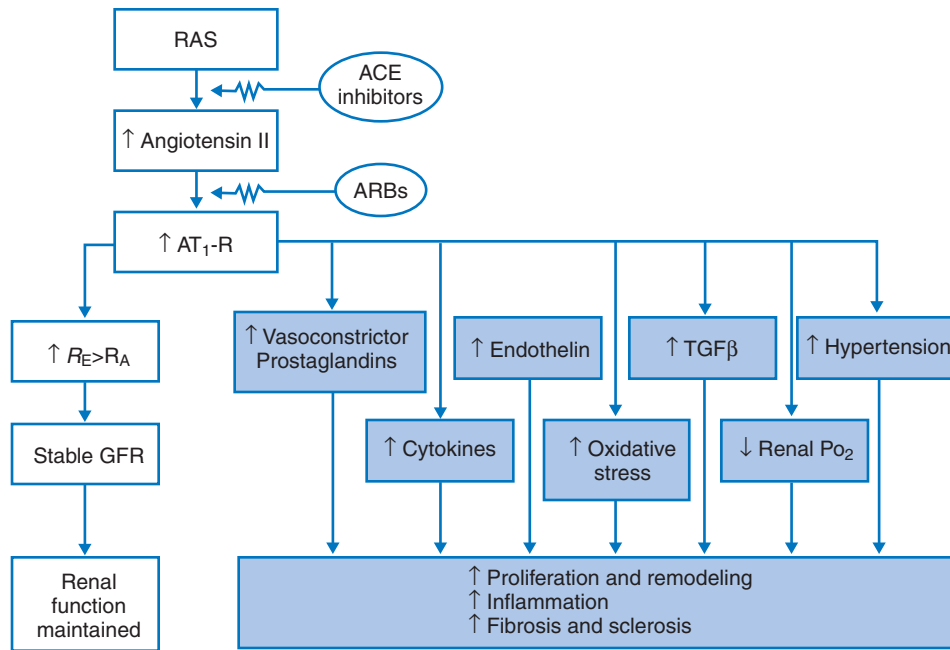

Figure 57-5 A diagrammatic representation of the contrasting effects of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy in patients with renovascular disease. Such therapy reduces the glomerular filtration rate (GFR) due to the effect of angiotensin II, increasing resistance of the efferent arteriole (R_E) compared to the afferent arteriole (R_A) of the poststenotic kidney. However, it counteracts many of the adverse mediators generated in response to angiotensin II action on type 1 receptors (AT_1-R) in blood vessels and kidneys. These include endothelin, vasoconstrictor prostaglandins, transforming growth factor- β ($TGF-\beta$), and numerous cytokines, as well as physiologic changes related to hypertension, hypoxia, and oxidative stress.

31% reduction in nonfatal reinfarction, and a 42% decline in nonfatal stroke.⁹⁰ Although these trials involved the use of aspirin in doses ranging from 300 to 1500 mg/day, a trial of 75 mg/day in patients with hypertension demonstrated a significant 15% reduction in cardiovascular events.⁹¹ This suggests that, even though there are no direct data in patients with RAS, long-term administration of aspirin in a dose as low as 75 mg/day is effective and should be recommended to patients with RAS. Thienopyridines such as clopidogrel or ticlopidine may also be useful for the prevention of cardiovascular events, either as alternatives or in addition to aspirin.

CONCLUSIONS AND RECOMMENDATIONS

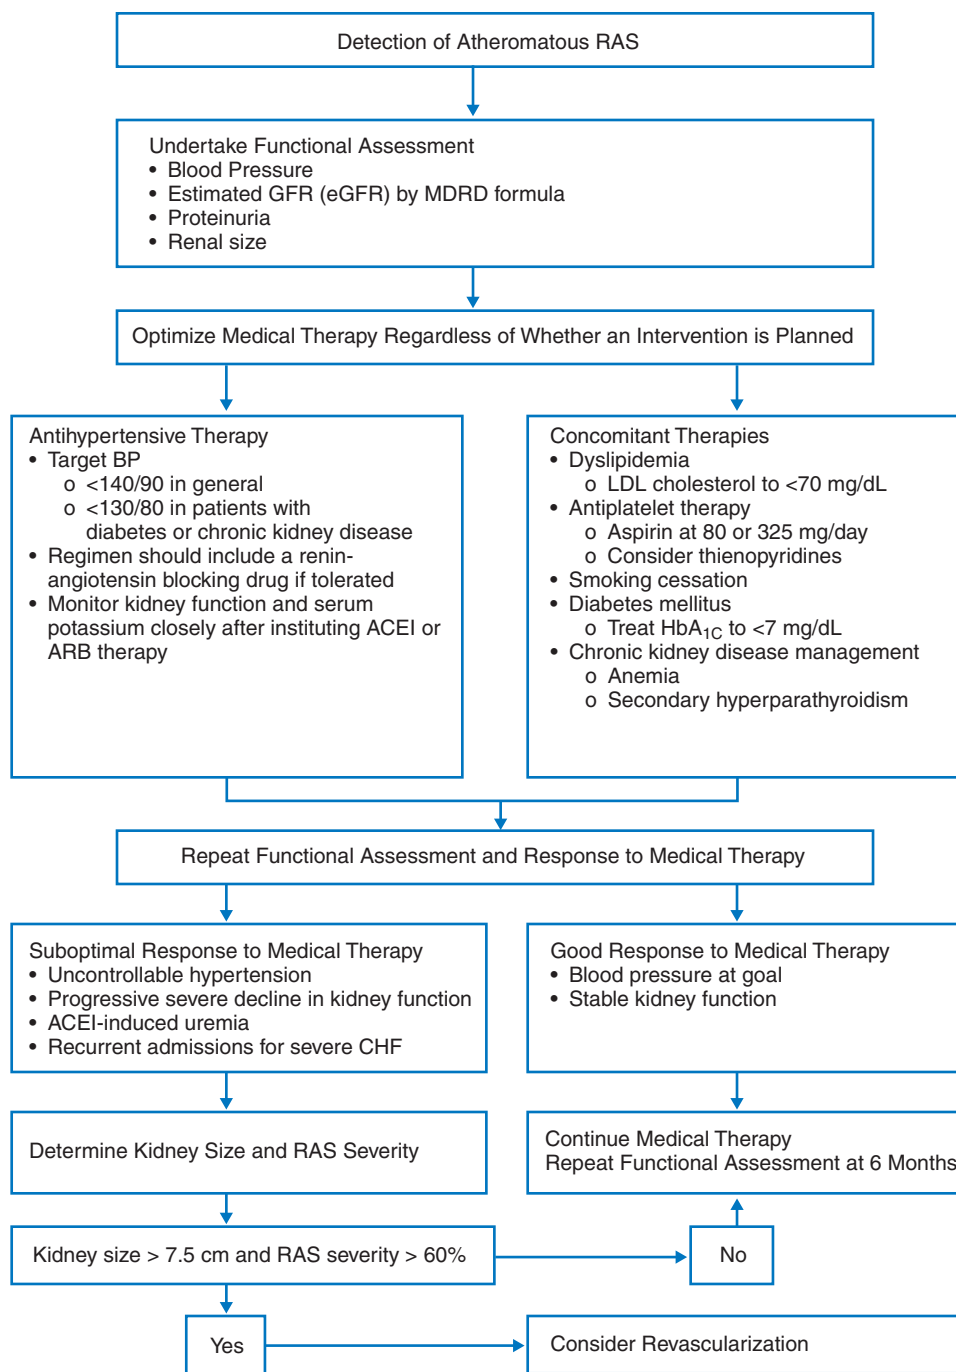

Although the studies are small and suffer from methodologic flaws, controlled clinical trials in patients with RAS have not shown any particular benefit of intervention over medical management for short-term changes in BP or renal function.^{14,60} Therefore, medical management is a reasonable choice for most patients with newly diagnosed renovascular disease. It is important to recognize that patients with atherosclerotic RAS are a high-risk group with poor outcomes, primarily due to adverse cardiovascular events. Therefore, regardless of whether an intervention is performed, all patients with atherosclerotic RAS require multifaceted medical intervention aimed at reducing their cardiovascular risk.

No long-term comparisons have been made between specific antihypertensive drugs in patients with renovascular

disease. Therefore, definite, evidence-based recommendations cannot be made. Nevertheless, as in other forms of hypertension, many patients benefit from a reduction in dietary salt intake and a low dose of diuretic. A reasonable goal for daily dietary salt intake is 100 mmol. The level of sodium intake can be assessed from the level of sodium excretion in a 24-hour urine collection. Data from a variety of studies in other settings suggest that blocking the renin-angiotensin-aldosterone system is beneficial both to slow progression of chronic renal disease and reduce cardiovascular risk. Case series suggest that ACE inhibitors or ARBs can be safely administered to patients with hypertension and RAS, often produce marked declines in BP, and may even improve clinical outcomes. Therefore, it is suggested that these drugs be included in the antihypertensive regimen for such patients. The small risk of severe acute renal failure in patients with bilateral high-grade RAS developing during renin system intervention mandates that serum creatinine, and serum potassium should be closely monitored after initiation of an ACE inhibitor or an ARB in this population. An early adverse change in renal function is not necessarily grounds to discontinue treatment. In any patient with an abrupt fall in BP, there may be a temporary decline in GFR with a rise of serum creatinine and BUN. This usually amounts to no more than a 20% to 30% increase, peaks in 3 to 7 days, and returns to baseline over the following few weeks or months of therapy. The trade-off hypothesis for beneficial and adverse effects of therapy in patients with renovascular hypertension is summarized in Figure 57-5.

Additional therapies depend on the clinical circumstances, concurrent disease, and identified cardiovascular risk factors

Figure 57-6 An algorithm for the approach to medical management of patients with renovascular disease. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CHF, congestive heart failure; GFR, glomerular filtration rate; LDL, low-density lipoprotein; MDRD, Modification of Diet in Renal Disease; RAS, renal artery stenosis.

(see Chapter 56). All patients require a lipid profile with correction of any identified increases in LDL cholesterol and lipoprotein(a) with appropriate use of statins, slow-release nicotinic acid, or other treatments (see Chapter 63). A low target for LDL cholesterol, such as 70 mg/dL, is indicated because the cardiovascular risk for patients with peripheral vascular disease or RAS is roughly equivalent to those with documented coronary artery disease. Consideration should be given to all patients for lifelong therapy with aspirin, at least in low doses (e.g., 80 mg once daily). The use of high-dose aspirin or other antiplatelet agents should also be considered. If the patient is a current smoker, a therapeutic antismoking program must be a high priority. Other rational recommendations in-

clude three to four periods of exercise of 20 to 30 minutes each week, a diet to limit intake of saturated fats and salt and, if necessary, a lower body weight.

Nontraditional cardiovascular risk factors have been identified in patients with renal insufficiency.⁹² These include hyperhomocysteinemia, oxidative stress, and nitric oxide deficiency related to accumulation of asymmetric dimethyl arginine^{93,94} (see Chapters 56, 64, and 65). The complications of chronic renal disease or diabetes, if present, should be treated according to published guidelines.

Patients who are established on medical therapy who do not have evidence of functional deterioration can often be managed by continued therapy under close medical supervision

with regular quantitative assessments, as indicated in Figure 57-6. Those who receive intervention with PTRAs, PTRAs-S, or reconstructive surgery also require close follow-up using similar quantitative measures, because there is approximately a 20% rate of restenosis, even in those treated by stenting, and a significant probability of developing a stenosis in the contralateral kidney.

A group of patients exists who either cannot be controlled adequately by medical therapy or who experience dangerous complications, such as recurrent flash pulmonary edema. Others have less to lose from a failed intervention, namely those who are already receiving dialysis therapy or are very close to ESRD. These patients may benefit from an intervention with PTRAs, PTRAs-S, or reconstructive surgery. (This is discussed further in Chapter 58.)

The individual steps in the algorithm shown in Figure 57-6 have not been subjected to properly controlled clinical trials. Therefore, they represent only an attempt at providing rational advice.

Few problems in nephrology are more controversial than decisions about when to undertake revascularization for renal artery stenosis (RAS). Technical advances related to endovascular stenting have led to widespread application of these procedures in the United States over the past decade. Minor degrees of stenosis may be detected “incidentally” in many patients with atherosclerosis elsewhere. These are often of minimal significance. However, high-grade RAS can lead to renovascular hypertension, which remains one of the most common secondary causes of hypertension. More severe lesions can produce critical loss of renal perfusion in the form of *ischemic nephropathy*, a potentially treatable form of progressive renal failure (Box 58-1). Advances in detection and imaging of RAS, in medical therapy of hypertension, and in endovascular methods, including vascular stents, make this a rapidly evolving field. With the use of endovascular stents, restoring the renal circulation becomes a realistic possibility for patients with ostial lesions, who were previously considered at unacceptable risk for major surgical procedures.

At the same time, application of endovascular procedures has expanded the range of clinicians caring for patients with refractory hypertension and declining kidney function. During the era of surgical reconstruction of renal arteries, the clinical care of refractory hypertension fell mainly to internists specializing in hypertension and kidney disease, who worked quite closely with vascular surgeons. Renal revascularization was applied cautiously because of the morbidity associated with aortic surgery and only after major efforts to ensure clinical benefit. As awareness of atherosclerotic renal artery disease has grown and noninvasive imaging has become more widely applied, general internists and cardiologists now address these problems. The finding that renal artery lesions commonly occur with other atherosclerotic disease has prompted some centers to perform aortic and renal angiography along with coronary angiography.^{1,2} Renal arterial lesions

that are detected are frequently treated with endovascular stents. During the years between 1996 and 2000 the number of Medicare claims for renal artery stenting rose from 7660 to 18,520. This was mainly due to procedures performed by interventional cardiologists³ (Fig. 58-1A). Recent guidelines proposed by interventional groups reinforce these practices, even while acknowledging the limited outcomes data to support this approach.^{4,5} This practice continues to expand. One stent manufacturer (Boston Scientific, personal communication) indicated that more than 60,000 procedures were undertaken during 2005. Whether these procedures produce objective clinical benefits is questionable, according to evidence of published studies of randomized, controlled trials.⁶ For this reason, the U.S. Centers for Medicare & Medicaid Services (CMS) is reviewing reimbursement criteria for renal artery stenting with a stated goal to limit Medicare reimbursement for this procedure. Several prospective trials are in progress in the United States and elsewhere to better define the natural history and need for intervention in the current era of cardiovascular risk reduction. The National Heart, Lung, and Blood Institute (NHLBI) is funding a randomized, prospective trial of intensive medical therapy with and without stenting—the Cardiovascular Outcomes of Renal Atherosclerotic Lesions (CORAL) trial, which is scheduled for completion in 2011.⁷

The purpose of angioplasty with or without stenting is to restore blood flow and perfusion pressure to the kidney beyond a stenotic lesion. Ultimately, these procedures are intended to improve blood pressure (BP) control and to reduce the risks of hypertension—in principle, to “cure” renovascular hypertension—and to salvage kidney function beyond a “critical” RAS. Although these goals seem quite reasonable, it remains difficult to identify individual patients who have the greatest likelihood of achieving them. Nephrologists recognize that invasive renal vascular procedures present hazards even in the best of circumstances. Complications from atheroemboli,

vessel dissection, contrast toxicity, and other adverse events sometimes worsen renal function and aggravate hypertension, such that renovascular procedures cannot be undertaken casually. Moreover, these proceedings entail considerable expense. Hence, the risks and benefits for each patient's situation require careful consideration. The goal of this chapter is to summarize our current state of knowledge regarding patient selection, technical features, outcomes, and hazards of renal artery angioplasty and stenting in the current era.

DEMOGRAPHICS OF RENOVASCULAR DISEASE

Patients with fibromuscular diseases of the renal arteries are more commonly young and female than those with atherosclerosis. The former constitute 16% to 20% of patients with renovascular lesions referred for vascular procedures, at least for refractory hypertension. It should be emphasized that patients with fibromuscular disease usually have normal renal function

and are at low risk for progressive occlusive disease and renal functional loss.⁸ Such patients are sometimes detected as a result of developing hypertension during pregnancy or at an early age. Most often patients with fibromuscular disease have normal-appearing aortic vessels and are at low risk for complications of vascular manipulation. As a result, the potential risks of angioplasty are low and the benefits of improved BP more likely to offer long-term advantage. As a result, revascularization is often recommended for these patients.⁹

The advancing age of the U.S. population is associated with the rising prevalence of RAS from atherosclerosis.¹⁰ Whether the true prevalence is increasing is not known. What is certain, however, is that the mean age of reported series of renal revascularization has increased by more than 15 years from the 1970s.¹¹ The median age of treated patients is now 71 years (see Fig. 58-1B). As a result, patients with atherosclerosis have a longer background history of hypertension and a greater risk of comorbid disease (including diabetes, peripheral vascular disease, coronary disease, and carotid disease). Atherosclerosis is a systemic disease. Thus, it is not surprising that some degree of atherosclerosis affects the kidney in 30% to 50% of individuals when atherosclerosis is detected elsewhere (e.g., during coronary or lower extremity angiography).¹² The benefits and goals of renal revascularization must be weighed in the context of "competing" risk from other cardiovascular diseases. These competing risks can offset the benefits of restoring the renal circulation in marginal cases.

RISKS OF DISEASE PROGRESSION

One of the compelling reasons to restore renal artery patency is the potential for untreated lesions to progress to total occlusion and functional loss of the entire kidney. Such arguments have led to speculation that unsuspected renal artery

Figure 58-1 **A**, Rise in the number of Medicare claims for renal artery revascularization during the years 1996–2000, corresponding to widespread application of endovascular stents. The largest rise in procedures came from interventional cardiologists (2.4-fold increase). (From Murphy TP, Soares G, Kim M: Increase in utilization of percutaneous renal artery interventions by Medicare beneficiaries 1996–2000. *Am J Roentgenol* 2004;183:561–568.) **B**, Mean ages of selected series of surgical or endovascular intervention for renal artery stenosis. Early data, including unilateral nephrectomy, are included as a reference point. The techniques available have changed, with a marked increase in the use of angioplasty and stenting in recent years. The ages and associated comorbid disease risks have increased considerably during this period. Reasons for the change in demographics include changes in survival from coronary disease and stroke, changes in medical therapy, and the ability to intervene safely in patients considered at unacceptable risk in the past (see text). PTRA, percutaneous transluminal renal angioplasty.

Figure 58-2 Rates of progressive vascular disease, as evidenced by increased flow velocities in 295 arteries measured prospectively at 6-month intervals between 1990 and 1997. The probability of disease progression was related to the initial severity of stenosis, but remarkably few proceeded to total occlusion (9/295 vessels, or 3%). Estimates of change in vessel characteristics are higher than the number demonstrating clinical progression in the form of either intractable hypertension or renal dysfunction (see text). (From Caps MT, Perissinotto C, Zierler RE, et al: Prospective study of atherosclerotic disease progression in the renal artery. *Circulation* 1998;98:2866–2872.)

occlusive disease may account for up to 14% to 20% of patients, particularly whites, reaching end-stage renal disease (ESRD).¹³ Doppler ultrasound studies conducted between 1990 and 1997 confirm that stenotic lesions can progress, as evidenced by increases in blood flow velocities over time (Fig. 58-2).¹⁴ The likelihood of progression is directly related to the severity of the initial stenosis. Remarkably, total occlusion was observed in only 9 of 295 vessels (3%). This is a lower frequency than had been reported in earlier angiographic series.

Whether progressive vascular stenosis by Doppler ultrasonography translates into clinical progression is less clear. Reports from The Netherlands of high-grade renal artery disease discovered incidentally suggest that none resulted in renal failure during follow-up periods of 8 to 10 years.¹⁵ Serial measurements of kidney size during Doppler ultrasound measurements identify loss of kidney volume as less frequent than a change in renal hemodynamics¹⁶ (Fig. 58-3). Follow-up studies of patients with incidental high-grade RAS (>70% lumen affected), who were managed without revascularization during

Figure 58-3 Cumulative rates of “atrophy,” defined as a 1-cm reduction in renal length in kidneys followed prospectively by Doppler ultrasonography between 1990 and 1997. The likelihood of loss of size was less than that for measurable progression of flow velocities; atrophy was infrequently associated with a rise in creatinine. Predictors of atrophy included peak systolic velocity above 400 cm/sec. (From Caps MT, Zierler RE, Polissar NL, et al: Risk of atrophy in kidneys with atherosclerotic renal artery stenosis. *Kidney Int* 1998;53:735–742.)

1989–1993 in the United States, indicate that only 10% to 15% come to revascularization based on progressive renal dysfunction or uncontrollable hypertension.¹⁷ Recent population-based studies indicate that 6.8% of individuals older than age 65 have more than 60% renal artery stenosis but that rates of progression appear to be approximately between 0.5% and 1.3% per year.¹⁸ During an 8-year follow-up, just 4% progressed to “significant” stenosis. These observations are supported by follow-up of 40 patients with high-grade RAS treated with “aggressive” medical therapy, only 6 of whom later went on to revascularization on clinical grounds.¹⁹ The hazard of RAS is different for patients with unilateral disease (one kidney affected by stenosis, the other without stenosis) compared to those with bilateral disease (usually identified as high-grade stenosis to both kidneys or stenosis to a solitary functioning kidney).²⁰ In the former, vascular progression, even to the loss of one kidney, is buffered by a “spare” contralateral kidney. Therefore, the change in renal function associated with unilateral disease is usually minor. Moreover, both kidneys are rarely affected to the same degree. Many clinical reports focus on tracking the “reciprocal creatinine” or other estimates of glomerular filtration rate (GFR) over time.²¹ Although this method is time-honored with regard to monitoring progression of parenchymal kidney diseases such as diabetic nephropathy, it has only limited relevance to tracking the decline in function associated with renovascular disease. Cases have been observed in which slope has changed from negative to zero with complete occlusion of one renal artery, a change that might wrongly have been attributed to a benefit of “successful” stenting as proposed by some interventional guidelines.²² Presumably, improved function of the other kidney must have offset loss of negligible function in the thrombosed kidney.

In the instance of RAS to the entire renal mass, however, progressive loss of blood supply does threaten renal function overall, making renal failure and circulatory congestion, or “flash” pulmonary edema, genuine concerns.²³ Understanding the true magnitude of progression risk for the individual patient is crucial to identifying the risk-benefit ratio regarding angioplasty and stenting. It is likely that current levels of disease progression will continue to fall. This may reflect more intense efforts at BP control, smoking cessation, and lipid lowering.

DIAGNOSTIC CONSIDERATIONS IN RENAL ARTERY DISEASE

Physicians in the United States are encouraged to obtain basic information regarding kidney function and cardiovascular risk and to follow recommendations of the Joint National Commission (JNC) to minimize testing and focus on BP reduction.²⁴ With the widespread application of effective antihypertensive medications, including agents that interrupt the renin-angiotensin system, such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), many individuals with RAS are treated effectively and are never detected (see Chapter 48 and Chapter 52 regarding recommendations for medical therapy). Thus, many patients considered candidates for renal revascularization have been treated for hypertension for a long time. Consideration for revascularization often begins as they develop recognizable syndromes of progressive renovascular disease, as summarized in Box 58-1. Most of these include a combination of

resistance to antihypertensive therapy and deterioration of renal function. Often, these signal more severe stenoses or the development of bilateral disease.

Diagnostic studies now focus primarily on establishing whether high-grade RAS is present, whether it affects both kidneys or the entire functioning renal mass, and whether it is amenable to endovascular repair or is associated with more widespread aortic disease, such as an abdominal aortic aneurysm. Biochemical studies to determine renin release or lateralization are less commonly performed. In many centers, angiography is reserved until these issues are resolved, with the intention of undertaking endovascular repair at the same sitting if needed. As a result, most individuals undergo some form of vascular staging, which may consist of Doppler ultrasonography, captopril renography, and magnetic resonance angiography (MRA) or computed tomographic angiography (CTA). The last two now produce excellent images, including localization of the site of lesions and associated aortic disease (Fig. 58-4). CTA has the disadvantage of requiring iodinated contrast and carries a risk of contrast nephrotoxicity, particularly in patients with preexisting impairment of kidney function or diabetes.²⁵ Although gadolinium contrast carries little or no nephrotoxic risk at the doses used for MRA, recent reports of nephrogenic systemic fibrosis have led the U.S. Food and Drug Administration (FDA) to express concern that gadolinium-based contrast may be a contributory factor. This rare condition, a disabling fibrotic process that restricts movement of skin, joints, and muscles,²⁶ has been reported to date only in patients with reduced GFR (<30 mL/min/1.73 m²),

Figure 58-4 Magnetic resonance angiogram in an 81-year-old woman with deteriorating renal function and accelerated hypertension. This study illustrates extensive aortic disease associated with high-grade stenoses of both renal arteries and a delayed nephrogram in the left kidney. Although these images can be obtained with little risk of nephrotoxicity, recent concerns about the potential for gadolinium-based contrast to produce nephrogenic systemic fibrosis limit its use to subjects with estimated glomerular filtration rate above 30 mL/min/1.73 m² (see text).

often in those with hepatorenal syndrome in and around the period of liver transplantation. Until now, no treatment for nephrogenic systemic fibrosis has proven effective; it appears to be irreversible. The FDA has offered an “alert” regarding the need to limit procedures in patients with estimated GFR (eGFR) less than 30 mL/min, attempt to avoid them in patients with eGFR less than 15 mL/min, and inform patients of the potential risks. There is a pressing need to improve alternative methods for imaging the renal vasculature in patients with reduced GFR.

Predictors of a favorable response to renal revascularization remain elusive. Recent progression of hypertension despite therapy or recent loss of GFR remain among the most valuable features. Some authors argue that demonstration of elevated resistive index on Doppler ultrasonography portends intrinsic fibrosis and small-vessel disease in the kidney that will not improve after stenting.²⁷ Other reports challenge this observation.^{28,29}

RENAL ANGIOPLASTY AND STENTING

Goals of Renal Angioplasty and Stenting

The goals of correcting RAS include improving BP and preserving renal function. These goals for clinical success differ from the goal of technical success, restoring vessel patency.

Angioplasty alone for fibromuscular disease can open the renal arteries with excellent results.³⁰ This disease often affects the midportion segments of the renal artery and may comprise “webs” with partial obstructive effects in series. Individuals with fibromuscular disease often have normal kidney function and may derive more clinical benefit than patients with parenchymal renal disease. Occasionally, fibromuscular disease and atherosclerosis may coexist and must be addressed separately in the same patient.

Atherosclerosis commonly affects the proximal portion of the renal artery, particularly at the ostium. It may represent extension of an aortic plaque into the renal artery. Such lesions typically do not respond well to balloon angioplasty alone and tend to recoil immediately after dilation. For that reason, stents have been employed to maintain vessel patency for ostial lesions. Randomized, prospective studies indicate that stents unquestionably improve primary patency rates for ostial renal artery stenoses.³¹ Although in the United States stents are approved by the FDA for use in the renal arteries only for *failed angioplasty*, interventional radiologists and cardiologists now commonly employ them for “primary” stenting of atherosclerotic lesions.

The role of distal embolic protection devices in the renal artery is unclear. Although these devices are approved for use in specific coronary artery procedures and are commonly used in carotid stenting, the anatomy of the renal arteries differs in some respects from those vessels. Whereas atheroemboli represent a major concern for the success of renal artery stenting, experimental studies indicate that embolic phenomena can occur at any stage of the procedure, including the initial passage of the guidewire, inflation of the balloon, and expansion of the stent. Clinical studies indicate that embolic phenomena can develop in subsequent days or weeks. Initial reports indicate that embolic protection devices can, in fact, capture embolic debris, but whether they improve long-term

results is not yet known. Initial experience in CORAL using a protection device led to enough adverse events that its use was discontinued.

Techniques of Renal Angioplasty and Stenting

Renal arteriography with angioplasty and stent placement should be performed in a peripheral vascular suite with digital subtraction capability by an individual who is properly trained and skilled in percutaneous vascular intervention. In general, these procedures are done under conscious intravenous sedation from a transfemoral approach. For patients with chronic renal insufficiency, especially those who are diabetic, an alternative to iodinated contrast material for arteriography should be considered. Although image quality may not be as good, carbon dioxide or gadolinium provide sufficient enhancement for diagnostic imaging and intervention and lack the nephrotoxicity of iodine. However, as noted above, the potential for gadolinium to predispose to nephrogenic systemic fibrosis favors avoiding this agent when the eGFR is lower than 30 mL/min/1.73 mL².

The tools for endovascular therapy have improved.³² Equipment manufacturers now provide a wide variety of smaller catheters (commonly 0.014 mm) and an array of low-profile systems. The interventionist can now safely open even the most severely stenosed renal artery arising from a tortuous, ulcerated aorta. Digital imaging systems with high-quality fluoroscopy, excellent image acquisition, and accurate stenosis assessment programs provide physicians maximum flexibility in treating patients with atheromatous disease in all vascular beds. The proliferation of these systems in cardiology catheterization laboratories, radiology angiography suites, and surgical operating rooms testifies to the broad acceptance of endovascular therapy for occlusive arterial disease by both the public and the majority of practitioners.

Patients with fibromuscular dysplasia are treated with balloon angioplasty alone. Atheromatous disease is now treated almost universally with balloon-expandable stents. Pre-stent placement planning has been simplified by the three-dimensional angiographic images generated via CTA and MRA. It is now common in most experienced centers to have such studies available before catheterization as part of a thorough workup to determine eligibility and suitability for invasive treatment.

Femoral access for stent placement is preferred for most patients. Some patients with severe inferior angled renal arteries may be better approached from the brachial artery. If a patient has adequate prior imaging of the aorta, it is not necessary to do an aortic flush. Direct baseline imaging of the renal artery is performed with a guide catheter chosen to fit the anatomy. The image intensifier is angled to produce a tangential view of the origin of the renal artery from the aorta. Confirming the degree of stenosis with imaging software is recommended, because simple visual estimates (the “eyeball” technique) overestimate the severity.³² Intravenous heparin is administered to achieve an activated clotting time of 225 to 300 seconds. Using a 0.014-mm wire, the stenosis is crossed and the wire advanced only as far as needed to gain purchase for catheter manipulation. If filter wire protection is desired, the wire can be positioned at this time. Some practitioners measure pressure gradients routinely as well, a practice recommended for borderline

lesions. In general, a 20 mm Hg systolic or 10 mm Hg mean gradient is considered significant.³² Most lesions do not require predilatation when using low-profile, premounted stents. The stent should be sized so that it completely covers the lesion and extends slightly into the abdominal aorta. The diameter should be such that the stent does not overexpand the natural diameter of the vessel. The balloon-mounted stent should be positioned across the lesion and checked with small contrast injections to allow for adjustment. Balloon expansion is done slowly while holding the system steady. The stent is allowed to “dog bone” slightly and can be adjusted for optimal positioning. Slow, gradual balloon inflation with a steady hand on the guide catheter, balloon, and wire can avoid movement of the stent during deployment.

After stent placement, careful imaging is important to confirm stent position and expansion and to identify renal artery branches. A nephrogram should be visualized. This step allows one to determine if additional stent expansion is needed. Documenting preservation of renal parenchyma or identifying embolic complications or peripheral branch dissections is helpful for immediate postprocedure management.

The presence of multiple renal arteries can complicate therapy. These arteries tend to be smaller caliber vessels that can originate from awkward locations. The likelihood of restenosis or technical failure is greater in smaller vessels.³³ It is our opinion that stenting arteries smaller than 4 mm in diameter should be avoided. Early renal artery bifurcations also can pose a technical challenge. They may require multiple stents with coordinated junctions (*kissing stents*). In patients with difficult anatomy, having two interventional operators with experience working together has proven to be useful.

After stent placement, patients are placed on an antiplatelet regimen (usually clopidogrel) for 6 to 8 weeks and evaluated with Doppler ultrasonography. Because renal artery stent restenosis is common, careful follow-up is needed to allow for timely re-intervention if in-stent hyperplasia occurs.

Embolic Protection Devices

The effect of renal artery stent placement on renal function remains ambiguous, in part because no randomized, prospective studies compare medical therapy directly with stent placement. Perhaps just as important, observational cohort studies from patients with reduced GFR indicate that renal function after stent placement sometimes improves (~25%), sometimes remains stable (no clinically important change, ~50%), but sometimes worsens (18%–24%).^{34,35} For some of those patients with functional deterioration, local and systemic embolization play a role. In patients with low functional reserve, even small amounts of microembolic particles may cause further losses in glomerular filtration. Investigators have explored the renal artery application of filtration devices designed for coronary and cerebral vascular procedures.

Walker and associates reported that particles as large as 3 mm in diameter could be aspirated from guide catheters placed into renal arteries during intervention.³⁶ Angiographers have observed atheromatous debris welling out of a backbleeding catheter hub in patients with advanced atherosclerosis. Hiramoto and colleagues reported that manipulating a 0.018-mm guidewire across an ex vivo aortorenal atheroma could release thousands of tiny particles and that stent expansion was associated with further embolic particle

release.³⁷ It is likely that nearly any vascular manipulation releases some embolic debris. Remarkably, overt clinical manifestations remain uncommon.

Although distal microembolization during renal artery stent placement undoubtedly occurs, its true prevalence is not known. Many patients appear to have sufficient renal functional reserve to mask the effect of microembolization. For those with preexisting renal insufficiency, the clinical effects of atheroemboli can be significant. In a prospective series of 95 cases with acute renal failure developing from atheroemboli, 37% of patients required dialysis, 24% progressed to ESRD, and mortality was 38%.³⁸ Krishnamurthi and colleagues reported a decreased 5-year survival in patients with renal biopsy-proven atheroembolus (54%) as opposed to those without (85%) after open renal revascularization.³⁹ There is no treatment for atheroembolism. Prevention is the only solution.

Currently available embolic protection devices are basically either balloon occluders or filters. A device developed for renal intervention (Angiogard, Cordis Corp, Warren, N.J.) was used in the CORAL trial, but its use was discontinued. Operator experience indicated many limitations, and it was considered uneconomical. Because of the variability of renal artery anatomy, not all cases will be suitable for embolic protection device use. Our experience is that effective use of these devices requires experience because improper use can result in significant complications.

Few published reports examine renal protection devices. Holden and associates achieved improved or stabilized renal function in 95% of 37 patients with renal insufficiency using the Angioguard device.⁴⁰ Embolic debris was demonstrated in 65% of cases. Henry and colleagues reported results in 105 poorly controlled hypertensive patients in which they used both balloon occlusion and filter types of protection devices during stent placement⁴¹; 39 of these patients had a serum creatinine of 1.5 mg/dL or greater. Particulate debris was captured in more than 80% of cases. At 6 months, only 1 of 91 patients who had moderate renal insufficiency had a deterioration in renal function, whereas 21 with renal insufficiency had improved renal function and 69 patients had stable function. At 2 years (75 patients), only 2 patients had deteriorations in renal function (3%). These results suggest a significant benefit to using a renal protection device as opposed to stenting without protection, based on historical comparisons.

Conversely, Cooper and colleagues reported their experience to the 2007 American College of Cardiology Innovation in Intervention Summit on a multicenter trial in which 100 patients undergoing renal artery stent placement were randomized to the use of an Angioguard device or double-blinded use of a glycoprotein IIb/IIIa inhibitor (abciximab) in a 2×2 factorial design (C. Cooper, personal communication). There was no benefit to renal function in the patients treated with the filter alone. Only patients who had both filter wire use and received abciximab had any improvement in renal function after stent placement.

Although distal protection during stent placement seems reasonable, much more work needs to be done. Optimal patient selection needs to be defined. Randomized trials are essential. An easily deployed device designed specifically for the renal arteries is required before this technology can be established for renal artery revascularization.

Outcomes of Renal Artery Angioplasty and Stenting

Endovascular procedures are evaluated by considering the benefits on BP control and renal function in comparison with complications.

Fibromuscular Disease

“Technical success” exceeds 90% in fibromuscular disease (Fig. 58-5). These lesions are made more complicated if they extend into segmental branches. Occasionally fibromuscular disease is associated with aneurysmal dilation, which does not benefit from angioplasty. Dilation of dysplastic webs occasionally leads to arterial dissection or occlusion of the small segmental vessels.

Blood Pressure Outcomes

Clinical effectiveness of intervention for fibromuscular disease is high. Some patients need no further antihypertensive medications (Table 58-1),^{8,42,43} and many others are considered

“improved.” As a result, many authors consider balloon angioplasty as standard therapy for fibromuscular disease. As noted by Aurell and Jensen, Ramsay and Waller,^{42,44} and others, reported response rates to percutaneous transluminal renal angioplasty (PTRA) differ widely between studies and between different time periods. This may be the case for several reasons that are worth emphasizing:

1. Target BP levels are changing, generally to lower levels. Earlier studies used criteria of achieved BPs lower than 160/95 mm Hg, or simply diastolic pressure lower than 90 mm Hg, whereas more recent targets seek to achieve BP levels lower than 140/90 mm Hg. Consequently, fewer patients remain medication-free or are considered “cured.”
2. Standards for measuring BP and administering antihypertensive therapy are highly variable. Therefore, interpretation of “benefit” is inconsistent.
3. Patient selection varies among studies, including such factors as duration of hypertension and urgency of intervention.

Figure 58-5 **A**, Focal fibromuscular disease in the midportion of the right renal artery in a 42-year-old female. Note that distal vessels are well preserved with normal renal function but severe hypertension. **B**, This lesion was dilated successfully using percutaneous transluminal renal angioplasty with an excellent technical result and clinical outcome.

*The percentage shown is the total for cured and improved.

Summary of published series for PTR (percutaneous transluminal renal angioplasty) for fibromuscular diseases between 1983 and 2003. Recent series emphasize the potential for high rates of technical success, with improved blood pressure control in 74% to 88% of subjects. Nonetheless, 12% to 26% of patients have little blood pressure response, and complication rates range between 7% and 28%. Patients with fibromuscular disease are at less risk for systemic emboli than those with aortic atherosclerotic disease.

Reproduced from Slovut DP, Olin JW: Current concepts: Fibromuscular dysplasia. *N Engl J Med* 2004;350:1862-1871 with permission.

Renal Function Outcomes

Most patients with isolated fibromuscular disease have normal renal function. Medial fibroplasia is the most common variant of fibromuscular disease and rarely progresses to renal insufficiency. Hence, there is little justification for undertaking balloon dilation of these lesions for preservation of renal function alone.

Atherosclerotic Disease

The results of PTRAs with or without stents for atherosclerosis are more ambiguous and merit close consideration. A recent review of the field commissioned by the U.S. Agency for Healthcare Research and Quality (AHRQ) concluded that “. . . the evidence is not sufficiently robust to determine the comparative effectiveness of angioplasty (with or without stenting) and medical treatment alone. . .”⁶

Blood Pressure Outcomes

Many reports are limited to retrospective observations of BP before and at intervals after a procedure, without standardization of conditions or antihypertensive therapy. Several summaries have been published comprising more than 1000 people subjected to PTRAs and stenting. Some of these are summarized in Tables 58-2A and B. Lack of standard medical therapy has led to reports of reduced “number of medications” with little regard for differences between medication regimens. This point deserves emphasis because three prospective, randomized controlled trials comparing medical therapy of atherosclerotic renal artery disease with PTRAs, in which therapy and BP measurement were standardized, found only minor BP benefits from PTRAs (Table 58-3).^{45–47} These

studies were small and limited by patient selection, but they underscore the effectiveness of current drug regimens and the relative infrequency of “cure” in patients with atherosclerosis. They excluded many patients with progressive renal dysfunction, accelerated hypertensive disease, or recent cardiovascular events.

The DRASTIC study (Dutch RAS Intervention Cooperative Study Group) included 106 patients with relatively resistant hypertension, randomized to either medical therapy or PTRAs. The lack of difference in BP after 1 year between patients treated with PTRAs and those treated medically led the authors to conclude that “angioplasty has little advantage over antihypertensive drug therapy.”⁴⁷ This study was analyzed under “intention to treat” statistical rules, in which 22/50 patients assigned to medical therapy (44%) crossed over to the PTRAs arm due to uncontrolled BP at 3 months. Some might argue that this group provides compelling evidence of medical treatment failures and the benefit of the renal revascularization for such individuals.

The ambiguity of these recent studies highlights changes in medical practice. In the era before potent antihypertensives, renovascular hypertension commonly presented as refractory to treatment, with accelerated or malignant-phase manifestations. Reports from emergency departments suggested that nearly 30% of hypertensive emergencies in white people were derived from individuals with renovascular hypertension. Some of these were refractory to therapy with the agents then available; the patients suffered recurrent episodes of malignant hypertension, sometimes requiring bilateral nephrectomy as a lifesaving measure.⁴⁸ With the introduction of more effective and tolerable antihypertensive regimens, particularly those capable of blocking activation of the renin-angiotensin system, an inability to control BP is a far less frequent motivation for renal revascularization. What must be considered in each case is whether the limits of antihypertensive therapy have been reached and whether progressive occlusive disease poses a hazard for the individual patient.

Table 58-2A Outcomes of PTRAs and Stenting

Blood Pressure	ATHEROSCLEROTIC DISEASE		
	“Cured”	Improved	Failed
Stent (N = 678)	20%	49%	31%
PTRAs (N = 644)	10%	53%	37%
Renal Function	“Improved”	Stable	Worse
Stent (N = 678)	30%	38%	32%
PTRAs (N = 674)	38%	49%	21%
Surgery (N = 733)	25%–30%	45%–50%	20%–25%

Summary of published outcomes of PTRAs (angioplasty) and stenting for atherosclerotic renal artery stenosis. Interpretation of these reports must be considered in the context of highly variable definitions of “cure” and “improved” blood pressure responses, which lead to high variability between reports^{42–44} (see text). Results in patients with atherosclerotic disease generally are worse than in those with fibromuscular disease. The results with PTRAs and stents are adapted from a recent “meta-analysis” of published series.⁵⁶

Renal Function Outcomes

Some authors argue that the primary motivation for renal revascularization is now “preservation of renal function.”⁴⁹ This premise is based on the potential for progressive loss of renal function beyond critical levels of RAS and the possibility of restoring blood flow with effective procedures. Dramatic proof of this concept is available from case studies of individual patients with advanced renal insufficiency regaining viable kidney function after successful PTRAs or surgery.^{50,51} In some instances, this has meant that they no longer require dialysis therapy. Few experiences are more rewarding to nephrologists. Even when advanced renal dysfunction is not present, it is sometimes prudent to revascularize the kidney to protect it from future progressive vascular occlusion. An example of this is illustrated in Figures 58-6 and 58-7.

However, this argument is tempered by review of renal functional outcomes in several recent series, summarized in Table 58-1. Remarkably, group mean measures of renal function, as reflected by serum creatinine levels, are rarely changed by renal revascularization, with either surgery or PTRAs. However, mean values obscure several distinctly different outcomes.³⁴ Some patients experience major improvements in renal function (20%–25%). Most have no detectable change in function (50%). Unfortunately, the first group is

Table 58-2B Effects of Renal Artery Revascularization versus Medical Treatment Alone on Clinical Outcomes

Outcomes	Strength of Evidence	STUDIES (PARTICIPANTS), N			Conclusion
		Randomized Trials	Other Comparative Studies	Cohort Studies	
Death	Weak	1 (55)	4 (381)	30 (4646)	No large difference in mortality up to about 5 yr between revascularization and medical treatment.
Kidney function	Acceptable	2 (103)	7 (428)	34 (4916)	No substantial difference in kidney function; improvements were reported in cohort studies only among patients receiving revascularization.
Blood pressure	Acceptable	2 (103)	8 (597)	34 (4275)	Some evidence that blood pressure may be lowered more after angioplasty than with medical treatment alone, particularly among patients with bilateral disease (range, no difference to 26/10 mm Hg lower after angioplasty); cure of hypertension was reported in cohort studies only among patients receiving revascularization.
Cardiovascular events	Weak	1 (55)	1 (52)	3 (560)	No large differences found in comparative studies up to about 4 yr.
Adverse events	Weak	2 (103)	4 (323)	31 (4906)	Evidence does not support meaningful conclusions about relative adverse events or complications from angioplasty compared with medical treatment.

Summary of randomized trials, comparative studies, and observational cohort studies with more than 5000 patients reviewed as part of an Agency for Healthcare Research and Quality (AHRQ) report on comparative effectiveness strategies for renal artery stenosis.⁶

Table 58-3 Three Randomized, Prospective Studies Comparing Medical Therapy and PTRAs (with and without Stents)

Study	Number of Subjects	Features	Outcome
Webster et al ⁴⁵	N = 55 Unilateral = 27	Run-in medical therapy	No difference in BP, renal function, survival ?Crossover?
Plouin et al ⁴⁶	N = 49 All unilateral	Multicenter Ambulatory BP monitoring at 6 months No ACE inhibitors	No difference in BP Slightly fewer meds in PTRAs group, more complications Crossover in medical therapy: 7/26 (27%)
Van Jaarsveld ⁴⁷	N = 106	Multicenter, office and automated BP measurement, lateralization studies (scan, renal vein renin)	No difference in BP at 12 mos Crossover in medical therapy: 22/50

Summary of three recent prospective, randomized, controlled trials comparing medical therapy to PTRAs in atherosclerotic RAS. These series were limited to selected groups of patients, but had the benefit of careful prospective use of antihypertensive medications, standardized BP measurement, and definitions of outcomes. The results of these trials are less dramatic than those of observational reports.⁴⁵⁻⁴⁷ ACE, angiotensin-converting enzyme; BP, blood pressure; PTRAs, percutaneous transluminal renal angioplasty.

Figure 58-6 Blood pressure and serum creatinine levels in a patient with bilateral renal artery stenosis treated with percutaneous transluminal renal angioplasty. Blood pressure control improved during more than 5 years of follow-up, although medication was still required, including an angiotensin-converting enzyme inhibitor. Most importantly, far advanced renal dysfunction (serum creatinine above 6 mg/dL) improved, avoiding need for renal replacement therapy. Although not uniformly observed, such cases establish the concept that angioplasty and stenting can provide major clinical benefits in selected cases. (Adapted from Textor SC, Wilcox CS: Ischemic nephropathy/azotemic renovascular disease. *Semin Nephrol* 2000;20:489–502.)

offset by a substantial fraction (15%–22%) who rapidly lose renal function.

Results in the latter group remain the Achilles heel of general application of renal revascularization, whether achieved by endovascular stenting or surgery. Nearly one in five subjects with advanced chronic kidney disease will lose additional renal function, sometimes drastically, as a result of the procedure. The precise reasons for this are not well understood. It is agreed that atheroemboli commonly develop within the renal parenchyma, sometimes producing irreversible renal injury.⁵² Importantly, adverse renal outcomes may only unfold days or weeks after the procedure. Patients who follow this course

Figure 58-7 **A**, Bilateral ostial atherosclerotic disease in a 63-year-old male first detected incidentally, then later associated with accelerated hypertension. **B**, Post-stent films indicate excellent vessel patency despite their proximal location, which would previously have made them unlikely to remain patent after percutaneous transluminal renal angioplasty alone.

have a far worse prognosis for renal and patient survival.^{38,53} Hence, the clinician must weigh the potential hazards of an adverse outcome of renal revascularization against the true potential for disease progression or adverse events from uncontrolled hypertension.

It has been difficult to predict who will gain from renal revascularization procedures. Greatly advanced renal dysfunction (serum creatinine > 3 mg/dL) is an adverse sign, as are small kidneys (<7 cm in length). Recent studies using Doppler “resistive index” suggest that high vascular resistance within the poststenotic kidney is an adverse sign.²⁷ The duration and rapidity of onset of renal dysfunction appear to be relevant, although these are difficult to quantify. Some individuals appear to have preserved renal parenchyma via capsular arteries and have been successfully restored to viable renal function after years on dialysis, although this is rare.

Complications of Angioplasty and Stenting

Procedure-related complications from PTRA with stenting (PTRA-S) are common, usually clinically insignificant, and directly proportional to the experience and skill of the operator.⁵⁴ Complications include events related to catheter insertion and aortoiliac manipulation, guidewire and catheter negotiation of

Box 58-2 Complications of percutaneous transluminal renal angioplasty and stenting

Most Common

Groin hematoma
 Contrast toxicity
 Renal artery dissection
 Segmental infarction/thrombosis

Most Severe

Cholesterol embolism
 Cerebral hemorrhage
 Bowel infarction

Vascular Events

Iliac artery dissection
 Aortic dissection
 Peripheral atheroemboli

Miscellaneous

Sepsis
 Stent migration
 Perinephric hematoma

the renal artery and branches, balloon angioplasty and stent placement itself, and adverse effects of contrast material on renal function (Box 58-2).

Groin hematoma after renal PTRAS occurs in at least 20% of patients. False aneurysms of the common femoral artery occur far less frequently and are now readily treated with ultrasound compression or thrombin injection. More serious is cholesterol or atheromatous embolization of either the lower extremities or kidneys, which can occur in as many as 10% of patients.⁵⁵ This can lead to a permanent reduction in renal function or even death.

Review of data from the Mayo Clinic in Rochester, Minn., during a 3-year period (1997–2000) indicates an overall major complication rate of 7.5% per attempted procedure in 140 consecutive patients. No deaths were directly attributable to PTRAS. Complications included renal artery rupture in 2%, partial kidney infarction in 2.7%, transient or permanent elevation of serum creatinine of 20% or more in 9.5%, procedure-induced requirement of hemodialysis in 2.7%, and blood transfusion in 2.7%.

As serious as these complications were, it is noteworthy that none of these patients required open surgical rescue. Stents allowed endovascular treatment of renal artery rupture or wire perforation and renal artery dissection. Renal artery stent placement is probably safer than balloon angioplasty alone. These data are supported by observations from a meta-analysis comparing 678 patients after renal artery stent placement and 644 patients treated with PTRAS alone. The authors concluded that technical success, vessel patency, and restenosis were improved by the use of stents. Remarkably, clinical outcomes in the short term (6–15 months) were no different between the PTRAS and PTRAS groups.⁵⁶

Restenosis

Although implantable metallic stents have expanded the population of patients eligible for PTRAS or PTRAS intervention, restenosis rates remain substantial (Fig. 58-8). A meta-analysis of 14 published series reporting on a total of 678 patients revealed

Figure 58-8 Angiogram demonstrating development of restenosis within an endovascular stent and development of a stenotic lesion at the distal portion of the stent. The latter may relate to movement of the kidney relative to a fixed stent. Such lesions may account for worsening hypertension and declining renal function and require repeat intervention. Rates of restenosis currently appear to be in the 14% to 20% range within the first year.

an angiographically proven restenosis rate of 17% (range, 0%–39%) during a follow-up period of 6 to 29 months.⁵⁶ Restenosis is related to renal artery size. Henry and colleagues⁵⁷ reported restenosis in 17.6% of stents 5 mm in diameter or less, whereas those 6 mm or larger had a 10.2% rate. This should limit the use of these devices in patients with multiple small renal arteries or severely atrophic kidneys. Studies of coated stents in the renal arteries have been disappointing,⁵⁸ further tempering the enthusiasm for stent placement in “incidental” lesions of marginal clinical significance, in which the probability of requiring reintervention for restenosis may exceed the probability of progressive disease needing intervention at all.¹⁷

Periodic Doppler ultrasonography is useful to evaluate in-stent stenosis.⁵⁹ The decision to redilate should be based on the clinical response to the initial intervention. Secondary patency rates are well over 85% and usually do not require additional stent placement. However, the costs of additional intervention are not trivial.

Selection of Patients for Percutaneous Transluminal Renal Angioplasty and Stenting

Selection for endovascular renal revascularization involves a considered judgment of risks and benefits for each patient. With current medical regimens using effective antihypertensive drugs and intensive measures to reduce cardiovascular risk, many individuals with RAS can be managed indefinitely without renal revascularization. There is sufficient ambiguity

as to the benefits of vascular intervention that several randomized, prospective trials (including CORAL, ASTRAL, NITER, and STAR) are in progress to better define these issues. The current issues are summarized in recent debates in the cardiology literature and position papers from nephrologists.^{60–63} Until results from such trials are available, clinicians will continue to apply their best judgment to individual cases.

Several points merit re-emphasis in this regard: Patients with unilateral renovascular disease with reasonable BP control and stable kidney function may gain little from vascular procedures; most will continue to need antihypertensive ther-

apy. Every effort should be directed to medical management, including limiting atherosclerosis by statins and providing meticulous control of BP and other risk factors, including cessation of smoking.

Patients with bilateral disease (or stenosis to a solitary functioning kidney) face particular risks for both deterioration of renal function and unsatisfactory BP control with medical management alone.¹⁷ Studies that most consistently indicate benefits to renal function after endovascular stenting are limited to patients with stenosis affecting the entire functioning renal mass.⁶⁴ Although many individuals with bilateral disease can be managed without clinical evidence of progression, they

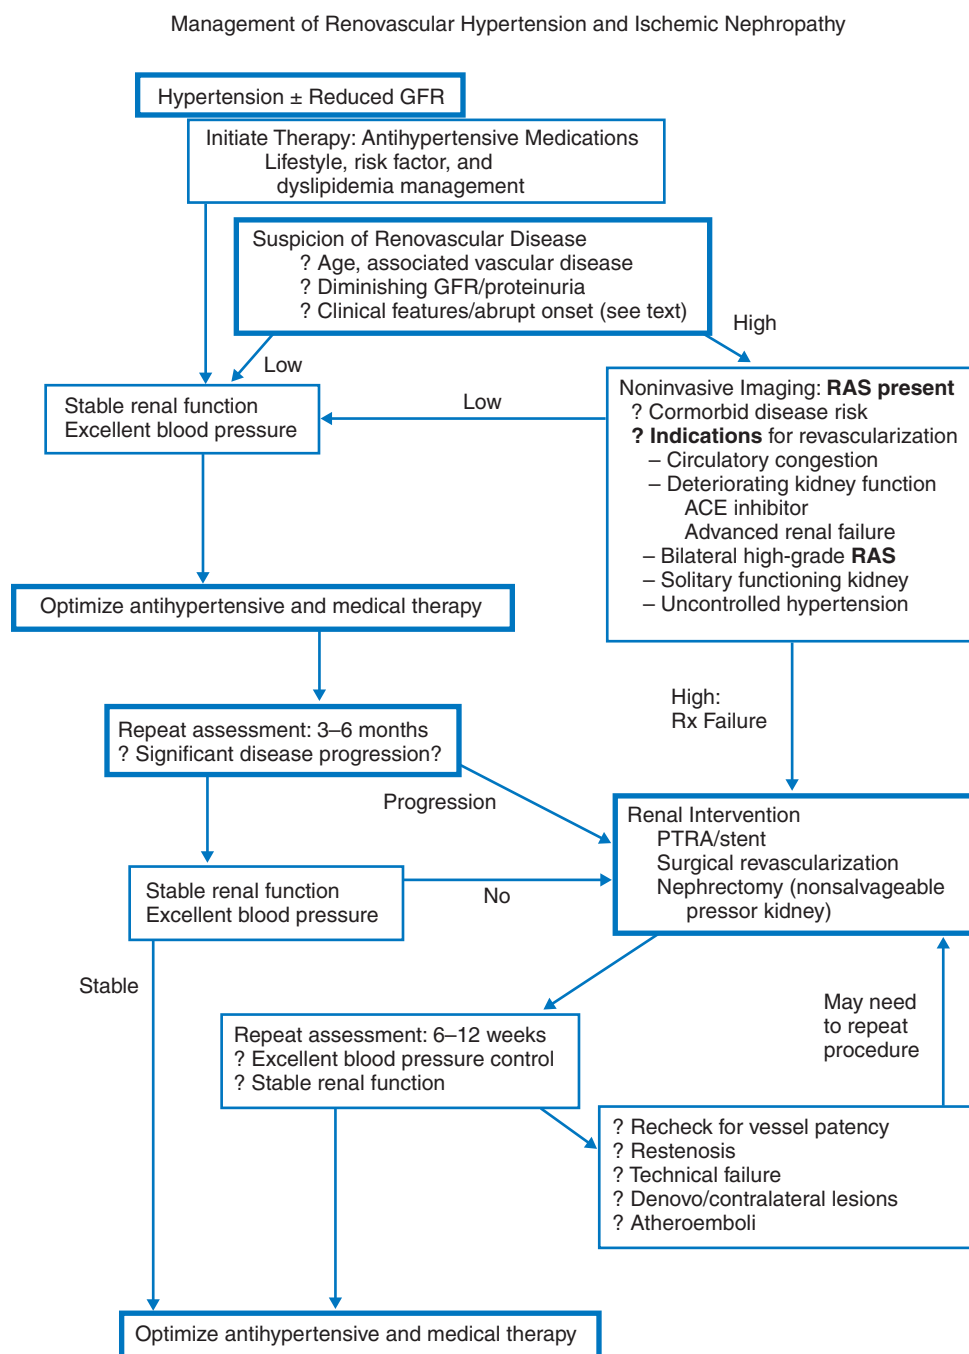

Figure 58-9 Algorithm for an approach to the management of patient with renal artery stenosis.

may have more to gain from successful renal revascularization than other groups, although this has not been proven.

Many patients fall between these limits, with relatively stable BP and kidney function, but at risk for progressive disease and extensive comorbid risk factors. They merit close follow-up and reconsideration based on demonstrated vascular progression. RAS is analogous to other vascular lesions, such as an abdominal aneurysm or carotid stenoses, both of which may exist for many years without posing a true hazard. Evidence of progression may be the critical determinant of who will gain the most from angioplasty or stenting in the kidney also.

SUMMARY

The endovascular techniques of angioplasty and stenting offer effective alternatives for restoring renal blood flow to a wide group of patients. Interventional procedures should be considered for patients with progressive hypertension or loss of renal parenchymal function due to renal artery lesions. There is a potential for recurrence (restenosis) and for serious adverse effects, although these are not common. Clinicians must balance the potential for benefit against the potential for adverse effects. An algorithm for the approach to management is presented in Figure 58-9.

Management of hypertension is a common challenge for physicians involved in the care of renal allograft recipients. Hypertension may appear at any time after engraftment, and ultimately afflicts 75% to 80% of patients in the current era of immunosuppressive therapy.¹ Advances in therapeutics for transplantation patients have reduced graft loss due to rejection.² Current recipients are older and have more comorbid disease. The most common cause of transplant failure is death with a functioning allograft, and the most common cause of death is cardiovascular disease. The risk of cardiovascular mortality in transplant recipients greatly exceeds that of the general population.¹ Clearly hypertension is a significant risk factor for accelerated atherosclerosis and premature coronary disease, and the impact of hypertension and other variables on cardiovascular risk is exaggerated in transplant recipients.^{3,4} In addition, hypertension increases the risk of allograft failure and may accelerate deterioration of graft function.^{5,6} Thus, the primary objectives for management of posttransplant hypertension include reducing cardiovascular morbidity and mortality and preserving allograft function.

CLINICAL FEATURES

Whereas more than 90% of cases of hypertension in the general population are *essential* hypertension, most cases of post-transplant hypertension have an evident cause. Although age, sex, and race predispose patients to essential hypertension, they do not significantly influence development of post-transplant hypertension. The nature of a recipient's original renal disease is of little importance. Posttransplant hypertension is usually mild to moderate in severity.⁷

In the past, hypertension was noted most frequently in renal transplant recipients with retained native kidneys or with a cadaveric organ. However, under current immunosuppressive protocols, the impact of calcineurin inhibitor therapy with cyclosporine or tacrolimus overrides the influence of other factors.⁸ Definable causes of posttransplant hypertension may be grouped conveniently as either intrinsic or extrinsic to the allograft (Box 59-1). Several pathogenic factors often coexist. Some causes are amenable to specific diagnosis and

correction; others are relatively fixed, needing long-term anti-hypertensive therapy. Virtually all posttransplant hypertension is related to impaired renal allograft function.

APPROACH TO THE PATIENT WITH HYPERTENSION AFTER RENAL TRANSPLANTATION

The initial challenge is to identify correctable causes. Immediately after transplantation, delayed graft function (with sodium and volume excess) may be the main cause of elevated blood pressure (BP). Inadequately controlled postoperative pain may contribute. Thereafter, new or worsening hypertension may represent the onset of acute rejection. Alternatively, because plasma levels of cyclosporine and tacrolimus are usually kept highest during the early post-transplant period, a dose-dependent elevation in BP often results. Six months after transplant, acute rejection becomes less likely; in the recipient with *de novo* or worsening hypertension, other causes should be considered. These include toxicity from calcineurin inhibitors, recurrent disease, chronic rejection, or transplant renal artery stenosis (TRAS). Finally, retained native kidneys may contribute to hypertension at any time.⁷

Initial studies should document allograft function (Fig. 59-1) with serum creatinine levels, 24-hour urinary protein excretion, and a reliable estimate of glomerular filtration rate (GFR) or renal plasma flow (RPF). Control of extracellular volume should be optimized. If allograft dysfunction is present, renal biopsy may distinguish specific causes.

Immunosuppressants play a major role in the pathogenesis of posttransplant hypertension. Thus, antirejection therapy may need reassessment. Calcineurin inhibitors (either cyclosporine or tacrolimus) remain the cornerstone of current immunosuppressive regimens. Although recent data indicate that hypertension is slightly less common with tacrolimus, both agents are nephrotoxic and—particularly at high blood levels—elevate BP.⁹ The dose of cyclosporine or tacrolimus should be optimized. Excessive reduction of the dose to reduce BP may increase the risk of acute rejection. When given in combination with cyclosporine, the immunosuppressant sirolimus

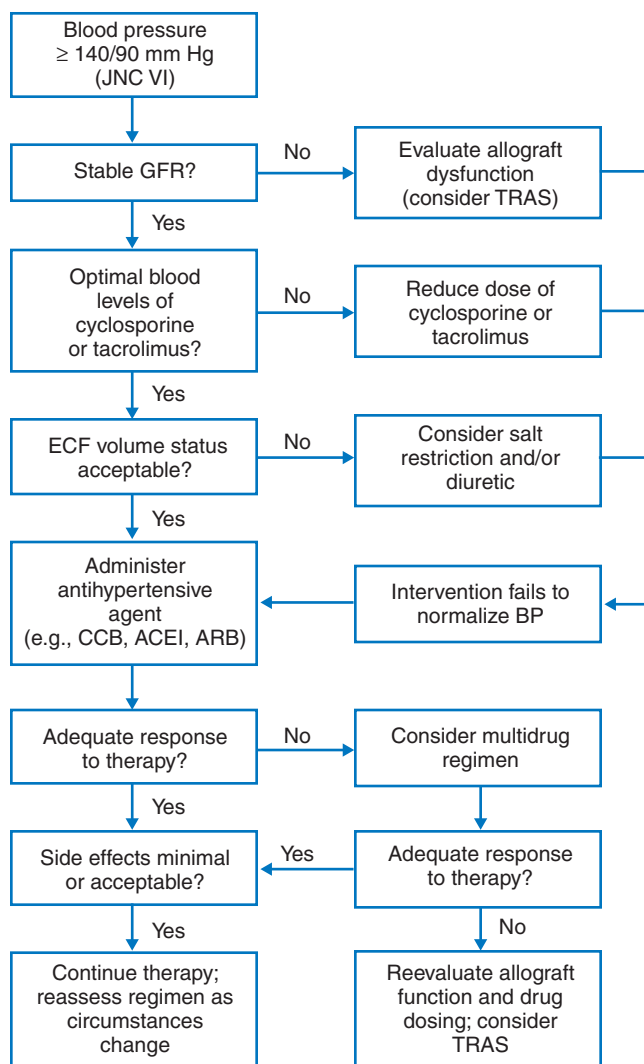

Figure 59-1 Diagnosis and management of hypertension in the renal allograft recipient. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; ECF, extracellular fluid; GFR, glomerular filtration rate; JNC VI, Sixth Report of the Joint National Committee²⁰; TRAS, transplant renal artery stenosis.

may potentiate hypertension, but independently it does not appear to cause high BP in transplant recipients.¹⁰ Although corticosteroids clearly contribute to hypertension, the influence of prednisone at a maintenance dose of 5 to 10 mg/day on BP seems minimal, and withdrawal of steroids remains controversial.¹¹ Azathioprine and mycophenolate mofetil seemingly have no adverse effect on BP.

Late onset of hypertension, particularly in a previously stable recipient, is suggestive of TRAS. Administration of an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB) may help to screen for hemodynamically significant stenosis because a low dose of an ACE inhibitor often causes an immediate and marked decline in GFR in TRAS. Such patients often demonstrate TRAS at angiography. Although radionuclide scanning and Doppler imaging may be useful adjuncts, magnetic resonance angiography has greatly simplified evaluation for TRAS. Use of conventional angiography and its risks can now be limited to patients with a high chance of benefiting from angioplasty or surgery.

Improvement in surgical experience and techniques has decreased the incidence of TRAS, which is now rarely seen but was once claimed to have an incidence of nearly 25%. Because TRAS can be treated and outcomes are excellent, the search for this now rare vascular complication should not be neglected. The most obvious clues are refractory hypertension and increasing serum creatinine level. Recently investigators have pointed to a history of acute rejection or delayed graft function and cytomegalovirus infection as other important clues to consider.^{12,13} Although technical causes of TRAS have lessened, the incidence of stenosis of the aortoiliac segment proximal to the graft may be increasing with older transplant recipients. Such lesions can also be diagnosed via Doppler ultrasonography and respond well to intervention.¹⁴

Outcomes from various radiologic and surgical forms of treatment of TRAS are good, with lowering of BP and return of serum creatinine to baseline values. Restenosis is common after angioplasty, less frequent after stent placement, and much less frequent after surgical intervention, but the risk varies in reverse order and depends on the expertise of the center.

CALCINEURIN INHIBITORS AND HYPERTENSION

The introduction of the calcineurin inhibitors (CNIs) cyclosporine and tacrolimus dramatically reduced acute rejection for transplant recipients. Long-term graft survival, free of rejection, became more common. However, both agents cause hypertension. Before the introduction of these agents, the incidence of posttransplant hypertension was approximately 50%, but with these agents it is 90% or greater. It has been suggested that a lower incidence of hypertension is seen with tacrolimus than with cyclosporine. However, these reports are inconsistent; lower doses are now given, and different methods of monitoring BP are used. Moreover, the drug manufacturer sponsors many of the studies. For example, a recent large study comparison suggested that low-dose tacrolimus resulted in better BP control than cyclosporine,¹⁵ whereas a large, controlled trial with cyclosporine C2 monitoring did not report differences in the incidence or severity of hypertension between the two agents.¹⁶ Although most transplant centers in the United States have switched from

cyclosporine to tacrolimus as their primary CNI, there does not seem to have been an improvement in either the incidence or prevalence of hypertension comparable to the 50% seen before routine use of CNIs.

The mechanisms of CNI-induced hypertension have not been identified with certainty. Sodium retention due to preglomerular vasoconstriction, sympathetic nerve stimulation, and direct effects of CNI on arterial vessels have all been documented. Controlling hypertension in patients treated with a CNI is difficult. Patients remain on multiple drug therapy. Suggested methods of treatment include using calcium channel blockers to reverse preglomerular vasoconstriction,¹⁷ switching from cyclosporine to tacrolimus,¹⁸ and minimizing the dose or withdrawing CNIs altogether.¹⁹ The latter seems to have the best effect on CNI-induced hypertension but carries the risk of acute rejection.

MANAGEMENT

Normalization of BP (<140/90 mm Hg) has always been the goal of treatment for hypertensive transplant recipients with stable allograft function or those with chronic rejection. However, recent recommendations from the Joint National Committee (JNC)²⁰ and the World Health Organization/International Society of Hypertension²¹ suggest a more aggressive target. A recent Task Force endorsed target BPs lower than 130/85 mm Hg for patients without proteinuria and 125/75 mm Hg for those excreting more than 1 g of urinary protein per day.¹

Blood pressure may fluctuate considerably in the transplant recipient because of use of varying doses of steroids and CNIs and changes in GFR, requiring vigilance by the physician and continuous reevaluation of treatment. Although the Sixth Report of the JNC emphasizes the role of “lifestyle modifications” in treating hypertension (including smoking cessation, weight loss, limited sodium intake, and exercise), renal transplant recipients will generally require additional pharmacologic therapy to achieve adequate BP control.^{1,20}

Calcium Channel Blockers

Calcium channel blockers (CCBs) effectively reduce BP in most patients. They attenuate both cyclosporine- and endothelin-induced vasoconstriction.²² These agents can prevent the acute deterioration in RPF and GFR that may accompany elevated cyclosporine blood levels. Theoretically, their other benefits include enhancement of immunosuppression, prevention of delayed graft function, and improvement of GFR in cyclosporine-treated allograft recipients.²³

Currently available CCBs differ in their effects on the metabolism of cyclosporine and tacrolimus, and on blood levels of the immunosuppressant sirolimus.¹⁰ Verapamil, diltiazem, and the dihydropyridine nifedipine reduce the hepatic metabolism of cyclosporine, thereby increasing its blood level by 40% to 50%. Although some investigators have found this interaction beneficial, it clearly complicates immunosuppressive management. Dosages of the CCB and of the immunosuppressant must be altered concurrently. Other investigators prefer nifedipine or isradipine, which have little effect on blood levels of cyclosporine or tacrolimus. Amlodipine has an intermediate effect on cyclosporine metabolism, and the dose does not usually need adjustment.²⁴

Calcium channel blockers are generally well tolerated. However, they may cause peripheral edema and can exacerbate cyclosporine-induced gingival hyperplasia. A retrospective study reported an increased risk of cardiac mortality in renal transplant recipients receiving dihydropyridine CCBs.³ The implications of this observation remain unclear.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Use of ACE inhibitors and ARBs to treat hypertension in transplant recipients is becoming increasingly common.^{25,26} These agents effectively reduce BP and exert a salutary impact on renal hemodynamics. However, their use in cyclosporine-treated patients has been associated with acute renal failure, hyperkalemia, and anemia. A theoretical basis for avoiding ACE inhibitors and ARBs in such patients is the physiologic similarity between TRAS and cyclosporine-induced afferent arteriolar vasoconstriction. Because angiotensin II is critical for maintaining glomerular perfusion in both situations, inhibition of its effect in the postglomerular circulation might adversely affect GFR. Indeed, in a recent crossover study comparing amlodipine with losartan, there was a similar efficacy in BP reduction but an increase in GFR with amlodipine versus a slight (though not statistically significant) decline with the ARB.²⁵ However, only losartan significantly reduced proteinuria and plasma levels of transforming growth factor- β_1 (TGF- β_1). These effects may be beneficial in preserving renal function and reducing risk of cardiovascular disease.

Although therapy with these agents must be introduced cautiously, paying close attention to renal function, potassium levels, and blood counts, the vast majority of transplant recipients tolerate ACE inhibitors and ARBs quite well. In some of the 10% to 15% of patients who develop anemia while receiving these drugs, we have at times prescribed recombinant erythropoietin to continue what appears to be beneficial therapy. Post-transplant erythrocytosis, a late complication seen most often in stable recipients with well-functioning grafts, resolves with ACE inhibitor or ARB therapy in most patients.²⁷

Diuretics

Diuretics are an important therapeutic option because of the volume expansion and salt sensitivity that often accompany post-transplant hypertension. Although salt restriction may pose less of a medical risk, it is rarely adequate to achieve or enhance BP control in this population. Diuretics are a useful adjunct for those who respond to a CCB or another vasodilator with suboptimal BP control or worsening edema. In this setting, a loop diuretic (furosemide or bumetanide) may be required to achieve adequate natriuresis. Thiazides increase the risk of hyperuricemia and hypercalcemia but may also be effective. Given the predisposition of transplant recipients to hyperkalemia, there is little role for potassium-sparing agents.

Other Agents

There appear to be no distinct advantages or disadvantages associated with use of other antihypertensive agents (described extensively elsewhere in Part XI: Management of Secondary Hypertension in this book.

Refractory Posttransplant Hypertension

Transplant recipients with refractory hypertension, or those who require more than three drugs to normalize BP, should undergo evaluation for TRAS. When TRAS is demonstrated, it appears that surgical repair offers the best hope for both immediate and long-term cures (92% and 82%, respectively). However, angioplasty may be successful in as many as three quarters of patients, with long-lasting remissions in 40% to 50%. Most transplant physicians would thus offer angioplasty as a first intervention, particularly for those patients with lesions removed from the vascular anastomosis. Proximal lesions or stenoses at the vascular anastomosis may more frequently require surgical intervention.

When TRAS is excluded in the patient with well-preserved allograft function and no evidence of rejection, bilateral native kidney nephrectomy is an option for intractable hypertension. In experienced hands this substantial operation can be performed safely and—for most patients—will improve control of posttransplant hypertension. Unfortunately, no diagnostic study accurately predicts who will benefit from surgery. With the currently available medical therapies, native kidney nephrectomy is rarely indicated.

		OVERVIEW OF HYPERTENSION MANAGEMENT IN ESRD	689

Hypertension is an increasingly common cause of end-stage renal disease (ESRD).¹ The prevalence of hypertension increases with declining renal function. When renal disease reaches end-stage, approximately 80% to 90% of patients suffer from significant hypertension. Diseases that predominantly affect the renal interstitium may produce a salt-losing state, with normotension or even episodes of hypotension and hypovolemia, whereas the more common arterial and glomerular diseases almost invariably cause hypertension. In a meta-analysis by Thompson and Pickering,² it was shown that ambulatory blood pressure monitoring (ABPM) for 44 hours and home blood pressure (BP) monitoring over a 1-week period are superior to the routine method of intermittent measurements of BP in the hemodialysis center in predicting end-organ damage and interdialytic BP control. Loss of the nocturnal decline in ABPM has been linked to left ventricular hypertrophy (LVH), adverse cardiovascular outcomes, and all-cause mortality in patients with ESRD.²

Blood pressure control usually improves after initiation of dialysis therapy. Nevertheless, more than 75% of people receiving outpatient hemodialysis are also receiving antihypertensive drug therapy. Cheigh and colleagues³ reported adequate control in only 15% of their patients monitored with ABPM over 48 hours despite widespread use of antihypertensive agents. The U.S. Renal Data System (USRDS) analyzed predialysis BP data on 5369 patients; even with antihypertensive therapy 63% of patients were hypertensive, which was classified as mild in 27%, moderate in 25%, and severe in 11%.⁴ Multivariate analysis showed that higher BP was associated with greater intradialytic weight gain, noncompliance with the dialysis regimen, and younger age. This last surprising finding perhaps reflects the observation that patients with congestive heart failure (CHF) or coronary artery disease (CAD) are generally older and have low BP.

Dialysis patients are more prone to accelerated atherosclerosis, independent of comorbid conditions or age.⁵

Longitudinal observations in the general population have concluded that atherosclerosis is retarded by control of BP, which also appears to increase life expectancy. Cardiovascular disease and cerebrovascular disease are the major causes of mortality in the ESRD population. Among patients receiving hemodialysis or peritoneal dialysis, the rates of cardiovascular disease (CVD) mortality are 3 to 20 times higher than in age-matched subjects.⁵ CVD is the primary cause of mortality and morbidity in the ESRD population, and is present in as many as 50% to 60% of ESRD patients. Some 28% of hemodialysis patients die each year, and CVD accounts for 45% of this alarming mortality. LVH occurs in 75%, CAD in 40%, and cardiac chamber dilation and CHF in 40% of dialysis patients. ESRD is associated with a 2- to 10-fold increased risk of cardiovascular events.⁶ It is difficult to assess the importance of hypertension for CVD risk in ESRD. Remarkably, despite the very high prevalence of CVD and of hypertension in the dialysis population, the largest studies have shown an inverse relationship between BP and total cardiovascular death in these patients.⁷⁻⁹ Closer examination of the data provides some insight into this paradox. First, the overall relationship between relative risk and BP is U-shaped (Fig. 60-1).^{7,8} Patients with a predialysis systolic BP below 120 mm Hg (>10%) and the relatively few (>5%) who have dialysis-resistant, severe hypertension with a postdialysis systolic BP above 180 mm Hg both are at increased risk. However, there is no trend for increased risk among the many patients with moderate hypertension, or even among the 10% with severe predialysis hypertension. The sharply increased risk among those with low BP may relate to the high proportion of these patients who have CHF and CAD. Whereas in the general population CHF presents with fluid overload, in the dialysis population these symptoms are managed by fluid removal at dialysis. Consequently, many dialysis patients with CHF are not recognized, and their predominant finding is hypotension.

Figure 60-1 The adjusted relative risk for mortality in end-stage renal disease patients established on maintenance hemodialysis as a function of systolic blood pressure, measured predialysis (solid circles and continuous lines) or postdialysis (open circles and broken lines). Compared to reference values at systolic blood pressure 120 to 149 mm Hg; * $P < 0.06$. Data are from 4500 patients. (Drawn from Port FK, Hulbert-Shearon TE, Wolfe RA, et al: Predialysis blood pressure and mortality risk in a national sample of maintenance hemodialysis patients. *Am J Kidney Dis* 1999;33:507-517.)

During the first 2 years of hemodialysis, low systolic BP is associated with a sharp increase in mortality.⁷ During more prolonged follow-up, increased mortality is apparent in those with a high systolic BP. This suggests that those with low BP are at risk for early death from CHF and CAD. If this group is excluded, and later deaths are examined, hypertension is seen to enhance cardiovascular death modestly. These results are probably influenced by the very high prevalence of prolonged hypertension and atherosclerosis in this population before they begin receiving hemodialysis. This presumably contributes to the greatly increased risk of CVD in those receiving hemodialysis even at a normal BP level. An analysis of 1053 patients on peritoneal dialysis from USRDS related systolic BP lower than 111 mm Hg with higher all-cause and cardiovascular mortality and related systolic BP higher than 120 mm Hg with fewer hospital days during the mean follow-up of 2 years.¹⁰

As anticipated, cerebrovascular death is predicted by predialysis hypertension.⁸ A Japanese study found that death from cerebral hemorrhage and the size of the intracerebral hematoma are positively related to BP in dialysis patients.¹¹ This confirms the very close association between incident BP and the occurrence and severity of cerebral hemorrhage in the general population.

No controlled interventional trials assess whether CVD is reduced by controlling hypertension in the hemodialysis population. Several lines of evidence from retrospective analyses support the benefit of angiotensin-converting enzyme (ACE) inhibitors in ESRD patients.^{12,13} The FOSinopril In DIALysis

(FOSIDIAL) study evaluated the effect of reducing BP by the ACE inhibitor fosinopril on cardiovascular events in ESRD patients with LVH. Some 400 ESRD patients were randomized to fosinopril or placebo and followed for 2 years. Although the BP was significantly lower in the fosinopril group, there were no statistically significant benefits.¹⁴ Good control of BP can cause regression of LVH in patients with ESRD, as in those with essential hypertension. Indeed, a controlled trial of ACE inhibitor therapy in normotensive hemodialysis patients over 2 years demonstrated regression of LVH in the treatment group, without a change in the control group.¹⁵

Sleep apnea is common in hemodialysis patients. In these patients nocturnal oxygen desaturation is related to “nondipper” BP status and predicts LVH.¹⁶ Because nocturnal BP is not routinely assessed, the high incidence of “nondipping” may confound the relationship between BP measured during the day at dialysis sessions and CVD mortality. Indeed, in a small study of 48-hour ABPM in hemodialysis patients, this measure of BP was shown to be a much better predictor of LVH than predialysis BP.¹⁷ Another study has reported a significant correlation between predialysis hypertension and cerebral atrophy in hemodialysis patients.¹⁸

These complex data suggest that low BP is a very serious prognostic sign in hemodialysis patients. Such patients should be urgently tested for occult CHF and CAD. Severe hypertension that is resistant to dialysis-induced fluid loss is also an established risk for CVD. Failure to detect a relationship between death from CVD and more modest elevations of BP may arise from a failure to detect nocturnal hypertension accompanying sleep apnea, the irreversible effect of pre-ESRD hypertension and atherosclerosis, and confounding effects due to early cardiovascular deaths from low BP. At this time, it seems reasonable to treat hypertension in patients receiving hemodialysis. Patients benefit from ABPM to assess their true BP burden and to diagnose and assess the effects of therapy on nocturnal hypertension or “nondipper” status.

PATHOPHYSIOLOGY

The pathophysiology of hypertension in renal failure has been reviewed¹⁹ and is summarized in Figure 60-2. Blood pressure is a reflection of cardiac output and total peripheral resistance. A third factor that determines systolic BP and pulse pressure, and becomes important in patients with decreased arterial compliance, is the reflection of the systolic pressure wave retrograde from the resistance vessels.²⁰ In the elderly, in diabetic patients, and in those with advanced atherosclerosis and vascular calcification, this pressure wave travels sufficiently fast to reach the ascending aorta during systole, thereby accentuating the systolic BP and widening the pulse pressure. Many different factors interact in patients with ESRD to produce hypertension.

Salt and Fluid Retention

A reduction in renal function, associated with a fall in the glomerular filtration rate (GFR), restricts the excretion of salt (NaCl) and fluid. Early in renal failure, there is generally an increase in cardiac output with a relatively low total peripheral resistance that may partly be a response to the development of anemia. With further declines in the GFR, total peripheral resistance begins to increase, reflecting an autoregulatory response

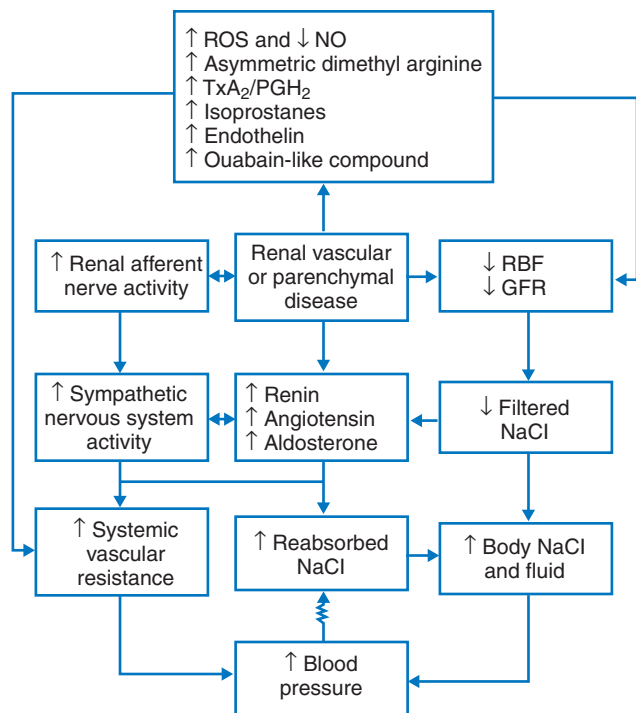

Figure 60-2 Some pathophysiologic mechanisms identified in patients, or animal models, that can increase blood pressure in chronic renal insufficiency. BP, blood pressure; GFR, glomerular filtration rate; NO, nitric oxide; PGH₂, prostaglandin H₂; RBF, renal blood flow; ROS, reactive oxygen species; TxA₂, thromboxane A₂. For full explanation, see text.

to a sustained increase in cardiac output. This phenomenon is known as *total body autoregulation*. However, activation of specific vasoconstrictor mechanisms and inhibition of vasodilator mechanisms can override this autoregulatory response.

Most studies of body fluid volumes in patients with renal insufficiency have shown an expansion of plasma, extracellular and intracellular fluid volumes, and of total body sodium and water.²¹ Prolonged expansion of extracellular fluid (ECF) volume may be the major factor underlying hypertension in ESRD. As the GFR declines, the fraction of patients with salt-sensitive hypertension increases exponentially. Scrupulous control of ECF volume by fluid removal at dialysis and restriction of salt and fluid intake between dialysis treatments can reverse hypertension in many patients. In a multivariate analysis of a large USRDS database, large intradialytic weight gain and noncompliance with the dialysis regimen were significant determinants of hypertension.⁴ These effects were most pronounced in those without CHF and with established hypertension. In a study conducted over 1 year, patients who were switched from conventional (three times per week) dialysis to dialysis six times per week had a significant reduction in BP, despite using fewer antihypertensive drugs.²² Survival rate in this selected group of compliant and motivated patients was excellent. Another small study compared extended standard hemodialysis (three sessions of 4.5 to 5 hours per week) with a slower ultrafiltration rate with short daily hemodialysis (six sessions of 2 hours per week). Daily hemodialysis produced better BP control in a group of older hypertensive patients with other cardiovascular morbidities.²³ Another small study reported similar BP levels among patients receiving conventional

dialysis or high-flux dialysis for a shorter time.²⁴ These data suggest that a more frequent dialysis and good control of salt and fluid intake between treatments can maintain a more normal level of ECF and can moderate hypertension. Indeed, hypertension is remarkably rare in patients receiving daily overnight hemodialysis.²⁵

Another technique to reduce thirst and thereby reduce the ECF volume is to reduce the dialysate sodium concentration. However, this can cause hypotension, dizziness, fatigue, and cramp. Another method is to use a variable sodium dialysis in which the dialysate [Na] is reduced exponentially from 155 to 135 mmol/L over 3 hours and maintained at this level for the last hour. A crossover study of this technique reported that it is tolerated, reduces intradialytic weight gain and the need for antihypertensives, and lowers BP.²⁶ Further study in larger groups is needed to evaluate this simple technique.

Structural Changes and Endothelial Dysfunction

Hypertension in patients with ESRD is associated with functional and morphologic changes in the resistance vessels. Vasodilation is limited by an increase of the media-to-lumen ratio in arterioles. There are increased levels of asymmetrical dimethyl arginine (ADMA, an endogenous nitric oxide synthase inhibitor), and endothelin, and diminished endothelium-dependent vasodilation in patients on dialysis. The impaired endothelial control of vascular smooth muscle tone is particularly important in those who are prone to intradialytic hypertension, whose inappropriately increased peripheral vascular resistance is not related to sympathetic stimulation or renin activation but correlates with the balance between nitric oxide metabolites and endothelin-1.²⁷

Endogenous Na⁺/K⁺-Adenosine Triphosphatase Inhibitor

A ouabain-like factor has been extracted from uremic serum that might be an endogenous natriuretic substance that can inhibit Na⁺/K⁺-adenosine triphosphatase (ATPase) in renal tubules, thus promoting salt excretion.²⁸ Elevated levels, as seen in uremia, could cause more generalized inhibition of Na⁺/K⁺-ATPase, leading to increased intracellular sodium in vascular smooth muscle cells, diminished Na⁺/Ca²⁺ exchange, and increased intracellular calcium concentration, thereby increasing vascular tone. Inhibition of Na⁺/K⁺-ATPase activity at synaptic neuronal clefts could reduce norepinephrine uptake, prolong activation of vascular smooth muscle cells, and further enhance vasoconstriction.

Renin-Angiotensin-Aldosterone System

Renin, angiotensin, and aldosterone are important in the pathogenesis of hypertension in most patients with chronic renal failure. In selected patients with intractable hypertension, BP control improves after bilateral nephrectomy and correlates with the pre-nephrectomy levels of plasma renin activity (PRA). Although PRA is normal or mildly elevated in most dialysis-dependent patients, the PRA is inappropriately high for the expansion of ECF volume and the high BP. Moreover, tissue angiotensin II may be important in patients in whom hypertension responds to ACE inhibitors yet the PRA is normal.

Angiotensin II may potentiate vascular and cardiac hypertrophy both as a vasoconstrictor and by trophic actions.

Sympathetic Nervous System

The sympathetic nervous system is implicated in the pathogenesis of hypertension in patients with ESRD. Total autonomic blockade, or selective inhibition of norepinephrine with debrisoquine, reduces total peripheral resistance and BP. However, plasma norepinephrine levels are variously reported as low, normal, or high, perhaps reflecting the complex nature of catecholamine release, reuptake, metabolism, and excretion in chronic renal failure. Converse and associates²⁹ made direct recordings of postganglionic sympathetic nerve activity using implanted microelectrodes. They reported that the frequency of sympathetic nerve discharge was nearly three times greater in patients receiving hemodialysis than in normal subjects. Interestingly, after bilateral nephrectomy, BP and peripheral vascular resistance were lowered, and normal rates of sympathetic nerve discharge were seen. These investigators concluded that chronic renal failure activates the sympathetic nervous system via afferent nerve signals arising in the failing kidney.

These studies demonstrate the complexity of the underlying pathophysiology of hypertension in ESRD. They provide a rational basis for using therapies aimed at reducing ECF volume, for using calcium channel blockers (CCBs) and therapies that interrupt the renin-angiotensin-aldosterone system or the sympathetic nervous system.

BLOOD PRESSURE GOALS

Values for lying and standing BP and heart rate should be obtained before and after dialysis treatment. Ideally, BP should be monitored periodically between hemodialysis sessions by 48-hour ABPM because casual measures do not reflect interdialytic BP control and cannot assess “nondipper” status.

The ideal target level for BP is controversial. Studies are lacking on BP goals that are safe and effective in minimizing cardiovascular events in ESRD. However, the Modification of Diet in Renal Disease (MDRD) study demonstrated that it was both feasible and safe, at least under protocol conditions, to have a reduced BP goal of approximately 120/75 mm Hg in patients with moderate or severe chronic kidney disease.³⁰ However, this study used a selected group that was free of recent cardiovascular or cerebrovascular disease.

We recommend a target predialysis systolic BP of 130 mm Hg in uncomplicated ESRD patients. This is based on experience gained by the MDRD, results from normal subjects in the epidemiologic study by MacMahon and Rodgers,³¹ and hypertensive subjects in a trial by Hansson and colleagues³² in which morbidity and mortality increased with BP levels above this target. It seems probable that many patients who have end-organ damage or LVH, and those with diabetes, would benefit from a lower systolic BP goal of 120 mm Hg. However, some elderly patients will not tolerate this lower BP and require a target of 140/90 mm Hg. Moreover, lower BPs are dangerous for patients who have recently sustained a stroke or an episode of coronary ischemia or myocardial infarction. It is important also to evaluate postdialysis BP in the standing position (or seated for those patients who cannot stand). A

reasonable goal is a systolic postdialysis BP of 110 mm Hg or above. It is preferable to assess BP intermittently with ABPM to assess the full BP burden and diurnal variation.

NONPHARMACOLOGIC TREATMENT

The first step in nonpharmacologic treatment is to set and to achieve a true target *dry weight*, defined as the weight at which intravascular volume is optimal. Weight above the target is accompanied by fluid overload, edema, and hypertension, whereas weight below target is accompanied by fatigue, orthostatic dizziness, hypotension during or between dialysis, excessive thirst, and cramps.³³

The dry weight must be maintained by a combination of scrupulous attention to salt and water restriction between treatments and effective dialytic fluid removal. Some studies suggest that when this goal is achieved, 85% of hemodialysis patients no longer need antihypertensive medication. In practice, this ideal is rarely achieved. Generally, daily salt restriction to 2 g and daily fluid restriction to 1.0 to 1.25 L produces a tolerable interdialytic weight gain of 2 to 3 kg.

It is advisable to remove fluid gradually during initiation of dialysis over 6 to 8 weeks to achieve the target weight and to prevent hypotension and severe cramps. Overuse of antihypertensives at this time can complicate the removal of fluid because of severe falls in BP. Therefore, a stepwise withdrawal of antihypertensive agents is recommended as body weight is reduced toward the target dry weight. Some hemodialysis patients who do not tolerate removal of fluid by conventional ultrafiltration respond to sequential hemofiltration and hemodialysis, or to treatment with isolated ultrafiltration on consecutive days until the target dry weight is achieved. Others respond to a variable sodium bath regimen.²⁶

Patients treated by continuous ambulatory peritoneal dialysis (CAPD) generally have better control of BP, probably because of the continuous and smooth ultrafiltration of fluid. Because daily NaCl and fluid losses are greater in CAPD, restriction of salt and water can be less stringent.

Other nonpharmacologic measures that help to control hypertension include reduction of body weight, regular exercise, avoidance of drugs causing hypertension (e.g., over-the-counter nasal decongestants and nonsteroidal anti-inflammatory drugs), and stress reduction. It is critical to tackle other cardiovascular risk factors, including smoking, dyslipidemia, and coagulopathy states (see Chapter 57).

PHARMACOLOGIC MANAGEMENT

Diuretics

Diuretics are reviewed in Chapters 33 and 51. Thiazide diuretics are generally ineffective when the GFR falls below 20 to 40 mL/min. Increasing dosage of loop diuretics is required in proportion to the reduction in GFR; they become ineffective when the GFR falls below 5 mL/min. An increase in urine output can be achieved in some hemodialysis patients by loop diuretics, reducing the interdialytic weight gain. However, because of the high doses needed in patients with ESRD (e.g., 100–250 mg of furosemide), plasma levels will be elevated and the likelihood of ototoxicity increased. Moreover, in a study of

CAPD patients with residual renal function, loop diuretics did not influence the rate of loss of renal function or the outcome.³⁴ Diuretics are often withdrawn as dialysis is initiated. However, in a study of 16,420 hemodialysis patients from the Dialysis Outcomes and Practice Patterns Study (DOPPS), diuretic use was associated with lesser interdialytic weight gain and lower odds of hyperkalemia. Patients with residual renal function who received diuretic therapy were almost twice as likely to retain renal function after 1 year in this study. Moreover, this group had a 7% lower all-cause mortality and a 14% lower cardiac-specific mortality risk.³⁵ It is important to emphasize that this is an observational study and does not prove that diuretics were the cause of these better outcomes.

Calcium Channel Blockers

These agents (Table 60-1) are reviewed in Chapter 53. They inhibit voltage-dependent Ca^{2+} channels in vascular smooth muscle cells and, to some extent, in cardiac cells. Three classes of chemical compounds and eight agents are currently approved for use in the United States.

These agents are readily absorbed after oral administration. No dosage adjustments of CCBs are required in dialysis patients because they are metabolized extensively in the liver, are not renally excreted, and are not significantly removed by hemodialysis or CAPD.

Calcium channel blockers are among the most frequently prescribed antihypertensive drugs in ESRD patients. Their antihypertensive efficacy, unlike all other classes of agents, is relatively well preserved in patients with volume expansion.

Calcium channel blockers are generally well tolerated in dialysis patients. Minor adverse effects relate to vasodilation and include dizziness, intradialytic hypotension (more marked in patients with high interdialytic weight gain), headache, flushing, and edema. Less common effects are nausea, constipation, skin rash, somnolence, and transient abnormalities in liver function tests. Studies in hypertensive patients without ESRD have implicated short-acting CCBs in increased cardiovascular morbidity and mortality. Short-acting agents are not recommended even for hypertensive urgencies. Verapamil and diltiazem have negative inotropic and chronotropic actions. Therefore, they should be used with great caution in patients with poor cardiac function or in those receiving β -blockers.

Because of their efficacy, their safety in renal failure, their removal by metabolism, and a low profile of adverse effects, long-acting CCBs are appropriate for hypertension in dialysis patients. They have added benefits in patients with ischemic heart disease, dilated cardiomyopathy, peripheral vascular disease, Raynaud's phenomenon, and vascular headaches. Further information is needed about their risk-benefit ratio for this group of patients.

β -Blockers

β -Blockers (Table 60-2) are reviewed in Chapter 51. They block renin release and initially reduce cardiac output, central adrenergic drive, and norepinephrine release. In patients with essential hypertension, cardiac output returns toward pretreatment levels over the first 1 or 2 months of therapy, and any fall in BP is due to a reduction in peripheral resistance. It

is not known if similar changes occur in hemodialysis patients. Labetalol and carvedilol also block α -adrenergic receptors, which significantly increases their antihypertensive efficacy, and carvedilol is an antioxidant drug. Moreover, these additional actions maintain cardiac output.

β -Blockers are either predominantly lipid-soluble (*lipophilic*) or water-soluble (*hydrophilic*). Lipophilic β -blockers such as propranolol or metoprolol are metabolized extensively in the liver and have a short duration of action. However, the metabolites may be active and may be hydrophilic, as in the case of acebutolol. Hydrophilic β -blockers such as atenolol and nadolol are long-acting, are excreted by the kidneys, and are removed during hemodialysis or CAPD. They accumulate in patients with renal failure. Therefore, nadolol, atenolol, acebutolol, and sotalol must be used with extra caution in patients with ESRD. Some noncompliant or confused patients may not be able to manage a daily intake of antihypertensives. For them, a dose of long-acting atenolol after hemodialysis provides a measure of BP control between dialysis. Nebivolol is a relatively new lipophilic β -blocker approved for hypertension that is devoid of intrinsic sympathomimetic or membrane-stabilizing activity. Its unique

properties are nitric oxide-mediated vasodilation, which appears to protect left ventricular function. It requires study in hemodialysis patients.

β -Blockers produce a spectrum of dose-dependent adverse effects. They can increase insulin resistance and dyslipidemia, which are correlates of cardiovascular mortality. However, these effects are less obvious with cardioselective agents such as metoprolol or those with intrinsic sympathomimetic activity such as pindolol. Other adverse effects include hyperkalemia, bradycardia, Raynaud's phenomenon, and central nervous system effects, including nightmares and sleep disturbance, fatigue, and depression. β -Blockers may exaggerate cardiac failure in poorly compensated patients or produce bronchospasm in patients with asthma; they may mask the symptoms of hypoglycemia in patients with diabetes.

β -Blockers can be used as antihypertensive agents in patients with ESRD. Antihypertensive efficacy in essential hypertension is greater in white than in black patients, in young than in old, and in those with high plasma renin levels. Therefore, they are most effective in ESRD patients who are maintained at a low target weight. Their beneficial effect on cardiovascular morbidity and mortality, on symptomatic angina,

and on preventing death in patients who have had a myocardial infarction have not been studied in ESRD. However, because of the experience with these drugs in other areas, they are our preferred treatment for ESRD patients with these conditions, even in a patient without significant hypertension.

An important finding in patients on hemodialysis with dilated cardiomyopathy is that after 1 year of treatment with carvedilol their left ventricular ejection fraction increased by 39%, and their left ventricular systolic and diastolic volumes decreased by 16% and 6%, respectively, compared with those treated with placebo. Remarkably, by the end of the second year of the trial, 49% fewer patients in the carvedilol group died compared with those receiving placebo.³⁶ These are some of the most positive clinical trial data in patients with ESRD. Although they require confirmation, these findings provide a strong rationale for the use of slow-release carvedilol in the many hemodialysis patients with dilated cardiomyopathy.

ACE Inhibitors

ACE inhibitors (Table 60-3) are reviewed in Chapter 52. They lower BP by reducing peripheral vascular resistance. They not only inhibit conversion of angiotensin I to angiotensin II in the circulation and tissues, but also inhibit bradykinin degradation by blocking kinase II. The increased bradykinin levels stimulate nitric oxide and prostaglandin synthesis. ACE inhibitors reset the baroreflex and dampen the sympathetic nervous system so that heart rate does not normally change.

ACE inhibitors are divided into three broad groups: sulfhydryl-containing (captopril), dicarboxyl-containing (lisinopril, benazepril, quinapril, ramipril, spirapril, perindopril,

enalapril, and cilazapril), and phosphorus-containing (fosinopril). Only captopril and lisinopril are active drugs; the others are prodrugs that are converted in vivo to active compounds.

Absorption of captopril is markedly affected by food. It should be taken 1 hour before meals. The active form of most ACE inhibitors and their metabolites is largely excreted by the kidneys. However, another important route of elimination for fosinopril, spirapril, and benazepril is by hepatic metabolism. In renal failure, this compensates for lack of renal excretion and prevents substantial accumulation of these agents. Quinapril is tightly bound to tissue angiotensin-converting enzyme, which prevents major accumulation in ESRD. Therefore, only modest dose reduction is required.

ACE inhibitors are generally well tolerated. Common adverse effects include cough in 5% to 20%. Serious hyperkalemia can occur but is uncommon in hemodialysis patients. Other adverse effects are quite rare but include skin rashes, angioedema, abnormal taste, neutropenia, and hepatotoxicity. Anaphylactoid reactions have been reported in patients on ACE inhibitors treated with the high-flux dialysis membrane AN69. Therefore, this membrane should be avoided in patients receiving ACE inhibitors.

ACE inhibitors (or β -blockers) are particularly effective in treating hypertension that is resistant to dialysis, in which high levels of plasma renin activity are encountered. In contrast, they have little antihypertensive action in patients who are overloaded with fluid and salt and in those who have very low levels of plasma renin activity. Other beneficial actions of ACE inhibitors in treating essential hypertension include an increase in large artery compliance, reduction in LVH, and improvement in insulin resistance. These drugs can moderate the excessive thirst that plagues some patients with ESRD. A

Table 60-3 Angiotensin-Converting Enzyme Inhibitors

Agent	Daily Dose in ESRD (mg)	Dose Modification in ESRD	REMOVAL WITH DIALYSIS	
			HD	PD
Benazepril	2.5–20 qid	50%–75% dose reduction	N	U
Captopril	12.5–25 qid	50% dose reduction, and once-daily dosing; additional dose post-HD	Y	N

controlled trial of fosinopril in 400 hemodialysis patients with LVH failed to detect statistically significant benefit.¹⁴

Angiotensin II Receptor Blockers

These drugs (Table 60-4) are reviewed in Chapter 52. They act by blocking the binding of angiotensin II to its type 1 receptors (AT₁). The role of angiotensin II type 2 receptors (AT₂) is unclear, and no therapeutic AT₂ receptor antagonists are available. Angiotensin receptor blockers (ARBs) reduce BP and inhibit the effects of angiotensin II on the kidney, sympathetic nervous system, and aldosterone secretion.

Losartan is readily absorbed. It has a bioavailability of 33%, and is metabolized in the liver to active metabolites. Losartan and its metabolite have plasma half-lives of 2 hours and 6 to 9 hours, respectively. Only 4% to 7% is excreted through the kidneys. Thus, accumulation in renal failure is not likely. The safety and efficacy of losartan in ESRD has been established in a controlled study.³⁷ Unlike an ACE inhibitor, losartan does not produce cough or angioedema, but it has other adverse effects that are similar to those of ACE inhibitors and may also cause headache, lightheadedness, and gastrointestinal prob-

lems. Other ARBs appear well tolerated and are effective in patients with ESRD. Because none is excreted significantly in an active form by the kidney, they do not accumulate in hemodialysis patients.

Centrally Acting Drugs

These agents (Table 60-5) reduce BP by activating α₂-adrenergic receptors and imidazoline-preferring receptors in the brain. This reduces sympathetic outflow and thus reduces peripheral vascular resistance.

Centrally acting drugs are well absorbed after oral administration. Methyldopa is metabolized to α-methylnorepinephrine, which is the active compound in the brain. The active metabolites of methyldopa and 50% of the dose of clonidine and guanfacine are excreted by the kidneys. Therefore, these drugs accumulate modestly in ESRD.

Sedation and dry mouth are dose-dependent adverse effects that usually improve after several weeks of treatment. Sexual dysfunction with decreased libido is common. Bradycardia, especially in patients with sinoatrial nodal disease, may necessitate discontinuation of treatment.

Clonidine has been used extensively in ESRD and is an effective antihypertensive. A clonidine transdermal patch is particularly beneficial when compliance is a problem. It provides useful background antihypertensive action in patients undergoing hemodialysis.

Table 60-4 Angiotensin Receptor Blockers

Agent	Daily Dose in ESRD (mg)	Removal with HD	Removal with PD
Candesartan	8–32	N	N
Eprosartan	400–800	N	N
Irbesartan	150–300	N	N
Losartan	25–100	N	N
Telmisartan	40–80	N	N
Valsartan	80–320	N	N

None of these agents requires major dose reductions in HD patients. ESRD, end-stage renal disease; HD, hemodialysis; PD, peritoneal dialysis.

Adrenergic Blocking Agents

These agents (Table 60-6) antagonize the action of catecholamines at postjunctional α₁-receptors, thereby inhibiting vasoconstriction. This results in dilation of arterial (resistance) and venous (capacitance) vessels that reduce peripheral vascular resistance and BP. Cardiac output and heart rate are not usually affected.

These drugs are well absorbed, metabolized extensively in the liver, and excreted in the bile. Very small amounts are excreted unchanged in urine. They do not accumulate in ESRD.

Short-acting adrenergic blocking agents can cause a first-dose phenomenon, in which marked hypotension and

syncope occur 30 to 90 minutes after taking the medication. Other adverse effects, such as headache, dizziness, drowsiness, and nausea, are usually transient. However, their use in ESRD can exacerbate hypotension during dialysis-induced fluid removal. Therefore, they require careful monitoring and are not the drugs of first choice for these patients.

Nonspecific Vasodilators

These drugs (Table 60-7) lower BP by acting directly on vascular smooth muscle cells. Minoxidil produces vasodilation through its metabolite, which activates ATP-dependent potassium channels in vascular smooth muscle cells, thereby increasing cellular potassium ion influx. This leads to cell membrane hyperpolarization, exit of calcium ions, and vasodilation. Minoxidil is readily absorbed and metabolized in the liver. Only 10% to 20% is excreted unchanged in urine.

Minoxidil remains an important agent for short-term treatment of severe and refractory hypertension in ESRD (see Fig. 60-3) despite an adverse-effect profile that includes pericardial effusion, hypertrichosis, tachycardia, sympathetic excitation, and postural hypotension. It is contraindicated in patients with diastolic dysfunction and severe LVH, in whom it can cause cardiac failure. It can induce nonspecific T-wave changes, rashes, Stevens-Johnson syndrome, glucose intolerance, formation of antinuclear antibodies, and thrombocytopenia.

Hydralazine is also a direct vasodilator, but its mechanism of action is not well understood. It causes quite marked tachycardia due to reflex sympathetic activation. It is well absorbed and is inactivated by acetylation in the liver and bowel. The rate of acetylation is genetically determined. The

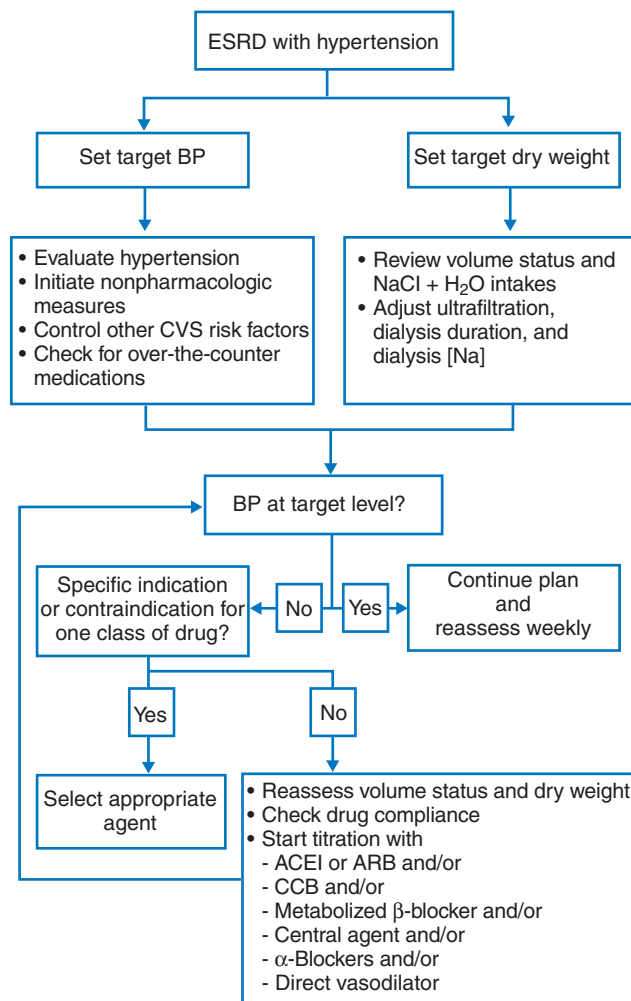

Figure 60-3 Algorithm for management of hypertension in hemodialysis patients. ACEI, angiotensin-converting enzyme inhibitor; BP, blood pressure; CCB, calcium channel blocker; CVS, cardiovascular system; ESRD, end-stage renal disease.

drug is excreted hepatically, but its metabolite is excreted primarily by the kidneys. It has a longer duration of action in patients with ESRD. Adverse effects include headache, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Other important, but less common, reactions include drug-induced lupus, hemolytic anemia, serum

sickness, and vasculitis. The use of hydralazine in ESRD has diminished with the advent of more effective agents that have fewer adverse effects.

Sodium nitroprusside is a nitrovasodilator with considerable value in hypertensive emergencies. It is converted in smooth muscle to nitric oxide, which activates guanyl cyclase, providing cyclic guanosine monophosphate, which leads to vasorelaxation. It is used parenterally in hypertensive emergencies (see Chapter 55). The thiocyanate produced during its metabolism is excreted solely through the kidneys and accumulates in patients with ESRD, in whom it causes lactic acidosis, central nervous system disturbance, seizures, and coma.

OVERVIEW OF HYPERTENSION MANAGEMENT IN ESRD

Our approach to hypertension management is reviewed in Figure 60-3. The first step toward controlling hypertension in ESRD is fluid management. Removal of salt and water with dialysis should be complemented by educating patients about restriction of their salt and water intake. If medications are required, they should be tailored according to the needs of each patient and their own associated medical conditions (see Chapter 56). BP control is improved by judicious use of ABPM to review control of arterial pressure and to make appropriate adjustment of treatment. Long-term studies of BP control in dialysis populations and the relative importance of different agents, in particular the role of ACE inhibitors and ARBs, are urgently required.

Activation of Mineralocorticoid Receptors by Decreased Metabolism of Cortisol at Target Sites	693
PHEOCHROMOCYTOMA	693

ADRENOCORTICAL DISORDERS

The adrenal cortex can cause hypertension through overproduction of 11-deoxycorticosterone (DOC), aldosterone, or cortisol. DOC and aldosterone are mineralocorticoids that produce hypertension primarily through salt and water retention. Cortisol is a glucocorticoid that can cause hypertension, in part by exerting a mineralocorticoid effect because of incomplete metabolism at target sites. The adrenal medulla can cause hypertension by overproduction of catecholamines from a pheochromocytoma.

Hypertensive Syndromes Due to Excess Production of 11-Deoxycorticosterone

Congenital adrenocortical disorders due to enzyme deficiency of either 11 β -hydroxylase¹ or 17 α -hydroxylase² reduce production of cortisol, leading to uninhibited secretion of corticotropin, which drives the zona fasciculata to increase production of DOC. In both 11 β - and 17 α -hydroxylase deficiency, physiologic replacement doses of dexamethasone (0.5–0.75 mg/day) decrease DOC production by inhibiting corticotropin release, resulting in normalization of arterial blood pressure (BP) and serum potassium concentration.

In generalized glucocorticoid resistance, cortisol secretion remains corticotropin-dependent but is reset to a higher than normal level.³ There is a corticotropin-dependent increase in mineralocorticoids (primarily DOC) and adrenal androgens. Because there is no peripheral resistance to these hormones, they produce their clinical effects of hypertension and hypokalemia (together with signs of excess androgens). Two strategies are used to treat generalized glucocorticoid resistance. The first employs large doses of dexamethasone (i.e., supraphysiologic amounts) to suppress corticotropin secretion. The second employs mineralocorticoid or androgen antagonists.

Hypertensive Syndromes Due to Excess Production of Aldosterone

Primary Aldosteronism

The therapeutic goals in all patients with excessive aldosterone production are threefold: first, to control BP; second, to correct hypokalemia, which is often associated with cardiac arrhythmias;

and third, to normalize plasma aldosterone concentration or block aldosterone activity with a mineralocorticoid receptor antagonist. Increasing evidence indicates that prolonged elevations of circulating aldosterone contribute to cardiac injury⁴ and progressive renal disease.⁵

Medical therapy (Table 61-1) is indicated in patients with adrenal hyperplasia, in those with adenoma who are poor surgical risks, and in those with bilateral adrenal adenomas. Total bilateral adrenalectomy has no place in the management of primary aldosteronism because adrenal insufficiency may be more difficult to treat than hypertension caused by aldosteronism. The hypertension associated with primary aldosteronism is salt and water dependent and is best treated by sustained salt and water depletion (Fig. 61-1).⁶

An approach to medical management of patients with primary aldosteronism is illustrated in Figure 61-2.⁷ An aldosterone receptor antagonist is given first to correct the hypokalemia. Prompt normalization of serum potassium occurs within 1 to 2 weeks without any change in BP. Thereafter, addition of a diuretic promptly reduces BP with maintenance of serum potassium at normal values. The usual doses of diuretics are hydrochlorothiazide 25 to 50 mg/day or furosemide 80 to 160 mg/day in combination with either spironolactone 100 to 200 mg/day or amiloride 10 to 20 mg/day.

In cases in which BP is not yet at goal after 6 to 8 weeks on maximal doses of the drug combination, addition of a β -blocker or a vasodilator may be necessary. For those patients who refuse surgery or are not surgical candidates, long-term administration of a mineralocorticoid receptor antagonist is an effective alternative. In our study of 24 patients treated medically for at least 5 years,⁸ systolic and diastolic BP decreased from a mean of 175/106 to 129/79 mm Hg and serum potassium increased from a mean of 3.0 to 4.3 mEq/L. There was no evidence of malignant transformation in any of the patients. Five tumors increased in size by at least 0.5 cm while maintaining their benign characteristics (as determined by computed tomography scan).

Placebo-controlled, randomized trials evaluating the relative efficacy of different drugs in the management of primary aldosteronism are not available. Spironolactone is highly efficacious and has always been the drug of choice. In addition, it is readily available and inexpensive. However, it is associated with undesirable side effects. Because it also blocks androgen and progesterone receptors, its chronic use often results in

Table 61-1 Drugs for the Medical Management of Primary Aldosteronism

Drug Class*	RECOMMENDED DOSES	
	Initial	Maximal
Mineralocorticoid Receptor Antagonists (Mineralocorticoid Dependent)		
Spironolactone	12.5–50 mg bid	75–100 mg bid
Eplerenone†	25–50 mg bid	100 mg bid
Decrease Epithelial Sodium Channels (Mineralocorticoid Independent)		
Amiloride	5–10 mg bid	20 mg bid
Triamterene	37.5–50 mg bid	100 mg bid

*Antihypertensive response can be enhanced with concomitant use of either hydrochlorothiazide (25–50 mg/day) or furosemide (80–160 mg/day).

†Doses are approximate. No published data of its use in primary aldosteronism exist.

Figure 61-1 The effect of adequate volume depletion on the blood pressure of patients with primary aldosteronism and resistant hypertension. Spironolactone (200 mg/day) and hydrochlorothiazide (50–100 mg/day) were added to current therapy. Blood pressure and plasma volume values were those obtained after 8 to 12 weeks of continued therapy. Mean arterial pressure (MAP) was significantly reduced in all. For the group as a whole, it fell from 138 ± 2 to 103 ± 9 (SEM) mm Hg ($P < .01$). Associated with reduction in MAP were decreases in plasma volume (from 114 ± 3 to 97 ± 2 [SEM]% normal) ($P < .01$). (From Bravo EL: Primary aldosteronism. Issues in diagnosis and management. *Endocrinol Metab Clin North Am* 1994;23:271–283.)

impotence, decreased libido, and gynecomastia in males and menstrual irregularities and breast engorgement or enlargement in females. These adverse events had no relationship to dose in one long-term study⁸ but were found to be dose-dependent in another study.⁹

Eplerenone is a highly selective mineralocorticoid receptor antagonist with none of the endocrine side effects of spironolactone. However, it has only 75% of the activity of spironolactone and has been approved only for the treatment of uncomplicated essential hypertension¹⁰ and for heart failure after acute myocardial infarction.¹¹ Its efficacy in patients with primary aldosteronism has not been reported.

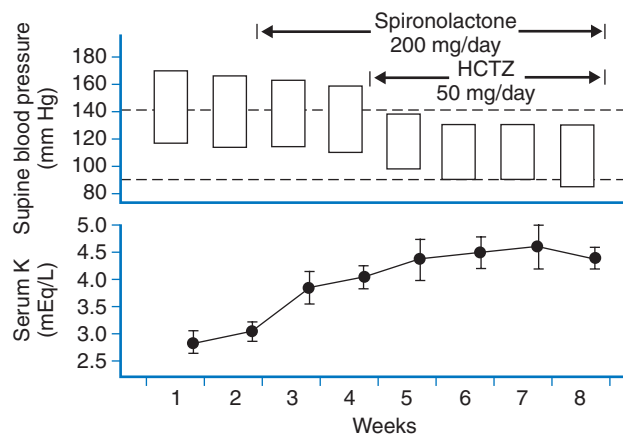

Figure 61-2 Diuretic therapy in primary aldosteronism. The effect of spironolactone combined with hydrochlorothiazide (HCTZ) on blood pressure and serum potassium concentrations in patients with aldosterone-producing tumors. (From Bravo EL, Dustan HP, Tarazi RC: Spironolactone as a non-specific treatment for primary aldosteronism. *Circulation* 1973;48:491–498. By permission from the American Heart Association, Inc.)

Potassium-sparing diuretics (amiloride, triamterene) decrease epithelial sodium channel activity in the renal collecting duct and can increase serum potassium values. Neither are effective antihypertensive agents by themselves. A diuretic should be added to achieve good BP control. These drugs do not block mineralocorticoid receptors, and persistence of elevated plasma aldosterone concentrations could lead to deleterious effects on the heart.¹² For this reason, they should not be used as first-line drugs in the management of patients with primary aldosteronism.

Agents that block transmembrane calcium flux and inhibit in vitro aldosterone production induced by angiotensin II, corticotropin, and potassium¹³ are potent direct arteriolar vasodilators and, in some studies, are reported to have natriuretic properties.¹⁴ For these reasons, calcium channel blockers should be ideally suited for treating the hypertension associated with excessive aldosterone production. In a study by Bravo

and colleagues,¹⁵ nifedipine (30–80 mg/day) was given for at least 4 weeks to 8 hypertensive patients with solitary adenomas, followed by the addition of spironolactone (100–200 mg/day) for 4 weeks, after which nifedipine was discontinued and patients remained on spironolactone alone. During the fourth week of each phase of the study, weekly averages of supine home BP, plasma volume, plasma renin activity (PRA), plasma aldosterone concentration, and serum electrolyte levels were assessed. Nifedipine decreased blood pressure, but not to normal levels ($157/97 \pm 4/4$ mm Hg [SE]), and did not alter plasma volume, PRA, aldosterone, or serum potassium concentration. Spironolactone normalized BP ($122/80 \pm 5/3$ mm Hg) and serum potassium concentration, reduced plasma volume, and increased PRA and plasma aldosterone concentration. Nifedipine plus spironolactone did not result in greater antihypertensive effect than spironolactone alone. These results suggest that nifedipine is not as efficacious as spironolactone in the treatment of primary aldosteronism.

Surgical excision of an aldosterone-producing adenoma normalizes BP and the biochemical defects in most patients. Surgery renders arterial pressure easier to control with medications. Neither the duration and severity of hypertension, nor the degree of target organ involvement, has any relationship to the arterial pressure response after surgery.¹⁶ One year postoperatively, approximately 70% of patients are normotensive, but 5 years postoperatively, only 53% remain normotensive. The restoration of normal potassium homeostasis is permanent.

Patients undergoing surgery should receive drug treatment for at least 8 to 10 weeks both to decrease BP and to correct metabolic abnormalities. These patients have significant potassium deficiency that must be corrected preoperatively because hypokalemia increases the risk of cardiac arrhythmias during anesthesia. Prolonged control of BP (at least 3 months before surgery) permits the use of intravenous fluids during surgery without producing hypertension and decreases morbidity. Administration of antihypertensive medications should normally be continued until surgery. Glucocorticoid administration is not needed before surgery. After removal of an aldosterone-producing adenoma, selective hypoaldosteronism usually occurs, even in patients whose PRA has been stimulated with chronic diuretic therapy.¹⁷ Potassium supplementation, therefore, should be given cautiously, and serum potassium values should be monitored closely. Residual mineralocorticoid activity is often sufficient to prevent excessive renal retention of potassium provided that sodium intake is adequate (i.e., at least 150 mEq/day). If hyperkalemia does occur, furosemide in doses of 80 to 160 mg/day should be started. Treatment with fludrocortisone is not usually necessary, but if it is required, 0.1 mg/day may be used as the initial dose with liberalized salt intake. Abnormalities in aldosterone production can persist for as long as 3 months after tumor removal.

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism is an inherited autosomal disorder that mimics primary aldosteronism.¹⁸ It is caused by a genetic mutation that results in a chimeric gene product fusing nucleotide sequences of the 11 β -hydroxylase and aldosterone synthase genes.¹⁹ The structure of the duplicated gene contains 5' regulatory sequences conferring the corticotropin responsiveness of 11 β -hydroxylase fused to more distal coding sequences of the aldosterone synthase

gene. This hybrid gene is regulated by corticotropin and has aldosterone synthase activity. It dictates ectopic expression of aldosterone synthase activity in the corticotropin-regulated zona fasciculata, which normally produces cortisol.¹⁹

No controlled studies of treatment of glucocorticoid-remediable aldosteronism have been reported. The suppression of corticotropin with exogenous glucocorticoid should correct all glucocorticoid-remediable aldosteronism abnormalities. However, this may cause complications of glucocorticoid administration. Moreover, patients may become mineralocorticoid-insufficient when therapy is initiated before the renin-angiotensin axis recovers fully. Additional treatment modalities include mineralocorticoid receptor blockade with spironolactone or inhibition of the mineralocorticoid-sensitive distal tubule sodium channel with amiloride.

Activation of Mineralocorticoid Receptors by Decreased Metabolism of Cortisol at Target Sites

Mineralocorticoid receptors in the distal nephron have equal affinity for their two ligands—aldosterone and cortisol—but are protected from activation by cortisol by 11 β -hydroxysteroid dehydrogenase (11 β -OHSD), which converts cortisol to the inactive cortisone.²⁰ The 11,18-hemiacetal structure of aldosterone protects it from the action of 11 β -OHSD. Consequently, aldosterone gains access to the receptors. When this mechanism fails within the kidney, cortisol increases sufficiently to activate mineralocorticoid receptors,²¹ resulting in antinatriuresis and kaliuresis, thereby producing hypertension and hypokalemia. A genetic disorder of the syndrome of apparent mineralocorticoid excess²² or prolonged ingestion of licorice or licorice-like compounds (such as carbenoxolone) both cause defects in the 11 β -OHSD enzyme type 2, which is the kidney isoform.²³ Such patients have clinical features similar to those with primary aldosteronism but have low aldosterone production. The features are reversed by spironolactone or dexamethasone but are exacerbated by administration of physiological doses of cortisol.

In patients with Cushing's phenomenon associated with ectopic corticotropin secretion, cortisol secretion may be so high that it exceeds the metabolic capacity of 11 β -OHSD enzyme type 2,²⁴ resulting in severe hypokalemic metabolic alkalosis and hypertension. The initial goal of therapy is blockade of the mineralocorticoid effects of cortisol to normalize serum potassium concentration and to control BP. The ultimate goal is to reduce plasma cortisol concentrations by resection of the ectopic source of corticotropin. If the ectopic sources of corticotropin cannot be localized, bilateral adrenalectomy is performed. If the patient is not a surgical candidate, cortisol production can be reduced with adrenocortical enzyme inhibitors, such as ketoconazole, metyrapone, aminogluthetamide, and etomidate.²⁵

PHEOCHROMOCYTOMA

The aim of management of pheochromocytoma (Box 61-1) is to prevent hypertensive crises and complications mediated by catecholamine-induced α -adrenergic receptor stimulation and to diminish postoperative hypotension. The use of α -blockers is advocated for control of BP. Phenoxybenzamine

Box 61-1 Suggested Approach to Preoperative Management of Patients with Pheochromocytoma

1. Start with doxazosin, 2 mg once daily. Increase by 2 mg every third day up to a total of 10 mg once daily.
2. Add a calcium channel blocker (amlodipine preferred) if blood pressure is not yet at goal.
3. Add β -blocker for persistent tachycardia or signs and symptoms of ischemic heart disease.
4. Other measures:
 - No diuretics unless deemed essential
 - High salt intake (10–12 g NaCl/day)
5. Therapeutic goals:
 - Supine BP < 140/90 mm Hg
 - No cardiac arrhythmias
 - No orthostatic hypotension
 - Completely asymptomatic for at least 6–8 weeks before surgery
 - Continue all medications on day of surgery

hydrochloride (Dibenzylamine, 10–20 mg tid to qid) is given in increasing doses until the BP is controlled and symptomatic paroxysms are prevented. Theoretically, phenoxybenzamine should permit vascular volume repletion, block α -adrenergic receptors noncompetitively, and disable the effects of released catecholamines.²⁶ Its blockade of presynaptic α_2 -adrenergic receptors produces significant tachycardia, which requires concomitant β -adrenergic blockade. It may prolong BP reduction after removal of the tumor because it decreases receptor number and synthesis. Total elimination of cardiovascular disturbances is seldom achieved despite adequate α -blockade. Significant elevations of BP are to be anticipated during manipulation of the tumor.²⁷

Other α -adrenergic antagonists may circumvent some of the disadvantages of phenoxybenzamine. Doxazosin is a selective postsynaptic α_1 -adrenergic receptor antagonist that does not produce tachycardia and has a shorter duration of action, thereby allowing more rapid adjustment of dosage and decreasing the duration of postoperative hypotension. It has been reported to be as potent as phenoxybenzamine with fewer adverse effects.²⁸ The initial dose of doxazosin is 2 mg once daily, increased as needed at increments of 2 mg every 3 days up to a total dose of 10 mg. No β -adrenergic blockade is required unless tachycardia is present. Labetalol is an α - and β -adrenergic blocker. It was reported to be effective in the control of BP and clinical manifestations associated with pheochromocytoma.²⁹ The initial dosage is 100 mg 4 times daily, increased stepwise to a maximum of 800 to 1600 mg/day. However, its safety has been questioned because it occasionally precipitates hypertensive crises.

Calcium channel blockers have also been successful in controlling BP in patients with pheochromocytoma.³⁰ These agents have the advantage of not producing overshoot hypotension or orthostatic hypotension and therefore may be used safely in patients who are normotensive but who have occasional episodes of paroxysmal hypertension. They are useful agents in managing cardiovascular complications because they may also prevent catecholamine-induced coronary vasospasm and myocarditis.³¹ They have none of the complications associated with chronic use of α -adrenergic blockers. In

doses of 40 to 60 mg/day, nifedipine normalizes basal BP in hypertensive patients and prevents the hypertensive response to provocative challenge. Verapamil and diltiazem produce similar results.³² It is likely that they reduce arterial pressure by inhibiting norepinephrine-mediated transmembrane calcium influx in vascular smooth muscle and not by decreasing catecholamine synthesis in tumors.

Doxazosin combined with a calcium channel blocker is often sufficient to control the signs and symptoms. A β -blocker may be added if there is persistent tachycardia. Patients should be advised to maintain a high salt intake (10–12 g NaCl/day). Diuretics should be discontinued unless they are deemed necessary. Hypertensive crises may be managed with intravenous phentolamine mesylate (Regitine) or sodium nitroprusside. Nifedipine, 10 mg orally or sublingually, has been used successfully.

Patients with pheochromocytoma have a high plasma volume requirement, both during and after surgery. The expansion of the intravascular volume approximately 12 hours before operation, with generous replacement of blood lost during the procedure, greatly reduces the frequency and severity of postoperative hypotension. Persistence of hypotension may be caused by hemorrhage, sudden increases in venous capacitance, inadequate volume repletion, or residual effects of preoperative α -blockade. Fluids should be administered first, keeping in mind that these patients require large amounts of volume after tumor resection. Pressor agents are not usually effective in the presence of persistent hypovolemia. It is often difficult to withdraw vasopressors once they have been started.

Until recently, a pheochromocytoma was removed only through an open approach. With technological advances and experience in minimally invasive techniques, the tumor can now be removed safely and successfully with laparoscopic surgery. In a recent study,³³ 14 patients who underwent laparoscopic surgery for pheochromocytoma were compared with 20 patients who underwent the traditional open approach. The intraoperative hemodynamic values during laparoscopic surgery (adrenalectomy) were comparable to those during open surgery. However, in patients undergoing laparoscopy, intraoperative hypotension was less severe (mean lowest BP, 98/57 mm Hg vs. 80/50 mm Hg, $P = .05$) and hypotensive episodes were less frequent (median, 0 vs. 2 episodes, $P = .005$). The median estimated blood loss was 100 mL (range, 100–200 mL) in the laparoscopy group and 400 mL (range, 150–1500 mL) in the open group ($P = .0001$). Surgery time was not different (196±69 min for open vs. 177±59 min for laparoscopy). Patients who underwent laparoscopy recovered quicker. The time to ambulation was 1.5 versus 4 days ($P = .002$). They resumed oral food intake sooner (median, 1 vs. 3.5 days, $P = .001$) and required fewer days in hospital (median, 3 vs. 7.5 days, $P = .001$). This study indicates that laparoscopic removal of pheochromocytoma is not only safe, but also has marked advantages over the open approach. Patients have faster recovery, shorter hospitalization, and better cosmetic outcome.

A STRATEGY FOR MAXIMAL RENOPROTECTION

709

Despite substantial advances in medical science over the past 50 to 60 years, there are as yet few effective treatments for specific renal diseases. Consequently, many cases progress to chronic renal failure and the population of patients requiring renal replacement therapy continues to grow rapidly. In the United States alone 335,963 people were receiving chronic dialysis and 136,136 had a functioning renal transplant at the end of 2004, resulting in annual Medicare costs of \$20.1 billion.¹ Moreover, the mortality rate on dialysis remains as high as 20% to 25% per annum,¹ and there is a worldwide shortage of organs for transplantation. The publication of a classification system for chronic kidney disease (CKD) by the Kidney Disease Outcomes Quality Initiative (K/DOQI)² and subsequent epidemiologic studies based on that classification have drawn attention to the fact that up to 17% of the U.S. population may suffer from CKD.³ There is thus an urgent need to identify undiagnosed cases and to minimize the risk of progression. It has been appreciated for several decades that substantial loss of functioning nephrons due to kidney disease of any etiology provokes a common syndrome characterized by systemic hypertension, proteinuria, and a progressive decline in glomerular filtration rate (GFR), the rate of which depends more on individual patient characteristics than specific disease etiology.^{4,5} These observations suggest that CKD progresses via a common pathway of mechanisms and that therapeutic interventions that inhibit this pathway may be successful in slowing the rate of progression of CKD irrespective of the initiating cause. We review experimental and clinical evidence in support of this hypothesis and discuss how interventions based on an understanding of common pathway mechanisms may be combined into a comprehensive strategy for achieving maximal renoprotection.

MECHANISMS UNDERLYING CHRONIC KIDNEY DISEASE PROGRESSION

Glomerular Hemodynamic Factors

When rats are subjected to surgical ablation of five sixths of their renal mass, they develop hypertension, proteinuria, and a progressive loss of GFR, features similar to those of human CKD. Brenner and colleagues, using micropuncture techniques, measured the glomerular capillary hydraulic pressure (P_{GC}) and GFR in single nephrons (single nephron GFR; SNGFR) and showed that when nephrons were lost, remaining glomeruli underwent hemodynamic adaptations resulting in substantial increases in SNGFR (glomerular hyperfiltration) and P_{GC} (glomerular capillary hypertension).⁶ The presence of structural injury to glomerular cells as early as 1 week after five sixths nephrectomy suggests that these hemodynamic changes provoke glomerular damage that results in a further loss of nephrons, thereby establishing a vicious cycle of progressive renal injury.⁷ Support for this hypothesis was provided by experimental studies showing that renoprotective interventions were associated with attenuation of the glomerular hemodynamic changes.

Low-protein diet feeding was associated with normalization of SNGFR and P_{GC} as well as substantial protection from progressive glomerular injury.⁶ Treatment with an angiotensin-converting enzyme (ACE) inhibitor had little effect on SNGFR but did normalize P_{GC} and afforded renoprotection, suggesting that P_{GC} rather than SNGFR was the critical determinant of glomerular injury in the remnant kidney.⁸ Treatment with a combination of hydralazine, hydrochlorothiazide, and reserpine resulted in a similar lowering of systemic blood pressure to

that seen with ACE inhibitor treatment but did not lower P_{GC} or prevent glomerulosclerosis.⁹ Micropuncture studies in a rodent model of diabetic nephropathy confirmed that glomerular hypertension and hyperfiltration are present. The importance of these hemodynamic factors in the complex pathogenesis of diabetic nephropathy was confirmed by experimental studies showing that normalization of P_{GC} by low-protein diet or treatment with an ACE inhibitor resulted in the prevention of progressive renal injury despite persistent chronic hyperglycemia.^{10,11}

Angiotensin II

Angiotensin II has been identified as an important mediator of the glomerular hemodynamic changes associated with progressive renal injury. Experimental studies have revealed several nonhemodynamic effects of angiotensin II that may also be important in CKD progression. These include loss of glomerular size permselectivity resulting in proteinuria, mesangial cell proliferation and induction of transforming growth factor- β (TGF- β) expression, stimulation of plasminogen activator inhibitor-1 production by endothelial and vascular smooth muscle cells, macrophage activation, and increased phagocytosis, as well as induction of cytokine expression and fibrogenic effects via aldosterone.¹² Angiotensin II has thus emerged as a central mediator in the pathogenesis of progressive renal injury and is therefore a logical target for interventions to slow CKD progression (Fig. 62-1).

Tubulointerstitial Fibrosis

In CKD, progressive glomerulosclerosis is accompanied by tubulointerstitial fibrosis, the extent of which correlates closely with prognosis.¹³ Several mechanisms have been proposed to

link glomerular and tubulointerstitial damage. These include adverse effects of the abnormal filtration of plasma proteins that provoke proinflammatory and profibrotic responses when absorbed by renal tubule cells,¹⁴ downstream effects of cytokines filtered or produced by injured glomeruli,¹⁵ misdirection of protein-rich glomerular filtrate into the interstitium,¹⁶ epithelial to mesenchymal transition of tubule cells to form interstitial myofibroblasts,¹⁷ and reduced perfusion of peritubular capillaries resulting in hypoxia.¹⁸ Mechanisms that may contribute to progressive renal injury are discussed further in the sections that follow and are summarized in Figure 62-1.

INTERVENTIONS FOR SLOWING THE RATE OF CKD PROGRESSION

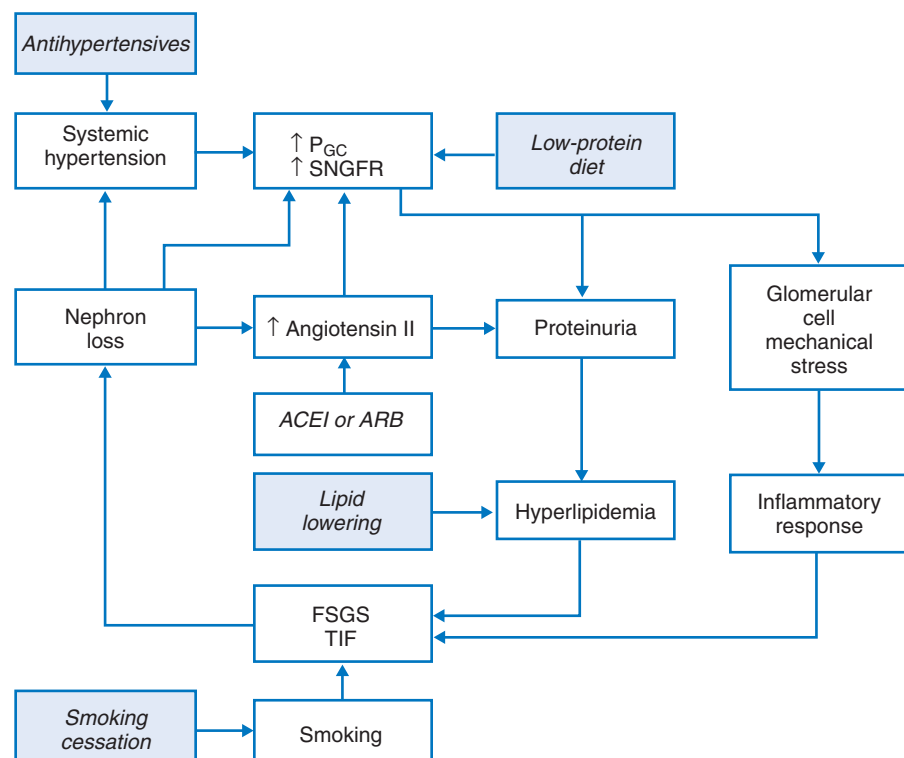

Antihypertensive Therapy

Optimal Blood Pressure

The treatment of systemic hypertension was the first intervention shown to significantly slow the rate of CKD progression, and it remains fundamental to renoprotective strategies. Among insulin-dependent diabetic patients with diabetic nephropathy, the initiation of antihypertensive therapy resulted in marked reductions in rates of GFR decline,^{19,20} implying that hypertension, an almost universal consequence of impaired renal function, also contributes to the progression of CKD. Similar observations were reported among patients with nondiabetic forms of CKD.^{21–23} Uncertainty remains, however, about how much blood pressure (BP) lowering is required to achieve optimal renoprotection.

The Modification of Diet in Renal Disease (MDRD) study sought to resolve this issue by evaluating whether lower than previously recommended BP targets afforded greater

Figure 62-1 Schema depicting the proposed mechanisms resulting in a common pathway of progressive nephron loss in chronic kidney disease and illustrating the actions of different interventions (*in italics*) in interrupting this pathway. ACEI, angiotensin-converting enzyme inhibitor; AngII, angiotensin II; ARB, angiotensin receptor blocker; FSGS, focal and segmental glomerulosclerosis; P_{GC} , glomerular capillary hydraulic pressure; SNGFR, single nephron glomerular filtration rate; TIF, tubulointerstitial fibrosis.

renoprotection than “usual” BP control among patients with predominantly nondiabetic CKD. Patients were randomized to a target mean arterial pressure (MAP) of 107 mm Hg (equivalent to BP of 140/90 mm Hg) or 92 mm Hg (equivalent to BP of 125/75 mm Hg). Whereas primary analysis did not show any overall difference in rate of GFR decline between these groups, patients randomized to the low BP group evidenced an early rapid decrease in GFR, likely due to associated renal hemodynamic effects, that obscured a later significantly slower rate of GFR decline than that observed in the “usual” BP target group. Baseline proteinuria more than 1 g/day was associated with more rapid GFR decline in usual versus low BP groups.²⁴ Secondary analysis revealed significant correlations between the rate of GFR decline and achieved blood pressure, an effect that was also more marked among those with greater baseline proteinuria. The authors conclude by recommending a BP goal of lower than 125/75 mm Hg (MAP = 92 mm Hg) for CKD patients with more than 1 g/day of proteinuria, and a goal of lower than 130/80 mm Hg (MAP = 98 mm Hg) for those with proteinuria of 0.25 to 1 g/day.²⁵ Subsequent follow-up of MDRD patients suggests that the benefits of lower blood pressure may become evident only over a longer period; after a mean of 6.6 years the risk of end-stage renal disease (ESRD) (adjusted hazard ratio [HR], 0.68; 95% confidence interval [95% CI], 0.57–0.82) was lower and that of a combined endpoint of ESRD or death (adjusted HR, 0.77; 95% CI, 0.65–0.91) was lower in patients randomized to the low BP target even though treatment and BP data were not available beyond the 2.2 years of the original trial.²⁶ Unfortunately, these results are confounded by the random use of ACE inhibitor treatment in the study. Consequently, it remains unclear whether the level of blood pressure attained is critically important in CKD patients receiving an ACE inhibitor or angiotensin receptor blocker (ARB). However, among patients with type 1 diabetes and established nephropathy receiving ACE inhibitor treatment, randomization to a low (MAP = 92 mm Hg) versus “usual” (MAP = 100–107 mm Hg) target blood pressure was associated with significantly lower levels of proteinuria after 2 years but no significant difference in the loss of GFR.²⁷ Secondary analysis of data from the Irbesartan Diabetic Nephropathy Trial (IDNT) revealed greater renoprotection among patients who achieved lower BP targets; an achieved systolic blood pressure higher than 149 mm Hg was associated with a 2.2-fold higher risk of developing ESRD or a doubling of serum creatinine versus an achieved systolic blood pressure lower than 134 mm Hg, independent of ARB treatment.²⁸

Other studies have failed to find additional benefit associated with lower BP targets. For example, intensive BP control was not associated with significantly improved preservation of renal function among patients with autosomal dominant polycystic kidney disease, but the authors point out that the study may not have had adequate statistical power to detect a difference.²⁹ In the African American Study of Kidney Disease and Hypertension (AASK), no significant difference in the rate of GFR decline was observed between patients randomized to MAP goals of no more than 92 mm Hg compared to those assigned to MAP goals of 102 to 107 mm Hg. One possible explanation for the lack of a benefit is that these patients generally had low baseline levels of proteinuria (mean urine protein, 0.38–0.63 g/day).³⁰ In the Ramipril Efficacy in Nephropathy 2 (REIN-2) trial, additional BP reduction (<130/80 mm Hg versus diastolic BP < 90 mm Hg irrespective of systolic BP) with a nondihydropyridine

calcium channel blocker (CCB) plus ACE inhibitor treatment in patients with nondiabetic CKD did not yield additional renoprotection.³¹ However, the degree of additional BP reduction (4.1/2.8 mm Hg) may have been insufficient or the specific antihypertensive agent may have been ineffective.

Two additional pieces of evidence support a lower BP target; a meta-analysis of 11 randomized trials that included 1860 patients revealed that the lowest risk of progression of nondiabetic CKD was associated with an achieved systolic blood pressure of 110 to 129 mm Hg, independent of ACE inhibitor treatment.³² Secondly, results from several clinical trials that included diabetic and nondiabetic CKD revealed a slower rate of CKD progression in patients achieving the lowest blood pressures.³³ Two recent reports raise a note of caution. They suggest that excessive lowering of blood pressure may be associated with adverse effects. In the same meta-analysis, an achieved systolic blood pressure lower than 110 mm Hg was associated with an increased risk of CKD progression (relative risk [RR], 2.48; 95% CI, 1.07–5.77),³² and in the IDNT an achieved systolic blood pressure lower than 120 mm Hg was associated with increased all-cause mortality and no further improvement in renal outcomes.²⁸

In summary, results from randomized trials comparing “low” and “usual” BP targets among CKD patients have not yielded unequivocal results, but the overall picture suggests that lower BP targets are associated with more effective renoprotection, particularly among those with significant proteinuria. These observations have led to a consensus that blood pressure should be lowered to less than 130/80 mm Hg in all patients with CKD^{33,34} and, for patients with more than 1 g/day of proteinuria, a blood pressure of less than 125/75 mm Hg should be achieved. Potentially dangerous hypotension, particularly in patients with autonomic neuropathy, labile blood pressure, or atherosclerosis with decreased vascular compliance, should be avoided.

Antihypertensive Drugs

Data from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) have been misinterpreted to imply that the choice of antihypertensive drug does not affect renal outcomes in patients with CKD. ALLHAT was designed to investigate the effect of antihypertensive drugs on cardiovascular outcomes in patients with hypertension and at least one cardiovascular risk factor; they found no significant difference in the incidence of the primary outcome of fatal ischemic heart disease or nonfatal myocardial infarction among patients randomized to treatment with a thiazide diuretic, a CCB, or an ACE inhibitor.³⁵ In a post hoc analysis there was also no difference found in the secondary outcome of ESRD or more than 50% decrease in GFR. Notably, patients with serum creatinine levels higher than 2 mg/dL were specifically excluded from the analysis, resulting in only a minority of patients (5662 of 33,357) having CKD (estimated GFR, <60 mL/min/1.73 m²), and there was no assessment of proteinuria.³⁶ In contrast to the ALLHAT results, a large body of evidence supports the use of ACE inhibitors or ARBs as first-line antihypertensive therapy in patients with CKD (see “Pharmacologic Inhibition of the Renin-Angiotensin System” in this chapter).

Nevertheless, dietary salt restriction and diuretics are important antihypertensive therapies in the treatment of CKD. Studies have demonstrated that high dietary sodium intake

may abrogate the antiproteinuric effect of ACE inhibitor treatment but that addition of a thiazide diuretic restores the antiproteinuric effect despite ongoing high sodium intake.³⁷ Addition of a thiazide diuretic to ARB treatment was found to reduce blood pressure and proteinuria in patients with IgA nephropathy.³⁸ We recommend dietary salt restriction with a thiazide diuretic as second-line antihypertensive therapy for patients with stage 1 to 3 CKD who are not achieving adequate BP control with an ACE inhibitor or ARB alone. With more advanced CKD, a loop diuretic should be used to reduce extracellular volume and blood pressure.

There is concern that the dihydropyridine class of CCBs may adversely affect the progression of CKD. In experimental studies dihydropyridine CCB treatment allowed greater transmission of systemic blood pressure to the renal microcirculation and was associated with more rapid progression of renal injury when compared to ACE inhibitor treatment in the five sixths nephrectomy model.³⁹ Whereas one relatively small study found no difference between the renoprotective effects of the dihydropyridine CCB nifedipine and the ACE inhibitor captopril,⁴⁰ but two larger studies have reported adverse outcomes associated with the use of dihydropyridine CCBs. A secondary analysis of data from REIN-2 found that treatment with the dihydropyridine CCBs nifedipine and amlodipine was associated with higher levels of proteinuria and more rapid GFR decline than other antihypertensives in patients who failed to achieve a MAP less than 100 mm Hg and were not receiving an ACE inhibitor.⁴¹ In AASK,⁴² patients with CKD and hypertension were randomized to treatment with an ACE inhibitor, the dihydropyridine CCB amlodipine, or a β -blocker and diuretic in combination. Amlodipine therapy was stopped prematurely due to identification of a more rapid decline in GFR compared to patients receiving the β -blocker or ACE inhibitor, particularly in the presence of proteinuria higher than 1 g/day. As discussed previously, the REIN-2 study found no additional renoprotection when a dihydropyridine CCB was added to ACE inhibitor treatment in patients with nondiabetic CKD.³¹

In contrast, nondihydropyridine CCBs lower P_{GC} , reduce proteinuria, and afford renoprotection in experimental studies. In one clinical study, the combination of ACE inhibitor and nondihydropyridine CCB treatment resulted in greater reduction of proteinuria than either treatment alone in patients with type 2 diabetes and overt nephropathy.⁴³ A meta-analysis of data from 28 randomized, clinical trials in hypertensive patients with proteinuria found a 2% increase in proteinuria with dihydropyridine CCB treatment versus a 30% reduction with nondihydropyridine CCB treatment despite similar effects on blood pressure.⁴⁴ Consequently, we recommend that dihydropyridine CCBs should be avoided in patients with CKD unless they are required as combination therapy with other antihypertensives to achieve the targets for BP control outlined in this chapter and used in combination with ACE inhibitor or ARB treatment. If possible nondihydropyridine CCBs should be used in preference to dihydropyridine CCBs.

Pharmacologic Inhibition of the Renin-Angiotensin System

A large number of published clinical trials and meta-analyses provide clear evidence to support the use of pharmacologic inhibitors of the renin-angiotensin system as an essential

component of any strategy aiming to achieve maximal renoprotection in patients with CKD (summarized in Table 62-1).

Angiotensin-Converting Enzyme Inhibitors

Diabetic Nephropathy

In 1993, the Captopril Collaborative Study Group demonstrated specific renoprotection attributable to ACE inhibitor treatment in human CKD for the first time.⁴⁵ In this study, 409 patients with type 1 diabetes and established nephropathy (proteinuria > 0.5 g/day; serum creatinine < 2.5 mg/dL) were randomized to receive captopril or placebo to achieve a BP goal of less than 140/90 mm Hg. After median follow-up of 3 years, captopril treatment was associated with a 50% reduction in the risk of the combined endpoint of death, dialysis, and renal transplantation and a 48% reduction in the risk of a doubling of serum creatinine level. Renoprotection was not attributable simply to the antihypertensive effects of ACE inhibitors because BP control was not statistically different between the groups. Subsequently, investigators evaluated whether ACE inhibitor would also benefit type 1 diabetic patients with microalbuminuria. A meta-analysis of 12 studies, including 689 patients with type 1 diabetes followed for at least a year, found that ACE inhibitor treatment was associated with a significant reduction in the risk of progression to overt nephropathy (odds ratio, 0.38) and three times the incidence of complete normalization of microalbuminuria.⁴⁶ Another study showed that ACE inhibitors prevented progression to overt nephropathy over 8 years and was associated with preservation of a normal GFR.⁴⁷ Finally, a subgroup analysis of the EUCLID study found that ACE inhibitor treatment reduced albuminuria by 12.7% among normotensive, normoalbuminuric type 1 diabetic patients; this trend was not statistically significant and was associated with a lower blood pressure.⁴⁸

Data on the renoprotective effects of ACE inhibitors in patients with type 2 diabetes are conflicting because studies have included relatively small numbers of patients and only one⁴⁹ was able to show a greater reduction in GFR decline associated with ACE inhibitors versus other antihypertensives.⁵⁰⁻⁵² In contrast, the diabetic subgroup analysis of the Heart Outcomes Prevention Evaluation (HOPE) study revealed beneficial effects of ACE inhibitor treatment in decreasing microalbuminuria⁵³⁻⁵⁵ and reducing the number of patients progressing from microalbuminuria to overt proteinuria among type 2 diabetic patients (risk reduction, 24%–67%).⁵⁶⁻⁵⁸ The HOPE study also revealed a 25% reduction in the combined primary endpoint of myocardial infarction, stroke, or cardiovascular death in ramipril-treated type 2 diabetic patients who had risk factors for cardiovascular disease. Finally, a beneficial role for ACE inhibitor treatment in primary prevention of nephropathy among 156 normotensive, normoalbuminuric type 2 diabetic patients has been reported, noting a 12.5% absolute risk reduction for microalbuminuria.^{59,60} Another study has reported similar benefit among 1204 hypertensive normoalbuminuric type 2 diabetic patients (estimated acceleration factor, 0.39 for trandolapril + verapamil versus placebo and 0.47 for trandolapril versus placebo; $P = .01$ for both).⁶⁰ On the other hand, one relatively large study found no renoprotective benefit of ACE inhibitor over β -blocker treatment among hypertensive type 2 diabetic patients with normoalbuminuria or microalbuminuria.⁶¹ Regarding meta-analyses, one included only studies of type 2 diabetes and concluded there was a statistically significant reduction in albuminuria associated with ACE

Table 62-1 Summary of Studies Showing the Renoprotective Effects of Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers in Diabetic and Nondiabetic Chronic Kidney Disease

CKD Type	Trial Outcome	Ref.
Angiotensin-Converting Enzyme Inhibitors (ACEIs)		
Type 1 DM + CKD	50% ↓ risk of dialysis, transplant, or death	45
Type 1 DM + μ A	↓ Risk of overt nephropathy (OR = 0.38)	46, 47
Type 1 DM + NA	12.7% ↓ in albuminuria (NS)	48
Type 2 DM + CKD	Benefit in only one study	49–52
Type 2 DM + μ A	24%–67% ↓ risk of overt nephropathy	53–58
Type 2 DM + NA	12.5% ↓ risk of developing μ A	59, 60
Nondiabetic CKD	↓ Creatinine doubling/ESRD (RR = 0.52)	66–69
Advanced CKD	43% ↓ risk of creatinine doubling, ESRD or death	70
Angiotensin Receptor Blockers (ARBs)		
Type 2 DM + μ A	↓ Risk of overt nephropathy (HR = 0.30)	76
Type 2 DM + CKD	25%–37% ↓ risk of creatinine doubling 23%–28% ↓ risk of ESRD	74, 75
Combination ACEI and ARB		
Type 2 DM + μ A	↓ BP and ↓ albuminuria vs. ACEI or ARB	90
Nondiabetic CKD	HR for ESRD 0.38–0.40 vs. ACEI or ARB	89
All CKD (meta-analysis)	Mean 440mg/day less proteinuria vs. ACEI	94

CKD, chronic kidney disease; ESRD end-stage renal disease; HR hazard ratio; μ A, microalbuminuria; NA, normoalbuminuria; OR odds ratio; RR, risk ratio.

inhibitor treatment versus placebo.⁶² A second, larger analysis combined data from studies of type 1 and type 2 diabetes and reported weak evidence that ACE inhibitors were associated with a reduced risk of doubling of serum creatinine (RR, 0.60; 95% CI, 0.34–1.05) or incidence of ESRD (RR, 0.64; 95% CI, 0.40–1.03) even though there was stronger evidence of reduced risk of progression of microalbuminuria to macroalbuminuria (RR, 0.45; 95% CI, 0.28–0.71). All-cause mortality was significantly reduced in patients receiving ACE inhibitors (RR, 0.79; 95% CI, 0.63–0.99).⁶³ Finally, a meta-analysis of 16 trials that assessed the effect of ACE inhibitors on reducing the risk of microalbuminuria in type 1 and type 2 diabetes found a significantly lower risk of developing microalbuminuria versus placebo (RR, 0.60; 95% CI, 0.43–0.84) or CCB treatment (RR, 0.58; 95% CI, 0.40–0.84).⁶⁴

Consequently, we recommend ACE inhibitor treatment for all type 1 diabetic patients with microalbuminuria or overt nephropathy. Insufficient data exist to support the use of ACE inhibitors in normoalbuminuric type 1 diabetic patients, but it seems reasonable to recommend ACE inhibitors for those with elevated blood pressure. There is no clear evidence of specific benefit associated with ACE inhibitors in slowing the progression of established nephropathy in type 2 diabetic patients, but this may be due to the lack of adequately powered studies. The

evidence does support the recommendation to use ACE inhibitors to reduce progression to overt nephropathy in type 2 diabetic patients with microalbuminuria or to prevent microalbuminuria from developing in patients with hypertension. Finally, cardiovascular disease is the most common cause of morbidity and mortality among type 2 diabetic patients, and ACE inhibitors should be considered to reduce cardiovascular risk in these patients.

Nondiabetic CKD

Regarding renoprotection in nondiabetic CKD, an early study reported a 53% reduction in the risk of reaching the combined endpoint of doubling of serum creatinine level or incidence of ESRD associated with ACE inhibitor treatment. However, blood pressure was lower among patients receiving an ACE inhibitor versus placebo, making it impossible to separate the beneficial effects of lowering blood pressure from any unique effects of ACE inhibitor treatment.⁶⁵ In the REIN study of 352 patients with nondiabetic CKD randomized to either ACE inhibitor or placebo, blood pressures were similar in the two groups. Among patients with at least 3 g/day of proteinuria at baseline, the study was stopped early because the rate of decline in GFR was significantly slower in patients receiving the ACE inhibitor (0.53 vs. 0.88 mL/min/mo).⁶⁶ There also was a significant reduction in

the risk of the combined endpoint of a doubling of serum creatinine or ESRD with ACE inhibitor treatment (risk ratio = 1.91 for the placebo group). When REIN patients who had received placebo were switched to an ACE inhibitor, there was a significant reduction in the rate of decline in GFR. Patients continuing ACE inhibitor treatment had a further reduction in the rate of GFR decline. Notably, patients who received ACE inhibitors from the start had a significantly lower risk of reaching ESRD than those subsequently switched to ACE inhibitors (RR for placebo group, 1.86; 95% CI, 1.07–3.26); over 36 to 54 months of follow-up, none of the patients who received ACE inhibitors from the start reached ESRD.^{67,68} When 186 REIN patients with less than 3 g/day of proteinuria were followed for a median of 31 months after randomization, similar results were seen. ACE inhibitor treatment significantly reduced the incidence of ESRD (RR for placebo group, 2.72; 95% CI, 1.22–6.08), particularly among those with a baseline GFR of less than 45 mL/min.⁶⁹ Even in advanced stages of CKD (244 patients with a serum creatinine of 3.1–5.0 mg/dL at baseline randomly assigned to ACE inhibitor treatment), ACE inhibitors are associated with a 52% reduction in proteinuria and a 43% reduction in the risk of the primary endpoint (doubling of serum creatinine, ESRD, or death).⁷⁰ A meta-analysis of 11 studies that included 1860 patients with nondiabetic CKD confirmed these findings⁷¹; ACE inhibitor treatment was associated with significantly lower risks of reaching ESRD (RR, 0.69; 95% CI, 0.51–0.94) or the combined endpoint of a doubling in serum creatinine or ESRD (RR, 0.70; 95% CI, 0.55–0.88). Thus, the renoprotective effects of ACE inhibitors are mediated by factors in addition to their antihypertensive and antiproteinuric effects, and benefits of their use were greater in patients with higher levels of baseline proteinuria but not in those patients with less than 0.5 g/day of proteinuria. Even in patients with autosomal dominant polycystic kidney disease, ACE inhibitor treatment reduced proteinuria, but the overall evidence of slowing CKD progression was inconclusive and limited to those with higher levels of proteinuria.⁷²

In addition to the renoprotective benefits of ACE inhibitor treatment, the HOPE study revealed substantial reductions in overall (RR, 0.84) and cardiovascular mortality (RR, 0.74) in patients receiving an ACE inhibitor versus placebo among 9297 patients at increased risk of cardiovascular disease.⁷³ Although the HOPE study did not include large numbers of patients with nondiabetic CKD, cardiovascular disease remains the single largest cause of morbidity and mortality in this population, and the HOPE study results provide a further rationale for the use of ACE inhibitor therapy in patients with CKD.

In light of these trials regarding renoprotection and the probable reduction in cardiovascular risk, we recommend ACE inhibitor treatment for all patients with CKD and proteinuria more than 0.5 g/day unless there are specific contraindications.

Angiotensin Receptor Blockers

Angiotensin receptor blockers inhibit the renin-angiotensin system by blocking angiotensin II subtype 1 (AT₁) receptors.¹² Despite differences in their effects on the renin-angiotensin system, experimental studies have found that ACE inhibitor and ARB treatment produce similar changes in glomerular hemodynamics and afford equivalent renoprotection in a variety of experimental CKD models.¹²

The simultaneous publication of three large randomized studies clearly established a role for ARB therapy in achieving

renoprotection in patients with type 2 diabetes. In the Reduction of Endpoints in NIDDM with Angiotensin II Antagonist Losartan (RENAAL) Trial, 1513 patients with overt diabetic nephropathy were randomized to ARB treatment or placebo and followed for a mean of 3.4 years.⁷⁴ ARB treatment was associated with significant, 25% reduction in the incidence of a doubling of baseline serum creatinine and ESRD (RR reduction = 28%). In the IDNT, 1715 patients with overt diabetic nephropathy were randomized to treatment with ARB, amlodipine, or placebo.⁷⁵ After a mean of 2.6 years, ARB treatment was associated with a 33% lower risk of doubling of serum creatinine versus placebo and a 37% reduction versus amlodipine. Although not statistically significant, the ARB was associated with a 23% reduction in the risk of ESRD versus placebo and amlodipine. Because achieved blood pressure between groups was closely matched in both of these trials, the additional renoprotective effects of ARB treatment cannot be attributed merely to their antihypertensive effects. A third study examined the renoprotective effects of an ARB (irbesartan) in 590 type 2 diabetic patients with hypertension and microalbuminuria.⁷⁶ Patients were randomized to irbesartan at two different doses (300 or 150 mg/day) or placebo. After 2 years there were significant differences in the incidence of overt proteinuria (5.2% vs. 9.7% vs. 14.9%); the higher dose of irbesartan was also associated with substantial reduction in the risk of overt nephropathy (HR, 0.30; 95% CI, 0.14–0.61 vs. placebo). The practical implication of this dose-dependent effect is that when ARBs are used to treat diabetic microalbuminuria, the dose should be titrated to the maximum antihypertensive dose.

A meta-analysis has confirmed the results of individual trials by showing a significant reduction in the risk of ESRD (RR, 0.78; 95% CI, 0.67–0.91) and doubling of serum creatinine (RR, 0.79; 95% CI, 0.67–0.93) as well as a reduction in risk of progression from microalbuminuria to macroalbuminuria (RR, 0.49; 95% CI, 0.32–0.75) among diabetic patients treated with ARB versus placebo.⁶³ Interestingly, there was no reduction in all cause mortality. In summary, clear evidence of the renoprotective effects of ACE inhibitor in type 2 diabetic patients with overt nephropathy is lacking, but there is sufficient evidence to support the use of ARB treatment to achieve renoprotection in these patients. ARB treatment is also effective in preventing progression from microalbuminuria to overt diabetic nephropathy. Preliminary results show that doses of ARB higher than the recommended maximum may result in greater lowering of proteinuria without a further reduction in blood pressure,^{77,78} but further trials are required before this can be recommended.

ACE Inhibitor versus ARB Treatment

Strict application of available evidence would result in a recommendation for ACE inhibitor treatment to achieve renoprotection in patients with type 1 diabetes and microalbuminuria or overt diabetic nephropathy, type 2 diabetes with hypertension or microalbuminuria, and nondiabetic CKD with proteinuria greater than 0.5 g/day. ARBs would be indicated for patients with type 2 diabetes and microalbuminuria or overt nephropathy. It should be noted, however, that no adequate placebo-controlled trials of ARB treatment in patients with type 1 diabetes or in those with nondiabetic nephropathy have been conducted, and few studies have directly compared ACE inhibitor and ARB treatment in patients with CKD. The only substantial trial was conducted in a mixed group of type 2 diabetic patients with microalbuminuria as well as macroalbuminuria and was designed to assess noninfe-

riority. There was no significant difference between ACE inhibitor and ARB treatment in the primary outcome—namely, a change in GFR—or in the secondary outcome of decreasing the urine albumin-to-creatinine ratio.⁷⁹ A meta-analysis of small trials comparing ACE inhibitor and ARB treatment in patients with diabetic CKD reported similar benefits with respect to incidence of ESRD, doubling of creatinine, and progression of microalbuminuria to macroalbuminuria.⁸⁰ Most national and international guidelines therefore recommend ACE inhibitor or ARB treatment for all forms of diabetic and nondiabetic CKD and leave the choice to individual physicians. One advantage of ARBs over ACE inhibitors is their more favorable adverse-effect profile. In clinical trials, ARBs have been reported to have adverse-effect profiles similar to placebo^{81,82}; in particular, they are not associated with the cough that may occur in up to 20% of patients receiving an ACE inhibitor. Among patients converted from ACE inhibitor to ARB therapy, recurrence of a cough was significantly lower than in patients rechallenged with an ACE inhibitor.^{83,84} In choosing between ACE inhibitor and ARB therapy for patients with type 2 diabetes and diabetic nephropathy, physicians have to consider evidence of proven renoprotection for ARB treatment versus a mortality benefit associated with ACE inhibitor treatment (in patients without established diabetic nephropathy).

One meta-analysis has called into question the value of renin-angiotensin system inhibition for renoprotection. Trials of ACE inhibitor and ARB treatment were pooled; when all studies of diabetic and nondiabetic CKD were considered, the analysis found a benefit in reducing the risk of ESRD (RR, 0.87; 95% CI, 0.75–0.99) and urine albumin excretion (mean, -15.7 mg/day; 95% CI, -24.7 to -6.7 mg/day) but no significant benefit in reducing the risk of doubling of serum creatinine (RR, 0.71; 95% CI, 0.49–1.04). When diabetic and nondiabetic studies were considered separately, no significant benefits were evident with respect to incidence of ESRD or doubling of creatinine, but the benefit for albuminuria reduction persisted. The authors concluded that any renoprotective effects of ACE inhibitor or ARB therapy result only from their antihypertensive effects.⁸⁵ These conclusions have been rejected by many nephrologists because of principal weaknesses: inclusion of data from the very large ALLHAT study, in which only a minority of patients (5662 of 33,357) actually had CKD³⁶; heterogeneity across trials, invalidating a pooling method; and lack of patient-level data.⁸⁶

Combination ACE Inhibitor and ARB Treatment

The added antihypertensive effects of combination therapy with ACE inhibitors and ARBs have made it difficult to separate the benefits of additional BP lowering from benefits directly attributable to dual blockade of the renin-angiotensin system. Two studies have reported an additional reduction in proteinuria and blood pressure in patients receiving combination versus monotherapy.^{87,88} One large study revealed additional renoprotective benefit with combination therapy in the absence of additional BP lowering: In the COOPERATE study, 263 patients with nondiabetic CKD were randomized to treatment with trandolapril or losartan or a combination of both.⁸⁹ In a unique study design, hypertension was intensively controlled with drugs other than renin-angiotensin system inhibitors before initiating the trial medication. If patients became hypotensive after adding the study medication, the dose of other antihypertensives was reduced. Combination therapy was associated with

significantly greater reductions in proteinuria (-75.6% vs. -44.3% with ACE inhibitor and -42.1% with ARB treatment) and a lower incidence of the primary endpoint (doubling of serum creatinine or ESRD; HR, 0.38; 95% CI, 0.18–0.63 vs. ACE inhibitor and HR, 0.40; 95% CI, 0.17–0.69 vs. ARB). Studies of diabetic CKD patients have been small or limited to microalbuminuria. The Candesartan And Lisinopril Microalbuminuria (CALM) study included 199 patients with type 2 diabetes, hypertension, and microalbuminuria, randomized first to ACE inhibitor or ARB therapy and then, after 12 weeks, to combination therapy or continued monotherapy. Combination therapy afforded greater reductions in blood pressure and albuminuria, but the incidence of macroalbuminuria and preservation of renal function were not reported.⁹⁰ Small studies have uncovered an additional BP lowering and proteinuria reduction when ARB treatment was added to patients with type 1 diabetes⁹¹ or type 2 diabetes⁹² but with persistent proteinuria and hypertension despite ACE inhibitor treatment. Two meta-analyses have confirmed the findings of the above individual trials; one analysis reported a small additional reduction in blood pressure with combination therapy that was largely attributable to the use of submaximal doses of ACE inhibitor or short-acting ACE inhibitors. Combination therapy in several studies was associated with additional reduction of proteinuria that was independent of blood pressure.⁹³ The other analysis found a significant additional reduction in proteinuria with combination therapy versus monotherapy that was evident in patients with diabetic and nondiabetic CKD (weighted mean difference, 440 mg/day; 95% CI, 289–591 vs. ACE inhibitor alone).⁹⁴

In summary, combination ACE inhibitor and ARB therapy seems to reduce blood pressure and proteinuria to a greater extent than monotherapy. Whether this effect is attributable to additional BP lowering that could be achieved by other antihypertensive agents remains unanswered, but the COOPERATE study suggests there is a unique benefit attributable to dual blockade of the renin-angiotensin system. Further studies are required to confirm the long-term benefits of combination therapy with respect to preservation of renal function in other groups of CKD patients, but we recommend that the combination should be considered in CKD patients who have not achieved therapeutic goals for BP and proteinuria reduction with ACE inhibitor or ARB monotherapy.

Safety Considerations

Despite the clear trial evidence of renoprotection by ACE inhibitors and ARBs, many physicians remain reluctant to prescribe these drugs because of concerns about a potential rise in serum creatinine or potassium level. It should be noted, however, that the incidence of these complications in published trials is low. Discontinuation of therapy due to uncontrolled hyperkalemia has been reported in only 0 to 4% of patients, and the overall incidence of hyperkalemia was not different in ACE inhibitor- versus non-ACE inhibitor-treated patients when data from 6 studies were combined.⁹⁵ The discontinuation of potassium supplements, avoidance of potassium-sparing diuretics, and dietary advice to avoid high-potassium foods may all help to reduce the incidence of hyperkalemia. Similarly, a progressive rise in serum creatinine rarely occurs in patients unless there is bilateral renal artery stenosis (in this case, ACE inhibitor and ARB treatment is contraindicated). It is important to appreciate that an initial increase in serum creatinine level probably results from the renal hemodynamic effects of ACE inhibitors or ARBs

and may predict greater renoprotective efficacy.⁹⁶ Provided that the increase in serum creatinine is less than 30% and that it is not progressive, an initial rise should not be an indication for discontinuing ACE inhibitor therapy. Patients with compromised renal perfusion due to intravascular volume depletion, for example, are most likely to exhibit a serious decline in renal function after the introduction of ACE inhibitor or ARB therapy. It is therefore important to ensure adequate hydration, omit or reduce diuretics for 48 to 72 hours, and avoid nonsteroidal anti-inflammatory drugs before starting an ACE inhibitor in CKD patients. In addition, the ACE inhibitor or ARB should be started at a low dose and titrated upward with repeated monitoring. Figure 62-2 is an algorithm to facilitate the safe initiation of ACE inhibitor or ARB treatment in patients with CKD.

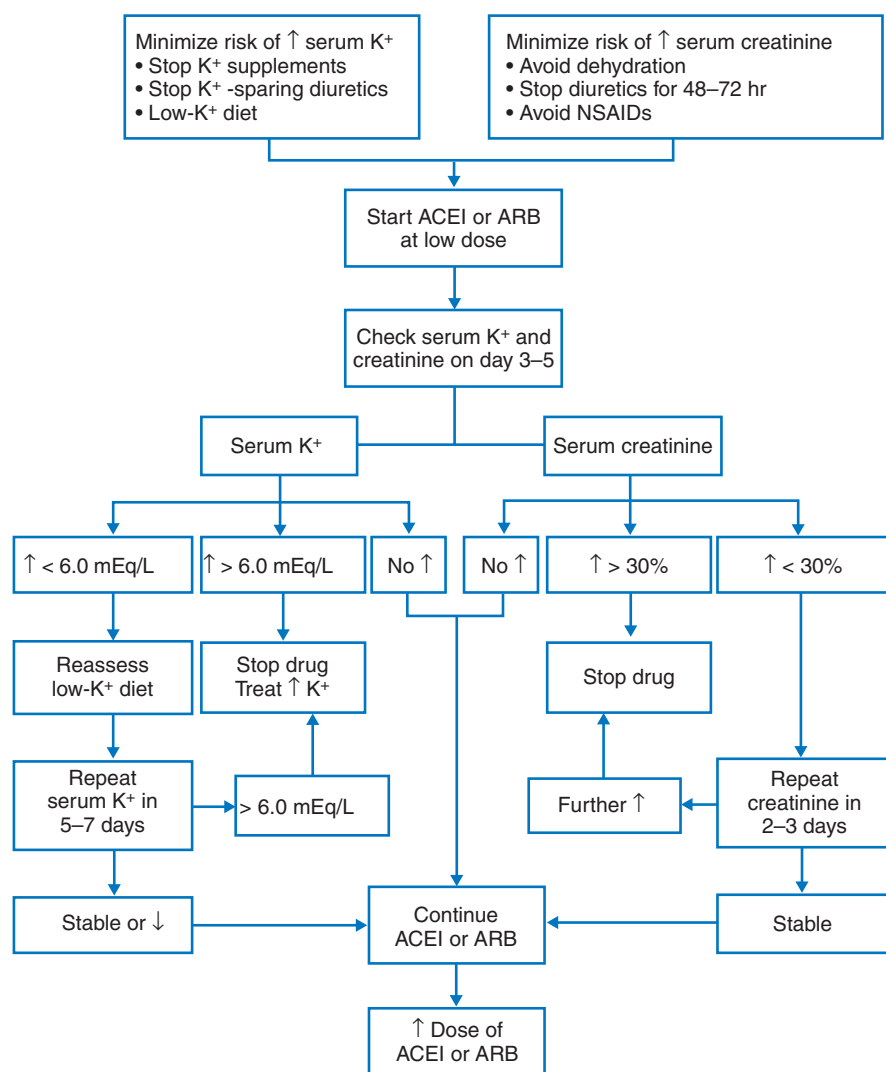

Proteinuria as a Therapeutic Target

Proteinuria has traditionally been regarded as a marker of glomerular filtration barrier integrity, and the extent of proteinuria has been used as an indicator of glomerular disease severity. Indeed, the severity of proteinuria at baseline is the most important independent predictor of renal outcomes in randomized trials of patients with diabetic nephropathy^{97,98} and nondiabetic CKD.^{66,99,100} It has also been proposed that proteinuria per se contributes to progressive renal injury¹⁴;

therefore, proteinuria reduction should be viewed as a therapeutic goal. For example, results from the MDRD showed that a reduction in proteinuria, independent of blood pressure, was associated with slower progression of CKD; the degree of benefit achieved through blood pressure lowering depended on the extent of baseline proteinuria.²⁵

Other studies have observed that the percentage reduction in proteinuria after initiation of ACE inhibitor or ARB treatment and the absolute level of proteinuria are independent predictors of the subsequent rate of decline in GFR among patients with diabetic nephropathy^{97,98} and nondiabetic CKD.^{100,101} A meta-analysis of data from 1860 patients with nondiabetic CKD confirmed these findings and showed that during antihypertensive treatment, the achieved level of proteinuria was a powerful predictor of the combined endpoint of doubling of baseline serum creatinine level or onset of ESRD (RR, 5.56; 95% CI, 3.87–7.98 for each 1 g/day increase in achieved level of proteinuria).¹⁰² One prospective study has reported improved preservation of GFR when ACE inhibitor or ARB therapy was titrated to the maximum antiproteinuric dose.¹⁰³ Whether or not proteinuria contributes directly to renal injury, the strong association between the degree of proteinuria reduction and renoprotection in clinical studies implies that minimization of proteinuria should be regarded as an important independent therapeutic goal in renoprotective strategies.

Figure 62-2 An algorithm for the safe initiation of ACE inhibitor or ARB treatment in patients with CKD. K⁺, potassium; NSAID, nonsteroidal anti-inflammatory drugs.

Dietary Interventions

Weight Loss

Obesity has been shown in experimental models to cause glomerular hypertension and hyperfiltration, factors that are central to mechanisms of CKD progression.¹⁰⁴ In humans as well, obesity is associated with glomerular hyperfiltration and albuminuria, both of which are reversed by weight loss.¹⁰⁵ Epidemiologic studies have identified obesity as a risk factor for CKD^{106,107}; in one study, obesity was an independent risk factor for progression of CKD (IgA nephropathy).¹⁰⁸ Large interventional studies of weight loss in patients with CKD are lacking, but based on the above data it seems reasonable to recommend weight loss in obese patients with CKD.

Sodium Restriction

In the general population high dietary sodium intake is associated with hypertension, and sodium restriction produces a significant reduction in blood pressure.¹⁰⁹ One observational study among patients with CKD reported that those who restricted their sodium intake to less than 100 mmol/day evidenced a lower rate of decline in GFR versus those with a high sodium intake (>200 mmol/day); there was no increase in proteinuria despite having lower creatinine clearance and higher levels of proteinuria at baseline. BP control was similar between the groups.¹¹⁰ Several other small studies have sought to investigate the effect of dietary sodium intake on CKD progression. A recent systematic review of 16 studies concluded that marked heterogeneity between the studies precluded meta-analysis.¹¹¹ Nevertheless, there was a general trend for increasing sodium intake to be associated with worsening albuminuria. Only two reports indicated no benefit from reducing dietary sodium, and both were of low methodologic quality. High dietary sodium intake has also been shown to negate the antiproteinuric effects of ACE inhibitor treatment,³⁷ as well as the antihypertensive response. Long-term randomized trials are required to define the role of sodium restriction in renoprotective strategies, but even the incomplete evidence available supports a recommendation for moderate dietary sodium restriction (<100 mmol/day) in patients with CKD.

Protein Restriction

Based on the notion that reducing the excretory burden on the kidneys would slow the rate of progressive injury, dietary protein restriction was among the first interventions proposed to slow CKD progression. Experimental studies showed that a low-protein diet normalized glomerular hemodynamics in the remnant kidney model⁶ and resulted in effective long-term renoprotection.¹¹² Unfortunately, clinical studies to date have failed to provide unambiguous evidence to support the use of protein restriction in human CKD.

In the MDRD study 585 patients with mostly nondiabetic CKD (GFR = 25–55 mL/min/1.73 m²) were randomized to “usual” (1.3 g/kg/day) or “low” (0.58 g/kg/day) protein diet in study A, and 255 patients with GFR = 13–24 mL/min/1.73 m² to “low” (0.58 g/kg/day) or “very low” (0.28 g/kg/day) protein diet (study B). After a mean of 2.2 years’ follow-up there was no difference in the rate of GFR decline in study A, and only a trend toward slower decline in the “very low” protein group in study B.²⁴ Further analysis, however, revealed that the desired protein intake was not achieved in the randomized groups; when data were analyzed according to

achieved dietary protein intake, a reduction in protein intake of 0.2 g/kg/day correlated with a 1.15 mL/min/year reduction in the rate of GFR decline, equivalent to a 29% reduction in mean rate of GFR decline, implying a 41% prolongation in renal survival.¹¹³ Several factors have been identified that may account for the inconclusive results of the MDRD study, including the generally slow rate of decline in GFR (4 mL/min/year or less), short follow-up, high proportion of patients with adult polycystic kidney disease, and random use of ACE inhibitors in the different groups. Evidence supporting a renoprotective effect of low-protein diet was provided by meta-analyses of randomized studies.¹¹⁴ Among 1413 patients with nondiabetic CKD from 5 studies (including those from study A of the MDRD), low-protein diet was associated with a relative risk of 0.67 (95% CI, 0.50–0.89) for ESRD or death. Similarly, among 108 type 1 diabetic patients from five studies, low-protein diet significantly slowed the increase in albuminuria or the decline in GFR/creatinine clearance (RR 0.56; 95% CI, 0.40–0.77). Unfortunately, long-term follow-up of the MDRD study A cohort has also proved inconclusive.¹¹⁵ Small studies suggest that the antiproteinuric effects of dietary protein restriction are additive to those of ACE inhibitor treatment,¹¹⁶ but large long-term studies are required to evaluate this further. Although no single study has yet provided conclusive evidence of the renoprotective effect of dietary protein restriction in humans, we believe that sufficient evidence exists to consider moderate protein restriction of 0.6 g/kg/day in patients with CKD and evidence of progression. In addition to possible renoprotective effects, dietary protein restriction results in reduced sodium, phosphate and acid intake, all of which are beneficial for CKD patients.¹¹⁷ The decision to institute dietary protein restriction should be individualized; it should be avoided in patients with low serum albumin due to severe nephrotic syndrome or malnutrition. Fortunately, Medicare will pay for dietician visits for CKD patients in the United States.

Treatment of Dyslipidemia

Chronic kidney disease is commonly associated with abnormalities of plasma lipids: elevated levels of the triglyceride-rich lipoproteins very low-density lipoprotein and low-density lipoprotein, and reduced levels of high-density lipoprotein.¹¹⁸ In addition to placing CKD patients at increased risk of cardiovascular disease, these lipid abnormalities may also accelerate the progression of CKD. In the MDRD study, low serum high-density lipoprotein cholesterol was an independent predictor of more rapid decline in GFR⁹⁹; in another study elevated triglyceride-rich apolipoprotein B-containing lipoprotein correlated significantly with the rate of deterioration of renal function.¹¹⁹ Hypercholesterolemia has been associated with more rapid progression among patients with diabetic^{120–122} and nondiabetic CKD.¹²³ Mechanisms offered to explain why hyperlipidemia might contribute to CKD progression include stimulation of mesangial cell proliferation, cytokine expression, and extracellular matrix synthesis^{124,125}; oxidation of LDL to form reactive oxygen species¹²⁶; and elevations in P_{GC}.¹²⁷ In experimental studies, treatment of hyperlipidemia has resulted in attenuation of renal injury in a variety of models of CKD.^{128,129} Results from large randomized trials of lipid-lowering therapy in CKD patients have not been reported, but a meta-analysis of 12 small studies that included both diabetic and nondiabetic CKD found that lipid-lowering therapy significantly reduced the rate of

decline in GFR (mean reduction, 1.9 mL/min/year).¹³⁰ Several secondary analyses of data from clinical trials also suggest that lipid-lowering therapy may slow CKD progression; these results should be interpreted with caution. Among patients with a history of myocardial infarction, pravastatin slowed the rate of GFR decline in patients with estimated GFR values less than 40 mL/min/1.73 m², particularly in patients with proteinuria.¹³¹ Similarly, in the Heart Protection Study, patients with previous cardiovascular disease or diabetes who were randomized to simvastatin treatment had a smaller increase in serum creatinine compared to those who received placebo.¹³² In an open-label study, atorvastatin treatment of CKD patients with proteinuria and hypercholesterolemia was associated with preservation of creatinine clearance, whereas those receiving placebo evidenced a significant decline.¹³³ On the other hand, lipid lowering with fibrates has not been associated with preservation of renal function,^{134,135} although one study did show reduced progression to microalbuminuria among type 2 diabetic patients receiving fenofibrate.¹³⁶ This suggests that some of the renoprotective effects observed above may be due to other, pleiotropic effects of “statins.” Pending the results of trials in CKD patients, these results, plus the fact that CKD patients are at substantially increased risk for cardiovascular disease, support a policy of active dietary and drug intervention to correct dyslipidemia to the levels recommended for other patients at high cardiovascular risk (low-density lipoprotein cholesterol < 100 mg/dL).¹³⁷

Smoking Cessation

Smoking has been identified as a risk factor for the development of microalbuminuria, overt proteinuria, and CKD progression in type 1 and 2 diabetes.^{138–141} Smoking is also a risk factor for progression in a variety of forms of nondiabetic CKD: Among patients with adult polycystic kidney disease or IgA nephropathy, smokers had a substantially increased risk of progression to ESRD versus nonsmokers¹⁴²; among patients with lupus nephritis,¹⁴³ the median time to ESRD was almost halved in smokers versus nonsmokers; patients with a primary glomerulonephritis and serum creatinine higher than 1.7 mg/dL were significantly more likely to be smokers than those with normal creatinine¹⁴⁴; and smoking was the most powerful predictor of a rise in serum creatinine level among patients with severe essential hypertension.¹⁴⁵ Epidemiologic studies have identified smoking as a risk factor for albuminuria,^{146,147} renal impairment,^{106,148,149} and ESRD.¹⁵⁰ Proposed mechanisms whereby smoking may exacerbate renal injury include sympathetic nervous system activation, glomerular capillary hypertension, endothelial cell injury, and direct tubulotoxicity.¹⁵¹ Although prospective studies showing renoprotective benefit from smoking cessation are lacking, these reports suggest that the kidney is another organ that is adversely affected by smoking. The well-established benefits of smoking cessation for prevention of lung and cardiovascular disease as well as malignancy mandate that all patients with CKD should be counseled to stop smoking and assisted in achieving this goal.

Control of Hyperglycemia

The role of glycemic control in diabetic renoprotection is discussed more fully in Chapter 28. Randomized trials have provided unequivocal evidence that tight glycemic control significantly reduces the risk of developing microalbuminuria or

overt nephropathy among patients with type 1 diabetes¹⁵² and type 2 diabetes.¹⁵³ Unfortunately the benefits of improved glycemic control in those who already have microalbuminuria are not well established. Only two of five small randomized studies have demonstrated a reduction in progression to overt nephropathy with “tight” versus “normal” glycemic control among type 1 diabetic patients with microalbuminuria.^{154–158} On the other hand, there is evidence of histologic reversal of diabetic glomerulopathy lesions in type 1 diabetic patients with normoalbuminuria or microalbuminuria after pancreatic transplantation.¹⁵⁹ No data are available to assess the renoprotective effect of tight glycemic control among diabetic patients with established nephropathy. Despite the fact that glycemic control has not been proven to prevent progression of diabetic nephropathy, these patients are also at risk of developing other microvascular and macrovascular complications. We recommend tight glycemic control (target HBA_{1C} < 7.0%) in all patients, regardless of the severity of diabetic nephropathy.

Monitoring

Regular monitoring is essential to facilitate optimization of therapeutic interventions for slowing CKD progression. Serum creatinine provides a relatively insensitive estimate of GFR, but a plot of values of the reciprocal of serum creatinine (1/Scr) versus time for an individual patient yields a linear relationship.^{4,5} This means that changes in creatinine clearance or GFR are also declining linearly with time; hence, the plot can be used to evaluate changes in progression of CKD.^{5,24} Alternatively, renal function is assessed using estimated GFR derived from a serum creatinine measurement using the 4-variable MDRD equation.¹⁶⁰ Like 1/Scr, sequential values of estimated GFR can be plotted, with the goal of reducing the rate of GFR decline to less than 1 mL/min/year, a rate associated with normal aging. Many laboratories now facilitate this by reporting the estimated GFR with every serum creatinine measurement. As noted, an alternative method of monitoring progression is to plot 1/Scr. As discussed, proteinuria should be assessed after each change in therapy, with the goal of reducing it to less than 0.5 g/day. The use of urine protein-to-creatinine ratio measurements, which correlate well with 24-hour urinary protein excretion, allows frequent monitoring with minimal inconvenience to the patient.¹⁶¹ Finally, blood pressure should be assessed at each examination and controlled to a level lower than 130/80 mm Hg. In some patients, particularly those affected by “white coat” hypertension, the use of home or ambulatory monitoring may be indicated.

Future Therapies

Currently available renoprotective therapies have in general achieved a slowing in the rate of progression of CKD, but relatively few patients have achieved complete cessation of progression and still fewer have evidenced a reversal of renal injury. Clearly, there is a need for more effective treatments. Novel renoprotective interventions are currently being investigated in experimental studies and clinical trials.

Drugs with Hemodynamic Effects

Endothelins are potent vasoconstrictor peptides that are up-regulated in experimental models of CKD and could contribute to the glomerular hemodynamic changes that are central

to CKD progression. In experimental diabetes, selective endothelin type A (ET_A) receptor antagonists, as well as combined ET_A/ET_B antagonists, ameliorate hypertension, renal vasoconstriction, proteinuria, and renal damage in experimental diabetes.¹⁶² Recent evidence suggests that ET_A blockade also exerts anti-inflammatory effects that contribute to renoprotection.¹⁶³ Vasopeptidase inhibitors are molecules that simultaneously inhibit both angiotensin-converting enzyme and neutral endopeptidase. This latter ecto-enzyme is localized principally in the brush border membrane of renal tubule cells and catabolizes several vasodilator molecules, including the natriuretic peptides, adrenomedullin, and bradykinin. Thus, vasopeptidase inhibitor treatment is associated with reduced production of the vasoconstrictor angiotensin II and accumulation of the above vasodilators. Vasopeptidase inhibitors are effective antihypertensive agents in both low and high renin states.¹⁶⁴ In experimental models, vasopeptidase inhibitors produced a greater lowering of P_{GC} than an ACE inhibitor and more effective renoprotection despite equivalent control of systemic blood pressure.^{165,166} Orally active inhibitors of renin are currently undergoing clinical trials and offer a novel pharmacologic intervention for inhibiting the renin-angiotensin system. Preliminary clinical evidence indicates that renin inhibitors are effective as antihypertensives,¹⁶⁷ but further studies are required to evaluate renoprotective benefits, as well as effects when combined with other renin-angiotensin system inhibitors.

Antiproteinuric and Antifibrotic Therapies

Recent insights into the role of proteinuria and fibrosis in CKD progression have prompted the development of several new therapies. For example, albuminuria can be reduced by preserving the integrity of the glomerular filtration barrier. In an experimental model of diabetes, glycosaminoglycan treatment has been shown to prevent the loss of glomerular basement membrane charge selectivity and to inhibit development of proteinuria. Treatment with sulodexide, an orally available glycosaminoglycan, reduced albuminuria among patients with type 1 or type 2 diabetes and microalbuminuria or microalbuminuria¹⁶⁸ and is currently being evaluated in clinical trials. Aldosterone has been identified as an important mediator of progressive renal injury via hemodynamic and profibrotic actions. Treatment with spironolactone and other aldosterone antagonists has produced renoprotective effects in experimental¹⁶⁹ and small clinical studies.¹⁷⁰ Further studies are required to evaluate the risk-benefit of this strategy in view of hyperkalemia, especially when a renin-angiotensin system inhibitor is combined with an aldosterone antagonist. Perfinidone is an orally active antifibrotic agent with evidence of renoprotective benefits in several experimental models of CKD. Importantly, these effects were additive to those of ARB treatment in one study,¹⁷¹ and clinical trials of perfinidone are underway. Hepatocyte growth factor is up-regulated in experimental models of CKD and appears to exert multiple antifibrotic effects. Treatment with hepatocyte growth factor prevents renal injury in several models; importantly, it was associated with reduced interstitial fibrosis in rats with established renal injury after five sixths nephrectomy.¹⁷² Bone morphogenetic protein-7 has emerged as an endogenous antagonist of TGF- β ; it also inhibits the epithelial to mesenchymal transition involved in interstitial fibrosis. Bone morphogenetic protein-7 treatment reduced interstitial fibrosis in the unilateral ureteric obstruction model¹⁷³ and ameliorated glomerulosclerosis as well

as interstitial fibrosis in an experimental model of diabetic nephropathy.¹⁷⁴

A STRATEGY FOR MAXIMAL RENOPROTECTION

We have considered a variety of interventions that have been shown to slow the rate of progression of CKD. At best, however, each intervention slows the rate of progression by approximately 50%. Therefore, we suggest that for maximal long-term renoprotection, a comprehensive strategy employing multiple elements directed at different aspects of the pathogenesis of progressive renal injury is required (see Fig. 62-1). Once treatments have been introduced, frequent monitoring of blood pressure, proteinuria, and GFR is essential so therapy can be escalated to achieve established therapeutic goals (Table 62-2). Our approach is analogous to that applied in modern chemotherapeutic strategies for cancer; multiple agents are used and treatment is directed toward correcting all signs of disease activity until the patient is said to be in "remission." Importantly, data from a small number of patients suggest that if remission is maintained in the long term, some recovery of renal function or "regression" of renal disease may be achieved.⁶⁸ Limited data already indicate that significant improvements in renoprotection can be achieved with a combination strategy. Among 160 type 2 diabetic patients with microalbuminuria, a combined approach of intensive therapy resulted in a marked reduction in the risk of overt nephropathy (odds ratio, 0.27).¹⁷⁵ Similarly, 9 of 13 patients with resistant nephrotic range proteinuria and CKD referred to a "remission clinic" achieved reduction of proteinuria to less than 1 g/day and stabilization of renal function after application of a similar intensive therapy protocol.⁹⁵ These recommendations are based on currently available

Table 62-2 A Comprehensive Strategy and Therapeutic Goals for Achieving Maximal Renoprotection in Patients with Chronic Kidney Disease

Intervention	Goal
1. ACEI or ARB treatment (consider combination therapy if goals not achieved with monotherapy)	Proteinuria < 0.5 g/day GFR decline < 1 mL/min/year
2. Additional antihypertensive therapy	< 125/75 mm Hg if proteinuria > 1 g/day < 130/80 mm Hg if proteinuria < 1 g/day
3. Weight loss if obese	
4. Dietary sodium restriction	< 100 mmol/day
5. Dietary protein restriction	0.6 g/kg/day
6. Tight glycemic control	HBA _{1c} < 7.0%
7. Smoking cessation	
8. Lipid lowering therapy	LDL cholesterol < 100mg/dL

ACE inhibitor, angiotensin-converting enzyme inhibitor: ARB, angiotensin receptor blocker; BP, blood pressure; GFR, glomerular filtration rate; HBA_{1c}, hemoglobin A_{1c}.

interventions and the monitoring methods already widely used, so a comprehensive approach to renoprotection is an achievable goal for all patients with CKD. Although it has been argued that there is a need for new renoprotective agents, it is also true that these available therapies have not yet been applied to all patients with CKD.¹⁷⁶ If widely implemented, a comprehensive renoprotective strategy may not only delay the need for dialysis in many patients, but may also substantially reduce the number of CKD patients progressing to ESRD. Recent reports of a small decline in the incidence of new patients starting dialysis therapy in the United States indicate that such strategies are starting to yield a benefit.¹

In the past few decades, several important clinical trials have documented that lowering of serum cholesterol reduces the risk for development of myocardial infarction and other complications of coronary artery disease (CAD). These trials have added strength to national recommendations for detection and treatment of high serum cholesterol levels. In the United States, the most recent guidelines on the clinical management of elevated serum cholesterol have been published by the National Cholesterol Education Program (NCEP) as the Adult Treatment Panel III (ATP III) report.¹ The report did not provide specific advice on treating lipid disorders in patients with chronic kidney disease (CKD). However, the general framework of the guidelines may apply to many CKD patients who are at increased risk for CHD. We review the general features of the ATP III report, but it must be pointed out that clinical judgment is required when determining therapies for patients with complex medical conditions such as CKD using the ATP III guidelines. We do not attempt to provide “hard and fast” rules for management of lipid disorders in patients with CKD but instead review available information about the nature of lipid disorders in different types of CKD and outline areas for potential intervention.

Many CKD patients are at increased risk for major cardiovascular events, either because they already have established atherosclerotic disease or because they have risk factors for CAD. In addition, CKD by itself probably imparts a higher risk independent of the usual cardiovascular risk factors.^{2,3} The extent of incremental risk likely depends on the type of CKD. Regardless, patients with most forms of CKD commonly have multiple cardiovascular risk factors. Among these are a variety of abnormalities in plasma lipoproteins. For these reasons, physicians who care for CKD patients often are faced with the need to make decisions whether to intervene in a given patient’s lipid disorder and, if so, how.

SUMMARY OF ATP III GUIDELINES AS RELATED TO CKD

Low-Density Lipoprotein Cholesterol: The Primary Target of Therapy

There are several classes of lipoproteins, such as low-density lipoproteins (LDL), very low-density lipoproteins (VLDL), high-density lipoproteins (HDL), and lipoprotein(a) [Lp(a)]. Of these, elevated serum LDL has the most robust relationship to CAD.^{1,4} LDL is usually identified in clinical practice as LDL cholesterol. The ATP III report recognizes it as the primary target of lipid-lowering therapy and provides a detailed listing of evidence supporting that concept. Recent clinical trials⁵⁻⁹ have documented that LDL-lowering therapy will reduce the risk for developing CAD by about one third. The Treat to New Targets (TNT) trial, performed in more than 10,000 patients with stable CAD, revealed that intensive LDL cholesterol lowering to obtain levels below 100 mg/dL (mean, 77 mg/dL) using high-dose (80 mg daily) versus low-dose (10 mg daily) atorvastatin was associated with improved cardiovascular outcome.¹⁰ Other lipoproteins are potential secondary targets of therapy. For example, many CKD patients have a lipoprotein abnormality called *atherogenic dyslipidemia*.¹ This disorder is characterized by raised serum triglyceride, small LDL particles, and low HDL cholesterol levels. It seems likely that LDL cholesterol should be the primary target of therapy in CKD patients, but the question of whether to intervene in those with atherogenic dyslipidemia is an important issue. Table 63-1 summarizes the ATP III classification of lipids, lipoproteins, and atherogenic dyslipidemia.

Table 63-1 ATP III LDL Cholesterol Goals and Cutpoints for Therapeutic Lifestyle Changes and Drug Therapy in Different Risk Categories and Proposed Modifications Based on Recent Clinical Trial Evidence

Risk Category	LDL Cholesterol Goal (Non-HDL Cholesterol Goals)*	Initiate TLC Based on LDL Cholesterol (or Non-HDL Cholesterol) Levels	Consider Drug Therapy Using LDL Cholesterol or (Non-HDL Cholesterol) Levels
High risk: CAD* or CAD risk equivalents† (10-year risk $\geq 20\%$)	<100 mg/dL (Optional goal: 70 mg/dL)	≥ 100 mg/dL¶	≥ 100 mg/dL (<100 mg/dL: consider drug options)**
Moderately high risk: 2+ risk factors‡ (10-year risk 10%–20%)	<130 mg/dL	>130 mg/dL¶	>130 mg/dL (100–129 mg/dL: consider drug options)††
Moderate risk: 2+ risk factors‡ (10-year risk $\leq 10\%$)	<130 mg/dL	≥ 130 mg/dL	≥ 160 mg/dL
Lower risk: 0–1 risk factor§	<160 mg/dL	≥ 160 mg/dL	≥ 190 mg/dL (160–189 mg/dL: LDL-lowering drug optional)

*Non-HDL cholesterol = VLDL cholesterol + LDL cholesterol; non-HDL cholesterol is about 30 mg/dL higher than LDL goal.

†CHD risk equivalents include clinical manifestations of noncoronary forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and carotid artery disease transient ischemic attacks or stroke of carotid origin or 50% obstruction of a carotid artery), diabetes, and two risk factors with 10-year risk for hard CHD of 20%.

‡Risk factors include cigarette smoking, hypertension (BP 140/90 mm Hg or antihypertensive medication), low HDL cholesterol (40 mg/dL), family history of premature CHD (CHD in male first-degree relative 55 years of age; CHD in female first-degree relative 65 years of age), and age (men 45 years, women 55 years).

§Almost all people with no risk factors or one risk factor have a 10-year risk of 10%, and 10-year risk assessment in people with no risk factors or one risk factor thus is not necessary.

¶Any person at high risk or moderately high risk who has lifestyle-related factors (e.g., obesity, physical inactivity, elevated triglyceride, low HDL-C, or metabolic syndrome) is a candidate for therapeutic lifestyle changes to modify these risk factors regardless of LDL-C level.

^{||}Electronic 10-year risk calculators are available at www.nhlbi.nih.gov/guidelines/cholesterol.

**When LDL-lowering drug therapy is employed, it is advised that the intensity of therapy be sufficient to achieve at least a 30% to 40% reduction in LDL-C levels.

††For moderately high-risk persons, when LDL-C level is 100–129 mg/dL, at baseline or on lifestyle therapy, initiation of an LDL-lowering drug to achieve an LDL-C level of 100 mg/dL is a therapeutic option on the basis of available clinical trial results.

ATP III, Adult Treatment Panel III report; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TLC, therapeutic lifestyle changes.

Risk Assessment: First Step in Risk Management

The ATP III report indicates that the intensity of risk-reduction therapy should be adjusted to the patient's absolute risk. An assessment of risk depends on identifying medical conditions that impart higher risk and risk factors for cardiovascular disease. Several forms of CKD may increase the risk for CAD independent of the major risk factors; nonetheless, CKD patients often have multiple, major risk factors (Box 63-1), including the emerging risk factors that are common in patients with CAD (Box 63-2). Some CKD patients will have a constellation of risk factors, called the *metabolic syndrome* (Box 63-3). This condition includes several borderline risk factors that when combined confer higher risk. In patients without CAD, the ATP III report recommends that risk assessment be carried out using the Framingham risk algorithm.¹¹ In patients with CKD, however, Framingham scores may not accurately predict future cardiovascular events, and the presence of multiple risk factors likely raises the risk for major cardiovascular events in patients with CKD even more than suggested by Framingham scoring.

High-Risk Conditions: Established CAD and Risk Equivalents

Conditions at highest risk deserve the most intensive lipid-lowering therapy. The ATP III report recognizes three categories of high-risk patients: (1) very high risk, defined as the presence

of established atherosclerotic cardiovascular disease and one or more of the following: multiple risk factors (especially diabetes, severe and poorly controlled risk factors (e.g., cigarette smoking), metabolic syndrome (especially high triglycerides ≥ 200 mg/dL and non-HDL cholesterol > 130 mg/dL with low HDL cholesterol ≤ 40 mg/dL) and acute coronary syndromes; (2) high risk, defined as those with established CAD; and (3) those with CAD risk-equivalents. According to the ATP III report, LDL

Box 63-1 Categorical Classification of Major Risk Factors

Cigarette smoking (any smoking in past year)
Hypertension (blood pressure $\geq 140/90$ mm Hg or on antihypertensive medication)
High LDL cholesterol (≥ 160 mg/dL)*
Low HDL cholesterol (<40 mg/dL)[†]
High plasma glucose (≥ 126 mg/dL)[‡]
Family history of premature coronary artery disease (in male first-degree relative < 55 years; in female first-degree relative < 65 years)
Age (men ≥ 50 years; women ≥ 55 years)

*High LDL cholesterol is not included in the "risk factor" count in ATP III because it is the target of therapy based on other risk factors.

[†]HDL cholesterol > 60 mg/dL counts as a "negative" risk factor; its presence removes one risk factor from the total count.

[‡]High plasma glucose is not included in the "risk factor" count in ATP III because its presence identifies a patient as having diabetes, which is counted as a CAD risk-equivalent.

Box 63-2 Emerging Risk Factors**Lipid Risk Factors**

Lipoprotein(a)
 Apolipoproteins (CIII, B, AI)
 Small lipoprotein particles (small LDL, small HDL)

Inflammatory Markers

High-sensitivity C-reactive protein
 Cytokines
 Fibrinogen

Prothrombotic Markers

Plasminogen activator inhibitor-1
 Fibrinogen
 Homocysteine

Box 63-3 Risk Factors of Metabolic Syndrome**Atherogenic dyslipidemia**

Elevated triglycerides (≥ 50 mg/dL)
 Small LDL particles
 Elevated non-HDL cholesterol (≥ 30 mg/dL)
 Low HDL cholesterol (< 40 mg/dL in men; < 50 mg/dL in women)
 High-normal blood pressure (120–139/80–89 mm Hg)
 Insulin resistance
 \pm Impaired fasting glucose (110–126 mg/dL)
 Proinflammatory*
 Prothrombotic state[†]

*Indicated by one or more of elevated high-sensitivity C-reactive protein (hs-CRP) (> 3.0 mg/L), homocysteine (≥ 15 mmol/L) or lipoprotein(a) [Lp(a)] (≥ 30 mg/dL), and fibrinogen. Elevated hs-CRP appears to be the most reliable indicator of proinflammatory state. Lp(a) can be elevated on a genetic basis.

[†]Indicated by elevated plasminogen activator inhibitor-1, fibrinogen, or clotting factor VIIc.

cholesterol in very high risk patients should be lowered to the optimal level of less than 70 mg/dL; in high-risk patients, it should be lowered to less than 100 mg/dL (see Table 63-1). Many CKD patients will fall into one of these categories, particularly those with diabetic nephropathy or patients with nondiabetic CKD and heavy proteinuria (see Primary Nephrotic Syndrome in this chapter). The conditions that define established CAD are (1) history of acute coronary syndromes (unstable angina or myocardial infarction), (2) history of angina pectoris, and (3) history of coronary artery procedures (coronary angioplasty or coronary artery bypass grafting).

Any patient with CKD who has one of these forms of established CAD can be considered at high risk for future events. These patients, therefore, are candidates for intensive lowering of LDL cholesterol to a goal of less than 100 mg/dL (in very high risk patients, the goal is < 70 mg/dL).

Lipid-lowering therapy is not the only intervention for patients with established CAD. The American Heart Association has published general guidelines for risk reduction in patients with CAD or other atherosclerotic diseases.¹² These guidelines, summarized in Box 63-4, include

smoking cessation, blood pressure regulation, physical activity as part of a program of cardiac rehabilitation, weight loss in overweight patients, appropriate antiplatelet therapy, and cardioprotective drugs (β -blockers and angiotensin-converting enzyme inhibitors). A large body of data supports benefits from each of these regimens.¹² Particular attention should be given to using a full range of risk-reduction modalities in patients with CKD who also have established CAD.

Patients with CAD risk-equivalents have one of the following: (1) a noncoronary form of atherosclerotic disease (peripheral arterial disease, carotid artery disease [carotid transient ischemic attacks], carotid stroke, $> 50\%$ obstruction of carotid artery) or abdominal aortic aneurysm; (2) diabetes mellitus; or (3) multiple risk factors, with 10-year risk for CAD higher than 10% (based on Framingham risk scoring).

Some investigators speculate that various forms of CKD constitute a CAD risk-equivalent similar to the presence of diabetes.¹³ Certainly a sizable fraction of CKD patients will have diabetes, warranting their inclusion in the category of CAD risk-equivalent. Whether kidney disease per se without diabetes or noncoronary forms of atherosclerosis confers a high-risk status probably depends on the type of CKD. Two questions must be considered: (1) What is the absolute risk for patients with various forms of CKD? and (2) How effective is LDL-lowering in reducing major coronary events in such patients? For both questions, the literature is limited and generalizations are difficult, so clinical judgment is required to determine if it is appropriate to classify particular patients as CAD risk-equivalents. Framingham risk scoring probably underestimates the 10-year risk for CAD patients with CKD and therefore is of limited value in assessing absolute 10-year risk. Observational studies from large numbers of unselected clinic patients suggest that the presence of stage 3 to 5 CKD is an independent risk factor for cardiovascular morbidity and all-cause mortality.¹⁴ It also is estimated that the 10-year CAD incidence among CKD patients is in the range of 20% based on Framingham risk score. Although the ATP III report does not consider the presence of CKD as a CAD equivalent, it seems reasonable to assume that most CKD patients with several major risk factors belong in the category of CAD risk-equivalents. The National Kidney Foundation guidelines for treatment of dyslipidemia in CKD recommend lowering LDL cholesterol into the optimal range (< 100 mg/dL).¹⁵ Standard doses of statin are recommended as first-line therapy in patients in whom this drug class is effective and generally well tolerated. For patients at very high risk, higher doses of statins or combining statins with cholesterol absorption inhibitors such as ezetimibe may be desirable. Cholesterol absorption inhibitors are generally better tolerated than bile acid resins or nicotinic acid derivatives, albeit more expensive.

For patients with established CAD or CAD risk-equivalents, the ATP III report recommends starting LDL-lowering drug therapy simultaneously with dietary therapy when LDL cholesterol levels are higher than 130 mg/dL. If baseline (or on-treatment) LDL cholesterol levels are in the range of 100 to 129 mg/dL, dietary therapy can be intensified first before starting (or intensifying) LDL-lowering drugs; in some cases, the LDL goal may be achieved without the need for starting (or changing) drug therapy.

Smoking

Goal to stop tobacco use altogether
Encourage patient and family to stop smoking
Provide counseling and use cessation programs as appropriate

Hypertension

Blood pressure goal < 130/85 mm Hg
Modify life habits to lower blood pressure (weight control, exercise, alcohol moderation, moderate sodium restriction)
Add blood pressure medication if needed to achieve blood pressure goal (consider ACE inhibitors and β -blockers for concomitant benefits)

Physical Activity

Minimum goal of 30 min three or four times per week
Assess overall risk to guide prescription
Encourage use of cardiac rehabilitation programs for patients with CAD (when available)
Encourage moderate intensity exercise

Weight Management

Goal to achieve desirable body weight
Provide counseling and use of professional dietitian as appropriate

Antiplatelet Agents/Anticoagulants

Start aspirin 80–325 mg/day if not contraindicated

β -Blockers

Start and continue for 6 mo minimum in high-risk patients (arrhythmia, LV dysfunction, include ischemia)

ACE Inhibitors

Start early in stable high-risk patients (anterior MI, previous MI, Killip class II: S₃ gallop, radiographic CHF)

ACE, angiotensin-converting enzyme; CAD, coronary heart disease; CHF, congestive heart failure; LV, left ventricular; MI, myocardial infarction.

Low-Density Lipoprotein-Lowering Therapies

Two modalities of LDL-lowering therapy are recognized in the ATP III report: therapeutic lifestyle changes and drug therapy. Therapeutic lifestyle changes go beyond LDL lowering by dietary therapy to achieve maximal risk reduction. The changes include (1) maximal reduction of saturated fats and cholesterol, (2) adding LDL-lowering adjuncts (plant stanol or sterols or increased viscous fiber), (3) weight reduction (in overweight or obese patients), and (4) increased physical activity.

When therapeutic lifestyle changes are recommended, dietary saturated fatty acids should be reduced to less than 7% of total energy intake, and dietary cholesterol to less than 200 mg/day. Physicians are advised to seek consultation from a registered dietitian or other qualified nutritional profes-

sional to provide patients with appropriate medical nutrition therapy. In the United States, Medicare pays for dietary consultation for CAD patients. A cholesterol-lowering diet is only one component of medical nutrition therapy for CKD patients. Adding LDL-lowering adjuncts can provide another 10% to 15% reduction in LDL cholesterol levels; these include plant stanols or sterols (2 g/day) and increased viscous fiber (10–25 g/day). Medical nutrition therapy should include calorie restriction in overweight patients. To match the patient's clinical needs, the physician should prescribe regular physical activity. Several drugs are available for LDL lowering (Table 63-2). The statins, bile acid sequestrants, and cholesterol absorption inhibitors mainly lower LDL. Fibrates and nicotinic acid can moderately reduce LDL levels, but they are used primarily for treatment of atherogenic dyslipidemia. The use of these drugs is considered for each category of CKD discussed.

Atherogenic Dyslipidemia and the Metabolic Syndrome

Atherogenic dyslipidemia is common in CKD patients and represents a potential secondary target of lipid-lowering therapy. It consists of raised blood levels of triglycerides, small LDL particles, and low HDL cholesterol levels. In some patients, weight reduction and increased physical activity may help normalize levels of triglyceride and HDL, but in some forms of CKD, atherogenic dyslipidemia results mainly from metabolic defects secondary to the kidney disease.^{16–18} The standard drugs for treatment of atherogenic dyslipidemia are fibrates and nicotinic acid. Unfortunately, both types of drugs can cause adverse effects that may be accentuated in CKD patients. For example, when fibrates are combined with statins, there is an increased risk for severe myopathy. This adverse effect is particularly dangerous in CKD patients because it may result in myoglobinuria and acute tubular necrosis.

In patients with atherogenic dyslipidemia, the primary target of therapy is still LDL. Nonetheless, the ATP III guidelines note that elevated VLDL cholesterol and triglycerides may contribute substantially to the risk for CAD. For this reason, the ATP III report identifies LDL plus VLDL cholesterol (also called *non-HDL cholesterol*) as a secondary target of therapy in patients with raised triglyceride levels. The goal for reduction of non-HDL cholesterol is a level 30 mg/dL higher than for LDL cholesterol. For example, with an LDL cholesterol goal of less than 100 mg/dL, the non-HDL cholesterol goal would be less than 130 mg/dL.

Some CKD patients have elements of the metabolic syndrome (see Box 63-3). Obesity is prevalent in patients with diabetic or nondiabetic forms of CKD and has been associated with increased risk for the development of kidney disease in the general population.^{19,20} The ATP III report criteria for a clinical diagnosis of the metabolic syndrome are shown in Table 63-3. Patients with three of the five abnormalities shown in this table are diagnosed as having the metabolic syndrome. If a patient with CKD also has the metabolic syndrome, more intensive treatment of serum lipids seems warranted. Dietary intervention and aerobic exercise are recommended in the ATP III report for those without kidney disease. The literature is limited on the benefits of weight loss in obese CKD patients, but it seems prudent to apply the ATP III recommendations to these patients as well.

Table 63-2 Drugs for Lipid Management

Drug Class	Drugs and Daily Doses	Lipid/Lipoprotein Effects	Adverse Effects	Contraindications	Clinical Trial Results
Bile acid sequestrants	Cholestyramine 4–16 g Colestipol 5–20 g	LDL C: 15%–30% HDL C: 3%–5% TG: No change or increase	Gastrointestinal distress, constipation, decreased absorption of other drugs	Absolute: dysbetalipoproteinemia, TG > 400 mg/dL Relative: TG > 200 mg/dL	Reduced major coronary events and CAD deaths
HMG-CoA reductase inhibitors (statins)*	Lovastatin 20–80 mg Pravastatin 20–40 mg Simvastatin 20–80 mg Fluvastatin 20–80 mg Atorvastatin 10–80 mg Rosuvastatin 5–20 mg	LDL C: 18%–55% HDL C: 5%–15% TG: 7%–30%	Myopathy, increased liver enzymes	Absolute: active or chronic liver disease Relative: concomitant use of certain drugs†	Reduced major coronary events, CAD deaths, need for coronary procedures, stroke, and total mortality
Cholesterol absorption inhibitor	Ezetimibe 10–20 mg	LDL: 20%–30%	No increase in myopathy	Absolute: None	
Nicotinic acid	Immediate-release crystalline 1.5–3 g Extended-release Niaspan 1–2 g Sustained-release 1–2 g	LDL C: 5%–25% HDL C: 15%–35% TG: 20%–50%	Flushing, hyperglycemia, hyperuricemia (gout), upper gastrointestinal distress, hepatotoxicity	Absolute: chronic liver disease, severe gout Relative: diabetes, hyperuricemia, peptic ulcer disease	Reduced major coronary events and (possibly) total mortality
Fibric acid derivatives	Gemfibrozil 600 mg bid Fenofibrate 200 mg Clofibrate 1000 mg bid	LDL C: 5%–20% HDL C: 10%–20% TG: 10%–50%	Dyspepsia, gallstones, myopathy (may be increased in patients with high TG)	Absolute: severe renal disease, severe hepatic disease Relative: severe renal disease	Reduced major coronary events, increased non-CAD mortality (in 2 of 5 clinical trials)

* Standard starting doses of statins are lovastatin (40 mg), pravastatin (40 mg), simvastatin (20 mg), fluvastatin (40 mg), and atorvastatin (10 mg).

† Cyclosporine, gemfibrozil (or niacin), macrolide antibiotics, various antifungal agents and cytochrome P450 inhibitors.

CAD, coronary artery disease; HDL, high-density lipoproteins; HMG-CoA, α -hydroxy- γ -methylglutaryl coenzyme A; LDL, low-density lipoproteins; TG, triglycerides.

Table 63-3 Clinical Diagnosis of the Metabolic Syndrome (based on any three of the following)

Risk Factor	Defining Level
Abdominal obesity (waist circumference)*,†	
Men	>102 cm (>40 inches)
Women	>88 cm (>35 inches)
Triglycerides	≥150 mg/dL
HDL cholesterol	
Men	<40 mg/dL
Women	<50 mg/dL
Blood pressure	≥130/≥85 mm Hg
Fasting glucose	≥110 mg/dL

*Overweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated than elevated body mass index with metabolic risk factors. Therefore, the simple measure of waist circumference is recommended to identify the body weight component of the metabolic syndrome.

†Some male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased (e.g., 94–102 cm; 37–39 inches). Such patients may have a strong genetic contribution to insulin resistance. They should benefit from changes in life habits, similarly to men with categorical increases in waist circumference.

AREAS FOR POTENTIAL INTERVENTION

Primary Nephrotic Syndrome

Hyperlipidemia is a typical feature of the nephrotic syndrome. In most patients, serum LDL cholesterol levels are raised^{21–24}; in some cases, VLDL cholesterol and VLDL triglycerides are increased as well.^{18,23} The mechanisms causing nephrotic hyperlipidemia are not fully understood and appear to be multiple. Hepatic overproduction of lipoproteins is related to depletion of serum albumin in in vivo and in vitro studies.^{25,26} Research in humans,^{18,23} as well as in experimental animals,^{27,28} indicates that catabolism of VLDL can be impaired, accentuating the high circulating triglyceride levels. Removal of LDL via LDL receptors also may be delayed,¹⁸ raising LDL cholesterol levels further. Nephrotic patients apparently have increased serum levels of cholesterol ester transport protein²⁹ This abnormality could account for the high content of cholesterol in LDL particles.²³ In short, a single mechanism probably cannot explain nephrotic hyperlipidemia.

Prolonged severe hyperlipidemia in patients with an irreversible nephrotic syndrome almost certainly promotes coronary atherosclerosis and predisposes to premature CAD.^{30–33} For such patients, application of the NCEP guidelines¹ for primary prevention seems appropriate. If LDL cholesterol levels exceed 100 mg/dL (or non-HDL cholesterol exceeds 220 mg/dL), cholesterol-lowering drugs can be employed in most patients. The goal of therapy for primary prevention is to reduce LDL cholesterol levels to less than 100 mg/dL (non-HDL cholesterol to < 130 mg/dL).

Several studies^{23,34–36} have demonstrated that hyperlipidemia in the nephrotic syndrome is responsive to statin drugs.

Statins lower both LDL cholesterol and VLDL cholesterol levels. Bile acid sequestrants also reduce LDL levels and enhance LDL lowering when given in combination with statins.³⁷ Even when triglycerides and cholesterol are high in nephrotic patients, statins are the preferred therapy because of their ability to lower levels of VLDL remnants as well as LDL.^{23,38} Nicotinic acid also reduces triglyceride levels³⁹ and may have additive effects with statins. The combination of statins plus fibrates has received little attention for patients with the nephrotic syndrome. Finally, it has been reported that LDL-pheresis can be used successfully to lower LDL in nephrotic patients with severe hypercholesterolemia.^{40,41}

Recommendations

In patients with the nephrotic syndrome, LDL is the primary target of therapy (Fig. 63-1). Statins are first-line therapy and at moderate doses can be used safely in most patients. There is little experience with high-dose statins. In nephrotic patients with severe hypercholesterolemia, it may not be possible to reduce LDL cholesterol to the near-optimal or optimal levels shown in Table 63-1. The LDL lowering that can be achieved with statin therapy nonetheless can be enhanced by adding a bile acid sequestrant. Statins also lower VLDL remnants and thus remain the preferred therapy in patients with combined elevations of LDL cholesterol and triglycerides. Addition of

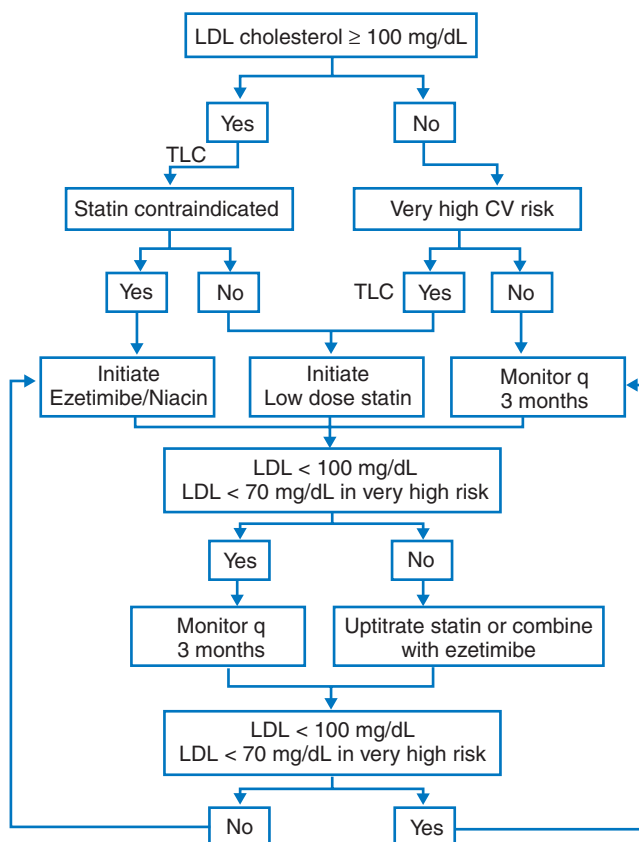

Figure 63-1 Management of hypercholesterolemia in chronic kidney disease. Very high risk ≥ 20% risk of MI in 10 years, coronary artery disease equivalent. TLC, therapeutic lifestyle changes; include low fat, low transfat diet, aerobic exercise 30 to 45 min 4 times/week, weight loss for overweight.

nicotinic acid to statin therapy can be considered for patients with combined hyperlipidemia. The combination of statin plus fibrate, however, should be used with caution; it may be contraindicated because of the increased risk of severe myopathy, rhabdomyolysis, and acute kidney disease.

Diabetic Nephropathy

One cause of the nephrotic syndrome in patients with type 1 or 2 diabetes is diabetic nephropathy. Lipid disorders are more common in patients with type 2 than type 1 diabetes. Diabetic dyslipidemia is essentially identical to atherogenic dyslipidemia (see Table 63-1).¹ When the nephrotic syndrome is present in patients with diabetes, LDL cholesterol levels are raised, and VLDL elevations are accentuated, causing combined hyperlipidemia.⁴² In patients with type 1 diabetes, the development of the nephrotic syndrome apparently produces a lipoprotein pattern resembling that of the primary nephrotic syndrome (i.e., a predominance of hypercholesterolemia).⁴³

Patients with diabetes are at high risk for CAD even before developing nephropathy.^{1,4} The high-risk status is due to at least two factors: metabolic risk factors that are especially common in type 2 diabetes,⁴⁴ and hyperglycemia, which appears to accelerate atherogenesis. Because of the high risk for major coronary events, the ATP III report designated diabetes as a CAD risk-equivalent. This designation was partly due to a high risk for future coronary events, but there were other reasons: once patients with diabetes develop CAD, they have a poorer prognosis for survival compared to nondiabetics with CAD.⁴⁵ Identifying a CAD risk-equivalent for a diabetic patient leads to treatment until the LDL cholesterol goal of less than 100 mg/dL is reached. Because many patients with diabetes also have elevated triglycerides, a non-HDL cholesterol goal of less than 130 mg/dL is indicated.⁴⁶ These goals are independent of established CAD. The use of cholesterol-lowering drugs to achieve LDL cholesterol goals in patients with diabetes is supported in secondary prevention trials by the favorable outcomes of statin therapy.^{47,48}

Available evidence indicates that the onset of nephropathy in patients with diabetes enhances CAD risk.⁴⁵ To lower cholesterol levels, combining a fibric acid derivative with a statin could be used, but there is an increased risk for myopathy. Therefore, prudence favors the use of a statin alone for most patients with diabetic nephropathy.

Recommendations

When a patient with diabetes also has CKD, that patient should be designated as having a CAD risk-equivalent, even if established CAD is not present. Regardless, the LDL cholesterol goal is less than 100 mg/dL and the non-HDL cholesterol goal is less than 130 mg/dL. To achieve these goals, LDL-lowering drugs are usually required; a statin is preferred (see Table 63-2). An alternative would be to combine a statin with a cholesterol absorption inhibitor, such as ezetimibe, because the combination is as effective as high-dose statin treatment. The combination may also be used for patients who cannot tolerate a high dose of a statin (e.g., patients receiving a fibrate or cyclosporine). A recent multicenter trial demonstrated that relatively low doses of extended-release nicotinic acid are well tolerated in patients with diabetes,⁴⁹ but for patients treated with a statin, lower doses of nicotinic acid are required to prevent worsening of diabetes.

CKD Not Requiring Dialysis

It is uncertain whether CKD before institution of dialysis independently raises CAD risk beyond that associated with major risk factors. Therefore, full attention should be given to modifying existing cardiovascular risk factors, such as cigarette smoking, hypertension, high LDL cholesterol, and low HDL cholesterol levels (see Box 63-1). Many CKD patients exhibit hypertriglyceridemia^{3,17} because of an underlying defect in the catabolism of VLDL triglycerides.⁵⁰ The result is an accumulation of VLDL remnants.¹⁷ Some investigators speculate that remnant lipoproteins are particularly atherogenic⁵¹ and should be treated independent of LDL cholesterol levels. This is an attractive hypothesis, although evidence that therapeutic reduction of VLDL levels will reduce CAD risk is lacking from clinical trials. Meta-analyses from clinical trials conducted exclusively in patients with early and later stages of CKD and post hoc analyses from clinical trials that included participants with early stages of CKD demonstrated that long-term treatment with statins was associated with reduction in risk for major coronary events.^{13,52-55} These studies suggest but do not prove that statin therapy is beneficial in patients with early and late stage CKD. Regardless, there are no definitive clinical trials demonstrating a benefit of cholesterol lowering in those with stages 4 and 5 CKD.

Recommendations

If a patient with CKD but not requiring dialysis has multiple CAD risk factors but no clinically manifested atherosclerotic disease, the LDL cholesterol target goal is less than 100 mg/dL (non-HDL cholesterol < 130 mg/dL).^{1,15} For untreated patients with LDL cholesterol (or non-HDL cholesterol) levels above the target for high-risk primary prevention, the preferred drug is a statin. If non-HDL cholesterol levels are maintained below the target without statin therapy but hypertriglyceridemia is present, a fibric acid derivative can be used.⁵⁶⁻⁵⁸ The dose of fibric acid derivative should be adjusted down as recommended in the package insert to reduce the risk for myopathy. In general, it is not appropriate to use a statin in combination with a fibric acid derivative in patients with CKD because of the increased danger of rhabdomyolysis and acute kidney disease.⁵⁹

CKD with Dialysis Treatment

The risk of acute coronary events and CAD death goes up dramatically in patients treated by hemodialysis or peritoneal dialysis.⁶⁰ The mechanisms underlying this increase in risk are poorly understood. Two pathologic factors acting at the level of coronary arteries likely play a role: coronary plaques may become more fragile and prone to erosion or rupture, and a hypercoagulable state may exist, which will increase the size of any newly formed thrombus. These two abnormalities could increase both the frequency and size of myocardial infarction. It is almost certain that hemodialysis patients have an absolute risk for major coronary events that is sufficiently high to justify classification as a CAD risk-equivalent. To date, however, no clinical trials have documented how much LDL-lowering therapy reduces the risk. Nonetheless, reduction of LDL cholesterol (and non-HDL cholesterol) levels may help to stabilize coronary plaques and reduce the high frequency of acute coronary syndromes in this population.

The major lipoprotein abnormality in dialysis patients with CKD is a high VLDL level, reflected as an increase in VLDL cholesterol and triglycerides.^{61–63} This abnormality results mainly from defective catabolism of VLDL particles.⁶¹ In patients treated with peritoneal dialysis, high VLDL triglyceride levels are particularly common, probably from both hepatic overproduction of VLDL triglycerides due to a high carbohydrate content in dialysis fluid and from defective clearance of VLDL due to loss of kidney function. VLDL remnants in dialysis patients may be unusually atherogenic; if so, efforts to reduce VLDL levels would be warranted. Unfortunately, no clinical trials have investigated whether lowering of serum VLDL levels in dialysis patients will reduce risk for major coronary events. Considering the high absolute risk for CAD in these patients, however, it is reasonable to institute therapy to decrease VLDL levels as part of an overall regimen to control cardiovascular risk factors.

Recommendations

Because dialysis patients are at higher risk for CAD, reduction of LDL cholesterol into the optimal range seems warranted; a recent study⁶⁴ suggested that statin therapy reduces total mortality in patients with end-stage renal disease. In the 4-D study, which included approximately 1200 type 2 diabetic patients treated by maintenance hemodialysis, atorvastatin (20 mg once daily) failed to exert an overall cardiovascular mortality benefit, although cardiac morbidity was significantly reduced. In this study, the achieved mean plasma LDL cholesterol level in those assigned to 20 mg of atorvastatin was 77 mg/dL.⁶⁵ Even so, patients on dialysis are probably at higher risk for myopathy with statin therapy because of kidney dysfunction combined with multiple medications.^{66–68} Based on currently available data, administration of a statin starting with a low dose and titrating upward to achieve the goals included in the ATP III report is a reasonable approach.^{65,69} Two large-scale ongoing clinical trials are designed to determine whether cholesterol-lowering agents, including statins and ezetimibe, can reduce cardiovascular morbidity and mortality among CKD patients, including those on hemodialysis. The results of these trials should provide additional information that will modify guidelines for therapy.^{70–72}

Many patients on dialysis have elevated triglyceride levels, and statin therapy can reduce levels of VLDL as well as LDL. An alternative approach is to reduce VLDL levels with a fibric acid derivative instead of with a statin.^{16,73,74} Fibrates may in fact be more widely used in clinical practice than statins, because of the high frequency of elevated triglyceride levels. Even so, it is uncertain whether reduction of VLDL levels by fibric acid derivatives gives as great a decrease in CAD risk as statins. A recent report⁶⁴ found no benefit from fibrate therapy in patients with end-stage renal disease.

CKD Post-Kidney Transplant

Cardiovascular disease appears to be a major cause of death in postkidney transplant patients⁶⁰ compared to dialysis patients. A different set of factors may be responsible for this increased CAD risk. Post-transplant, the patients are more likely than dialysis patients to have high cholesterol levels, seemingly related to the use of immunosuppressive agents.^{75,76} The ALERT study demonstrated a trend for reducing cardiovascular morbidity

and mortality among postkidney transplant patients treated with fluvastatin. This trend was not statistically significant, although there were fewer cardiac events, including nonfatal myocardial infarctions, in the fluvastatin-treated group.⁷⁷

Recommendations

The aim of therapy in postkidney transplant patients is to reduce LDL cholesterol levels to target goals (i.e., to <100 mg/dL) in patients with established CAD and CAD risk-equivalents.¹⁵ Parallel reductions of non-HDL cholesterol levels are recommended for patients with hypertriglyceridemia. If drug therapy to lower serum cholesterol levels is required for post-transplant patients, statins appear to be the preferred agents.^{75,76} Certainly they are more effective than fibric acid derivatives for lowering LDL and VLDL cholesterol levels. Nevertheless, it must be kept in mind that the combination of a statin with cyclosporine is accompanied by increased risk for severe myopathy.

Hyperhomocysteinemia

Joyce M. Gonin and Christopher S. Wilcox

CHAPTER CONTENTS

METABOLISM 725

PHARMACOLOGIC THERAPY 726

Homocysteine is a sulfa-containing amino acid that circulates in oxidized, reduced, and complex forms. About 75% is bound to albumin, and routine assays measure total homocysteine (i.e., free plus bound homocysteine, or tHcy).^{1,2} Homocysteine is manufactured in all cells, including erythrocytes. Consequently, it leaks into plasma in blood samples. Blood samples, therefore, must be cooled to 4°C, centrifuged, and the plasma separated rapidly to avoid artificially high plasma tHcy values. Reported normal values vary widely between laboratories but average 6 to 10 $\mu\text{mol/L}$. Hyperhomocysteinemia implies a value more than two standard deviations above normal; this is typically 12 to 16 $\mu\text{mol/L}$.

More than 90% of patients with end-stage renal disease (ESRD) receiving hemodialysis or continuous ambulatory peritoneal dialysis have hyperhomocysteinemia. Plasma levels of tHcy appear to be elevated to a similar degree in patients treated by either continuous ambulatory peritoneal dialysis or hemodialysis.^{3–5} After renal transplantation, tHcy levels fall, but less than anticipated from the improvement in renal function.⁶

Very severe hyperhomocysteinemia ($>100 \mu\text{mol/L}$) occurs as a genetic metabolic defect and is associated with early and severe atherosclerosis. Mild hyperhomocysteinemia (12–20 $\mu\text{mol/L}$) occurs in otherwise normal people, often as a manifestation of vitamin B deficiency. Patients with ESRD usually have moderate hyperhomocysteinemia (20–100 $\mu\text{mol/L}$). Conflicting data exist regarding the relationship between hyperhomocysteinemia and cardiovascular disease. In retrospective and cross-sectional studies of the general population, a consistently strong relationship is seen between homocysteine concentrations and cardiovascular events.⁷ This finding, however, is not confirmed in all prospective studies.⁸ Five retrospective^{9–12} and three prospective studies^{13–15} concur that tHcy is an independent risk factor for the development of cardiovascular disease in patients with ESRD. Two recent reports have contradictory results, suggesting that the highest incidence of cardiovascular events is associated with the lowest quartile for homocysteine concentrations.^{16,17} A subsequent study revealed that this phenomenon applied only to individuals with chronic inflammation and malnutrition, as defined by low serum albumin and high C-reactive protein values.¹⁸

The major determinant of tHcy in patients with chronic kidney disease is an increase in the serum creatinine concentration or a reduction in the glomerular filtration rate.¹⁹ Among patients with ESRD, malnutrition, low serum albumin

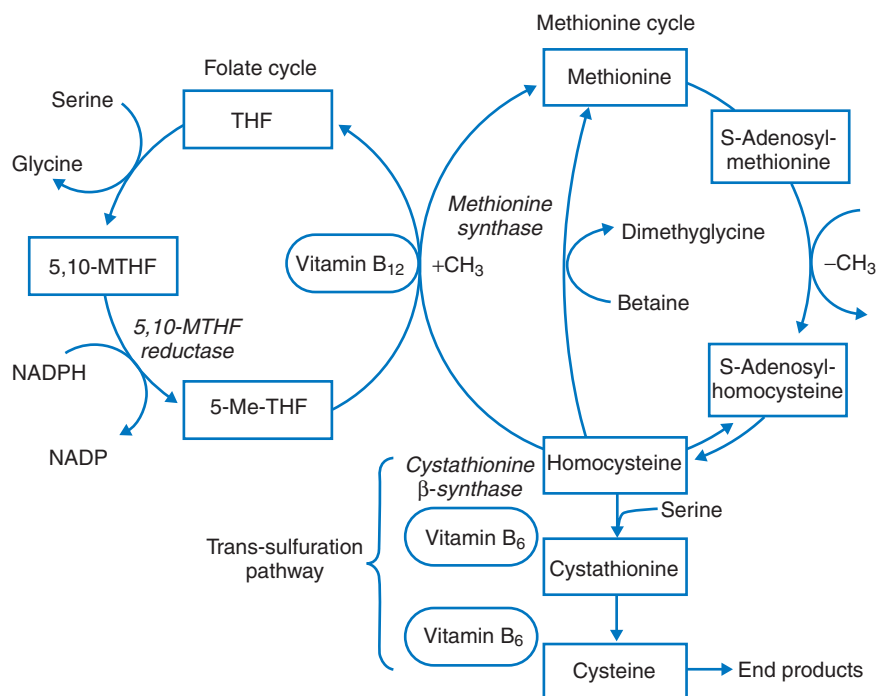

concentration,²⁰ and high-flux hemodialysis²¹ predict lower levels of tHcy. The polymorphism status for 5,10-methylene tetrahydrofolate reductase (MTHFR) has a relatively minor effect on tHcy levels in ESRD patients.²²

The mechanism causing hyperhomocysteinemia in ESRD remains obscure.² Therapy is empiric and remains highly unsatisfactory. Because no effective treatment has been devised to normalize tHcy in ESRD patients, it has not been possible to establish whether reversal of hyperhomocysteinemia reverses the associated risk of cardiovascular disease. Three large randomized trials are being conducted in patients with chronic kidney disease to evaluate the effect of treatment of hyperhomocysteinemia on cardiovascular outcome. The FAVORIT study will examine the effect of lowering homocysteine in 4000 renal transplant patients. Available data suggest that treatment with folic acid can normalize homocysteine in this population.²³ The Atherosclerosis and Folic Acid Supplementation Trial (ASFAST) will evaluate the effect of folic acid on cardiovascular outcome and endothelial function in 315 predialysis and dialysis patients.²⁴ The Homocysteinemia in Kidney and End State Renal Disease Study (HOST) is a U.S. Veterans Administration-industry funded study initiated in 2001 to assess the effects of 4 years of a daily regimen of folic acid, pyridoxine, and vitamin B₁₂ on vascular outcomes.

METABOLISM

Homocysteine is metabolized to methionine via the remethylation pathway. Alternatively, it may be metabolized by transsulfuration (Fig. 64-1).¹ Two hypotheses have been proposed to explain hyperhomocysteinemia in renal failure: homocysteine metabolism and excretion by the kidneys may be impaired or extrarenal homocysteine metabolism is impaired. Homocysteine transsulfuration and remethylation enzymes are present in the kidney; a study in the rat showed that homocysteine is taken up and metabolized by the kidney.²⁵ However, two studies in humans with normal renal function did not find a significant arteriovenous difference in homocysteine concentration across the kidney.^{26,27} Whole-body sulfur amino acid metabolism studied using a stable isotope method has demonstrated that total remethylation and transmethylation flux are decreased in ESRD patients, whereas the transsulfuration rate was similar to controls.^{28–30} ESRD patients do fail to up-regulate the transsulfuration pathway in response to hyperhomocysteinemia.³¹

Figure 64-1 A diagrammatic representation of the pathways for methionine and homocysteine metabolism. 5,10-MTHF, 5,10-methyltetrahydrofolate; 5-Me-THF, 5-methyltetrahydrofolate; THF, tetrahydrofolate. (Reproduced from Kitiyakara C, Gonin J, Massy Z, et al: Non-traditional cardiovascular disease risk factors in end-stage renal disease: Oxidative stress and hyperhomocysteinemia. *Curr Opin Nephrol* 2001;9:477–487.)

Remethylation via methionine synthase depends on the active form of folate, 5-methyltetrahydrofolate (5-Me-THF), and the active form of vitamin B₁₂. The transsulfuration pathway is initiated by cystathionine β-synthase, which catalyzes the conjugation of homocysteine and serine to form cystathionine. This is a vitamin B₆-dependent pathway. Therefore, folate, vitamins B₁₂ and B₆, or their active metabolites are essential for homocysteine metabolism. Indeed, defects in these three vitamins account for most cases of mild hyperhomocysteinemia in the general population.³²

B vitamins are water-soluble and are removed significantly during dialysis. Therefore, dialysis patients normally receive a water-soluble multivitamin. One widely used capsule, Nephrocaps, contains folic acid 1 mg, vitamin B₆ 10 mg, and vitamin B₁₂ 6 μg. Such a prescription should maintain plasma vitamin levels in the normal range for most dialysis patients.³³ There is a strong inverse relationship between the log of plasma folate concentration and the log of plasma tHcy concentration in both healthy adults and those with ESRD. However, the relationship is shifted to higher plasma levels of homocysteine in patients with ESRD.¹⁰ This has prompted the hypothesis that ESRD is a state of folate- and B vitamin-resistance, requiring supranormal doses of these vitamins to reverse the defect.

PHARMACOLOGIC THERAPY

Prospective trials in patients with ESRD have evaluated the effects on hyperhomocysteinemia of folic acid (or its derivatives), vitamins B₆ and B₁₂, serine, and betaine.

The efficacy of supplementation with B vitamins in patients with ESRD has been the subject of 18 prospective clinical trials.^{4,5,16,22,34–48} Despite this wealth of information, there are no firm conclusions about the role of vitamin supplementation in doses above those routinely recommended (folic acid 1 mg, vitamin B₆ 10–50 mg, and vitamin B₁₂ 5–50 μg daily).

Even though no consistent conclusions can be drawn from these trials, some trends are apparent:

1. All trials except two^{44–46} report a statistically significant reduction in tHcy with folate supplementation. However, those two negative trials are among only three trials that were placebo-controlled,^{34,44–46} and both used very high doses of folic acid (30 or 60 mg daily)^{45,46} or of a folate metabolite (intravenous leucovorin 100 mg, three times per week).^{44,46} The majority of fully controlled trials have failed to show any detectable reduction in tHcy even with massive supplemental doses of folic acid. The reason for the modest reductions seen in most uncontrolled trials is not yet clear but may relate to better compliance with vitamin replacement therapy.
2. Larger decreases in tHcy usually occur during active treatment, in part because routine vitamin supplementation is withdrawn before the trial starts, suggesting that the baseline tHcy level is what has been changed. In fact, participants in the two negative trials,^{44–46} as well as those from some positive trials,^{4,34,37,39,42} were studied while maintaining the standard of care prescription with folate. In some studies, the routine vitamin supplement was withdrawn before the trial.^{5,35,36,40} On the whole, participants in these trials had the highest pretreatment values for tHcy, probably reflecting some B-vitamin deficiency caused by dialytic losses. Consequently, these patients generally had the most robust responses to folate therapy (Fig. 64-2A). Clearly, these trials are severely flawed; it has been known for many years that B-vitamin deficiency develops quite rapidly in hemodialysis patients if they are not provided with a routine supplement to replace dialysis losses.
3. There is no clear benefit from additional supplementation of vitamins B₆ and B₁₂ over responses that are achieved with folic acid alone. This issue was studied specifically in

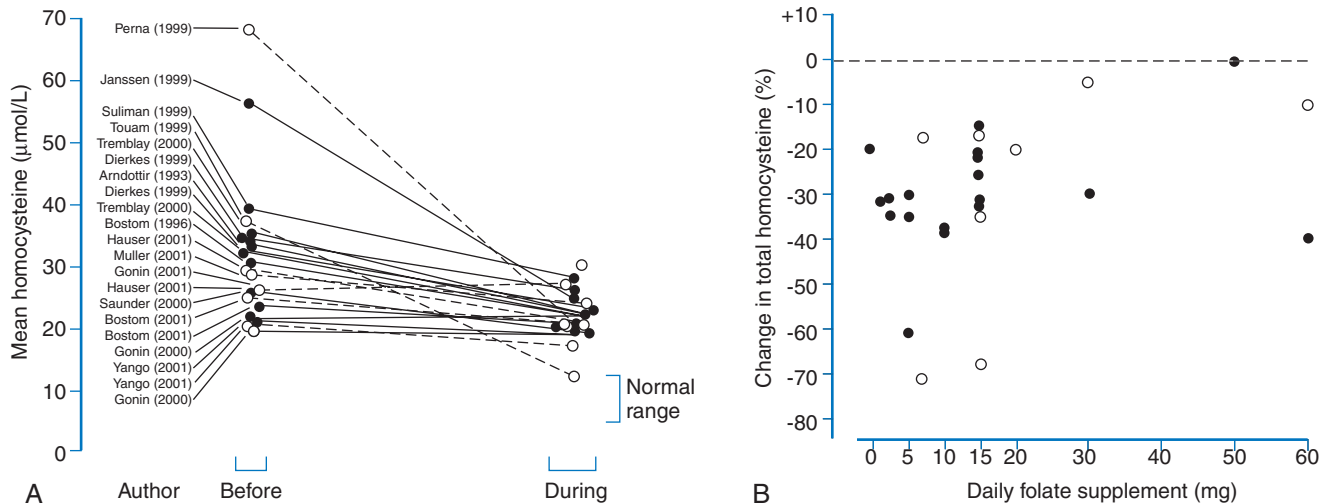

Figure 64-2 Mean data from prospective trials of supplementation with folic acid (*solid symbols*), or folate metabolites or analogues (*open symbols*) given with or without other treatments, such as vitamins B₆ and B₁₂. **A**, Mean total homocysteine (tHcy) for trial subjects before and during folate supplementation; the shaded area represents the normal range. **B**, Relationship between the mean fractional change of plasma tHcy concentration during therapy and the daily dose of folate or folate metabolite or analogue used.

one controlled trial in which groups of hemodialysis patients received either placebo, folic acid 30 mg or 60 mg, vitamins B₆ and B₁₂, or all three treatments together. There was no significant difference in any group relative to the placebo control.^{45,46}

- Although there are substantial, and largely unexplained, variations in the values for plasma tHcy before supplementation, all trials report mean values during supplementation of 12 to 27 $\mu\text{mol/L}$ (see Fig. 64-2A).
- The trials that used folate metabolites (5 Me-THF)^{35,39,41} or folinic acid (leucovorin)^{37,40,42,44,46–48} produced similar results to folic acid. Indeed, within-trial comparisons of folic acid and its metabolic derivatives have shown no significant differences.^{37,39,41,42}
- In only two trials were the values for tHcy normalized in the majority of patients. Touam and colleagues⁴⁰ supplemented patients with a single postdialysis injection of folinic acid (50 mg) given once weekly and 250 mg of vitamin B₆ after each dialysis session. They reported normalization of total plasma homocysteine levels. However, a subsequent study found no benefit of equimolar folinic acid over folic acid.⁴² In a small study by Gonella and colleagues,⁴⁸ 89% of patients on hemodiafiltration treated with folinic acid and vitamins B₆ and B₁₂ for 4 months had normalized homocysteine values. This may reflect the process of hemodiafiltration as compared to routine hemodialysis.
- Supplementation with serine alone or in addition to folate metabolites produces no further fall in tHcy.^{44,46}
- No relationship is apparent between the fractional change in tHcy concentration during therapy and the daily dose of folate (or metabolite) that is given as a supplement (see Fig. 64-2B). For example, one trial reported that compared to no vitamin supplements, supplementation with folic acid 1 mg daily reduced tHcy levels by 32%; an increase to 10 mg daily produced no further change.³⁶ The highest doses of folic acid (60 mg daily) or folinic acid (100 mg/day intravenously three times per week) tested have been reported to reduce tHcy by 38%²² or to have no significant effect whatsoever.^{44–46} The

complete absence of a relationship between the dose of folic acid delivered and the change in tHcy among the numerous trials summarized in Figure 64-2B refutes the hypothesis that hemodialysis patients have resistance to the effects of folic acid on tHcy. They also cast very serious doubt about the effectiveness of folic acid, above a routine replacement dose of 1 mg daily.

- Several studies have suggested that intravenous vitamin B₁₂, when added to high-dose folic acid and pyridoxine, may achieve a reduction of homocysteine of 32% to 50%.^{49–52} It has been suggested that inhibition of methionine synthase in uremia contributes to hyperhomocysteinemia in ESRD patients and that pharmacologic concentrations of vitamin B₁₂ given intravenously may increase methionine synthase activity via a post-translational mechanism.⁵³ These conditions require validation in formal trials.

An alternative approach to the lowering of homocysteine in ESRD is the administration of acetylcysteine, a thiol-containing antioxidant. Scholze and associates showed that a single dose of intravenous acetylcysteine given during a dialysis session lowered tHcy from 20 mmol/L to 2.2 mmol/L, compared to a reduction from 19.8 mmol/L to 11.9 mmol/L with placebo. Although tHcy rebounded after dialysis, it remained significantly lower in the treated group 2 days later.⁵⁴ In another randomized, controlled trial, 1200 mg of acetylcysteine was given orally twice a day for 4 weeks to patients with ESRD. The tHcy was lowered by 19% compared to 8% in the placebo group. Unfortunately, this difference was not statistically significant,⁵⁵ which casts doubt on the efficacy of oral acetylcysteine in these patients.

These reports lead to the following conclusions:

- Presently there is no rational justification for recommending more than routine vitamin supplementation with a daily dose of folic acid (1 mg), vitamin B₆ (10–50 mg), and vitamin B₁₂ (5–50 g) in ESRD patients.
- There is no benefit from active folate metabolites or folate analogues over folic acid itself.

- Intravenous vitamin B₁₂ may be more beneficial than oral vitamin B₁₂, but this requires validation before routine recommendation.
- The potential benefits of *N*-acetylcysteine remain unproven.
- There must be powerful, uncontrolled, and presently unrecognized factors in the studies to account for the high degree of variability reported in responses to vitamin supplementation.

Figure 64-2A demonstrates that ESRD patients should normally be able to achieve a predialysis tHcy concentration of less than 30 $\mu\text{mol/L}$. Patients with higher values require assessment to ensure that they have been prescribed, and are indeed receiving, the routine vitamin supplement. If this does not explain the above-average plasma level of tHcy, the plasma levels of folate, vitamin B₁₂, and vitamin B₆ should be assessed to ensure that they are within the normal range. Occasionally, patients present with very high values for tHcy due to unrecognized concurrent disease, such as pernicious anemia or hypothyroidism, or because of concurrent therapy with antifolate drugs such as methotrexate. An algorithm for evaluation and treatment of hyperhomocysteinemia in renal disease is presented in Figure 64-3.

Clearly, the present state of knowledge concerning hyperhomocysteinemia in patients with ESRD is highly unsatisfactory. On the one hand, hyperhomocysteinemia is almost universal in

these patients and is a powerful predictor of associated or future development of cardiovascular disease. On the other, treatment is generally ineffective in normalizing hyperhomocysteinemia, and available clinical trials are so discordant that strong conclusions concerning the need for more than routine supplementation with folate and B vitamins are not warranted. Therapeutic advances may have to await the outcome of scientific studies that disclose the mechanism of hyperhomocysteinemia in ESRD and evaluate whether reductions in tHcy, or prolonged supplementation with high doses of B vitamins, indeed have beneficial effects in reducing cardiovascular disease in patients with ESRD.

CHAPTER CONTENTS

STUDIES IN THE GENERAL POPULATION 731

SUMMARY 733

STUDIES IN PATIENTS WITH CHRONIC KIDNEY DISEASE 732

Reactive oxygen species (ROS) include superoxide anions, hydroxyl anions, and hydrogen peroxide. Superoxide anion is the primary ROS, and it interacts with other molecules to generate secondary ROS, including reactive nitrogen species. ROS are produced as a by-product during oxygen metabolism. In physiologic concentrations ROS act as signaling molecules and play an important role in the regulation of renal and vascular functions.¹⁻⁵ In vascular endothelial cells, ROS regulate vascular tone, oxygen sensing, cell growth and proliferation, apoptosis, and inflammatory responses. Because of their highly reactive nature, the generation and elimination of ROS are very tightly regulated. Loss of this regulation with increased ROS accumulation leads to oxidative stress (OS), which causes vascular dysfunction by several mechanisms: Superoxide anion reduces the bioavailability of vasodilator nitric oxide and forms peroxynitrite, which inactivates prostacyclin synthase.⁶ This reaction reduces the production of vasodilator and antiplatelet prostacyclins. By oxidizing low-density lipoprotein, ROS facilitates its uptake by macrophages via the scavenger receptor CD36, resulting in foam cell formation, an early event in atherosclerosis.⁷

An important interaction also occurs between OS and the production of methylated arginines that include asymmetric dimethylarginine (ADMA).⁸ Asymmetric dimethylarginine is an endogenous inhibitor of endothelial nitric oxide synthase, and its levels are universally elevated in patients with chronic kidney disease (CKD).⁹ OS increases the plasma levels of ADMA by inhibiting the activity of dimethylarginine dimethylaminohydrolase, the major enzyme responsible for ADMA metabolism. OS also up-regulates the expression of protein arginine methyltransferases, the enzymes that methylate arginine residues on proteins.^{8,10} Plasma ADMA levels predict the presence of cardiovascular disease (CVD) and all-cause mortality in the normal population and in patients with CKD.¹¹

In a remnant kidney model of CKD, the advanced oxidation protein products accelerated renal fibrosis, suggesting a deleterious effect of OS on CKD progression.¹² OS is highly prevalent in all stages of CKD¹³⁻¹⁵ and therefore represents a logical therapeutic target.

STUDIES IN THE GENERAL POPULATION

Despite the compelling clinical and experimental data, large randomized, controlled studies in the general population using antioxidant vitamins that include vitamin C and vitamin E (α -tocopherol) failed to show an improvement in the primary or secondary cardiovascular endpoints (or in overall mortality).¹⁶⁻¹⁸ Even in patients with mild to moderate renal insufficiency, treatment with 400 IU of vitamin E in the HOPE study had no beneficial effect on cardiovascular endpoints or proteinuria in a group of high-risk patients.¹⁹ Before attempting to interpret these studies, their limitations must be noted: First, none of these studies actually measured any parameters of OS; the effectiveness of the antioxidant intervention in these studies is not known, partly due to the lack of an easily measurable, standardized, and widely available marker of OS for clinical use.²⁰ This is complicated by the fact that none of the available markers of OS have been prospectively shown to predict adverse cardiovascular outcome or mortality. Second, the optimum dose of vitamin E is not known. The doses used in the cited studies failed to reduce urinary 8-isoprostanes, a marker of lipid peroxidation, in healthy smokers.²¹ A dose of 300 mg/day (equivalent to 660 IU/day) of synthetic vitamin E given to 10 healthy subjects failed to increase plasma total antioxidant activity despite a 30% rise in plasma levels.²² Third, the bioavailability of vitamin E is highly variable and is regulated by α -tocopherol transfer protein. Genetic factors account for up 22% of the total variance in serum α -tocopherol levels.²³ Furthermore, serum α -tocopherol concentrations correlate poorly with dietary intake. Increased serum levels are seen with rising serum lipid levels, whereas smoking decreases the α -tocopherol bioavailability.²⁴ The attainment of an effective plasma level can only be ensured by measuring serum α -tocopherol levels, and this was not done in large trials. Establishing the relationship between a reduction in oxidative stress parameters (if any) and plasma levels of α -tocopherol in properly controlled dose-response studies in a group of subjects with oxidative stress is needed but absent. Last, several antihypertensive agents exhibit clinically significant antioxidant properties, and some of their apparent blood

pressure-independent beneficial effects in CVD seen in large clinical trials may in fact be due to antioxidant properties. Therefore, interventional studies to test the antioxidant hypothesis should not be limited to testing vitamins and their analogues.

STUDIES IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Most studies of CKD patients have been carried out in dialysis-dependent patients. They can be divided into two main categories: studies that used systemic vitamin E and studies that used vitamin E-coated hemodialysis membranes. Among the latter (Table 65-1), only two studies used reasonable surrogate clinical endpoints of CVD, namely the progression of aortic calcification²⁵ and changes in carotid intimal thickness.²⁶ The remainder used biochemical parameters of OS or immunologic parameters related to inflammatory responses to the hemodialysis membrane exposure, which is a measure of membrane biocompatibility.²⁷⁻²⁹ Exposure of the patient's blood to an artificial membrane (and possibly back-diffusion of pyrogens or endotoxins in the dialysate) elicits a strong cellular immunologic response, manifested by leukopenia, complement activation, and production of free oxygen radicals by the activated white blood cells.³⁰ The hemodialysis procedure itself can contribute to OS and endothelial dysfunction.³¹ To ameliorate hemodialysis-induced OS, many manufacturers offer vitamin E-coated dialyzers. In these dialyzers α -tocopherol is bonded to a cellulose- or polysulfone-based membrane. The membrane has other

modifications that affect its function and biocompatibility.³² The inner surface of the hollow fiber is bound, via an acrylic polymer, to a complement-inhibiting fluororesin polymer and to an oleyl alcohol chain that inhibits platelet aggregation. The oleyl alcohol chain itself is bonded to α -tocopherol by hydrophobic-hydrophobic bonds. These modifications decrease the number of hydroxyl groups in the cellulose membrane and thereby increase its biocompatibility. Several studies have shown a beneficial effect of vitamin E-coated dialyzers on various parameters of OS and immunologic reaction to hemodialysis. Most of these studies, however, are small, unblinded, and poorly controlled; a critical flaw is that most have used less biocompatible membranes as controls. Furthermore, the clinical relevance of the measured biomarkers in these studies is not known. Although the concept of vitamin E-coated membranes is interesting, larger randomized, controlled studies with hard clinical endpoints are needed to prove their utility; current evidence does not support their use in routine clinical practice at present.

Table 65-2 lists studies that have examined systemic antioxidant agents, including *N*-acetylcysteine, α -tocopherol, and antihypertensive agents with antioxidant activity. The Secondary Prevention with Antioxidants of Cardiovascular disease in End-stage renal disease (SPACE) trial randomized 196 high-risk hemodialysis patients who had underlying CVD to either 800 IU/day of α -tocopherol or a placebo for a median follow-up of 519 days. The patients treated with α -tocopherol had a 54% relative-risk reduction in the primary endpoint of new cardiovascular events and acute myocardial infarction; the difference was statistically significant, but there was no difference in fatal myocardial infarction, CVD mortality, and all-cause

Table 65-1 Selected Studies of Vitamin E-Coated Hemodialysis Membranes

Year	Control Membrane	N	Duration	Study Design	Outcome
2006	Polysynthane	20	2 mo	Randomized	↓OS parameters and cytokines ⁴³ greater ↓ with IV vitamin C
2005	PS	31	18 mo	RCT, crossover	↓OxLDL, MDA-LDL, ADMA ⁴⁴
2004	PS and hemophane	14	3 mo	Crossover	↓ Monocyte CD40, CD86; ↑lectin-induced T-cell proliferation ⁴⁵
2003	Cellulose	34	1 yr	Randomized	↓Carotid IMT, RBC viscosity, erythropoietin requirement ²⁶
2002	CA	8	6 mo	Randomized	↓ <i>Jun</i> N-terminal kinase activation ⁴⁶
2002	Cellulose	10	3 mo	Randomized, crossover	↓Leukopenia, LDL oxidation, LDL, PMN superoxide generation ⁴⁷
2001	AN*	16	2 mo	Randomized, crossover	↓Intradialytic elastase, vitamin C oxidation; ↑basal vitamin C ⁴⁸
2000	Cellulose	7	10 wk	Randomized, crossover	↓Neutropenia, C3a, PMN activation, MPO ⁴⁹
2000	Various	110	2–9 mo	Randomized, crossover Cross-sectional	↓Leukocyte DNA 8-oH2dG, granulocyte ROS generation ⁵⁰
1999	Cellulose	50	2 yr	Randomized	↓LDL oxidation, MDA, % increase in aortic calcification ²⁵

*Synthetic biocompatible membrane.

ADMA, asymmetric dimethylarginine; AN, acrylonitrile and metacrylate sulfonate copolymer; CA, cellulose acetate; IMT, intimal media thickness; IV, Intravenous; LDL, low-density lipoprotein; MDA, malondialdehyde; MPO, myeloperoxidase; OS, oxidative stress; OxLDL, oxidized LDL; PMN, polymorphonuclear leukocytes; PS, polysulfone; RBC, red blood cell; RCT, randomized controlled trial; ROS, reactive oxygen species; 8-oH2dG, 8-hydroxy, 2'-deoxyguanosine.

Table 65-2 Selected Studies of Systemic Antioxidant Therapy in ESRD Patients

Year	N	Intervention	Duration	Study Design	Outcome
2006	19	Valsartan and amlodipine	6 wk	Randomized, double-blind, crossover	↓ OS parameters, ADMA, SDMA both drugs ⁴¹
2006	29	α-Tocopherol 400 mg	5 wk	Randomized	No effect on CRP, ICAM-1, E-selectin, PAPP-A ⁵¹
2006	47	α-Tocopherol 300 mg daily	20 wk	Randomized, placebo-controlled	↓ EOF, LPO ⁵²
2005	44	Atorvastatin ± α-tocopherol 800 IU	12 wk	Randomized, double-blind, placebo-controlled	↓ In vitro LDL oxidizability; no effect on oxLDL ⁵³
2003	134	N-Acetylcysteine 1200 mg daily	14.5 mo	Randomized, placebo-controlled	↓ Composite CVD events; no effect on mortality ³⁴
2002	196	α-Tocopherol 800 IU daily	519 days	Randomized, placebo-controlled	↓ MI, CVD events; no effect on mortality ³³
2000	22	α-Tocopherol 1200 IU daily	1 dose	Randomized, crossover	↓ IV iron-induced LPO ⁵⁴
1985	30	α-Tocopherol 600 mg daily	30 days	Randomized	↑ Hematocrit ⁵⁵
1984	35	α-Tocopherol 400 IU daily	20 wk	Randomized, placebo-controlled	No effect on hematocrit ⁵⁶

ADMA, asymmetric dimethylarginine; CRP, C-reactive protein; CVD, cardiovascular disease; EOF, erythrocyte osmotic fragility; ESRD, end-stage renal disease; ICAM-1, intercellular adhesion molecule-1; IV, intravenous; LPO, lipid peroxidation; MI, myocardial infarction; OS, oxidative stress; oxLDL, oxidized LDL; PAPP-A, pregnancy-associated plasma protein-A; RCT, randomized controlled trial; SDMA, symmetric dimethylarginine.

mortality among the treatment groups.³³ The second trial randomized 134 hemodialysis patients to receive either a reduced thiol-containing compound *N*-acetylcysteine or a placebo.³⁴ After a median follow-up of 14.5 months, the group treated with *N*-acetylcysteine had a statistically significant, 40% relative-risk reduction in the primary endpoint of cardiovascular events. There was, however, no difference in CVD mortality or death from any cause. The effects of these interventions on parameters of oxidative stress were not measured in either of these studies. Although these studies are encouraging because they demonstrate that either of two chemically dissimilar drugs that may be antioxidants do in fact reduce new myocardial infarctions, the results are presently inadequate to warrant the widespread use of antioxidant therapy in this patient population. Larger randomized studies will be needed to determine the true extent of any beneficial effect of such interventions, not only on reducing cardiovascular events, but also on decreasing overall mortality.

Antagonists of the renin-angiotensin-aldosterone system reduce oxidative stress in animal models of hypertension.³⁵ Moreover, some widely used antihypertensive drugs have a biochemical configuration that confers a direct antioxidant effect in vitro, including amlodipine,³⁶ carvedilol,³⁷ and hydralazine.³⁸ None of these have been widely studied as antioxidant strategies in CKD patients. The renin-angiotensin-aldosterone system antagonists block angiotensin II-induced superoxide generation by nicotinamide adenine dinucleotide phosphate oxidase.³⁹ The dihydropyridine calcium channel blocker amlodipine scavenges superoxide by donating two extractable protons in its dihydropyridine ring.⁴⁰ The angiotensin receptor blocker valsartan and amlodipine reduces OS in patients on hemodialy-

sis independent of the blood pressure-lowering effects of these drugs.⁴¹ This reduction in OS is associated with a parallel reduction in plasma levels of ADMA and symmetric dimethylarginine; this suggests a strong link between OS and methylarginine metabolism. Because ADMA is one of the strongest predictors of CVD and mortality, it represents a novel therapeutic target for further studies with clinical endpoints.

SUMMARY

Oxidative stress is highly prevalent at all stages of CKD. It may contribute to the very high CVD mortality and the progressive deterioration in renal function. End-stage renal disease patients on maintenance hemodialysis are exposed to a multitude of unique stimuli that exacerbate OS. Although large randomized trials in the general population using α-tocopherol have been disappointing, this type of therapeutic intervention may be more relevant to CKD patients, who have high levels of OS. Given the complexity of OS, no single intervention may be adequate to address the many contributing mechanisms. Multiple agents administered systemically or modifications of the dialysis procedure may be needed to establish benefit. Novel agents, such as superoxide dismutase and glutathione peroxidase mimetics, should be explored because they exhibit strong antioxidant activity in experimental models of OS.⁴² Large randomized controlled trials with CVD and overall mortality as endpoints are needed to confirm the beneficial effects of antioxidant therapy seen in small trials. It is my opinion that the strength of current evidence does not support the use of antioxidant therapy in patients with CKD.

The cost of care for patients with chronic kidney disease (CKD) and end-stage renal disease (ESRD) is a huge economic burden. In 2004, CKD and ESRD patients together consumed 23.7% of Medicare expenses, although they accounted for only 5.7% and 1.1% of the Medicare population, respectively.¹ There are now 385,000 people in the United States with a diagnosis of ESRD, but 19.2 million Americans are living with some form of CKD, constituting 11% of the adult U.S. population. For this reason the Centers for Disease Control has labeled CKD as a “public health disease that needs a public health action plan.”² It is not only about the numbers: CKD patients have premature morbidity, a poor quality of life, and higher mortality. Therefore, we believe all methods should be used to slow the progression of renal disease and delay the onset of dialysis for CKD patients. The available methods include maintaining stringent control of blood pressure, use of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, maintaining glycemic control, targeting cardiovascular risk factors, and using controlled-protein diets to preserve the nutritional status of these patients. Before discussing the nutritional requirements of patients with CKD and the role of low-protein diets in the progression of renal disease, we clarify the commonly misunderstood term malnutrition in renal patients.

MALNUTRITION IN RENAL DISEASE

Malnutrition refers to abnormalities caused by an insufficient or imbalanced diet; hence, it should be cured simply by increasing dietary protein. Abundant evidence shows that patients with

CKD, including those treated by peritoneal dialysis or hemodialysis, have decreased body weight and subnormal values of serum proteins.³⁻⁵ The mechanisms for these abnormalities are complex and have not been fully identified, but assigning their cause to protein-energy malnutrition alone is misleading because they frequently cannot be overcome simply by supplying more food or altering the composition of the diet. Studies of rodents with experimental uremia and investigations of patients with kidney failure have suggested several other mechanisms that can account for fatigue, loss of lean body mass, and low serum proteins, the abnormalities mistakenly assigned to malnutrition (Fig. 66-1).⁶

Hypoalbuminemia and Inflammation

A low serum albumin level is clinically important because it is the strongest independent predictor of total and cardiovascular mortality in ESRD patients.^{4,5} Much has been made of low serum albumin being an index of malnutrition, yet there are several other causes besides malnutrition for low serum albumin and loss of protein stores in renal patients.⁶ The serum albumin concentration is influenced by age, fluid overload, capillary leakage, and inflammation in addition to the amount of dietary protein consumed.^{7,8} Regarding its clinical relevance, there is a strong association between the severity of atherosclerosis, a low serum albumin level, and high C-reactive protein level in CKD patients.⁹ In incident dialysis patients studied prospectively, malnutrition assessed by means of Subjective Global Assessment is best predicted by levels of C-reactive protein and interleukin-6 but not by serum albumin.¹⁰ In this

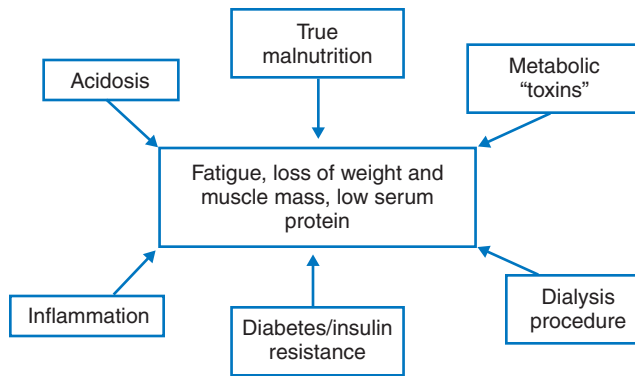

Figure 66-1 Factors leading to the fatigue, loss of lean body mass, and low serum proteins associated with loss of kidney function.

study, low serum albumin predicted mortality and a high interleukin-6 was the most reliable predictor of the presence of cardiovascular disease.¹⁰ In dialysis patients, albumin generation and serum albumin levels are negatively correlated with markers of inflammation, including C-reactive protein, fibrinogen, and interleukin-6.¹¹ Contact of blood with “foreign” surfaces, such as the hemodialyzer membrane or peritoneal dialysate, activates several humoral and cellular pathways, with higher levels of C-reactive protein and other pro-inflammatory cytokines.^{11,12} The common thread in inflammatory conditions that cause loss of muscle mass is activation of protein breakdown. This has been demonstrated repeatedly in models of sepsis and inflammatory conditions.¹³ These findings suggest that inflammation, mediated by pro-inflammatory cytokines, causes hypoalbuminemia, loss of lean body mass, and the development of cardiovascular disease in CKD patients. In summary, a normal or low serum albumin concentration may not accurately reflect total albumin mass and should not be used as the sole indicator of protein stores.

Metabolic Acidosis

Metabolic acidosis is common in kidney failure; it acts to stimulate the irreversible destruction of the essential, branched-chain amino acids and accelerates the degradation of protein, especially of muscles.^{14,15} Moreover, metabolic acidosis can cause endocrine abnormalities, including insulin resistance, decreased serum leptin level, and inflammation, among patients with CKD.¹⁶ Correction of acidosis in patients treated by chronic ambulatory peritoneal dialysis suppresses the ubiquitin-proteasome proteolytic system and leads to gain of body weight.¹⁷ Evidence also indicates that acidosis contributes to the low level of serum albumin in dialysis patients.^{18,19} Therefore, metabolic acidosis in CKD patients should be corrected because it contributes substantially to the abnormalities presumed to be caused by malnutrition.

Insulin Resistance

Because diabetes is a common cause of CKD and uremia causes resistance to the hypoglycemic action of insulin, it is likely that diabetes or insulin resistance causes abnormalities similar to those caused by malnutrition.²⁰ Experimentally, acute diabetes mellitus causes rapid loss of body weight and

muscle mass due to activation of the ubiquitin-proteasome proteolytic system in muscle.²¹ These catabolic responses are rapidly reversed by insulin but are independent of the acidosis of acute diabetes.²²

Another potential cause of ESRD-associated abnormalities in weight, muscle mass, and serum proteins is the hodgepodge of accumulated waste products and metabolic abnormalities caused by the loss of kidney function. Again, this mechanism is not directly connected to an inadequate diet. In fact, the contrary is true because an excess of protein-rich foods only increases the accumulation of waste products such as phosphates, acid, and nitrogen-containing products.²³ To date, no cause-and-effect association has been demonstrated between the accumulation of nitrogen-containing waste products and a specific syndrome, despite intriguing investigations about links between unidentified “middle molecules” and depressed appetite.²⁴

In summary, there are several adverse consequences of CKD, including the constellation of signs and symptoms glossed over as malnutrition. However, assigning these abnormalities to protein-energy malnutrition alone is misleading because these cannot be overcome by simply supplying more food.

ASSESSMENT OF NUTRITIONAL STATUS IN RENAL DISEASES

Because loss of lean body mass is a serious concern for patients with CKD, it is important to use longitudinal assessments of nutritional status to recognize substrate deficiencies early. No single method of assessment has been validated to accurately evaluate variables that affect nutritional status, so a number of indices are needed to define the nutritional status of patients (Box 66-1).

There must be a medical history for the type of renal disease and comorbid conditions, plus a physical examination. The dietary history should include the amount and patterns of nutrient intake, and a dietitian should obtain information about socioeconomic circumstances that could interfere with dietary needs. The energy level, appetite, physical activity, use of medications, and the use of dietary and herbal supplements, alcohol, and illicit drugs must also be documented.²⁵

The most common methods for estimating intake in patients with renal disease are dietary recalls, dietary diaries, and determination of protein equivalent of nitrogen appearance (PNA). The dietary recall (usually obtained for the previous 24 hr) is a simple, rapid method of obtaining a crude assessment of dietary intake.²⁶ Dietary diaries are written reports of foods consumed during a specified length of time (i.e., 3–7 days). However, the validity and reliability of dietary interviews and diaries depend on the patient’s ability to provide accurate data and the ability of the dietitian to conduct detailed and probing interviews.

Protein Equivalent of Nitrogen Appearance

This method for estimating protein intake is based on the concept that ingested nitrogen is equal to total nitrogen excretion if there is no change in body nitrogen pool. Ingested protein plus the products arising from endogenous protein are metabolized to several nitrogenous products (e.g., urea,

amino acids, peptides, urate, and creatinine). If nitrogen balance is neutral (neither catabolism nor anabolism), the nitrogenous products that are removed from the body through urine, stool, and skin plus any change in the body's urea nitrogen pool are equal to the nitrogen intake. Because urea is the principal nitrogen waste product, protein intake in stable CKD patients can be estimated from the urea appearance rate in urine.^{27,28} The urea nitrogen appearance rate (i.e., urine urea excretion plus accumulation) parallels protein intake, but nonurea nitrogen excretion (i.e., the nitrogen in feces and urinary creatinine, uric acid, ammonia, peptides, and so forth) does not vary substantially with dietary protein; it averages 0.031 g N/kg daily.

In the steady state (when blood urea nitrogen and weight are constant), the urea nitrogen appearance equals urinary urea nitrogen excretion. Consequently, nitrogen intake equals urinary urea nitrogen plus 0.031 g N/kg. To convert grams of nitrogen into its protein equivalent (PNA), multiply it by 6.25, because proteins on average consist of 16% nitrogen. This method of estimating protein intake can be used for assessment of compliance with a prescribed diet, as illustrated by the example in Box 66-2.

There are important limitations in interpreting urea-derived estimates of dietary protein intake. First, in catabolic states (e.g., acidosis, infection), endogenous protein breakdown can increase urea appearance so PNA will exceed protein intake estimates. Conversely, when a patient becomes anabolic, PNA will underestimate actual protein intake. Second, day-to-day variations in protein intake are reflected rapidly by the PNA, so a single measurement may not tell us about average

Box 66-2 Estimation of Protein Intake for a Patient Prescribed a Diet Containing 1 g protein/kg/day

A patient weighs 70 kg and the 24-hr urinary collection contains: volume 2400 mL, creatinine 1100 mg, protein 7 g, urea nitrogen 7.9 g

$$\begin{aligned} \text{Nitrogen balance (B}_N\text{)} &= \text{nitrogen intake (IN)} - \\ &\quad \text{urea nitrogen appearance (U)} - \\ &\quad \text{nonurea nitrogen excretion (NUN)}^* \\ \text{B}_N &= \text{IN} - \text{U} - \text{NUN} \end{aligned}$$

If the patient is in steady state and is compliant, nitrogen input equals output, therefore:

$$\begin{aligned} \text{IN} &= \text{U} + \text{NUN} \\ &= 7.9 \text{ g N/day} + \\ &\quad (70 \text{ kg} \times 0.031 \text{ g N/kg/day} + \\ &\quad 7 \text{ g urinary protein} \times 0.16) \\ &= 7.9 \text{ g N/day} + [2.17 \text{ g N/kg/day} + \\ &\quad 1.12 \text{ g N/kg/day}] \\ &= 11.19 \text{ g N/day} \end{aligned}$$

Assuming that protein is 16% nitrogen (i.e. conversion factor is 1/0.16 = 6/25), the patient is eating:
11.19 × 6.25 = 70 g protein/day

*Nitrogen in feces, urine creatinine, uric acid, other unmeasured nitrogen-containing compounds, and urinary protein > 5 g.

protein intake over the month. Finally, protein nitrogen appearance may not accurately estimate intake at extremes of protein intake. This is due to increased nitrogen losses through unmeasured pathways of excretion at higher protein intake and greater endogenous protein catabolism at lower protein intake.²⁹ Regardless, this method is much more accurate and reproducible than dietary history or recall methods.

Biochemical Values and Nutritional Assessment

Serum levels of albumin and prealbumin are often used as biochemical markers to assess visceral protein stores, to monitor the adequacy of responses to a nutritional intervention, and to identify patients who are at risk for complications or are responding poorly to medical/surgical treatment. However, there is substantial evidence that a low serum albumin level in CKD patients is generally due to inflammation rather than decreased dietary protein.³⁰ When comparative analysis of predictors of outcome in ESRD was studied, no significant difference in serum albumin levels was found between malnourished and well-nourished ESRD patients.³¹ The serum prealbumin concentration also reflects its role as a negative acute-phase reactant; it is influenced by inflammation and is thus considered to be no more sensitive or accurate than serum albumin as a marker of visceral protein stores.²⁶

Serum transferrin concentration is frequently reduced in renal failure independent of malnutrition, perhaps due to fluctuation in iron stores. Serum transferrin rises in iron deficiency, in pregnancy, and in the early phases of acute hepatitis; it decreases with certain chronic infections, liver diseases, cancer, and iron loading. In summary, no single serum protein measurement is ideal for detecting protein malnutrition.

Low serum bicarbonate levels in CKD patients usually reflect development of metabolic acidosis. In CKD and dialysis patients a low serum bicarbonate is also indicative of the amount of protein intake, because metabolism of amino acids, particularly cysteine and methionine, generates protons. As noted, metabolic acidosis affects nutrition by stimulating protein catabolism, and correction of acidosis decreases whole-body protein degradation.³² The serum creatinine level in CKD patients is reflective of the estimated glomerular filtration rate (GFR), but in ESRD patients it may have some nutritional significance as a reflection of muscle mass and a decrease in meat in the diet. Likewise, a low serum potassium level in CKD patients is mostly due to the use of diuretics, whereas in ESRD patients this finding should raise the suspicion of a poor nutritional intake.

Anthropometrics are used to assess adipose stores and lean body mass. This series of noninvasive, inexpensive measurements, which include body weight, percent of usual weight, skeletal frame size, body mass index, body fat, and fat-free mass, can be determined reliably.³³ A decline in anthropometric measurements can detect a loss of lean body mass during long-term evaluations. The key is to have consistency in the measurements, preferably by having them performed by a single individual. Unfortunately, very little data are available on how closely subnormal anthropometric values correlate with an adverse clinical outcome in CKD patients, and the techniques have been used only for research purposes. Cross-sectional studies of large groups of patients do show a linkage between large body size and reduced risk of mortality in hemodialysis patients.^{34,35} Body size is best estimated by body mass index, a measure of body fat based on height and weight that applies to both adult men and women. On the other hand, increased body mass index has been shown to be an independent risk factor for appearance of proteinuria, poor control of hypertension, adverse cardiovascular and mortality outcomes, and the progression of CKD.^{36–39}

Subjective Global Assessment

Subjective Global Assessment is a nutritional assessment technique based on evaluating subjective and objective patient information, including medical history and physical examination, gastrointestinal symptoms, body weight patterns, and patient functional capacity, plus the presence of comorbid conditions that could affect nutritional requirements. The patient is assigned to one of the three nutritional status groups: (A) well nourished, (B) mildly to moderately malnourished, or (C) severely malnourished. The Subjective Global Assessment method was developed for hospitalized patients but has been used to assess nutritional status and predict increased risk of morbidity and mortality in CKD and ESRD patients.^{40–42} Limitations of the Subjective Global Assessment include a heavy reliance on subjective judgment; it may not identify functional impairment due to malnutrition, and it also does not identify the type or amount of nutritional support needed to provide repletion of lost body protein stores. In summary, no single parameter has been defined to evaluate the variables that affect the nutritional status of CKD patients. Consequently, we recommend a complete nutritional evaluation using all the categories listed in Box 66-1.

MANAGEMENT OF NUTRITIONAL ISSUES IN CHRONIC KIDNEY DISEASE

The goals of dietary therapy for patients with CKD are to diminish the accumulation of nitrogenous wastes and limit the metabolic disturbances characteristic of uremia, to prevent malnutrition, and to slow the progression of renal failure. Protein-restricted diets improve uremic symptoms because they reduce the levels of uremic toxins, most of which result from the metabolism of protein. A low-protein diet also ameliorates specific complications of CKD, including metabolic acidosis, renal osteodystrophy, hyperkalemia, and hypertension, because a diet that is restricted in protein is invariably restricted in the quantities of sulfates, phosphates, potassium, and sodium eaten each day.^{43,44} These considerations explain why dietary protein restriction has been used for decades to treat chronically uremic patients. However, there are some fundamental concerns regarding use of low-protein diets in CKD patients: (1) Do they change the progression of renal failure? (2) Are low-protein diets safe? and (3) Does delaying the start of renal replacement therapy affect patient outcomes?

Low-Protein Diets and Progression of Chronic Renal Failure

A number of studies have examined the influence of dietary protein restriction on the progression of renal disease, but many of these reports suffer from problems in design, differences in measurement of efficacy, a limited sample size, the type of diet, and degree of compliance with the diet.

The randomized, controlled trials that have enrolled only insulin-dependent diabetes patients have shown improved preservation of kidney function in patients assigned to a low-protein diet when compared to patients eating unrestricted amounts of dietary protein.^{45–48} The number of diabetic patients studied in these trials was generally small, and the duration of follow-up was short. To examine this question in a larger number of patients, meta-analyses have been used; their results conclude that there is a significant benefit from low-protein diets in preserving the renal function of diabetic patients.^{49–51}

Trials enrolling nondiabetic and noninsulin-dependent diabetic CKD patients in a randomized fashion have not consistently demonstrated that dietary protein restriction slows progression, at least when analyzed according to the prescribed diet. In the largest trial to address this question, the Modification of Diet in Renal Disease (MDRD), patients were randomized to protein intakes of 1.3 and 0.6 g/kg per day, with or without aggressive blood pressure control; when renal failure was more advanced, protein intake was 0.6 g protein/kg/day or 0.28 g/kg/day supplemented with ketoacids.⁵² The intention-to-treat analysis of the results (i.e., the outcome regardless of whether patients did or did not ingest the prescribed diet) did not demonstrate a statistically significant benefit of the low-protein diet on the rate of loss of GFR. However, when the results were analyzed according to the degree of compliance with the low-protein diet, significant slowing of the loss of GFR was seen, as well as a substantial delay until patients reached the stage of disease when dialysis was required.⁵³ Similarly, all the other randomized trials (Table 66-1) studying the effect of protein restriction on the progression of renal disease suffered from significant

Table 66-1 Randomized Controlled Trials of Effect of Protein-restricted Diets on the Progression of Renal Failure

Ref.	Patients (N)	Mean Follow-up (mo)	Prescribed Protein for Randomized Groups (g/kg/day)	Actual Protein Intake (g/kg/day)	Outcome of Trial
Jungers et al ¹²⁰	14	9	0.6 vs. 0.4 + KA	0.7 vs. 0.4 + KA	Time to dialysis longer and mean slope of $1/S_{Cr}$ lower in KA group
Bergström et al ¹²¹	16	12–24	Unrestricted vs. 0.4 + EAA	0.86 vs. 0.65	Slope of $1/S_{Cr}$ and drop in CrCl similar
Ihle et al ¹²²	64	18	Unrestricted vs. 0.4	>0.75 vs. 0.4	Significantly less decrease in GFR and progression to end-stage in low-protein group
Rosman et al ¹²³	239	48	Unrestricted vs. 0.4–0.6	No data available	Renal survival better in low-protein group after 2 yr but no difference after 4 yr
Locatelli et al ¹²⁴	456	24	1.0 vs. 0.6	0.9 vs. 0.78	No difference in renal survival
William et al ¹²⁵	95	19	>0.8 vs. 0.6	1.0–1.14 vs. 0.69	Rate of fall of CrCl and $1/S_{Cr}$ similar
Klahr et al ⁵² Study A	585	26	1.3 vs. 0.58	1.1 vs. 0.77	The intention-to-treat analysis revealed no difference in GFR decline; when analyzed by degree of compliance low-protein group has significant slowing in GFR
Study B	255	26	0.58 vs. 0.28 + KA	0.73 vs. 0.48	No difference in slowing of GFR; on secondary analysis lower protein intake caused slower mean decline in GFR but no independent effect of KA
D'Amico et al ¹²⁶	128	27	1.0 vs. 0.6	1.1 vs. 0.8	Low-protein group had significant lower risk of progression

CrCl, creatinine clearance; EAA, essential amino acids; GFR, glomerular filtration rate; KA, ketoacids; S_{Cr} , serum creatinine.

differences in the prescribed and actual protein intake, thus confounding the interpretation of results.

Other shortcomings of the MDRD trial explain why this study did not find a slowing of loss of the renal function in CKD patients eating low-protein diets. First, the criteria for entering the MDRD study did not include a requirement that patients were, in fact, losing renal function; approximately 15% of the Study A control group had no evidence of progressive loss of GFR. This factor would increase the number of patients required to demonstrate a benefit from dietary manipulations. Second, the overall rate of loss of renal function in this study was slower than predicted.

Third, a disproportionate number of patients (~20%) had polycystic kidney disease. These patients are known to benefit minimally from dietary restriction, at least in terms of slowing progression of renal insufficiency, and so including these patients in the study might have obscured a benefit of the dietary manipulation. Fourth, patients in the MDRD study were not controlled for angiotensin-converting enzyme inhibitor therapy. Because these drugs can slow the loss of kidney function, their random use would make it more difficult to detect any benefit of eating a low-protein diet on preserving residual kidney function. Finally, the MDRD study lasted an average of only 2.2 years. This is

important because the patients with modest CKD (Study A) had an initial rapid loss of GFR just after initiation of the low-protein diet followed by a slower loss of GFR. The long-term (up to 6 years) follow-up of patients after completion of the MDRD trial failed to show conclusive benefit of dietary protein restriction on progression of renal insufficiency.⁵⁴ However, the patients were not given dietary protein targets nor was there any measurement of protein intake. It is difficult to make any decision about the impact of a diet with such information.

In summary, the evidence to date has not settled the debate as to whether a low-protein diet is effective in slowing the loss of residual renal function in a large proportion of CKD patients. A recent meta-analysis of low-protein trials in nondiabetic CKD favors the reduction of renal death by 31% as compared with higher or unrestricted protein intake.³³

Are Low-Protein Diets Safe?

Nonacidotic patients with CKD are remarkably efficient in adapting to dietary protein restriction. Goodship and associates showed that such patients reduce rates of amino acid oxidation and protein degradation in the same fashion as normal adults when their protein diet is restricted from 1.0 to 0.6 g/kg/day.⁵⁵ The same adaptive metabolic responses are activated when the diet is restricted to only 0.3 g/kg/day and a supplement of essential amino acids or their nitrogen-free analogues (ketoacids) is given. Such a dietary regimen maintains both neutral nitrogen balance and indices of adequate nutrition over 1 year of observation.⁵⁶ The supplement is required when the diet is so restricted to meet the requirements for essential amino acids.

The finding that dialysis patients often have low levels of serum proteins and evidence of malnutrition has led some to suggest that low-protein diets should be used cautiously or avoided in CKD patients and that early start of dialysis therapy should be considered.^{57,58} It is true that if CKD patients are not properly instructed and supervised, there may well be a spontaneous decrease in protein intake and deterioration of some nutritional indices. On the other hand, hypoalbuminemia in these patients can be linked as much to evidence of inflammation as it is to dietary inadequacy. In fact, CKD patients treated with low-protein diets were found to have an increase in serum protein concentrations at the initiation of dietary therapy.^{59,60} A low-protein diet is also associated with improved survival of CKD patients who subsequently began dialysis.⁶¹ Finally, there is abundant evidence that with proper implementation, a low-protein diet yields neutral nitrogen balance and maintenance of normal serum proteins and anthropometric indices during long-term therapy.^{56,62,63} Once on dialysis, patients treated with supplemented very low-protein diet rapidly increase their protein intake and gain in lean body mass.⁶⁴ In 5-year follow-up after initiation of renal replacement therapy, these patients revealed low mortality, correlating with age of the subject but not to nutritional parameters at the end of supplemented very low-protein diet therapy.⁵⁹

Does Delaying the Start of Renal Replacement Therapy Affect Patient Outcomes?

The Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines for initiation of dialysis were appropriately updated in 2006, shifting the focus from relying solely on a specific level of

GFR to include other factors, such as nutrition; acid-base and bone metabolism; homeostasis of potassium, sodium, and volume; and quality-of-life considerations.⁶⁵ Observational studies clearly indicate that patients with comorbidities are sent to dialysis therapy at a higher level of estimated GFR.^{65,66} The concerns about protein malnutrition in patients with delayed start of dialysis are unfounded. On the contrary, abundant evidence demonstrates that protein malnutrition is common in dialysis patients, suggesting that dialysis therapy could itself be a contributing factor to malnutrition.^{67–71} Finally, those studies reporting a negative impact of low residual renal function on survival at the start of dialysis therapy are flawed by failure to take into account *lead-time bias*, the effect whereby measuring survival from the start of dialysis increases apparent survival of those who begin dialysis with more residual renal function (i.e., earlier in the course of the disease) than those who start dialysis with less residual renal function.⁷² When CKD patients were followed from an estimated creatinine clearance of 20 mL/min, and divided into early and late start groups by the median estimated creatinine clearance (8.3 mL/min) for all patients at the initiation of dialysis, there was no benefit of survival from earlier initiation of dialysis.⁷³ More recently, Beddhu and colleagues examined data from the Dialysis Morbidity and Mortality Study, Wave 2, to evaluate if beginning dialysis at higher levels of creatinine clearance or GFR (estimated from the MDRD formula) would improve mortality.⁷⁴ They found an increase in mortality for each 5 mL/min increase in GFR at the initiation of dialysis. The authors concluded that there is insufficient evidence to advocate early initiation of dialysis. This observation is supported by another recent cross-sectional study that showed 2-year survival was determined by premorbid conditions rather than the timing of initiation of dialysis.⁷⁵ This argument is further strengthened by another recent study of patients age 70 years or older with very advanced CKD (GFR, 5–7 mL/min) but no uremic symptoms, when randomly assigned to initiate dialysis or supplemented very low-protein diet had similar 1-year mortality with fewer hospitalizations.⁷⁶

In summary, no substantial evidence demonstrates improved survival with early initiation of dialysis in ESRD, nor is it associated with a better health-related quality of life.⁷⁷ The results of clinical trials evaluating the effect of low-protein diets on the progression of CKD to date have not settled whether such diets will be effective in slowing the loss of residual renal function in a large proportion of patients. When properly applied, these diets do not lead to malnutrition, even in patients with advanced renal insufficiency.^{56,59,63} For these reasons, we recommend nutritional consultation be offered to all patients with moderate CKD, along with management of other important risk factors that affect progression of renal disease, such as optimal control of blood pressure, use of drugs blocking angiotensin II responses, treatment for hyperglycemia, and treatment for dyslipidemia. This wholesome approach requires education of the patient and interaction with a skilled dietitian who monitors intake of protein and calories and performs periodic assessment of the nutritional status of the patient.

Dietary Protein Prescription for Chronic Kidney Disease Patients

The optimum level of protein intake for patients with moderate to advanced CKD cannot be deduced from published

trials. In western societies typical protein intake by healthy individuals is 1 to 2 g/kg/day, well above the World Health Organization recommended daily protein allowance of 0.8 g/kg/day (minimum daily requirement is 0.6 g/kg/day).⁷⁸ In response to a decrease in the amount of protein eaten, healthy subjects can and will activate the following adaptive mechanisms to promote neutral nitrogen balance: (1) amino acid oxidation is suppressed, allowing more efficient utilization of dietary essential amino acids; (2) as dietary protein intake approaches 0.6 g/kg/day, another adaptive response is activated, suppression of protein degradation, along with increasing protein synthesis. The increase in protein synthesis is of less magnitude than the limitation of protein degradation. Notably, patients with uncomplicated CKD will activate the same metabolic responses to dietary protein restriction, even if the patient is eating only approximately 0.3 g protein/kg/day plus a supplement with nitrogen-free analogues of essential amino acids (ketoacids).^{56,62} Similar responses are activated in CKD patients with the nephrotic syndrome. In these patients, however, the degree of suppression of amino acid oxidation is pro-

portional to the net protein intake (the amount of dietary protein minus the urinary loss of protein).⁷⁹ These critical adaptive responses, which act to maintain protein balance, can be impaired by factors that are commonly present in CKD patients, such as metabolic acidosis, inflammation, and infection. Based on these findings, we support the K/DOQI recommendations that patients with advanced renal disease (GFR < 25 mL/min), with or without symptoms attributable to uremia or with uncontrolled progressive renal insufficiency, be treated with a well-planned low-protein diet providing 0.6 g protein/kg/day²⁶ (Table 66-2). For individuals who will not accept such a diet or who are unable to maintain adequate protein-energy intake with such a diet, an intake can be increased up to 0.8 g protein/kg/day. Further increment in protein intake will not only generate more urea, but will also contribute to metabolic acidosis and renal osteodystrophy through hyperphosphatemia. At least 50% of the protein intake for all of these patients should be of high biologic value. The diet should be designed by a nutritionist with an interest in the implementation of diets for CKD patients to take advantage of

Table 66-2 Recommended Nutrient Intake in Chronic Kidney Disease Patients

Nutrient	Daily Recommendations
Protein*	
GFR (mL/min/1.73m ²)	Amount of protein (g/kg of ideal body weight)
>50	No restriction recommended
25–50	0.6–0.75 controlled
<25	0.6 or 0.3 plus supplementation [†]
Renal transplant recipient	
Early phase or acute rejection	1.3
Stable phase	As CKD
Nephrotic patient	0.8 + 1 g of protein/g of proteinuria
Energy	
<60 yr old	≥35
>60 yr old	30–35
Carbohydrates	
	35% of nonprotein calories
Fat	
	Polyunsaturated-to-saturated ratio of 2:1
Phosphorus	
	800–1000 mg
	No restriction in transplant recipient if serum phosphorus is normal
Calcium	
	Should not exceed 2.5 g (dietary + calcium-based binders)
Potassium	
	Individualized
Sodium and Water	
	As tolerated, to maintain body weight and blood pressure

*At least 50% of proteins should be of high biological value.

[†]Mixture of essential amino acids and ketoacids.⁵²

the patient's food preferences and to ensure an adequate intake of calories and vitamins.

Energy Requirements

It is important to monitor energy intake because a diet containing too few calories will compromise the patient's ability to achieve nitrogen balance and lead to loss of muscle mass. It has been shown that a diet providing about 35 kcal/kg/day is necessary to maintain neutral nitrogen balance in patients with CKD.⁸⁰ Energy requirements for healthy CKD patients are not different from those for healthy adults.^{81,82} Unfortunately, there is no simple method of estimating calorie intake, so the clinician must rely on repeated measurements of weight and muscle mass plus input from the dietitian.

Bicarbonate Therapy

To date there has been only one published randomized, controlled trial of use of oral bicarbonate in patients with mild to moderate CKD.⁸³ Maintaining serum bicarbonate and 22 to 26 mmol/L results in attenuation of rise in blood urea nitrogen and parathyroid hormone compared to those given placebo. Correction of metabolic acidosis in CKD patients results in improved measures of nutritional status, such as Subjective Global Assessment and PNA, and reduced hospitalization rates.^{84,85} We recommend that predialysis patients or dialysis patients should have stabilized serum bicarbonate levels above 22 mmol/L.

Dietary Phosphorus

The increased incidence and severity of vascular calcification in uremia is attributed to the abnormalities of mineral metabolism, which are common in CKD patients, especially those on dialysis. Cross-sectional studies in patients with advanced CKD have clearly shown that the presence of arterial calcification is associated with adverse clinical outcomes, including myocardial infarction, congestive heart failure, endocarditis, valvular heart disease, and death.^{86,87} Vascular calcification is more common and severe in diabetic patients with stage 3 to 5 CKD compared to diabetics with an early stage or no CKD.^{88–90} For CKD patients on dialysis an association between elevated serum phosphorus, calcium-phosphorus product ($\text{Ca} \times \text{P}$), or elevated parathyroid hormone and the risk for all-cause mortality and cardiovascular disease is clearly established.^{91–93} These findings highlight the importance of controlling mineral metabolism from the early stages of CKD. When kidney function declines by 20% to 25%, phosphate retention develops; this plays a major role in causing secondary hyperparathyroidism even without detectable elevation of serum phosphorus levels. Thus, dietary counselling for reduced phosphorus intake should be instituted in patients with CKD who approach stage 3, limiting the intake of high-phosphorus foods, mainly dairy products and protein-rich foods. The recommended phosphorus intake for patients with hyperphosphatemia irrespective of the stage of CKD is 800 to 1000 mg/day.⁹⁴ For patients who in spite of dietary phosphorus restriction cannot control serum phosphorus levels, phosphate binders are required. For patients who have a high serum calcium-phosphorus product, the initial choice should be a noncalcium-containing phos-

phorus binder. If necessary, aluminum hydroxide should be used for only brief periods (especially in dialysis patients) to reduce the risk of aluminum toxicity. When serum calcium is low, calcium-based phosphate binders (carbonate or acetate) are effective and inexpensive.

Dietary Calcium

Biochemical measurements are not reflective of calcium nutritional status in subjects with normal kidney function nor in patients with CKD.⁹⁴ The major indirect measures of calcium nutritional adequacy are skeletal health assessed by risk of fractures, bone mass measurements, and desirable rates of calcium retention. Based on these surrogate markers, the recommended adequate intakes of calcium in healthy adults is about 1.3 g/day, with a tolerable upper level of 2.5 g/day.⁹⁵ In CKD patients decreased intestinal calcium absorption is thought to be linked to vitamin D deficiency; because an excess of phosphates in intestinal secretions will bind calcium, the CKD patient requires a higher intake of elemental calcium. Still the total should not exceed 2500 mg/day, including both dietary sources and calcium from phosphate binders.⁹⁶ As CKD progresses and patients are also prescribed vitamin D analogues to control secondary hyperparathyroidism, there is risk for developing hypercalcemia or elevated serum calcium-phosphorus product ($\text{Ca} \times \text{P}$); thus, calcium-based drugs should not be the phosphate binders of choice. Again, dietary education is critical because dietary indiscretion, even by patients who are compliant with phosphate binders, leads to a rise in the calcium-phosphorus product, increasing the likelihood of spontaneous precipitation of calcium and phosphorus throughout the body.

Sodium

Control of blood pressure should be a part of any strategy directed at slowing the progression of CKD.⁵² It is easy to achieve a recommended 2-g sodium diet when dietary protein is restricted; it will potentiate the efficacy of antihypertensive medicines.^{43,97} Moreover, in edematous states, it is difficult if not impossible to achieve a net loss of sodium (and hence, extracellular volume) with diuretics unless dietary sodium is restricted.

Trace Elements and Vitamin Requirements

In uremia, there are significant alterations in blood and tissue concentrations of trace elements and vitamins. These derangements are due to a decrease in glomerular filtration, impaired tubular function, and protein binding of micronutrients. In addition, an inadequate diet or altered gastrointestinal absorption in patients with advanced uremia may limit the absorption of trace elements and vitamins. The water-soluble vitamin requirements for CKD patients are not different from those for healthy adults.⁹⁸ Pharmacologic doses of folic acid have been recommended for lowering plasma homocysteine levels, but whether this decreases cardiovascular risk in renal patients is yet to be established. Results of the two ongoing multicenter clinical trials are expected to provide more conclusive evidence as to whether lowering homocysteine levels in CKD patients with folic acid or vitamin B reduces the risk of cardiovascular

disease.^{99,100} Current expert opinion suggests that it is prudent to supplement rather than risk the deficiency, especially when supplementation is safe at the recommended level.¹⁰¹ Serum levels of 25-hydroxyvitamin D, as a measure of body stores of vitamin D, are decreased in patients with stage 4 or higher CKD as compared to the general population.¹⁰² In these patients, 25-hydroxyvitamin D insufficiency (<30 ng/mL) increases risks for secondary hyperparathyroidism, increased prevalence of vertebral fracture, and insulin resistance; it also has a possible role in the progression of renal disease.^{102–104} We recommend measuring 25-hydroxyvitamin D level in all patients with stage 3 or higher CKD, irrespective of serum parathyroid hormone levels. For those patients with serum 25-hydroxyvitamin D insufficiency, supplementation with an oral vitamin D, such as ergocalciferol 50,000 IU every month for 6 months, is recommended. For more severe 25-hydroxyvitamin D deficiency (<15 ng/mL), the same dose should be given weekly for the first 3 months.⁹⁴ Vitamin C intake should be limited to 100 mg/day, because higher doses of supplementation can lead to tissue deposition of oxalate crystals, hastening renal insufficiency and increasing the risk of myocardial infarction, shunt failure, and muscle weakness in dialysis patients.¹⁰⁵ Vitamin A and retinol-binding protein plasma levels are increased in renal patients, so vitamin A–containing multivitamin preparations for kidney disease patients should be avoided. There is no evidence that vitamin E reduces the risk of cardiovascular events and routine supplementation is not recommended.¹⁰⁶

In summary, the daily requirements for most trace elements and vitamins in renal patients are quite similar to those of healthy adults.⁹⁸ Patients with CKD who do not have a good appetite are advised to take B-complex vitamin, along with folic acid. Some of the common prescription brands with this combination include Nephro-Vite, Nephrocaps, and Nephroplex.

NUTRITIONAL ISSUES IN RENAL TRANSPLANT PATIENTS

A successful renal transplant into a patient with ESRD restores near-normal renal function and is expected to correct the nutritional abnormalities arising from uremia. The renal transplant recipient typically experiences a marked improvement of appetite, leading to weight gain. Nevertheless, these patients face many nutritional challenges that demand close dietary monitoring. The commonly prescribed immunosuppressives (i.e., corticosteroids, calcineurin inhibitors, and sirolimus) are known to induce metabolic adverse effects, such as protein hypercatabolism, hyperlipidemia, glucose intolerance, hyperkalemia, hypophosphatemia, hypomagnesemia, and obesity. The nutritional status after transplant is also determined by preexisting medical conditions, such as protein losses, renal osteodystrophy, hyperlipidemia, and cardiovascular disease. Moreover, these patients suffer from declining renal function due to recurrent acute or chronic rejection, varying degrees of proteinuria, hypertension, and poorly controlled diabetes. In the early postrenal transplant period the nutritional challenge is to counter the metabolic effects of protein hypercatabolism, hyperlipidemia, and hyperglycemia. For the stable transplant recipient, the nutritional status should be optimized, including weight gain, obesity control, and lipid control. With a failing

graft, nutritional management is similar to that recommended for advanced CKD.

Dietary Protein and Calorie Prescription for Renal Transplant Patients

Soon after transplantation, there is a marked increase in amino acid and protein catabolism due to the use of large doses of steroids plus surgery-related stresses. Patients with preexisting malnutrition are at risk for poor wound healing and susceptibility to infection. Based on these concerns, a dietary protein intake of 1.3 g/kg body weight/day is recommended for the early postrenal transplant patient.¹⁰⁷ However, these recommendations are based on only a few nitrogen balance studies. The optimum dietary protein intake for transplant patients on maintenance immunosuppressive therapy is not well established. Transplant recipients have been shown to maintain neutral nitrogen balance on a low-protein intake of 0.6 g/kg/day as long as their energy intake is maintained at least 28 kcal/kg/day.¹⁰⁸ Results of a 12-year follow-up on renal function in transplant recipients consuming protein intake of 0.8 g/kg/day compared to those with protein intake of 1.4 g/kg/day showed those with the lower protein intake maintained unchanged renal function, whereas patients with the higher protein intake lost more than 40% of excretory efficiency.¹⁰⁹ Based on limited available data, it is reasonable to recommend protein intake of 0.8 g/kg/day along with minimal energy intake of 30 to 35 kcal/kg/day for stable renal transplant patients. Those patients with progressive graft failure should have a more stringent protein intake of 0.6 g/kg/day, because there is evidence that a low-protein diet is also associated with a reduction in proteinuria and decreased activity of the renin-angiotensin system.¹¹⁰ During an acute rejection episode requiring treatment with high doses of corticosteroids, protein catabolism increases, yielding high blood urea nitrogen levels. Protein restriction in such patients can lead to severe negative nitrogen balance, so increasing protein intake to 1.2 g/kg/day is appropriate.

Obesity, defined as body mass index of more than 30 kg/m² or more than 130% ideal body weight, is present in 12% to 40% of recipients within 1 year after renal transplant.^{111,112} Obesity is associated with decreased graft survival and increased prevalence of cardiovascular disease after transplantation.^{113,114} For stable transplant recipients who require weight reduction, a caloric intake of 25 kcal/kg/day along with appropriate dietary and lifestyle measures, including an exercise program, should be recommended. Weight reduction diets in obese, hyperlipidemic transplant recipients cause a modest reduction in cholesterol levels, although statin drugs are usually required.¹¹⁵ The American Heart Association one-step diet is a reasonable initial approach for hyperlipidemic renal transplant patients. This diet, consisting of less than 300 mg of cholesterol per day (with a goal of <250 mg/day), 30% total calories as fat, 50% as carbohydrate, and 20% as protein, is easily attainable and is familiar to renal dietitians.¹¹⁶

Dietary Phosphorus and Calcium after Renal Transplantation

Transient hypercalcemia and low-normal serum phosphorus levels can be observed after a successful kidney transplant. These

biochemical changes are due to persistent hyperparathyroidism, improved parathyroid hormone sensitivity, and recently described non-parathyroid hormone humoral factor.^{117,118} A phosphaturic action of steroids must also be considered; an increase in serum phosphorus levels after reduction of steroid doses has been reported.¹¹⁹

The major improvement over a patient's pretransplant renal diet is the liberalization of dietary phosphorus. Nevertheless, oral phosphate supplements are required for periods of up to 1 year after renal transplant. In the absence of hypercalcemia, calcium intake through diet and supplements should be limited to about 1000 to 1500 mg/day.

In summary, a successful renal transplant allows greater dietary freedom and resultant weight gain. Immunosuppressive medications contribute to the protein hypercatabolism, hyperlipidemia, hyperglycemia, and propensity toward weight gain. Protein requirements during the early phase are similar to the requirements of healthy adults. As GFR declines with failing graft, protein restrictions similar to those for CKD patients are re-instituted. Further, maintenance of optimal body weight, along with changes in lifestyle measures, including an exercise program, should be part of nutritional management in all renal transplant recipients.

Anemia is a common problem for chronic kidney disease (CKD) patients. It may occur relatively early in the course of CKD and cause significant symptoms such as dyspnea and fatigue. By end-stage renal disease (ESRD) the majority of patients have significant anemia. Anemia is associated with important medical complications such as cardiac hypertrophy and an increased risk of death.¹ The clinician's task is to recognize the presence of anemia, to conduct an appropriate diagnostic evaluation, and to initiate treatment and monitor its effectiveness.

PATHOPHYSIOLOGY

The anemia of CKD is multifactorial in origin, but erythropoietin deficiency is the most important etiologic factor.² Erythropoietin is a glycoprotein hormone produced in renal peritubular cells. It stimulates erythropoietic progenitor cells in the bone marrow. Its greatest effect is on erythroid colony-forming units, cells that bear the highest concentration of erythropoietin receptors of any erythroid precursor.³ When erythropoietin is not present, these cells rapidly undergo necrosis and apoptosis. Erythropoietin facilitates the survival of and increases the colony-forming units erythroid that are maturing into precursors of erythrocytes, including the first circulating form, the reticulocyte.

Under normoxic conditions, erythropoietin is produced at low, relatively continuous levels. When tissue hypoxia is present, erythropoietin production is greatly increased, with serum concentrations increasing 100- to 1000-fold. Hypoxemia or anemia may stimulate erythropoietin production; the presence of tissue hypoxia is sensed by the recently identified hypoxia inducible factor-1 (HIF) complex.⁴ One component of this dimeric compound, HIF-1 α , is rapidly degraded under normoxic conditions. When hypoxia is present, dimerization with HIF-1 β occurs, yielding a HIF-1 complex that stimulates the activation of more than 90 oxygen-sensitive genes including erythropoietin.

Serum erythropoietin levels tend to be elevated by CKD, but are still insufficient for the degree of anemia present.^{5,6} Some degree of response to anemia is maintained, at least until the late stages of CKD, but when creatinine clearance is less than 40 mL/min, the hemoglobin (Hgb) and serum erythropoietin concentrations become somewhat dissociated. Even in dialysis patients, however, a small erythropoietic response remains. In certain renal diseases, such as polycystic kidney disease, erythropoietin production may be somewhat preserved.

After the classic experiments of Eschbach and Adamson, the primary role of erythropoietin deficiency became clear. However, the relative importance of erythropoietic inhibitors remains controversial.⁷ Both the beneficial effect of dialysis on improving anemia and the demonstration of a shortened erythrocyte half-life in ESRD suggest that there is at least some contribution of circulating inhibitors of erythropoietic responses to the anemia of kidney disease.

DEFINING ANEMIA IN CHRONIC KIDNEY DISEASE

The absolute Hgb level that defines anemia in CKD has been determined by the National Kidney Foundation's Kidney Disease Outcome Quality Initiative anemia guidelines as a level of less than 13.5 for men and 12.0 for women.⁸ Periodic measurement of Hgb, to screen for anemia, is necessary for managing patients with CKD. The Kidney Disease Outcome Quality Initiative guidelines recommend testing at least once per year, but the decision to test for anemia first requires that CKD has been recognized, and this can sometimes prove problematic. For example, in older adults with mildly elevated serum creatinine, a clinician may fail to appreciate that there has been a substantial loss of renal function. Specifically, a 70-year-old woman with a serum creatinine level of 1.5 mg/dL has a creatinine clearance less than 50 mL/min, yet this level of serum creatinine may obscure the diagnosis. Failure to diagnose CKD and

recognize the associated anemia is a missed opportunity to improve the patient's life through treatment.

IMPACT OF ANEMIA IN CHRONIC KIDNEY DISEASE

The primary adverse effect of anemia in CKD is the development of unpleasant symptoms such as fatigue and dyspnea that impair the individual's quality of life.⁹ Symptoms are due to the direct as well as the compensatory biologic effects of anemia. Decreased erythrocyte mass results in decreased oxygen-carrying capacity to the body's tissues and organs. The reduction in oxygen delivery leads to compensatory changes such as increased cardiac output and vasodilation. This increases tissue perfusion and partially offsets the reduction in blood oxygen-carrying capacity, but there is a cost: increased cardiac work leading to cardiac hypertrophy and increased risk of cardiovascular disease.

The reduction in quality of life from anemia has been well documented. Treatment for anemia in CKD patients results in partial recovery, rehabilitation, and restoration of well-being.⁹⁻¹² There is general improvement in quality of life on partial to full correction of anemia. In an early study, Delano¹⁰ treated 37 hemodialysis patients with epoetin to achieve partial correction of anemia. The mean hematocrit increased from 19.8% before therapy to 31.5% after therapy, and there was an improved sense of well-being in 84% of patients, with improvements in appetite (81%), sexual function (62%), socializing (70%), and sleep (68%).

Anemia in CKD has also been associated with left ventricular hypertrophy, an increase in the risk of hospitalization, and mortality.¹³⁻¹⁷ It is unclear whether the relationship to mortality and hospitalization risk is causal as treatment studies have generally not demonstrated these benefits in outcomes.¹⁸⁻²¹ In contrast, the relationship to left ventricular hypertrophy is more likely to be causal, given the increased workload of the heart when anemia is present. Levin and colleagues²² found the association to be strong; each 1-g/dL decrease in Hgb was associated with a 6% increase in risk of left ventricular hypertrophy (LVH).²² The prevalence of LVH increases in relation to lower levels of kidney function, reaching 74% at the initiation of hemodialysis.²³ Despite the clear association between anemia and LVH in CKD, treatment studies have generally not found a decrease in LVH with erythropoietin treatment.^{20,21,24}

EVALUATION OF ANEMIA IN CHRONIC KIDNEY DISEASE

The intensity of the ensuing evaluation and treatment depends to an extent on the significance of symptoms. The clinician must ask directed questions of the patient related to energy, fatigue, shortness of breath, chest pain, and other symptoms. Symptoms may develop gradually, and the patient may partially compensate with restrictions in activities. To avoid this misdiagnosis, questions should probe changes in activity level, and the patient should be asked to compare current capabilities to previous abilities.

The diagnostic evaluation should be based on the premise that although most anemia in CKD proves to be due to erythropoietin deficiency, other causes of anemia may be present

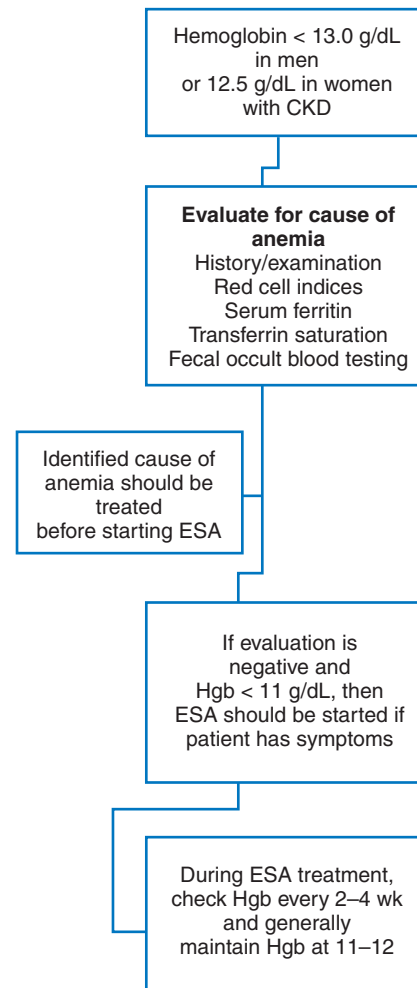

Figure 67-1 Algorithm for anemia evaluation in chronic kidney disease (CKD). ESA, erythropoiesis-stimulating agent; TSAT, transferrin saturation.

(Fig. 67-1). One of the most common management errors is to falsely assume that erythropoietin deficiency is causing anemia and to miss an important diagnosis such as gastrointestinal bleeding or vitamin B₁₂ deficiency. In summary, any cause of anemia present in the age-related normal population of adults can cause anemia in CKD patients.

Because the diagnosis of erythropoietin deficiency is one of exclusion, the evaluation should focus on excluding other causes of anemia with an appropriate history, examination, and laboratory testing. The complete blood count should be reviewed for any related problems in the leukocyte or platelet cell lines. Red blood cell indices should be examined, and the anemia classified as microcytic, normocytic, or macrocytic. The anemia of kidney disease usually results in a normocytic erythrocyte classification. If microcytosis is present, then iron deficiency, thalassemia, and myelodysplasia should be considered. With macrocytosis, folic acid and vitamin B₁₂ deficiency must be excluded. Fecal blood testing should be performed to evaluate for occult gastrointestinal bleeding. Serum ferritin and transferrin saturation should be measured to exclude iron deficiency. When there are appropriate clinical problems, multiple myeloma should be considered.

If the initial diagnostic evaluation is unrevealing, then a diagnosis of renal anemia due to erythropoietin deficiency is most likely. There is no utility in measuring serum erythropoietin because the deficiency is relative, not absolute (serum erythropoietin levels are generally higher in CKD patients compared with adults without kidney disease). However, the serum level is insufficient for the degree of anemia present, indicating that there is a relative deficiency. When ESRD is present, erythropoietin levels are substantially decreased, and overt erythropoietin deficiency is present.

TREATMENT OF THE ANEMIA OF CHRONIC KIDNEY DISEASE

General Concepts

After other causes of anemia have been excluded, treatment should be considered. Until recently, erythropoietin therapy involved only the administration of recombinant human erythropoietin. However, there are drugs currently in development that increase erythropoiesis without being erythropoietin analogues. Consequently, the preferred acronym is therapy with erythropoiesis-stimulating agents (ESAs).

The established benefits of ESA treatment are avoidance of blood transfusion and improvement in quality of life. However, the literature does not support an evidence-based Hgb level at which treatment should be initiated. The Kidney Disease Outcome Quality Initiative 2007 anemia update recommends that treatment of anemia should be individualized based on a patient's clinical characteristics.²⁵ If a patient has a decreased Hgb but no decrement in his or her quality of life, there is no pressing need to initiate ESA treatment. For example, if the Hgb is 10.2 g/dL, but there are no symptoms present and the patient is highly active, then treatment should not be initiated. In contrast, if symptoms are present, then treatment should be started when Hgb is less than 11 g/dL. Furthermore, if the patient has symptoms such as fatigue and dyspnea or feels cold despite Hgb levels higher than 12 g/dL, then treatment can be initiated (but the ESA costs may not be reimbursed). However, the latter clinical condition is unusual, and ESA treatment should not be used to increase Hgb to more than 13 g/dL because of the increased risk of adverse outcomes (see later).

Treatment with Erythropoiesis-Stimulating Agents

Because an adequate supply of iron is required for an optimal response to ESA, iron deficiency must be treated before initiating ESA therapy. Once the patient is iron replete, ESA dosing

should begin. Unfortunately, there have been few studies that compare different strategies of initiating ESA treatment. A reasonable approach is to correct anemia in a gradual, gentle manner, avoiding overshoot of the Hgb to more than 12 to 13 g/dL. Specifically, an increase in Hgb of 1 g/dL per month will improve symptoms while reducing the risk of complications such as uncontrolled hypertension.

For patients with CKD, ESA treatment is often inconvenient and requires extra office visits, so a goal of therapy should be to avoid excessively frequent drug administration. In our clinic, we usually initiate treatment with either epoetin alfa or darbepoetin alfa, with injections once every 1 to 2 weeks (Table 67-1). Some patients may require more frequent injections, but most patients will have a beneficial response with this approach. For hemodialysis patients, ESAs are often administered intravenously three times weekly because of the convenience of readily available intravenous access. However, there is no pharmacologic or medical reason for such frequent injections and less frequent injections can be effective in achieving the desired Hgb level.

The ability to extend dosing intervals may vary with the ESA; darbepoetin alfa has differences in its sialic acid composition that prolong its serum half-life compared with epoetin alfa.²⁶ However, the lack of comparative studies between epoetin alfa and darbepoetin alfa makes it difficult to differentiate between the drugs with respect to extended dosing intervals in nondialysis CKD. Studies for each drug have suggested that the dose interval can be extended to once monthly in selected patients.^{27,28} A drug currently in development, CERA (continuous erythropoietin receptor activator), has a serum half-life 5 to 16 times as long as that of epoetin alfa and has been found to maintain stable Hgb levels with monthly dosing.²⁹

When initiating ESA treatment, Hgb and iron stores should be assessed every month. Monthly iron testing during ESA treatment initiation is necessary due to the rapid transfer of iron from storage tissues to the erythron as Hgb levels increase. Many patients will develop iron deficiency during this period, resulting in diminished response to ESA therapy. This is particularly true for hemodialysis patients, in whom iron stores are also challenged by repeated blood loss. Obviously, if the Hgb is increasing too slowly or rapidly, then the ESA dose should be decreased accordingly.

The treatment target published in the Kidney Disease Outcome Quality Initiative anemia guidelines is an Hgb level of 11 or 12 g/dL. As with all clinical practice guidelines, clinical judgment must be used when applying this recommendation in the context of an individual patient. The guidelines recommend not targeting Hgb levels greater than 13 g/dL. With the Hgb level in this range, the clinician must assess the patient's

Table 67-1 Erythropoiesis-Stimulating Agent Treatment for Patients with Chronic Kidney Disease

	IV Half-life	FDA Label Dose	FDA Label Dose Interval	Comments on Actual Clinical Practice
Epoetin alfa	8 hr	50–100 U/kg	tid	Often converted to once-weekly or less frequent administration
Darbepoetin alfa	25 hr	0.45 µg/kg	Once weekly	Often given every 2 wk or less frequently
CERA placeholder	134 hr			

CERA, continuous erythropoietin receptor activator.

symptoms; if fatigue or dyspnea persists, then cardiovascular, pulmonary, or other causes of symptoms should be pursued.

Complications of Erythropoiesis-Stimulating Agent Treatment

The primary complication found during treatment with ESAs is the development or worsening of hypertension.³⁰ It is likely that this occurs in 20% to 30% of patients treated.³¹ The mechanism has not been fully elucidated but may relate to loss of the compensatory vasodilatation that should occur with anemia.³² Because hypertension is a cardiovascular risk factor and there is a high prevalence of cardiac disease among CKD patients, avoiding uncontrolled hypertension is critically important. Furthermore, in CKD patients who are in the predialysis stage of their disease, hypertension plays a central role in determining progression of kidney disease (see Chapters 60 and 62).

There does not appear to be significant differences between the risk of hypertension with different ESAs, but with all ESAs, avoidance of excessively rapid increases in Hgb is important. An overshoot to Hgb levels of more than 13 g/dL will increase the risk of cardiovascular diseases. If blood pressure increases during therapy, then the antihypertensive drug regimen should be adjusted accordingly. If severe hypertension develops, then the ESA should be temporarily held. It is rare for permanent cessation of therapy to be required.

Other complications of ESA treatment are rare. Seizures and encephalopathy were reported during early trials of epoetin alfa, probably related to hypertension and excessively aggressive treatment.^{33–35} These complications rarely occur with appropriate monitoring. Pure red cell aplasia, a condition detected by severely diminished erythropoiesis due to the development of antierythropoietin antibodies, was reported in Europe, peaking in 2002.^{36–38} Cases outside of Europe were extremely rare. The majority of cases occurred with subcutaneous injection of epoetin alfa, and the patients lost all response to ESAs, becoming transfusion dependent. The cause of this problem was determined to be a change in the manufacturing practice, and correction of the problem has essentially eliminated pure red cell aplasia.

The Risk of Mortality with Higher Hemoglobin Levels

In March 2007, the U.S. Food and Drug Administration revised prescribing instructions for ESAs to include substantially higher levels of warnings related to safety. This followed the publication of two studies, the Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta (CREATE) and Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR); both studies uncovered strong trends for increased risk of death with ESA treatment designed to achieve higher Hgb targets.^{24,39} Three published studies, CHOIR, CREATE, and the Normal Hematocrit Cardiac Trial, included 3268 hemodialysis and nondialysis CKD patients. Each study revealed a trend for an increased risk of death from 21% to 48% with higher Hgb targets (*P* values of .07, .08, and .14, respectively).^{18,24,39} Taken together, these studies and related results from studies of cancer patients have created strong and consistent evidence that indicates that using ESAs to target Hgb levels greater than 13 g/L is

harmful. Accordingly, the 2007 update to the Kidney Disease Outcome Quality Initiative anemia guidelines warns against targeting Hgb greater than 13 g/dL.²⁵

Suboptimal Responses to Erythropoiesis-Stimulating Agent Treatment

The response of an individual patient to ESA treatment is highly variable. Approximately 10% to 20% of patients have significant degrees of hyporesponsiveness.^{40,41} The definition used for hyporesponsiveness varies but operationally is defined as difficulty maintaining Hgb levels greater than 10 to 11 g/dL. In some patients, the Hgb level can be maintained only with very high doses of ESAs (e.g., epoetin alfa doses greater than 36,000 U/kg in a hemodialysis patient).

When ESA hyporesponsiveness is present, the underlying reason should be sought. The most frequent and therapeutically important cause is iron deficiency.⁴² In hemodialysis patients, repeated losses of blood in dialysis lines and filters, frequent blood testing, surgery, and access bleeding cause iron deficiency. The incidence of iron deficiency in CKD patients is not clear, but it probably occurs less frequently than in hemodialysis patients.

Diagnosis of iron deficiency in CKD patients has been primarily based on the use of two tests: serum ferritin and transferrin saturation. Serum ferritin is a reflection of iron storage but can be greatly affected by other factors such as inflammation, infection, and nutritional status.^{43,44} These noniron effects dilute the ability of serum ferritin to diagnose iron deficiency in CKD accurately. In fact, the sensitivity of serum ferritin (100–200 ng/mL) as an index of true iron deficiency in patients on hemodialysis has usually been found to be less than 50%.^{45–47} Transferrin saturation is calculated as serum iron divided by total iron binding capacity (closely related to the serum transferrin concentration). It is a reflection of the small but important pool of circulating iron. It is a more sensitive marker of iron status in CKD patients than serum ferritin, but it is less specific. Therefore, the characteristics of these tests result in a difficult clinical paradox: the serum ferritin level is often very high, concomitant with a low level of transferrin saturation. These divergent data leave the clinician with a diagnostic and therapeutic dilemma, one that is currently difficult to unravel.

Treatment with iron is frequently necessary for patients treated by hemodialysis (Fig. 67-2). A series of studies has found that oral iron has no demonstrable efficacy in these patients. In contrast, intravenous iron treatment is highly effective and in studies in which the Hgb level has been maintained within a target range, intravenous iron treatment can reduce the ESA dose requirements by 25% to 75%.^{48–56} In clinical practice, this translates into the ability to achieve Hgb levels greater than 11 g/dL more consistently.

There are currently three intravenous iron drugs that are widely available (Table 67-2). Iron dextran is highly effective but associated with occasional anaphylactic reactions.^{57,58} Ferric gluconate and iron sucrose are nondextran forms of iron that probably have a much lower risk of anaphylaxis. In hemodialysis patients, a typical treatment strategy is to administer 1000 mg when iron deficiency develops. The treatment regimen is to give divided doses of 50 to 125 mg at successive hemodialysis treatments. An alternative approach to treatment is the periodic and regular administration of smaller doses of

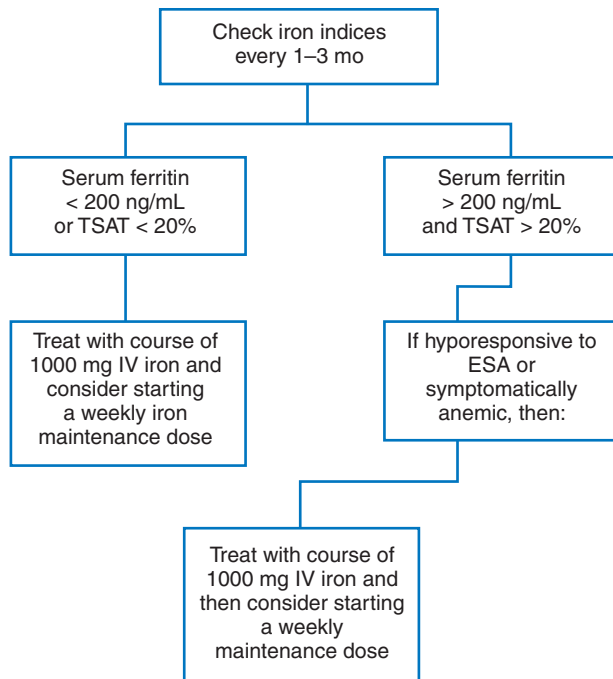

Figure 67-2 Algorithm for iron management in hemodialysis.

intravenous iron (e.g., iron sucrose 50 mg/wk). It is unclear which of these approaches is more effective.

In undialyzed CKD patients or those treated by peritoneal dialysis, iron deficiency probably occurs less frequently than in hemodialysis patients, but the efficacy of oral iron in these groups of patients has not been established as no studies comparing oral iron treatment with placebo or no iron treatment have been published. Still, we recommend assessing iron stores regularly because most patients treated with ESAs generally require iron supplements to support increased erythropoiesis adequately. A generic oral iron supplement may be sufficient for most patients.

The role of intravenous iron in nondialysis CKD or peritoneal dialysis patients has not been established. In nondialysis

CKD patients, there have been four randomized, controlled trials comparing intravenous iron with oral iron treatment.⁵⁹⁻⁶² Two of the four showed no significant difference in efficacy between the groups. The other two studies found superior efficacy for intravenous iron. In the latter studies, there was only a modest degree of benefit. Intravenous iron treatment is inconvenient in nondialysis CKD patients, and occasionally severe hypotension occurs. When these considerations are balanced against only a modest benefit of intravenous iron, it appears clear that intravenous iron should be reserved only for nondialysis CKD patients with severe iron deficiency.

Other causes of ESA hyporesponsiveness include the presence of inflammation, infection, hyperparathyroidism, excessive blood loss, and superimposed hematologic diseases such as megaloblastic anemia and myelodysplasia.⁴¹ Of these, inflammation may be the most important. A number of reports indicate that inflammation, usually signified by elevated C-reactive protein levels, is strongly associated with decreased ESA responsiveness.^{44,63} The mechanisms by which inflammation hinders response to ESA treatment are multifactorial. One important component is a reduction in iron utilization and availability. When inflammation is present, the hepatic protein hepcidin blocks entry of iron from intestinal absorption and release of stored iron in tissues into the circulation.⁶⁴ The effect is that less iron is available for erythropoiesis. Although the cause of inflammation is often not clear, when present, as indicated by elevated CRP levels, an evaluation for occult infection should be conducted. Nassar and colleagues⁶⁵ have reported that infections in unused arteriovenous grafts may be a common cause of inflammation and ESA hyporesponsiveness. They found that removal of the infected graft led to a significant improvement in ESA response.

Anemia, defined by the World Health Organization as a hemoglobin (Hb) level less than 13 g/dL in males and postmenopausal females and less than 12 g/dL in premenopausal females,¹ is present virtually in all patients with chronic kidney disease (CKD), including patients with impaired renal function, renal transplant recipients with allograft dysfunction, and those treated with long-term dialysis.²⁻⁴

The prevalence of anemia in CKD depends in part on the study population and in part on the level of Hb defined as constituting anemia. In a Canadian multicenter cohort study of patients referred to nephrology services, the prevalence of anemia was 25% in patients with creatinine clearance greater than 50 mL/min and increased stepwise to 87% when creatinine clearance was less than 25 mL/min.⁵ In another cross-sectional study of adult patients with CKD, the mean level of Hb was 12.8 ± 1.5 in patients with CKD stage 1 and 2, 12.4 ± 1.6 in CKD stage 3, 12.0 ± 1.6 in CKD stage 4, and 10.9 ± 1.6 g/dL in CKD stage 5.⁶ The Kidney Disease Outcome and Quality Initiative (K/DOQI) clinical practice guidelines and clinical practice recommendations for anemia in chronic kidney disease concluded that there is a definite trend toward lower Hb levels at lower levels of glomerular filtration rate.⁷

The anemia of renal failure is characterized by normocytic and normochromic red blood cells, a low reticulocyte count for the degree of anemia, and a hypoplastic erythroid series in the bone marrow with normal leukopoiesis and megakaryocytopoiesis.⁸ The red cell mass and its adaptation to changes in oxygen need depend on erythropoietin. Both the oxygen sensor and the site of synthesis of erythropoietin (peritubular capillary endothelial cells) are in the renal cortex.⁹ Erythropoietin is detectable in blood after bilateral nephrectomy, consistent with experimental findings that approximately 10% is produced by the liver. Erythropoietin stimulates proliferation and maturation of erythroid colony-forming units. It decreases programmed cell death, or apoptosis of erythroid progenitor cells in the bone marrow by binding to a receptor on the surface of erythroid cells, promoting a cascade of

events starting by activation of JAK2 tyrosine kinase. There also is cell proliferation.¹⁰

Human erythropoietin was purified in 1977, and its molecular structure was characterized in 1986 as a sialylglycoprotein composed of 165 amino acids. Its plasma level normally ranges between 15 and 25 mU/mL but may increase 100-fold in anemia. Erythropoietin production in CKD patients is diminished, but the erythropoietin-Hb feedback still operates, although at a lower set point.

In addition to the hypoproliferative, normochromic, and normocytic anemia in CKD, there is a hemolytic component. Red cell half-life is reduced to approximately one half to two thirds of normal, possibly due to uremic toxins. The anemia of CKD can also be related to iron and folate deficiency, blood loss from repeated venipuncture or blood left in the dialyzer and tubing during dialysis, hyperparathyroidism, and aluminum toxicity.

The anemia of CKD has been associated with fatigue, decreased mental capacity, erectile dysfunction, altered menstrual cycles, immunodepression, a bleeding tendency, and, most importantly, cardiovascular complications.¹¹⁻¹⁵ Thus, anemia is indirectly responsible for decreased quality of life in CKD patients.

THERAPY FOR ANEMIA

Initial Evaluation

The correction of anemia in CKD patients is aimed at relieving symptoms, improving the quality of life, and possibly increasing patient survival (Box 68-1). In the opinion of the Anemia Working Group who constructed the revised K/DOQI guidelines, all CKD patients should be tested for Hb levels at least yearly; more frequent measurements are indicated in selected patients.⁷ The K/DOQI guidelines conclude that evaluation of anemia should be considered for Hb less than

Box 68-1 Anemia Evaluation in Patients with Chronic Kidney Disease

Who must be evaluated for renal anemia

All patients with chronic kidney disease

When

Hemoglobin concentration

<13.5 g/dL in adult males

<12.0 g/dL in adult females

What must be evaluated

Red blood cell indices: MCV, mean corpuscular hemoglobin, reticulocyte count

Iron status: serum iron, ferritin, transferrin saturation, hypochromic red blood cells (if test is available)

Assessment of occult gastrointestinal blood loss, serum vitamin B₁₂ folate; tests for hemolysis; hematological evaluation if there is clinical suspicion of other causes of anemia

MCV, mean corpuscular volume.

13.5 g/dL in adult males and less than 12 g/dL in adult females. The European Best Practice Guidelines¹⁶ have slightly different Hb cutoff levels. The treatment targets are based on Hb rather than hematocrit (Hct) levels because the stability of stored sample is greater and there is less variability with automated analyzers.¹⁷

In addition to Hb, the initial evaluation should include red blood cell (RBC) indices and a reticulocyte count as well as serum iron, total iron binding capacity, transferrin saturation, and serum ferritin.

Additional evaluations are warranted if there is a suspicion of occult blood loss from the gastrointestinal tract; the stool occult blood test is simple and inexpensive and should be included whenever there is iron deficiency.¹⁸ Determination of folate and vitamin B₁₂ levels is not recommended unless there is an obvious cause of deficiency. Determination of plasma erythropoietin concentration is not recommended in European and American guidelines (see Chapter 67).

Choice of Erythropoiesis-Stimulating Agents

The efficacy of the first erythropoiesis-stimulating agent (ESA), human recombinant erythropoietin (rhEPO) in reversing the anemia of uremia was established in the United States and in Europe and rhEPO quickly became available for clinical use.² There are two forms of rhEPO, epoetin alfa and epoetin beta, produced from genomic DNA and complementary DNA, respectively; they differ in their oligosaccharide components. Experimental and clinical findings suggest their pharmacological activity and other biological effects are similar. Epoetin alfa has an average half-life of 4 to 13 hours after IV administration and approximately 24 hours after SC injection (the maximum level is only approximately 10% of that achieved by the same IV dose). The kinetics of epoetin beta are similar to those of epoetin alfa. Both preparations appear to be eliminated primarily by nonrenal mechanisms. Darbepoetin alfa or novel erythropoiesis-stimulating protein is a molecule that stimulates erythropoiesis by the same mechanisms as rhEPO.¹⁹ It has an elimination half-life two or three times longer than rhEPO; the mean

half-life of darbepoetin is 49 hours when given subcutaneously and 21 hours when given intravenously. Therefore, it requires less frequent dosing. It is as effective and safe as rhEPO in the anemia of CKD. Interestingly, ESA therapy brings red cell survival back to normal associated with increased erythrocyte elasticity and deformability as well as the antioxidant enzymatic system of red blood cells. ESA treatment aims to make blood transfusions unnecessary, to prevent the consequences of anemia, and to improve rehabilitation and the quality of life.

Target Hemoglobin

The complexity of establishing a target level for Hb has been recently highlighted.²⁰ In 2001, the K/DOQI anemia guidelines recommended a Hb target level of 11.0 to 12.0 g/dL in CKD patients.²¹ Observational studies have shown that mortality rates were lower in hemodialysis (HD) patients who have Hb values close to 11 to 12 g/dL compared with HD patients with lower levels. Results from randomized, controlled trials comparing Hb targets suggest that partial correction of anemia to levels of approximately 11 to 12 g/dL leads to an improved quality of life.²² Finally, limited evidence suggests that partial correction of anemia to levels of 11 to 12 g/dL is associated with partial regression of left ventricular hypertrophy.^{23–26} The 2006 K/DOQI anemia guidelines confirm the recommendation that the lower limit for Hb level for patients with CKD should be 11 g/dL, but this is still lower than the normal range of Hb according to the World Health Organization definition of anemia.²⁷ The issue of risks and benefits with the upper limit of Hb correction has been addressed. A study of more than 1200 HD patients with significant cardiac disease had to be discontinued because of a trend toward higher mortality in the group targeted with an Hct of 42%. The difference between the treated and control groups did not reach statistical significance.²⁸ Recently, two studies involving a large population of patients were published in the *New England Journal of Medicine*, the Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta (CREATE)²⁹ trial and the Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR).³⁰ Results of the CREATE trial showed that in CKD patients with an estimated glomerular filtration rate of 15 to 35 mL/min, the correction of anemia to a normal Hb range of 13.0 to 15.0 g/dL did not decrease the incidence of cardiovascular events when compared with partial correction of anemia (Hb value of 10.5–11.5 g/dL). The most surprising finding of this study was that a high target Hb level did not ameliorate left ventricular hypertrophy.

In the CHOIR trial, an Hb target of 13.5 g/dL versus 11.3 g/dL was associated with increased risk of death, myocardial infarction, and hospitalization for congestive heart failure and stroke; there was no improvement in the quality of life.

There are ongoing multicenter trials of complete versus partial correction of anemia in CKD patients. While waiting for publication of these trials, the available evidence suggests caution in treating the anemia of CKD patients.³¹ A target Hb value between 11 and 12 g/dL, as suggested by K/DOQI anemia guidelines, should be considered the goal of ESA therapy.

Dose and Route of Administration

The safe and effective rate of increase in Hb level is 1 to 2 g/dL per month. The recommended initial SC dose for adults is 80 to 120 U/kg per week, typically given in two to three doses

of 6000 U/week. The recommended IV regimen is 120 to 180 U/kg per week, typically given as 9000 U/week in three divided doses.

Starting doses of 100 U/kg three times weekly by IV injection increase Hb levels in 90% of patients, whereas a dose of 50 U/kg produces target Hb levels in 70% of patients. An increase of more than 3 g/dL in 4 weeks should be avoided because of the potential exacerbation of hypertension.³² Doses exceeding 300 U/kg usually do not elicit more vigorous erythropoietic response. The Hb and Hct should be monitored every 1 to 2 weeks until the target Hb is reached and then every 2 to 4 weeks. If the increase in Hct is less than 2% in 4 weeks, the rhEPO dose should be increased by 50%; if it is more than 8%, the rhEPO should be decreased by 25%. It takes 4 weeks to assess the response to a change in dose and an increase in dose should not exceed 30 U/kg three times per week. When the Hb or Hct value is near the target, the dose should be decreased by approximately 25 U/kg three times per week to avoid overshooting the target; the dose is then down-titrated gradually.

Regarding the route of administration, the average rhEPO dose needed to maintain an Hct of 33% was lower when administered subcutaneously. In the maintenance phase of anemia treatment, the median IV dose necessary to keep Hb at approximately 12 g/dL is approximately 75 U/kg three times per week, but limits are wide; some patients need 25 U/kg three times per week and others more than 200 U/kg three times per week. Subcutaneous ESA maintenance doses can be substantially lower; patients on continuous ambulatory peritoneal dialysis have been effectively managed with SC doses of ESA less than 40 U/kg three times per week. The suggested initial dose of darbepoetin is 0.45 μ g/kg once weekly (SC or IV). To change from rhEPO to darbepoetin, the rhEPO dose can be divided by 200 to obtain the darbepoetin dose.

An alarming side effect of ESA can be the development of anti-EPO antibodies and pure red cell bone marrow aplasia (PRCA).³³ There have been more than 200 reported cases of PRCA, and virtually all cases occurred in CKD patients who received a particular epoetin alfa product, Eprex, in single-use syringes.³⁴ The underlying cause may have been organic compounds acting as adjuvants because changes in storage and handling and discontinuation of SC administration of Eprex have led to a sharp decline in the incidence of anti-EPO antibody-mediated PRCA in CKD patients. Fortunately, EPO-related PRCA is extremely rare given the widespread use of EPO.

Iron Supplementation

Iron deficiency is frequent in CKD patients and is the main cause of hyporesponsiveness to ESA.³⁵ Therefore, iron status should be monitored before and after beginning ESA therapy and at regular intervals (usually every 2–3 months). Iron stores are most accurately assessed by staining the bone marrow for hemosiderin, but this is expensive, and generally the iron status is assessed from serum iron and ferritin and transferrin saturation. Ferritin is secreted by the reticuloendothelial cells in proportion to the intracellular iron concentration.³⁶ A ferritin level less than 100 ng/mL indicates iron deficiency (<50 ng/mL indicates absolute iron deficiency); a serum level greater than 600 ng/mL reflects iron overload. When the level is greater than 300 ng/mL, iron supplementation is generally not needed

(see Chapter 67), but iron deficiency can develop with ESA therapy because of consumption of iron deposits. Iron is also required when the transferrin saturation is less than 20%. Inadequate iron stores will prevent a vigorous response to ESA, and this can be a therapeutic problem despite a normal serum ferritin level; this condition is called functional iron deficiency. In this case, the developing RBCs are hypochromic. A quantitative assessment of the amount of Hb in newly released RBCs can be made by measuring the percentage of circulating red cells that are hypochromic, defined as a mean erythrocyte Hb concentration less than 28 g/dL. When the hypochromic cells exceed 10% (the normal range is <2.5% of circulating RBCs) in patients without a hemoglobinopathy or inflammatory disease, functional iron deficiency is present. More sophisticated tests for iron deficiency include determination of serum transferrin receptor concentrations and measurement of free erythrocytic protoporphyrin. The serum transferrin receptor concentration is measured with monoclonal antibodies; it increases with the severity of iron store depletion. The percentage of hypochromic RBCs is a better marker for assessing iron availability for Hb synthesis than transferrin saturation, but the test is not universally available, whereas ferritin and transferrin saturation are widely available and used to monitor iron status.

Iron supplements are given to keep serum ferritin greater than 100 ng/mL, transferrin saturation greater than 20%, and hypochromic red cells less than 10%. HD patients usually require 150 mg of iron to achieve a 1-g/dL increase in Hb. This requirement is difficult to achieve by oral medications, and IV iron administration is preferred. During correction of the anemia, 1000 mg of iron given over 6 to 12 weeks should ensure adequate supplementation.

There are three forms of iron that can be given intravenously: iron dextran, sodium ferric gluconate, and iron sucrose. The European Best Practice Guidelines³⁷ suggested that the first choice should be iron sucrose; the second choice is ferric gluconate, and iron dextran is not generally recommended because of the risk of serious adverse reactions. All IV iron formulations have been associated with vasoactive reactions and hypotension, but the rate of adverse reactions with IV iron dextran is reportedly 0.6% to 0.7% of patients. Therefore, a test dose is recommended before IV iron dextran is administered. Unfortunately, a successful test does not exclude a subsequent reaction on its administration.³⁷ The K/DOQI anemia guidelines strongly recommend that IV iron dextran be administered only by trained personnel and that proper emergency medications be readily available.³⁸ A test dose is not recommended before giving other iron preparations.

The protocol for IV iron dextran or iron gluconate in HD patients with absolute iron deficiency is 100 mg of iron dextran or 125 mg of iron gluconate during each dialysis for 10 or 8 doses, respectively. For maintenance iron therapy and for treating and preventing functional iron deficiency, the recommendation is 25 to 100 mg of IV iron dextran every week for 10 weeks or 31.25 to 125 mg of iron gluconate every week for 8 weeks (responses are evaluated by an increase in transferrin saturation and serum ferritin).³⁸

The ideal route of iron administration for pre-HD CKD and for peritoneal dialysis patients is not established. A daily oral dose of approximately 200 mg of elemental iron is appropriate for most patients (approximately one sixth will be absorbed). Commercial oral iron preparations differ in their

content of elemental iron; a 325-mg tablet provides 107 mg of ferrous fumarate, 65 mg of ferrous sulfate, or 39 mg of ferrous gluconate. When ferritin has a downward trend during oral iron supplementation, IV iron dextran may be necessary.

Side Effects

The incidences (per patient-year) of some adverse events are 0.75 for hypertension, 0.25 for clotted vascular access, 0.11 for hyperkalemia, and 0.048 for seizures. The association with seizures not related to hypertension is questionable because seizures can occur in patients not receiving ESA (0.05–0.10 per patient-year). Still, the rate of seizures appears to be higher during the first 90 days of ESA therapy, and strict control of the rate of the Hb increase (<1.5 g/dL every 4 weeks) and close monitoring of blood pressure are warranted. Hyperkalemia presumably reflects less efficient dialysis because the higher Hct decreases the plasma that can be treated and reflects poor dietary compliance with avoiding potassium-rich foods (it has been proposed that decreased dietary compliance is attributable to an improved sense of well-being). The aggravation or appearance of hypertension in patients during ESA therapy has been attributed to increased whole-blood viscosity, reversal of hypoxia-dependent peripheral vasodilation, and activation or enhancement of vascular responsiveness to vasoactive agents. Other suggested mechanisms include a functionally or structurally decreased cross-sectional area of the peripheral vascular bed, normalization of cardiac output, and an increase in RBC mass with minimal decrease in plasma volume. Risk factors for developing or worsening of hypertension in dialysis patients include preexisting hypertension, rapid correction of anemia, and high doses of ESA. Notably, IV administration of ESA and “nondipper” conditions were not identified as risk factors. Increases in blood pressure are generally reported during the first 90 days of therapy. In most cases, hypertension is controlled by reducing dry body weight, starting or increasing antihypertensive therapy, and reducing the dose of ESA. No patient should be excluded from ESA treatment because of increased risk of hypertension.

Causes of an Inadequate Response in Addition to Iron Deficiency

When iron stores are repleted, more than 95% of patients will respond to ESA treatment by attaining the target Hb within 3 to 6 months. An inadequate response to ESA is defined as a failure to attain the target Hb in 6 months despite maximum ESA doses and adequate iron stores. Maximum rhEPO doses are 300 U/kg/week SC and 450 U/kg/week IV. A blunted or absent response may be due not only to iron deficiency but also to aluminum overload, underlying infectious, inflammatory or malignant diseases, gastrointestinal or other sources of blood loss, underlying hematologic disease, severe hyperparathyroidism, folate or vitamin B₁₂ deficiency, the presence of circulating inhibitors of erythropoiesis, and down-regulation of erythropoietin receptors on the surface of committed cells.³⁹

In HD patients, aluminum overload may provoke microcytic anemia even though iron stores are normal. Aluminum and iron share common pathways for intestinal absorption, transport in the plasma, binding to transferrin, and uptake into cells. Iron-depleted rats are more susceptible to aluminum accumulation, and this may influence patient responses as well. In HD patients, it is suggested that transferrin-bound aluminum may interfere with the insertion of iron into proto-

porphyrin to form heme. For example, a high plasma aluminum is related to a smaller erythropoietic response to ESA plus higher levels of protoporphyrin in red cells. Ferrochelatase activity and erythropoietic responses were not correlated. Fortunately, aluminum accumulation is becoming less common with increased use of deionizers and decreased use of aluminum-containing phosphate binders; aluminum in bone biopsy samples has an incidence of less than 5%. If suspected, aluminum toxicity should be documented with serum aluminum greater than 50 ng/mL and an increase in serum aluminum greater than 175 ng/mL after the deferoxamine (an aluminum-binding agent) challenge of a single IV dose of 500 to 1000 mg. Chelation treatment with IV deferoxamine can improve aluminum-induced microcytic anemia; it could also restore responsiveness to ESA.³⁸

Erythropoiesis is negatively regulated by several macrophage-derived cytokines, including tumor necrosis factor α , interleukin-1, interleukin-6, and tumor growth factor β . These cytokines are all elevated in inflammatory processes and exert inhibitory effects on the erythroid progenitor cells, the targets of ESA. Cytokines may also impair iron metabolism by sequestering iron inside the macrophages. Characteristically, the anemia of chronic infectious and inflammatory diseases has a low reticulocyte count for the degree of anemia, and RBCs are often microcytic or hypochromic despite normal or increased levels of serum ferritin.^{40–44} Does this kind of anemia respond to ESA? There is evidence that ESA can overcome the inhibition of erythropoiesis caused by inflammatory cytokines in chronic disease. Unrecognized infection or subtle inflammation can contribute to the anemia of uremia, and this is a diagnostic and therapeutic challenge; the anemia may be resistant to ESA at usual doses but responds, at least partially, to high doses.

HD patients with severe hyperparathyroidism need significantly more ESA.⁴⁵ Vitamin B₁₂/folate deficiency is no longer considered a problem for ESA therapy. Some commonly used drugs may influence erythropoiesis: Angiotensin-converting enzyme inhibitors can inhibit erythropoietin production and adversely affect erythropoiesis.^{46,47}

BLEEDING IN CHRONIC KIDNEY DISEASE PATIENTS

An increased tendency to bleed as a major feature of uremia has been known for centuries.^{48,49} Ecchymoses, epistaxis, and gastrointestinal bleeding are common, and subdural hematomas occur in 5% to 15% of HD adults. Hemopericardium and subcapsular hematoma of the liver occur but fortunately are less frequent than bleeding manifestations. The bleeding tendency increases the risk of surgery or invasive procedures in dialysis patients. Although the pathogenesis of uremic bleeding is multifactorial, the central factor is altered platelet function and an altered platelet-endothelium interaction.^{50,51} The best measure of the platelet–vessel wall interaction is the bleeding time, a simple method tested by making a small incision of the skin (usually in forearm) and measuring the time from the first drop of blood to the last oozing of blood from the cut.⁵² A normal bleeding time is 1 to 7 minutes, and the key to interpretation is to carefully standardize the technique; untrained personnel account for the substantial variation in the bleeding time. A prolonged bleeding time is a feature of uremic patients, but the prolongation does not correlate with retained metabolites

including urea, creatinine, phenol, phenolic acids, and guanidin succinic acid; it is correlated with the Hct value.⁵³ Notably, the platelet count and other coagulation parameters (partial thromboplastin time, prothrombin time, fibrinogen) are not altered in uremia (see Box 68-1).

von Willebrand's factor (vWF) is an adhesion molecule that promotes platelet adhesion and aggregation to subendothelial collagen through an interaction with GPIb/IX receptors. This initiates a sequence of events resulting in the production of thromboxane A₂, a potent platelet-aggregating agent. In uremia, vWF is functionally defective and thromboxane A₂ formation is impaired.^{54,55} Conversely, vascular synthesis of the antiaggregating prostaglandin I₂ is enhanced in uremia, tipping the balance in favor of reduced platelet aggregation.

The anemia of uremia has consequences for the rheology of platelets because they flow in the midstream, away from the endothelium, thereby decreasing the chance of platelet–vessel wall interaction.⁵⁶ Platelet dysfunction is potentiated by the use of aspirin and other nonsteroidal anti-inflammatory drugs. Such drugs should be prescribed for uremic patients only cautiously.⁵⁷ The pathogenesis of uremic bleeding is reviewed in references 50 and 51.

Therapy for Bleeding in Uremic Patients

Dialysis

HD shortens the prolonged bleeding time of uremic patients and partially corrects platelet dysfunction and the abnormal platelet-endothelial interaction. Unfortunately, removal of uremic toxins by HD is not enough to correct fully the hemostatic defects of uremia.⁵⁸ Moreover, the need for heparin administration to prevent clotting of the dialyzer suggests that HD (or at least heparin) should be avoided during active bleeding. It has been suggested that peritoneal dialysis is

more effective in patients with uremic bleeding than HD, and tests of platelet function suggest this is the case, but controlled studies of clinical responses are lacking. Several methods have been proposed to minimize blood loss during HD in bleeding patients. These include regional heparinization and the use of low molecular weight heparins, prostacyclin, or no anticoagulation at all. The method of choice at our center involves frequent flushes of saline through the dialyzer at intervals but no heparin. This approach gives the best results when used in association with hemodiafiltration. The method is used after major surgery or trauma in HD patients (Table 68-1).

Correction of Anemia

Anemia has a major adverse influence on the bleeding time and bleeding tendency of uremic patients. An initial study of six uremic patients demonstrated that RBC transfusions shortened the bleeding time and controlled abnormal bleeding. This was subsequently confirmed in a larger group of patients.⁵⁶

Relieving uremic anemia by ESA can also improve the hemostatic defects and normalize the bleeding time. Therefore, correction of the anemia, either by acute RBC transfusion or the use of ESA, is currently a major overall strategy for preventing and controlling abnormal bleeding in uremia.⁵⁹

Cryoprecipitate and Desmopressin

Cryoprecipitate contains coagulation factor VIII, vWF, fibrinogen, and fibronectin. It has been used in uremic patients with very long bleeding times that were resistant to blood transfusions or HD or both.⁶⁰ In six uremic patients treated by infusing 10 units of cryoprecipitate, there was normalization or significant shortening of the bleeding time. Surgical procedures were undertaken in a few patients without excessive blood loss. The effect, however, was delayed (the nadir of

Table 68-1 Therapeutic Strategies for Uremic Bleeding

Treatment	Indication	Dose	EFFECT		
			Start	Peak	End
Blood or RBCs	Prophylaxis of bleeding in high-risk patients	According to the severity of anemia	Hct = 28%–32%		Relate to RBC life span
Recombinant human erythropoietin	Prophylaxis of bleeding in high-risk patients with anemia	80–120 U/kg IV	Hct = 28%–32%		
Cryoprecipitate*	Acute bleeding episodes	10 bags	1 hr	4–12 hr	24–36 hr
Desmopressin†	Acute bleeding episodes	0.3 µg/kg IV‡ 0.3 µg/kg SC 3.0 µg/kg intranasal	1 hr	2–4 hr	6–8 hr
Conjugated estrogens	Major surgery or when long-lasting effect is required	0.6 mg/kg/day IV infusion for 5 consecutive days	6 hr	5–7 days	21–30 days

*Its use is not recommended because there is no uniformly observed favorable effect.

†It loses efficacy when administered repeatedly.

‡Added to 50 mL saline and infused over 30 minutes.

Hct, hematocrit; RBCs, red blood cells.

bleeding time occurred at 4–6 hours after the infusion) and was transient, lasting no longer than 24 to 36 hours. Cryoprecipitate infusion did not improve defects of platelet aggregation, even though blood levels of factor VIII and vWF, which were normal or high before infusion, increased. Notably, the use of cryoprecipitate carries a risk of transmitting viral diseases such as hepatitis and acquired immunodeficiency syndrome.

Desmopressin

Desmopressin, 1-deamino-8-D-arginine vasopressin (DDAVP), a synthetic derivative of antidiuretic hormone, was introduced in the late 1970s to control abnormal bleeding in patients with von Willebrand's disease and mild hemophilia A.⁶⁰ DDAVP acts by increasing the release of vWF multimers from endothelial stores. DDAVP has been studied in uremic patients as a potentially safer alternative to cryoprecipitate.^{61,62} An open-label, controlled trial showed that DDAVP at a dose of 0.4 µg/kg IV shortened the prolonged bleeding times of CKD patients.⁶³

This result was confirmed in a randomized, placebo-controlled, double-blind, crossover trial carried out in 12 uremic patients with a history of abnormal bleeding and prolonged bleeding times. The patients were infused with DDAVP 0.3 µg/kg IV in 50 mL saline, and the bleeding time was normalized in nine patients within 1 hour of infusion, decreased to less than 10 minutes at 2 hours and 4 hours, and returned to baseline by 8 hours (Box 68-2). There were no significant changes in platelet adhesion or aggregation, residual prothrombin, serum thromboxane B₂, or platelet cyclic adenosine phosphate, but the level of vWF increased above the elevated baseline values. DDAVP was well tolerated and caused no change in Hct or plasma osmolality. The effectiveness of DDAVP in shortening bleeding time and/or controlling abnormal bleeding associated with invasive procedures (biopsies and major surgery) in CKD patients has been substantiated by studies in which the drug was given intravenously, subcutaneously, or intranasally. Repeated

infusions during major surgery are associated with tachyphylaxis, probably due to depletion of vWF stores in endothelial cells. Although remarkably free of serious side effects, DDAVP is reported to cause a mild to moderate decrease in the platelet count, facial flushing, mild transient headache, nausea, abdominal cramps, mild tachycardia, water retention, and hyponatremia. There also is a single report of a patient who suffered a stroke immediately after infusion of DDAVP.

Based on the currently available results, it appears that DDAVP (0.3 µg/kg either IV or SC or as 3 µg/kg intranasally) is useful for treating acute bleeding and preventing abnormal bleeding that could occur with surgery or invasive procedures; DDAVP seems preferable to cryoprecipitate because of variations in clinical response and the risk of transmitting viral disease. The authors do not use cryoprecipitate.

Conjugated Estrogens

In an initial report, six uremic adults with a bleeding tendency and prolonged bleeding time were given conjugated estrogens (orally in one patient, intravenously in the other five) for a total dose of 30 to 75 mg over 2 to 5 days.⁶⁴ Bleeding times shortened in all patients within 2 to 5 days of starting treatment; it became normal in four patients and remained normal for 3 to 10 days after discontinuation of the drug. In a subsequent placebo-controlled, double-blind, crossover trial, conjugated estrogens were administered to six uremic patients with anemia and prolonged bleeding times. The dose was 0.6 mg/kg in 50 mL of saline and was infused intravenously over 40 minutes per day for 5 days (see Box 68-2). The bleeding time shortened within hours of the first infusion, and the effect lasted as long as 14 days (or 9 days after the last infusion). No changes were noted in levels of or the multimeric structure of vWF. No serious side effects were observed.⁶⁵

A dose-finding study showed that 0.3 mg estrogens/kg had no significant effect on bleeding time, but there was a clear response to a cumulative dose. The effect of a single infusion of 0.6 mg/kg disappeared within 72 hours, but four or five infusions given at 24 hours apart resulted in marked shortening of the bleeding time and this effect was maintained for 14 days. Oral estrogens are also useful. Abnormal bleeding was corrected with regimens of 0.6 mg/kg/day IV for 5 days plus 60 mg/day PO for 5 days. Results from a small, placebo-controlled trial of four uremic patients indicate that conjugated estrogens given orally at a dose of 50 mg/day may markedly shorten the prolonged bleeding time after an average of 7 days of treatment; the dose may also control abnormal bleeding.⁶⁶ In addition to transient hot flushes (rare), minor side effects of conjugated estrogen include nausea, vomiting, loss of libido, and gynecomastia; these problems may limit prolonged use, particularly in men. The risks of malignancy and thromboembolic complications with intermittent high-dose conjugated estrogens are unknown. A recent review offers an evidence-based approach to current recommendations for uremic bleeding.⁶⁷

Thrombotic Complications

Even though uremia is associated with a bleeding tendency, thrombotic occlusion of the dialysis vascular access is a frequent complication. Approximately 0.5 to 0.8 episodes of fistula thrombosis occur per patient per year. The cause of vascular

Box 68-2 Treatment of Renal Anemia with Erythropoiesis-Stimulating Agents

Choice of ESA erythropoiesis-stimulating agent: epoetin alfa, epoetin beta, darbepoetin.

The three erythropoiesis-stimulating agents are to be considered equivalent

Route of administration: subcutaneous administration is recommended, although in HD patients, intravenous route is preferred for practical reasons

Starting dose

Epoetin

80–120 U/kg/wk SC in two or three doses

120–180 U/kg/wk IV in two or three doses

Darbepoetin

0.45 µg/kg administered once weekly

Target hemoglobin: 11–12 g/dL

Desired hemoglobin increase rate: 0.3–0.5 g/wk

Interval to dose change: 4–6 wk

Dose change: Up-titration or down-titration by 25% of initial dose

Table 68-2 Summary of Relative Effects of Treatments of Uremic Bleeding

	Prevention of Platelet Dysfunction	In Acute Bleeding	Reduce Bleeding Time	Normalize Bleeding Time
Dialysis	+	–	++	+
Correction of anemia	+	+/-*	++	+
Cryoprecipitate	–	++	++	+
Desmopressin	–	+++	+++	++
Conjugated estrogens	–	+	++	+

*Correction of anemia in acute bleeding is achievable with red blood cell transfusion.

–, ineffective; +, moderately effective; ++, effective; +++ very effective.

access thrombosis is a stenotic lesion in the venous end of the anastomosis in approximately 75% of all cases. Other causes include sustained hypotension, excessive fistula compression, and a high Hct. Treatment of and prophylaxis against vascular access thrombosis are very important issues as the life of dialysis patients depends on the availability of a functioning vascular access, and this complication causes hospitalization and significant costs.^{68,69} There are pharmacologic approaches to preventing clotting of the dialysis access, but no study has formally compared the efficacy of surgical thrombectomy with pharmacologic thrombolysis. Beathard⁷⁰ reported that thrombolysis is safe and as effective as surgical therapy in treating thrombosed dialysis access grafts. Because it preserves vascular access sites and yields long-term patency rates superior to those for surgical thrombectomy, it should be regarded as the treatment of choice. Thrombolysis is often the only choice for permanent catheters. Urokinase and tissue plasminogen activator are the agents most often employed successfully.^{71,72}

The efficacy of prophylaxis using antiplatelet drugs in prolonging the patency of vascular grafts has been assessed in clinical trials, but the results are inconclusive. A randomized, double-blind trial in 44 patients found that aspirin 160 mg/day was better than placebo in preventing shunt thrombosis in uremic patients. It reduced the incidence of thrombi from 0.46 to 0.16 per patient per month ($P < .005$).⁷³ Other reports conclude that even low doses of aspirin also prolong the bleeding time, and occasional patients given aspirin will develop severe gastrointestinal bleeding. A meta-analysis of nine trials comprising 418 patients indicated that antiplatelet treatment (essentially aspirin alone or aspirin plus dipyridamole) reduced the risk of vascular occlusions by 70%.⁷⁴ The mean duration of these trials, however, was only 2 months. The absolute benefit of antiplatelet therapy appeared greater in patients with an arteriovenous shunt compared with results in patients with fistulas.

Few clinical studies have tested the effect of the antiplatelet agent ticlopidine in preventing the primary occlusion of arteriovenous fistulas. There appears to be a decreased incidence of thrombosis in treated patients.⁷⁵ All these studies, however, were small in size and of short duration.

A ticlopidine analogue, clopidogrel, was evaluated in a randomized, controlled trial to prevent graft thrombosis. The study was stopped early because of an excessive risk of bleeding in the active treatment group.⁷⁶

There are few uncontrolled studies that have examined the effectiveness of systemic anticoagulation with warfarin in pre-

venting occlusion of permanent central venous catheters (placed for purposes other than dialysis). Results of these studies suggest that low, fixed-dose warfarin may reduce the risk of venous thrombosis. It is not known whether this result can be extrapolated to HD permanent catheters (Table 68-2).

CHAPTER CONTENTS

RENAL OSTEODYSTROPHY	765	Dialysis Adequacy	769
High-Turnover Bone Disease	766	Calcimimetic Agents	769
Low-Turnover Bone Disease	766	Parathyroidectomy	770
PREVENTION OF PHOSPHORUS RETENTION AND HYPERPHOSPHATEMIA	766	<i>Postparathyroidectomy Management</i>	770
Dietary Phosphorus Restriction	766	PERSISTENT SECONDARY HYPERPARATHYROIDISM AFTER RENAL TRANSPLANTATION	770
Phosphate Binders	767	CALCIPHYLAXIS	770
Calcium-Based Phosphate Binders	767	Daily Dialysis	770
<i>Sevelamer Hydrochloride</i>	768	Sodium Thiosulfate	770
<i>Lanthanum Carbonate</i>	768	Parathyroidectomy	771
<i>Aluminum Hydroxide and Aluminum Carbonate</i>	768	Phosphate Regulation	771
<i>Magnesium Carbonate</i>	768	Pain Management	771
Vitamin D Deficiency	768	Wound Care and Antibiotics	771
Use of Active Vitamin D Sterols	769	Other	771
<i>Calcitriol</i>	769		
<i>Paricalcitol</i>	769		
<i>Doxercalciferol</i>	769		

A 40-year-old dialysis patient is 87 times more likely to suffer a hip fracture than a healthy control,¹ and a 25-year-old dialysis patient is more than 100 times more likely to suffer a cardiovascular event than a healthy control.² Chronic kidney disease (CKD)—mineral and bone disorder is implicated in the pathogenesis of both outcomes. Renal osteodystrophy was first described in 1943 and has many names. With the introduction of the new classification of CKD (CKD staging) and the Kidney Disease Outcome and Quality Initiative (K/DOQI) guidelines in 2003, more and more patients are being referred to nephrologists for management of CKD and its related mineral and bone disorder.³ With loss of glomerular filtration, there is phosphorus retention, a decrease in calcitriol, and other factors that stimulate parathyroid (PTH) secretion and growth of the parathyroid glands. Even with normal serum calcium and phosphorus concentrations, patients with CKD stage 3 or 4 can still have an elevated PTH level. Levels of serum calcium and phosphorus are maintained within normal range in these patients because there is secondary hyperparathyroidism (HPT).³⁻⁶ It should be diagnosed and dealt with early to preserve bone health; for diagnosis, the K/DOQI guidelines recommend measuring serum calcium, phosphorus, and intact PTH in all patients with CKD stages 3, 4, and 5 at regular intervals. There is strong evidence that the driving force for all these abnormalities is phosphate retention, which is a direct result of decreased excretion of phosphates by the damaged kidney. Treatment is based on decreasing phosphate

accumulation by decreasing phosphate intake. Phosphate retention increases PTH and decreases calcitriol directly and also indirectly by increasing the concentration of fibroblast growth factor-23.⁷ Decreased levels of calcitriol lead to an additional stimulus of PTH. Hence, serum phosphorus must be kept within the target range by restricting the diet and limiting phosphate absorption from the intestine.

RENAL OSTEODYSTROPHY

Renal osteodystrophy occurs in CKD—mineral and bone disorder.⁸ It should be emphasized that renal osteodystrophy is a qualitative disorder of bone in CKD patients. Dual x-ray absorptiometry scans or other imaging modalities are quantitative tests of bone mineral content and are not very helpful in determining the pathologic bone turnover states associated with various stages of CKD. Serum markers of bone metabolism such as alkaline phosphate, PTH, and osteocalcin are good predictive markers of the different types of bone turnover disease, but the definitive diagnosis can only be made by bone biopsy. This is true because bone is in a constant state of remodeling and is a buffer for calcium and other minerals; if serum calcium decreases, then PTH increases to release calcium from the bone. Conversely with a high calcium intake, calcium is deposited in bone. The iliac crest is the usual site of bone biopsy for assessment of bone, but before the biopsy, a

patient should receive different types of tetracycline at 30 days and again at 4 days before biopsy to evaluate the amount and type of the bone formed during the time interval of administering the two tetracycline labels. Symptoms of renal osteodystrophy are nonspecific and may even be absent. They include pain and stiffness in joints, spontaneous tendon rupture, a predisposition to fractures, and proximal muscle weakness. A similar set of symptoms may be seen in both the low- and high-turnover type of skeletal abnormality.

High-Turnover Bone Disease

Calcium and phosphorus levels are disturbed with advancing kidney disease causing secondary HPT and parathyroid hyperplasia. The increase in PTH has skeletal and extraskeletal manifestations, as outlined in Figure 69-1. One skeletal abnormality is high-turnover bone disease, which is associated with increased levels of intact PTH in serum. Other signs of ongoing bone reabsorption are increases in serum phosphorus, alkaline phosphate, and osteocalcin. Secondary HPT can be present with serum calcium levels that are increased, normal, or low, but when PTH is high, it inhibits osteoclast apoptosis, causing increased bone resorption. At the same time, osteoblasts are stimulated to replace resorption areas with rapid bone formation, resulting in replacement of the normal lamellar bone with structurally inferior woven bone. There is fibrosis and sometimes cyst formation, hence yielding the name osteitis fibrosa cystica. Parathyroid hyperplasia and high-turnover bone disease are more recognized in patients

with CKD stage 5 but can be present at any stage of CKD. Treatment of this disorder is effective control of serum PTH using therapy as outlined later in the chapter.

Low-Turnover Bone Disease
