Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

Salus servandra per scientiam doctrinamque

(Let us provide healing through science and learning)

I acknowledge my great fortune to have learnt the science of nephrology and hypertension from the best in the field: Faisal S. Nashat, MD; Sir Stanley Peart, FRS; Gerhard Giebisch, MD; and Barry M. Brenner, MD, and to have had the strong support for my work from George E. Schreiner, MD, who endowed the chair that I hold and Ms. Alma L. Gildenhorn, who chairs the board of the Cardiovascular Kidney Hypertension Institute that I direct.

Aureus et carus umor fluat abunde

(O precious golden fluid, may it flow in abundance)

I express my deepest gratitude to those most influential in teaching me the practice of nephrology and hypertension and the skills needed to develop a clinical and research program: William Slater, MD; William E. Mitch, MD; and Craig C. Tisher, MD.

“During my years of teaching literature at Cornell and elsewhere I demanded of my students the passion of science and the patience of poetry.”

Vladimir Nabokov

(Strong Opinions, Interviews, 1962)

***“Sell your cleverness and buy bewilderment;
Cleverness is mere opinion, bewilderment intuition.”***

Jalal al-Din Rumi

Persian poet and mystic, 1207–1273

(Masnavi, Book IV, Story II, as translated by E. H. Whinfield, 2000)

The ideas and stimulating discussions that I have received from many colleagues, fellows, and students at the Universities of Oxford, Cambridge, and London in the UK and Harvard, Florida, and Georgetown in the U.S.A. have been an inspiration for me.

***“Though I have all faith, so that I could remove mountains,
and have not love, I am nothing.”***

First Letter of St. Paul to the Corinthians, Chapter XIII

Holy Bible

Most important has been the sense of purpose and strength that accrues to my life and achievements from the love, understanding, and support of my dear wife, Linda; our beloved children, Mark, Juliette, Stuart, and Philip; and grandchildren Henry, Isabelle, Anna, and Lauren; and from my dear brother, Frank, and his family.

In Memoriam

Stuart and Imogen Wilcox

and

Alex and Petra Wilcox

Preface

Therapy in Nephrology & Hypertension is a companion to Brenner & Rector's *The Kidney*. It provides comprehensive information and detailed discussion on the most critical areas relating to therapy. The aim is to provide a thoughtful overview of the rationale, specifics, efficacy, toxicity, and limitations of current therapeutics in renal disease and hypertension. A world-leading panel of expert contributors has been challenged to summarize and critique current clinical trials and to make their own treatment recommendations based on the results of these trials or, when these are not available, their own best clinical practice. They provide the background to these decisions and the details of the drugs used. Where possible, they have included an algorithm to summarize the steps involved in selection and monitoring of drug treatment.

The first two editions were coauthored with Hugh R. Brady. Sadly, his new responsibilities as President of University College, Dublin, Ireland, have precluded his involvement in this third edition. He has been hard indeed to replace. Rather than select another co-editor, I have chosen to distribute the editorial duties amongst a group of seven section editors. Each is a world expert in the fields that he or she covers. This ensures that the best current authors in the field have been selected to write the chapters and that the material has been critiqued by another true expert. I have been delighted with the results. This injection of new ideas and directions has led to the inclusion of many new chapters. Thirty of the 93 chapters have new primary authors.

Every chapter in this edition has been thoroughly revised and updated. Where new treatment modalities have been discovered and released, or new trials are available, these are included in the updated chapters.

It is you, the readers, who will evaluate the success of this textbook. Your comments, criticisms, and suggestions following its publication are greatly appreciated. They will be incorporated into the planning of the next edition. Please write to

me to express comments on specific chapters, whether encouraging or otherwise, and any specific information or topics that you consider are either missing or inadequately or incorrectly covered. It is my aim to provide a comprehensive and up-to-date, fully referenced, and authoritative review of all the major areas of treatment in nephrology and hypertension by acknowledged experts in the field. I have retained the original concept of many short chapters since I believe this makes a large book, such as this, more accessible and readable and allows me to draw on a large expert authorship.

I wish to thank Barry Brenner for his continuing encouragement and trust in me to edit this important companion to his authoritative book; the many individuals at Saunders and Elsevier Science Publishing who have helped me pilot this project from inception to completion, most notably Ms. Pamela Hetherington, Ms. Adrienne Brigido, and Ms. Susan Pioli, who have undertaken the lead roles in preparing this new edition for publication; Ms. Emily Wing Kam Chan, who so diligently kept authors and section editors apprised of the progress of chapters and collated the entire book as chapters were passed on from section editors; and my wife for her understanding and support for this, yet another major academic project that necessarily takes time away from what we would otherwise spend together. Most important, I thank the section editors for the extraordinary dedication that they have shown to this project. Not only did I entrust them to recommend the selection of topics and authors, but also to read and correct the first proofs and to be the primary contacts for the authors as their chapters made their way through the process of submission, selection, correction, and final printing. Finally, I thank with great sincerity the many authors who have devoted their time and effort in busy academic lives to provide detailed, comprehensive, and fully referenced new chapters for this book.

ESTABLISHING ACUTE RENAL FAILURE

Acute Kidney Injury and the RIFLE Criteria

The introduction of a clear-cut clinical definition of acute renal failure with diagnostic criteria is an important advance in our thinking about patients with acute renal failure. The need was obvious because a doubling in serum creatinine in acutely hospitalized patients increases the mortality to 30%. Another doubling in serum creatinine increases this mortality to 60%.¹ A group of nephrologists and critical care specialists (since expanded to the Acute Kidney Injury Network) formulated the RIFLE criteria (www.ccm.upmc.edu/adqui/ADQI2/ADQI2g1.pdf).² The acronym RIFLE stands for the increasing severity classes Risk, Injury, and Failure and the two outcome classes Loss and End-stage kidney disease (Fig. 1-1). The three severity grades are defined based on the changes in serum creatinine or urine output, where the worst of each criterion is used. R, I, and F represent a 25%, 50%, or 75% decrease in glomerular filtration rate (GFR) (or corresponding increase in serum creatinine) and/or oliguria (<0.5 mL/kg/hr) for 6, 12, or 24 hours, respectively. These criteria are easily remembered; most clinical laboratories in the United States and Europe now calculate the GFR by means of the Modification of Diet in Renal Disease study formula. The appearance of R, I, or F in any patient is, of course, good grounds to rule out urinary tract obstruction with diagnostic ultrasonography to preclude postrenal causes of acute renal failure. The two outcome criteria, loss and end-stage kidney disease, are defined by the duration of renal function loss.

Urinary Indices

Although earlier clinicians seem to have had few problems in recognizing established acute renal failure, we have greater

difficulties today. Prerenal azotemia is said to account for 40% of cases in hospitalized acute renal failure patients and 60% of community-acquired cases.^{3,4} However, how do we distinguish between established acute renal failure and prerenal azotemia? The authors of the two cited reports were not precise in their estimates but espoused renal indices in making this distinction (Box 1-1). Some early investigators relied on specific gravity to reflect tubular function. All performed microscopy and were impressed by muddy brown urinary sediments. Urinary sodium, fractional excretion of sodium, urine-to-plasma creatinine ratio, urinary osmolality, urine-to-plasma osmolality ratio, serum urea-to-creatinine ratio, and fractional excretion of urea appear to give variable and inconsistent results.⁵ Bagshaw and colleagues⁶ reviewed 27 papers on the subject that included approximately 1500 assessed patients. About half the patients were septic. Inadequate timing, lack of adequate controls, failure to perform all the tests, and lack of documented established acute renal failure or prerenal azotemia criteria were among the confounders. The authors concluded that the scientific basis for urinary indices and microscopy, particularly in septic acute renal failure patients, is weak. In his critique and commentary, Schrier⁷ observed that fractional excretion of sodium or a renal failure index (urine sodium/urine-to-plasma creatinine ratio) less than 1.0 occurs in 85% to 94% of patients with prerenal azotemia and only in less than 4% of patients with oliguric established acute renal failure. These figures should inspire confidence. Nevertheless, in a sheep model of sepsis, renal blood flow increased remarkably (contrary to what was expected), while GFR and urinary output decreased.⁸ Moreover, urinary sodium, fractional excretion of sodium, and fractional excretion of urea all decreased, suggesting that these indices are not reliable markers of a prerenal reduced renal blood flow state.⁹

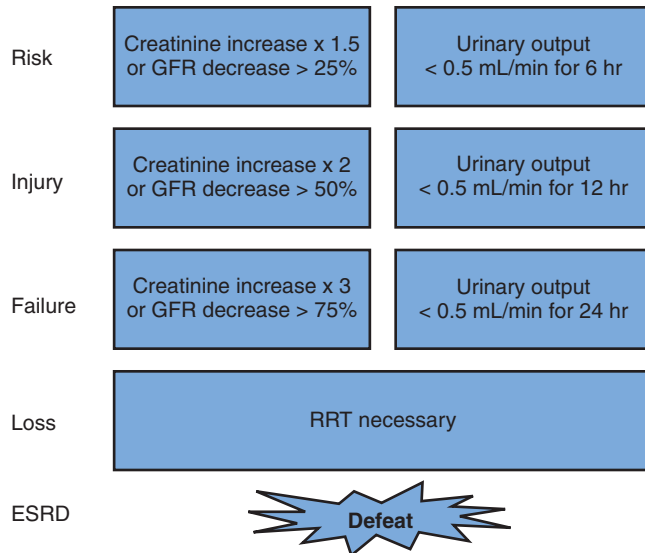

Figure 1-1 The remarkable RIFLE criteria to classify acute renal failure are shown. On the left are GFR (serum creatinine or cystatin C increases). On the right, even easier, are the urinary output criteria. Remarkably, this simple system exhibits high sensitivity on steps 1 to 3 and high specificity on steps 3 to 5. The breakdown variable is renal replacement therapy (RRT) and end-stage renal disease (ESRD). All consulting nephrologists should use the RIFLE criteria to facilitate patient care and to educate the non-nephrologic community. GFR, glomerular filtration rate.

Fractional excretion of urea warrants a special mention. In Europe, where loop diuretics are considered a vitamin—or a food—rather than a drug, nephrologists are faced with the problem that all patients have been subjected to loop diuretics before they are called. This state of affairs makes urinary sodium values and fractional excretion of sodium worthless as indicators. Carvounis and colleagues¹⁰ tested 50 patients with prerenal azotemia, 27 of whom had been treated with diuretics and 25 of whom were shown to have established acute renal failure. They reported that a low (<35%) fractional excretion of urea was more sensitive and specific than fractional excretion of sodium for differentiating prerenal azotemia from established acute renal failure.

To summarize, renal indices will remain valuable exercises for residents and fellows on every nephrology service. They are also a valuable activity in terms of teaching renal physiology. Nevertheless, their value in diagnosing established acute renal failure, particularly in septic patients, remains unconvincing. Thus, *caveat emptor!*

VOLUME REPLACEMENT

Assessing the State of Hydration

A prospective, randomized trial has amply demonstrated that early goal-directed therapy provides significant benefits with respect to outcome in patients with severe sepsis and septic

Box 1-1 Common Renal Indices Assessing Tubular Function*

Urinary Concentration

Specific gravity (>1.020)
Urine osmolality (UOsm > 500 mOsm/kg H₂O)
Urine/plasma osmolality ratio (>1.5)
Urine/plasma creatinine ratio (>20:1)

Urine Sodium

UNa (<20 mmol/L)
 $FE_{Na} = (U_{Na}/S_{Na}) \div (U_{Cr}/S_{Cr}) \times 100 (<1\%)$

Urea Based

Serum urea-to-serum creatinine ratio (>10:1) when urea is expressed as blood urea nitrogen (BUN mg/dL)
 $FE_{Un} = (U_{Urea}/S_{Urea}) \div (U_{Cr}/S_{Cr}) \times 100 (<35\%)$

*Renal indices to separate established acute renal failure from prerenal azotemia has a time-honored role in acute nephrology. However, the value of renal indices is questionable. FE_{Na} and FE_{Urea} are probably the most discriminatory; the latter is of value in patients given loop diuretics. The RIFLE criteria are probably superior in terms of sensitivity (lower values) and specificity (higher values), respectively.

FE_{Na} , fractional excretion of sodium; FE_{Un} , fractional excretion of urea; S_{Cr} , serum creatinine; S_{Na} , serum sodium; S_{Urea} , serum urea; U_{Cr} , urinary creatinine; U_{Na} , urinary sodium; U_{Urea} , urinary urea.

shock.¹¹ Volume expansion is a major part of the goal-directed therapy. All nephrologists would agree that volume expansion should be conducted in any hypovolemic patient to ameliorate prerenal azotemia and to avoid prerenal azotemia from developing into established acute renal failure. However, how good are we at determining whether a patient is hypovolemic? McGee and colleagues¹² reviewed this issue systematically. They searched Medline, personal files, and bibliographies of textbooks on physical diagnosis and identified 10 studies investigating postural vital signs or the capillary refill time of healthy volunteers, some of whom underwent phlebotomy of up to 1150 mL of blood, and four studies of patients presenting to emergency departments with suspected hypovolemia, usually due to vomiting, diarrhea, or decreased oral intake. McGee and colleagues¹² found that when clinicians evaluate adults with suspected blood loss, the most helpful physical findings are either severe postural dizziness (preventing measurement of upright vital signs) or a postural pulse increment of 30 beats per minute or more. The presence of either finding had a sensitivity for moderate blood loss of only 22%; however, the corresponding specificity was 98%. Supine hypotension and tachycardia were frequently absent, even after up to 1150 mL of blood loss. Surgeons in both world wars reported that soldiers with hemorrhagic shock actually had bradycardia approximately one third of the time. The finding of mild postural dizziness had no proven value. In patients with vomiting, diarrhea, or decreased oral intake, the presence of a dry axilla supports the diagnosis of hypovolemia, and moist mucous membranes and a tongue without furrows argue against it. McGee colleagues¹² also found that in adults, the capillary refill time and poor skin turgor had no diagnostic value. Thus,

in patients with vomiting, diarrhea, or decreased oral intake, few findings have proven utility. Clinicians are left to measuring serum electrolytes, serum blood urea nitrogen, and creatinine levels when diagnostic certainty is required, provided they are confident in the renal indices described above. The clinical assessment of hypovolemia, although we all cling to our tests and firm beliefs in assessing whether a patient is “dry” (clinically, a meaningless term), would appear to be of little value.

In terms of volume expansion, we are not much better. Observing neck veins, listening for rales, poking for edema are all time-honored hallmarks to establish volume expansion or at least adequate filling pressures. Commonly, radiographs are obtained to assess volume status. Ely and colleagues¹³ performed a prospective evaluation of 100 patients who had pulmonary artery occlusion pressure measured. Patients were divided into those who had a pulmonary artery occlusion pressure less than 18 mm Hg or more than 18 mm Hg. Objective (measured) vascular pedicle width and cardiothoracic ratio were better than any subjective interpretation of the radiographs. The authors found that the classic clinical signs of jugular venous distention, crackles on auscultation, and peripheral edema were poor indicators of volume status in these patients and were commonly frankly misleading. Furthermore, the pulmonary artery catheter itself is commonly misleading. Marik¹⁴ termed the intravascular volume assessment, even with a pulmonary artery catheter, “a comedy of errors.” Befuddled clinicians should not believe that the pulmonary artery catheter is a “dipstick” to assess “fullness of the tank.” The pulmonary artery occlusion pressure cannot be a measure of ventricular preload because preload is a function of muscle fiber length (end-diastolic volume) and not end-diastolic pressure. Several randomized trials have questioned the value of pulmonary artery catheters in supplementing intensive care management; however, that topic is beyond the scope of this chapter.

Nonetheless, clinicians must make decisions about volume status and act accordingly. Most patients in the intensive care unit will have at least a central venous catheter. These catheters permit two measurements that are helpful in assessing oliguria. The first is the measurement of the central venous pressure itself and the second is its change in response to volume challenge. Here, care must be taken with patients receiving mechanical ventilation. In such patients, a central venous pressure greater than 10 mm Hg may still represent volume depletion. In ventilator-dependent patients, if the systolic blood pressure decreases after each lung inflation, cardiac filling pressures may very well be inadequate. Also helpful is the measurement of the central venous oxygen saturation. The value is generally approximately 70% (P-central-venous O₂ 40 mm Hg). If the value is less than 50% (P-central-venous O₂ < 28 mm Hg), low cardiac output could be present. In patients with pulmonary artery catheters (or equivalent systems), oxygen delivery and oxygen use should be measured. Determining oxygen use is the primary utility of the pulmonary artery catheter.

Picking the “Right” Volume Expander

In 1861, Thomas Graham investigated the diffusion phenomenon and found that some substances could traverse a parchment membrane and others could not. He classified

the substances as crystalloids or colloids accordingly. Crystalloid fluids are electrolyte solutions with small molecules that disperse freely throughout the extracellular space. The principal components are sodium and chloride. As a result, crystalloid volume resuscitation will expand the interstitial volume rather than the plasma volume. Infusion of 1 L of 0.9% sodium chloride (commonly and mistakenly called *physiologic saline*) adds 275 mL to the plasma volume and 825 mL to the interstitial volume. The total volume expansion is 1100 mL because the solution (154 mmol Na and 154 mmol Cl) is sufficiently hypertonic to shift fluid from the intracellular to the extracellular space. So much for isotonic physiologic sodium chloride! Furthermore, 0.9% sodium chloride contributes to hyperchloremic metabolic acidosis (Cl 154 mmol/L). Four liters of sodium chloride administered over a short period (not an uncommon practice in our intensive care unit) will reduce pH from 7.4 to 7.3.

Sidney Ringer and Alexis Hartmann provided us with an alternative to 0.9% saline that has been in use since the 1930s. Lactated Ringer’s solution has the advantage of being more physiologic; however, the solution may bind certain drugs, including aminocaproic acid, amphotericin, ampicillin, and thiopental. Lactated Ringer’s solution is also contraindicated when diluting red blood cell transfusions, since the solution can bind citrated anticoagulants in blood products. Contrary to popular belief, lactated Ringer’s solution will not raise serum lactate levels significantly.

Dextrose solutions (50 g in 1000 mL or 5%) will not increase the plasma volume appreciably and are therefore useless in patients with volume depletion. Routine or aggressive infusion of dextrose-containing solutions can be harmful. When circulatory flow is compromised (shock), 5% dextrose can contribute to metabolic acid production. A 5% dextrose infusion promotes cell swelling. When dextrose is added to isotonic saline (D5 normal saline), the infusion fluid is hypertonic to plasma (560 mOsm/L). If glucose use is impaired (not unheard of in very ill patients), the hypertonic infusion creates an undesirable osmotic force that can promote cell contraction. Finally, hyperglycemia, resulting from dextrose infusions, has numerous deleterious effects including immunosuppression, increased risk of infection, brain injury aggravation, and increased mortality. The fact that more than 10% of intensive care unit patients are diabetic does not inspire confidence. The deleterious effects of hyperglycemia and the benefits of lowering blood sugar in critically ill patients have been convincingly shown in both surgical and medical intensive care unit patients.^{15,16}

Are colloid-containing fluids better? Colloid fluids are more effective than crystalloids in expanding the plasma volume because they contain large, poorly diffusible, solute molecules that create an oncotic pressure to keep water in the vascular space. In healthy subjects, the colloid oncotic pressure of plasma is approximately 25 mm Hg while lying down; when standing, the value decreases to 20 mm Hg. A 1-L 5% albumin solution results in a 700-mL increment in the plasma volume and in only a 300-mL increase in the interstitial volume. Thus, 70% of this infusion remains in the intravascular space. Colloid fluids are threefold more effective in increasing intravascular volume than crystalloid solutions.

Albumin is expensive. Thus, alternatives are popular. Hydroxyethyl starch (hetastarch) is a chemically modified starch polymer that is available as a 6% solution in isotonic saline. There are three types of hetastarch solutions based on the average molecular weight, 450, 200, and 70 kd for high, medium, and lightweight hetastarch, respectively. In the United States, the heavy weight is favored. Hetastarch undergoes hydrolysis by amylases in the blood. The products less than 50 kd are eliminated by the kidneys (if these are working). Hetastarch can interfere with tissue factor and von Willebrand factor. Overt bleeding is uncommon but can complicate bypass operations. Hetastarch may increase serum amylase levels as a form of macroamylasemia, which is not a toxic effect. Anaphylactic reactions can occur with hetastarch but are rare. Dextran is similar in kind and in substance to hetastarch solutions.

The colloid-crystalloid debate (warfare) continues, and no end is in sight. The fact that an acute blood loss is accompanied by a dramatic interstitial fluid volume deficit raised hopes for the crystalloid camp. However, clinicians prefer blood pressure to be measurable and to be maintained. What should we do? To help us, outcomes experts conducted a systematic review of randomized, controlled trials of resuscitation with colloids compared with crystalloids for volume replacement of critically ill patients.¹⁷ The analysis was stratified according to patient type and quality of allocation concealment. Despite the inclusion of 37 randomized trials, resuscitation with colloids was associated with an increased absolute risk of 4% mortality, or four extra deaths for every 100 patients resuscitated. There was no evidence of differences in effect among patients with different types of injury that required fluid resuscitation. Suffice it to say, this meta-analysis generated much controversy.

The last word should have been the SAFE study.¹⁸ In this study, 6997 patients requiring fluid resuscitation were randomized to 4% albumin or normal saline. The primary endpoint was death from any cause. The outcomes in the two groups were similar. However, the patients died of various causes, and there is no way to determine whether an intravenous fluid was somehow directly related to death. Subsequently, other studies have been published, including a recent study investigating three fluids in 129 children with dengue shock syndrome.¹⁹ Ringer's lactate, 6% hydroxyethyl starch, and 6% dextran 70 were compared in the study. First, as a tribute to the investigators, only one patient died in the study. The treatments did not differ in outcomes. The authors concluded that initial resuscitation with Ringer's lactate is indicated for children with moderately severe dengue shock syndrome. Dextran 70 and 6% hydroxyethyl starch performed similarly in children with severe shock; however, dextran had more side effects.

Could hypertonic saline (hypertonic resuscitation) provide an answer?^{20,21} A 7.5% sodium chloride solution has an osmolality 8.5 times that of plasma. The additional volume would come from the intracellular space. Preliminary data exist that suggest a role for such an approach. However, currently no controlled data exist. In case the notion results in discomfort, the idea that Na and Cl determine extracellular fluid volume (aside from the amount sequestered in bone) may require revision. An additional storage space for sodium influencing volume regulation may exist in proteoglycan-containing connective tissue.²²

The resuscitation fluid should be selected based on the need of a specific problem in any given patient. For example, crystalloid fluids are designed to fill the extracellular space. They are particularly indicated when the interstitial space is compromised and would be appropriate for use in patients with loss of both interstitial and intravascular volume. Colloid fluids are designed to expand the plasma volume and are appropriate for patients with hypovolemia related to acute blood loss. Albumin-containing colloid fluids are appropriate for patients with hypovolemia associated with hypoalbuminemia. Tailoring fluid therapy to specific problems of fluid imbalance is the best approach to volume resuscitation in the intensive care unit. Most patients with acute kidney injury (AKI) can probably be managed with crystalloid volume replacement.

Monitoring and Administration

Blood loss is classified by the American College of Surgeons in terms of amount.²³ Class I is approximately 15%, class II is 15% to 30%, class III is 30% to 40%, class IV is more than 40%. The latter two classes generally would be picked up as AKI, at least according to the RIFLE criteria based on oliguria. Tachycardia is generally absent in the supine position; indeed, bradycardia may be present. Blood pressure is an insensitive marker of blood loss. The use of the hematocrit to estimate blood loss is naive and inappropriate.²⁴ Central venous and pulmonary artery catheters are commonly inserted into hypovolemic patients. Cardiac filling pressures will generally overestimate the intravascular volume status in hypovolemic patients.²⁵ Oxygen transport parameters may be very helpful as discussed earlier. If a pulmonary artery catheter is in place, its value lies in measuring Do_2 and Vo_2 . Compensated hypovolemia is identified by a normal Vo_2 ($>100 \text{ mL/min/m}^2$) and an O_2 extraction less than 50%. Hypovolemic shock is identified by an abnormally low Vo_2 ($<100 \text{ mL/min/m}^2$) and an extraction rate greater than 50%. Lactate, Paco_2 , and HCO_3 values can be obtained and are valuable monitoring parameters.

The Trendelenburg position (legs elevated and head below the horizontal plane) does *not* promote venous return to the heart and, according to careful study, is a worthless maneuver for this purpose. Friedrich Trendelenburg (1844–1924), an innovative surgeon, developed the position to perform perineal operations and *not* to treat shock. Generally, the central veins are cannulated in patients for volume resuscitation because larger veins permit more rapid fluid infusions, or so most clinicians believe. However, the rate of volume infusion is determined by the dimensions of the vascular catheter and not by the size of the vein. Hagen and Poiseuille showed clearly that wider bore (radius) and shorter length determine how fast infusions can run. The relationship they defined is $Q = \Delta P(\pi r^4/8 \mu L)$, where r is radius and L is length. Thus, short peripheral 14- or 16-gauge 5-cm catheters will allow a gravity crystalloid flow rate of 200 and 150 mL/min, respectively. The Hagen-Poiseuille relationship also predicts how fast whole blood and packed erythrocytes will flow. The μ value refers to viscosity. Whole blood flows approximately half as fast as crystalloid, whereas packed erythrocytes flow approximately one fourth as fast. A short, large catheter in a peripheral vein is of far greater value in treating shock than a small-bore, long central catheter.

The first priority in the volume-depleted patient is to support cardiac output. Worthwhile points to remember are that (1) colloid fluids are more effective than whole blood, packed cells, or crystalloids for increasing cardiac output; (2) erythrocyte concentrates are relatively ineffective in promoting cardiac output and flow slowly; (3) colloids add to the plasma volume, whereas crystalloid fluids primarily add to the interstitial volume; and (4) for a given effect on cardiac output, the volume of crystalloids must exceed that of colloids by approximately a factor of 3.

Role of the Fluid Challenge

What to do when we have little idea of what we are doing (Fig. 1-2)? This situation is common in critical care medicine,

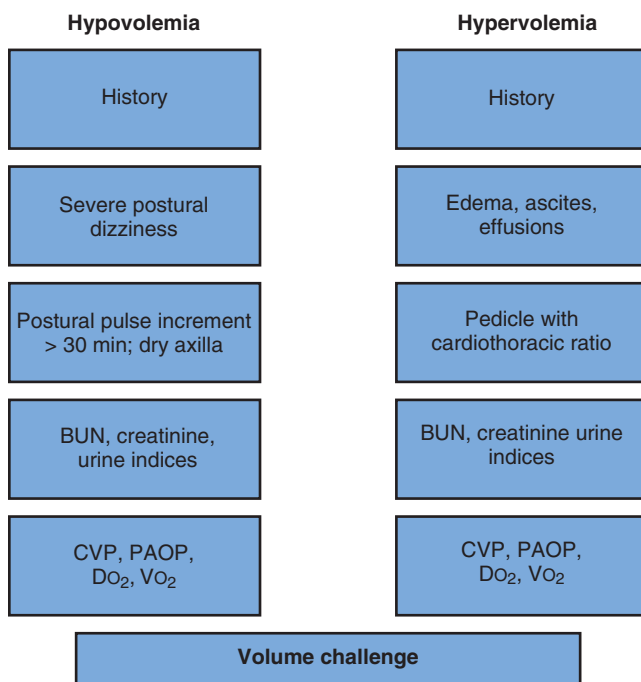

Figure 1-2 The first step in assessing volume status in the critically ill is to keep in mind that all our clinical assessments, laboratory tests, and modes of patient monitoring are fallible and fraught with error. Severe postural dizziness is defined as the inability to stand upright. Postural pulse increment greater than 30 per minute may be absent with acute hemorrhage. Systolic blood pressure decreases (>20 mm Hg), although popular, have a sensitivity and specificity of approximately 10%. Serum and urine chemistries may also be misleading. Edema and ascites speak to the extracellular fluid volume, not to the circulating fluid volume. A chest radiograph may be helpful. Central catheters are not infallible “dipsticks” and commonly mislead. Careful clinical longitudinal assessment, measurement, and documentation are warranted. (Adapted from McGee S, Abernethy WB 3rd, Simel DL: The rational clinical examination. Is this patient hypovolemic? *JAMA* 1999;281:1022–1029; Ely WE, Smith AC, Chiles C, et al: Radiologic determination of intravascular volume status using portable, digital chest radiography: A prospective investigation in 100 patients. *Crit Care Med* 2001;29:1502–1512; and Marik PE: Assessment of intravascular volume: A comedy of errors. *Crit Care Med* 2001;29:1635–1636.)

and the fluid challenge strategy commonly helps and, if carefully done, should do no harm. Volume challenges of 500 to 1000 mL for crystalloids or 300 to 500 mL for colloids over the course of approximately an hour have been suggested for patients suspected of having sepsis, septic shock, or volume depletion due to other causes.²⁶ There is no evidence to favor crystalloid or colloid fluids in this regard. In patients with hypoalbuminemia (<3 g/dL), 5% albumin should be seriously considered for volume resuscitation.

Flushing the Kidneys: Role of Diuretics

Furosemide in the AKI setting is particularly deserving of a few comments. Furosemide is probably the most frequently administered drug in patients meeting the RIFLE criteria. In fact, the most common reason for nephrologic consultation in our hospital is, “This patient refuses to respond to furosemide.” Mehta and colleagues²⁷ have investigated this issue. They determined whether the use of diuretics (mostly furosemide) was associated with adverse or favorable outcomes in critically ill patients with acute renal failure. Mehta and colleagues conducted a cohort study of 552 patients with acute renal failure in intensive care units at four academic medical centers. Patients were categorized by the use of diuretics on the day of nephrology consultation and, in companion analyses, by diuretic use at any time during the first week after consultation. They found that diuretics were used in 59% of patients at the time of nephrology consultation. This author is certain that in Europe the figure would be much closer to 100%. The patients treated with diuretics on or before the day of consultation were older and more likely to have a history of congestive heart failure, nephrotoxic (rather than ischemic or multifactorial) origin of acute renal failure, acute respiratory failure, and lower serum urea nitrogen concentrations. Mehta and colleagues²⁷ found that diuretic use was associated with a significant increase in the risk of death or nonrecovery of renal function. The increased risk was borne largely by patients who were relatively unresponsive to diuretics. Mehta and colleagues concluded that diuretics in critically ill patients with acute renal failure were associated with an increased risk of death and nonrecovery of renal function. The data were observational. The frustrated physicians probably gave the sicker, more oliguric patients more diuretics than the healthier patients. Numerous trials have been conducted on furosemide in the acute renal failure setting in the hope that the drug might decrease oxygen consumption or provide some other advantage for recovery. All controlled trials in this regard were negative. A recent meta-analysis underscored this point.²⁸ Nevertheless, the practice of administering furosemide to all persons with oliguria of any degree persists. Mehta and colleagues stated that in the absence of compelling contradictory data from a randomized, blinded clinical trial, the widespread use of diuretics in critically ill patients with acute renal failure should be discouraged.²⁷ The findings of Mehta and colleagues have had no effect on medical practice thus far, but should have. What do physicians seek to achieve with furosemide—a lower RIFLE score?

Management of Myoglobinuria

Myoglobinuria is a regular feature in trauma patients, but is also observed in any case of muscle injury. The presence of urinary myoglobin does not necessarily denote AKI; however, its absence indicates a substantial decrease in risk.²⁹ Muscle

necrosis releases particularly large amounts of potassium and phosphorus. Myoglobin, when resorbed by the tubular cells, promotes substantial oxidative stress when the iron is released. Aggressive volume resuscitation to prevent hypovolemia and maintain renal blood flow is indicated. Alkalinization of the urine may help limit the renal injury. Trauma teams managing disaster or combat victims regularly begin aggressive volume expansion as soon as an extremity avails itself to allow vessel cannulation. This approach appears prudent. Israeli military physicians report that managing crush injuries with aggressive volume expansion and urine alkalinization protects from AKI.³⁰ However, the authors addressed the issue of trauma victims who, in all likelihood, have severe blood loss necessitating goal-directed therapy. Older patients with heart disease and other concomitant medical problems, such as developing myoglobinuria complicating statin therapy, should not necessarily be treated in the same fashion merely because they have an elevated creatine kinase level or urine that contains myoglobin.

ELECTROLYTE DISTURBANCES

Hypernatremia

Hypernatremia ($\text{Na} > 150$ mmol/L) associated with AKI is common and occurs in both children and adults. Here, volume assessment and the osmolar disturbance must be considered separately. Generally, hypernatremia coexists with volume contraction. However, the intensive care unit is an exception. The coexistence of hypernatremia and edema that develops in an intensive care unit invariably points to physician-induced therapeutic misadventures.³¹ Conscious patients are generally able to protect themselves from this dilemma. When the constellation of volume expansion and edema develops on an outpatient basis, the physician should suspect (salt poisoning) abuse.³²

In a recent review of 105 children admitted to a general pediatrics department, hypernatremic dehydration (volume contraction) represented 12% of all dehydration forms.³³ Half of the children were in shock. Severe dehydration was present in 90% of patients, and neurological signs were observed in 77%. The initial mean serum sodium concentration was 159 mmol/L. Acidosis and AKI were present in 97% and 77% of patients, respectively. The predominant cause of hypernatremic dehydration in these children was diarrhea (94%). The children were given intravenous rehydration with 5% glucose solution at an average of 147 mL/kg/day and containing a mean sodium level of 42 mmol/L. Serum sodium was normalized within the first 72 hours. The mortality rate was 11%. Another hypernatremia in infants relevant to nephrologists is that associated with breast-feeding.³⁴ This serious complication occurs when breast-feeding is insufficient and is often associated with hyperbilirubinemia. Neonatal hypernatremic dehydration results from inadequate transfer of breast milk from mother to infant. Furthermore, poor milk drainage from the breasts can result in persistence of high milk sodium concentrations. Breast-feeding-associated hypernatremia results only when breast-feeding is not properly established. The failure to diagnose hypernatremic dehydration can have serious consequences, including AKI, seizures, intracranial hemorrhage, vascular thrombosis, and death. Most breast-feeding-associated hypernatremia could be prevented if infants

with excessive weight loss or inadequate breast milk transfer were judiciously given expressed breast milk if available and formula if necessary until breast milk production increases and breast-feeding difficulties are addressed by a health care provider well trained in lactation support.

Hypernatremia with AKI is a frequent problem in elderly individuals.³⁵ Changes in the physiologic responses to water deprivation are of particular interest in understanding the pathogenesis of hypernatremia in the elderly. In older persons, there are deficits in both the intensity and threshold of the thirst response. The ability to concentrate the urine also declines with age. There are both a decline in the GFR and an increased incidence of renal disease with advancing age, which may contribute to impaired ability to conserve water. Because of a decrease in the percentage of total body water with age, equal volumes of fluid loss in young and old individuals may represent more severe dehydration in the elderly. The correction of hypernatremia in the elderly requires particular care in terms of administering glucose-containing solutions. Hyperglycemia, coupled with hypernatremia, is particularly undesirable. Continuous venovenous hemofiltration has been used in patients with serum sodium concentrations greater than 200 mmol/L to lower the serum sodium concentration in a controlled fashion.³⁶

Hyperkalemia

The most celebrated life-threatening electrolyte disturbance in patients with acute renal failure is hyperkalemia. The Cochrane database has reported on management.³⁷ Based on small studies, inhaled β -agonists, nebulized β -agonists, and intravenous insulin and glucose were all effective, and the combination of nebulized β -agonists and insulin and glucose was more effective than either alone. Dialysis was invariably effective. The results were equivocal for intravenous bicarbonate. Potassium-absorbing resin was not effective after 4 hours. The Cochrane authorities concluded that nebulized or inhaled salbutamol and intravenous insulin and glucose are the first-line therapies for the management of emergency hyperkalemia that are best supported by the evidence. Their combination may be more effective than either alone and should be considered when hyperkalemia is severe. In adult patients with coronary heart disease, nebulized or inhaled salbutamol would not appear to be a good idea. The experts concluded that further studies of the optimal use of combination treatments and of the adverse effects of treatments are needed.

Kamel and Wei³⁸ recently reviewed controversies in treating hyperkalemia. They concluded that insulin and glucose were frontline and that β -agonists were ineffective in a significant number of patients. Sodium bicarbonate should be reserved for patients who concomitantly have severe metabolic acidosis. Kamel and Wei³⁸ were also reluctant to use exchange resins in patients with acute hyperkalemia. The intravenous administration of calcium salts for hyperkalemia is commonly recommended.³⁹ Intermittent injections of 10 mL of 10% calcium gluconate and/or calcium chloride are given according to guidelines (www.clinicalschool.swan.ac.uk/wics/itugl/hik.him). Calcium salts do not alter the serum potassium concentration, although reversal of electrocardiographic findings is immediate and dramatic. The role of calcium remains unclear because the effect is only

transient; calcium works in a minute, but the effect is also gone in minutes. Therefore, concomitant therapies (insulin and glucose) must be given. Furthermore, calcium should obviously not be given together with sodium bicarbonate because of precipitation. Nonetheless, the successful management of 46 cases of battlefield acute renal failure in Korea by the U.S. Army employed a continuous infusion containing calcium gluconate, sodium bicarbonate, insulin, and glucose.⁴⁰ Presumably, the amounts of sodium bicarbonate and calcium were low or the two were not given concomitantly.

Final words about the electrocardiogram are worthy of mention. Life-threatening hyperkalemia can occur with a relatively normal electrocardiogram, albeit it is unusual. Flat P waves, widened QRS complex, and tented T waves are welcome hyperkalemia signs that are taught to every medical student and illustrated in every textbook. However, these classic signs may be absent and instead there may be merely peculiar QRS conduction delays and more nonspecific signs. The wary clinician is duly suspicious.

Metabolic Acidosis

This topic and its treatment are discussed elsewhere. For intensivist nephrologists, type B lactic acidosis induced by metformin deserves a comment. The drug, which is indicated in almost all overweight patients with the metabolic syndrome, polycystic ovarian syndrome, and type 2 diabetes mellitus, has a mode of action that is now quite well understood.⁴¹ Unfortunately, the drug can induce type B (without shock) lactic acidosis, and the risk is actually only relevant when renal function is impaired. Metformin should not be given to persons with a GFR less than 60 mL/min. In an earlier review, this author handled this topic fairly lightly,⁴² but has since seen several patients with profound lactic acidosis that could only be attributed to metformin. In all cases, physicians had failed to discontinue the drug, despite an obvious decrease in renal function. Discontinuing metformin is the cornerstone of treatment.

MANAGING OTHER UREMIC COMPLICATIONS

Uremic Bleeding and Thrombosis

Uremic platelets function less well than platelets in a normal environment. Early studies proposed a role for guanidinosuccinic acid that accumulates when renal function falls to low levels. This idea was probably not a bad one because we now know that guanidinosuccinic acid in uremic blood depends on amidine being transferred to aspartic acid from L-arginine. L-Arginine is the major substrate of nitric oxide (NO) synthase. NO is the major modulator of vascular tone (endothelial function) that limits platelet adhesion to endothelium and platelet-platelet interaction, increasing the formation of cell cyclic guanosine monophosphate. Guanidinosuccinic acid causes cultured endothelial cells to produce NO. An increase in NO may also decrease fibrinogen binding to the platelet GP IIb/IIIa receptor. Noris and Remuzzi⁴³ point out that uremia is a high NO state, at least as far as the platelet is concerned. Platelets from uremic patients produce more NO. N^G-monomethyl-L-arginine restores platelet stickiness

and responses to adenosinediphosphate in uremic platelets. Noris and Remuzzi⁴³ argue that uremic bleeding is largely due to an exuberant formation of NO by uremic vessels, a process that is guanidinosuccinic acid dependent.

Nevertheless, treating uremic patients with N^G-monomethyl-L-arginine seems premature. NO synthase is already inhibited by asymmetrical dimethyl arginine that accumulates in patients with decreased renal function. Brunini and colleagues⁴⁴ suggest that reduced plasma L-arginine and NO production as well as increased tumor necrosis factor α , fibrinogen, and C-reactive protein levels in uremic patients cause increased aggregability of platelets, which could conceivably occur when uremic patients are poorly nourished and poorly dialyzed.

Treatment options center on recombinant erythropoietin or darbepoietin- α , adequate dialysis, desmopressin, tranexamic acid, or conjugated estrogens.⁴⁵ Thrombotic complications in uremia are caused by increased platelet aggregation and hypercoagulability. Erythrocyte-platelet aggregates, leukocyte-platelet aggregates, and platelet microparticles are found to a greater degree in uremic patients compared with healthy individuals. Increased platelet phosphatidylserine expression initiates phagocytosis and coagulation. Therapy with antiplatelet drugs does not reduce vascular access thrombosis but instead increases bleeding complications. Heparin-induced thrombocytopenia (type II) may develop in hemodialyzed patients, but is fortunately relatively uncommon. Furthermore, heparin-induced thrombocytopenia antibody-positive uremic patients generally develop only mild thrombocytopenia and only very few thrombotic complications. Substitution of heparin by hirudin, danaparoid, or regional citrate anticoagulation is an option in individual cases.

Drug-Dosing Principles

A scholarly chapter on this complicated issue follows, allowing only a few general comments here. Critical illness has a great impact on many pharmacokinetic parameters. An increased volume of distribution often results in drug underdosing, whereas organ impairment may lead to drug accumulation and overdosing. Renal replacement therapy (RRT) in critically ill patients with renal failure may significantly increase drug clearance, requiring drug-dosing adjustments. Drugs significantly eliminated by the kidney are likely to experience substantial removal during RRT, and a supplemental dose that corresponds to the amount of drug removed by RRT should be administered. Mechanisms of drug removal during RRT have been investigated in detail, along with methods for measuring or estimating RRT drug clearances. Numerous investigators have outlined approaches for drug-dosing adjustments, and the pharmacologic principles, particularly for antibiotic prescription, are readily available elsewhere.

Renal Replacement Therapy

Approximately 70% of patients with established acute renal failure require RRT. The primary indications remain volume expansion, electrolyte disturbances (primarily hyperkalemia), acid-base disorders (usually metabolic acidosis), and encephalopathy (uremic symptoms). The eponym A-E-I-O-U still serves a purpose in terms of student instruction (acidosis, electrolytes, intoxication, [volume] overload, and uremia).

However, the indications have been modified and made less restrictive, particularly as innovative therapies have become available. Uremic encephalopathy is an unusual indication nowadays. There are no creatinine or GFR values that absolutely indicate dialysis; the decision remains a clinical judgment. For hemodialysis and hemofiltration, appropriate blood access is required. Large-bore, double-lumen vascular catheters are used for this purpose. The catheters are introduced into the internal jugular or femoral veins. Subclavian vein access is relatively contraindicated because injury to this vessel is common. Subclavian vein thrombosis makes the peripheral veins of the corresponding extremity useless in terms of long-term hemodialysis blood access.⁴⁶ Should AKI patients with central access catheters receive thrombosis prophylaxis? They probably should.⁴⁷

The dialysis care of AKI patients requiring it is outlined in detail elsewhere, and state-of-the-art recommendations are made. However, many patients requiring RRT receive much less than they deserve or what their physicians have prescribed. Venkataraman and colleagues⁴⁸ reviewed the records of AKI patients undergoing intermittent dialysis and found that they were prescribed 25 mL/kg/hr (too little in this author's view). However, they received only 16.5 mL/kg/hr. The logistics of dialysis in intensive care units is difficult; competing machinery, diagnostic test scheduling, multiple care teams, and other confounders all contribute to the dilemma.

Recovery and Prognosis

In the past, failure to recover from acute renal failure was associated with renal cortical necrosis, commonly after postpartum hemorrhage. Today, in younger individuals, non-Shiga's toxin-mediated hemolytic uremic syndrome is a prominent cause. Not appreciated particularly by non-nephrologist clinicians is the role of cholesterol emboli as a cause for nonreversible acute renal failure.⁴⁹ Few studies have addressed the issue of long-term outcome in established acute renal failure patients. Bagshaw⁵⁰ focused on this issue. He found that the survival rates were variable and ranged from 46% to 74%, 55% to 73%, 57% to 65%, and 65% to 70% at 90 days, 6 months, 1 year, and 5 years, respectively. Older age, comorbid illness, illness severity, septic shock, and RRT after cardiac surgery were associated with reduced survival. Recovery to independence from RRT occurred in 60% to 70% of survivors by 90 days. Health-related quality of life was generally good and perceived as acceptable. Acute renal failure survivors often experienced difficulty with mobility and limitations in activities of daily living. RRT was costly and achieved marginal cost-effectiveness in terms of quality-adjusted survival for those with a higher probability of survival. Bagshaw concluded that the long-term survival after acute renal failure was poor. Yet, most survivors recover sufficient function to become no longer dependent on RRT.

In the past, post-acute renal failure/post-obstructive diuresis were commonly observed during the recovery from acute renal failure, particularly when dialysis was not often used. One reason for this phenomenon was probably related to volume expansion. However, tubular dysfunction, particularly after obstruction, can occur. A patient with Burkitt's lymphoma and obstructing lymph nodes may claim the world's record. The patient developed anuria after aggressive chemotherapy and bowel surgery.⁵¹ During recovery, as the patient's creatinine

concentration decreased from 7 to 1.5 mg/dL over a 5-day period, his urinary output increased from 0 to more than 80 L/day. The volume replacement given the patient was always close to, but less than, his output, suggesting that the clinicians were not contributing to the situation. Furthermore, daily weights did not suggest that volume expansion was responsible. The dramatic situation subsequently resolved. Clinicians must be aware that postoperative intra-abdominal hypertension is associated with acute renal failure as well as with subsequent post-obstructive diuresis. Abdominal pressures can be monitored via the bladder. Because acute renal failure is commonly elicited by shock, checking posterior pituitary function and renal concentrating ability is worthwhile in patients who are polyuric during recovery. Central diabetes insipidus after shock syndromes is well-known but less appreciated outside of the obstetrical service. Severe ischemic injury may also result in permanent alteration of renal capillary density and the predisposition to the development of renal fibrosis, with subsequent nephrogenic diabetes insipidus.

Management of the recovery phase of acute renal failure focuses on attention to details. Intake and output are routinely measured in every intensive care unit, whereas a general resistance to obtaining daily weights seems to be an international phenomenon. Strict and specialized hemodynamic monitoring is warranted. Medical management must be designed to avoid serious hemodynamic and metabolic disorders.

Established acute renal failure is similar to acute respiratory distress syndrome in that it is not a primary disease, but a complication of other disease processes, particularly septic shock.^{52,53} Consequently, the mortality rate of acute renal failure mirrors the mortality rate of the primary diseases responsible for its development. Because these primary diseases have a high mortality rate, the fact that the mortality rate of acute renal failure has remained unchanged in the past 60 years is not surprising.⁵²⁻⁵⁴ Furthermore, the fact that hemodialysis and other RRTs have not altered mortality also comes as no surprise. Unfortunately, this state of affairs has escaped the evidence-based medicine crowd that preaches discarding those interventions that have not been shown to improve mortality.

SUMMARY 30

DOPAMINERGIC AGENTS IN ACUTE RENAL FAILURE

Dopamine was first described by Barger and Dale¹ in 1910 and has been used in clinical practice since the 1960s. Its popularity stems from early work suggesting that at low doses, it had the ability to increase renal blood flow (RBF), diuresis, and natriuresis in both animal studies² and studies with healthy human volunteers.^{3,4} It remained the mainstay of both treatment and prevention of acute renal failure (ARF) for three decades. However, since the 1990s, the evidence base for low-dose dopamine has been called into question and during the 2000s, the evidence against it being beneficial has become substantial.

Fenoldopam mesylate is a selective DA₁ receptor agonist. It is currently being used for treatment of hypertensive crises.⁵ It has been hypothesized that fenoldopam may be beneficial in the treatment or prevention of ARF because of its DA₁ receptor selectivity.⁶

The following section looks at the physiology of dopamine and fenoldopam in both health and critical illness, and the reasons why dopamine was initially thought to be beneficial. It also covers the evidence for and against both dopamine and fenoldopam in the prevention of ARF in high-risk patients and in the treatment of ARF in the critically ill.

Dopamine

Physiology of Intrarenal Dopamine

Dopamine is synthesized by the kidney and is a critical regulator of sodium excretion.^{7,8} It achieves this by directly inhibiting sodium reabsorption via inhibition of sodium transporters along almost the entire length of the nephron and by interacting with

other regulators of sodium excretion, including atrial natriuretic peptide, catecholamines, vasopressin, angiotensin, and prostaglandins.⁸ This physiologic role of dopamine is important to the understanding of the effects of exogenous dopamine and is therefore discussed briefly in this section.

Proximal tubule epithelial cells synthesize dopamine from the substrate L-dopa using the enzyme L-amino acid decarboxylase. L-Dopa enters the cell from the tubular lumen by a sodium-coupled transport mechanism. Dietary sodium load is the major factor controlling intrarenal dopamine synthesis; the exact mechanism linking increased salt intake to increased renal dopamine synthesis is not understood. Upon synthesis, intrarenal dopamine may act in an autocrine fashion by binding dopamine receptors on the proximal tubule cell or pass along the urinary space to bind to specific receptors on distal portions of the nephron. Importantly, the natriuretic effect of dopamine is prominent in states of sodium loading and is weak or negligible in salt-depleted states.^{9,10}

Dopamine inhibits the activity of the Na/K ATPase in the proximal tubule, the thick ascending limb of Henle, the distal tubule, and the collecting duct. Dopamine also has profound effects on sodium entry into tubule cells via inhibition of the Na/H exchanger and Na/PO₄ exchanger in the proximal tubule. Dopamine also inhibits the Na/Cl cotransporter in the thick ascending limb and the vasopressin-stimulated sodium transporter in the collecting duct.

Intrarenal dopamine interacts with other hormonal regulators of sodium excretion. For example, the natriuretic effect of atrial natriuretic peptide is dependent on renal dopamine receptors. Conversely, the inhibitory effect of dopamine on the proximal tubule Na/H exchanger is potentiated by atrial natriuretic peptide. Dopamine and α -adrenergic agonists counteract each other's effect on basolateral Na/K ATPase. In addition,

dopamine inhibits the stimulatory effect of angiotensin on Na/K ATPase in part by inhibition of angiotensin I receptor expression. Vasopressin-dependent sodium and water transport in the cortical collecting duct is inhibited by stimulation of dopamine receptors at these sites. Finally, dopamine enhances the synthesis of other locally acting natriuretic compounds, such as prostaglandin E₂.

Dopamine receptors are expressed on the renal vasculature.¹¹ DA₁ receptors are localized within the vessel wall media, whereas DA₂ receptors are present in the adventitia and are probably localized presynaptically on sympathetic nerve terminals. The vascular effects of dopamine in the kidney are mediated by dopamine released by dopaminergic nerves and circulating dopamine but not dopamine synthesized by the proximal tubules.⁸

Recent studies have examined the activity of renally synthesized dopamine in disease. In patients with both acute and chronic heart failure, proximal tubular uptake of the precursor L-dopa is enhanced perhaps to preserve renal dopamine production.¹² Patients with renal parenchymal disease have reduced activity of their renal dopaminergic system.¹³

Effects of Exogenous Dopamine on Renal Function in Healthy Persons

Dopamine can bind to at least three types of receptor: the dopamine receptor, the β -adrenoreceptor, and the α -adrenoreceptor.¹⁴ There are differences in the affinity of these receptors for dopamine, and this accounts for the dose-response profile observed with infusion. In general, selective dopamine receptor stimulation occurs within an infusion rate range of 0.5 to 3.0 $\mu\text{g}/\text{kg}/\text{min}$. Further increases in infusion rate between 3 and 10 $\mu\text{g}/\text{kg}/\text{min}$ result in increasing β -adrenoreceptor stimulation, and increased α -adrenoreceptor stimulation occurs at a rate between 5 and 20 $\mu\text{g}/\text{kg}/\text{min}$. These dose ranges are only approximate and must be interpreted with caution because they were derived from small studies using healthy patients.¹⁴ In general, studies have shown a poor correlation between infusion rates and plasma dopamine levels in critically ill patients.¹⁵ There is a high interpatient and inpatient variability in the effects of any given dopamine infusion rate.¹⁶ Thus, low-dose dopamine should not be referred to as renal dose dopamine because at this infusion rate (0.5–3 $\mu\text{g}/\text{kg}/\text{min}$) it is possible that all three receptor types are stimulated. Consistent with this, tachycardia is frequently seen in patients receiving low-dose dopamine.¹⁷ Dopamine clearance is reduced in critically ill patients and in patients with renal impairment.¹⁵

In healthy adults, dopamine infusion increases RBF; the mechanism for this effect is dependent on the infusion rate.^{3,18,19} At low infusion rates, dopamine induces renal vasodilation and increases RBF and can do this without any change in systemic hemodynamics—an effect mediated by dopaminergic receptors on the intrarenal vasculature.^{20,21} This effect can be mimicked by selective DA₁ receptor agonists such as fenoldopam.⁶ Stimulation of presynaptic DA₂ receptors on sympathetic nerve terminals with inhibition of norepinephrine release may further augment renal vasodilation and RBF.²² With higher infusion rates, RBF is increased as a consequence of increases in cardiac output, mediated by β -adrenoreceptor stimulation.²³ In healthy humans, low-dose dopamine counteracts the reduction in RBF observed with norepinephrine infusion.^{24,25}

Knowledge of how low-dose dopamine affects the intrarenal distribution of blood flow is important because specific areas of the kidney are more susceptible to ischemic injury

than others. Most animal models have shown a preferential increase in cortical flow with dopamine.⁷ This was confirmed in humans by Hoogenberg and colleagues²⁴ using a xenon washout technique. Dopamine-induced prostaglandin E₂ production may also enhance inner medullary blood flow.²⁶ Thus, dopamine may shunt blood away from the outer medulla, which would be detrimental in states of renal hypoperfusion given that the outer medulla contains the pars recta of the proximal tubule and the medullary thick ascending limb, two highly metabolically active portions of the nephron. In a study of patients with severe sepsis, low-dose dopamine increased RBF, but this was accompanied by a reduction in the renal oxygen extraction ratio, which led to no net change in renal oxygen consumption.²⁷

Low-dose dopamine has minimal effects on the glomerular filtration rate (GFR) in healthy subjects.^{16,19} Most studies report a mild increase in the GFR of approximately 10% to 20%, whereas others report no change as assessed by creatinine clearance or iothalamate clearance. Increases in the GFR are mediated by preferential afferent arteriolar vasodilation and an increase in intraglomerular pressure, as demonstrated in single-nephron studies.²⁸ The ultrafiltration coefficient remains unchanged with dopamine infusion.⁷ The selective DA₁ receptor agonist fenoldopam did not change the GFR in healthy adults.⁶

The hemodynamic effects of low-dose dopamine infusion on healthy subjects differ with age, race, extracellular fluid volume status,²⁹ and duration of infusion.³⁰ In neonates, activation of α -adrenoreceptors occurs at much lower infusion rates.³¹ In general, the selective vasodilatory effects of dopamine are not seen in young children.³² With increasing age, the effects of dopamine on RBF and GFR are attenuated, perhaps because of impaired renal prostaglandin production.^{33,34} Blacks are more likely to exhibit pressor responses to low-dose dopamine than whites.³⁵ Blacks also appear to be more resistant to the natriuretic effects of dopamine.³⁵

A natriuresis is the most consistent physiologic response to low-dose dopamine in healthy humans.¹⁹ This effect is rapid in onset and may be profound. It is abrogated by extracellular fluid volume depletion²⁹ and typically wanes after 24 hours of infusion, perhaps as a result of counteractive antinatriuretic factors or perhaps dopamine receptor down-regulation.^{3,30,36,37} Oral dopamine receptor antagonists commonly used as antiemetic agents or to enhance gastric motility may or may not counteract the hemodynamic and natriuretic effects of dopamine.^{38,39} In addition to the direct tubular effects of dopamine, dopamine infusion may induce natriuresis by inhibiting adrenal aldosterone production.^{40,41}

Effects of Exogenous Dopamine on Renal Function in Disease States

Whereas low-dose dopamine consistently causes renal vasodilation in healthy adults, this effect is often attenuated or absent in critically ill patients (Table 2-1). Several factors may account for this, such as abnormal vasculature (e.g., atherosclerosis), hypertensive arteriopathy and renal artery stenosis, and counterregulatory effects of other vasoactive hormones, including increased activity of the renin-angiotensin-aldosterone system and the sympathetic nervous system.

Both extracellular volume depletion and hypoxemia have been shown to abrogate the renal effects of dopamine.^{29,42} Some clinical settings in which studies have reported diminished effects of dopamine include chronic kidney disease,⁴³

cardiac failure,³ septic shock treated with norepinephrine,⁴⁴ hypertension,⁴⁵ critically ill patients in intensive care units (ICUs),^{17,46} and after vascular surgery.^{40,47}

ter Wee and colleagues⁴³ found patients with chronic kidney disease to be less responsive than normal individuals to the renal vasodilatory action of dopamine. The increase in RBF and GFR observed with low-dose dopamine correlated with the baseline GFR. Patients with a baseline GFR of less than 50 mL/min showed no change in RBF or GFR with dopamine infusion.⁴³ McDonald and colleagues³ showed that low-dose dopamine does not increase RBF in patients with clinical and radiologic heart failure.

Girbes and colleagues⁴⁰ looked at patients undergoing infrarenal aortic surgery. They found that low-dose dopamine did increase RBF, but this was accounted for by an increase in cardiac output rather than selective renal vasodilation. In a prospective crossover study comparing dobutamine and dopamine in critically ill patients, dopamine acted primarily as a diuretic and had no effect on creatinine clearance, whereas dobutamine, which had a greater effect on cardiac index, increased creatinine clearance. Lauschke and colleagues⁴⁸ looked at low-dose dopamine in patients with and without ARF. Dopamine was found to reduce renal resistive indices in patients without ARF, but increased resistive indices in patients with ARF. This suggests that dopamine can worsen renal perfusion in patients with ARF.

A study that did find an initial increase in creatinine clearance in critically ill patients treated with low-dose dopamine showed that this effect had disappeared after 48 hours, suggesting a tolerance to the effects of dopamine over time.³⁶ Marik⁴⁹ found that high levels of renin in critically ill patients may counteract the effects of dopamine.

In addition to these studies showing the reduction of the hemodynamic effects of dopamine in disease states as compared with healthy adults, it has been demonstrated that there is a poor correlation between dopamine infusion dose and dopamine plasma level,¹⁵ calling into doubt the concept of low-dose dopamine.

In summary, the hemodynamic effects of dopamine that have been demonstrated in healthy adults are reduced in a

number of disease states. The only effects that persist are increased diuresis and natriuresis.⁵⁰

Value of Low-Dose Dopamine in Preventing Acute Renal Failure in High-Risk Patients

A limitation of the efficacy of any treatment designed to prevent ARF is the difficulty in predicting its occurrence and hence the correct timing of treatment. However, when patients are about to undergo a high-risk procedure, prophylactic administration of renoprotective agents can be timed appropriately. In these circumstances, judgment is required as to whether it is appropriate to expose all patients to the potential side effects of a given drug when the potential benefit may be gained by only a few patients. Several well-defined clinical situations are associated with renal hypoperfusion and a high risk of developing ARF. These include cardiac, vascular, and biliary surgery, renal and liver transplantation, and exposure to radiocontrast agents or vasoactive drugs. The prophylactic administration of low-dose dopamine in an attempt to prevent renal hypoperfusion and injury has been evaluated in these settings. Some of the studies looking at these individual populations are discussed and the larger meta-analyses that look at all these groups as a whole are reviewed. The major trials are summarized in Table 2-2.

Cardiovascular Surgery

Five studies have examined the efficacy of low-dose dopamine infusion in the prevention of ARF during cardiac surgery.⁵¹⁻⁵⁵ Three studies have examined the efficacy of low-dose dopamine infusion in the prevention of ARF during peripheral vascular surgery.^{47,56,57} All studies failed to demonstrate a beneficial effect of dopamine on renal function, as assessed by urea (blood urea nitrogen [BUN]), creatinine, or creatinine clearance. However, the incidence of ARF in the control groups of some of these studies was low (perhaps a result of study participation), making it difficult to detect a benefit of dopamine. Three studies examined evidence of more subtle ischemic renal damage by measuring markers of tubule injury such as urinary retinal binding protein and β_2 -microglobulin.⁵¹⁻⁵⁵ Overall, prophylactic low-dose dopamine infusion appeared to be

associated with increased renal tubular injury. A second study by Yavuz and colleagues⁵⁸ in patients undergoing coronary artery grafting showed a higher creatinine clearance in patients treated with both dopamine and diltiazem than those treated with either drug alone or placebo. However, it was a small study, with each of the four groups containing only 15 patients. The other studies looking at cardiac surgery were also relatively small (between 22 and 82 patients). Jones and colleagues⁵⁹ recruited 1100 patients undergoing cardiopulmonary bypass, to be prospectively randomized to dopamine, furosemide, mannitol, or control (ISRCTN 98672577, www.controlled-trials.com). This will perhaps provide more evidence in this particular subgroup of at-risk patients.

Liver Transplantation and Hepatobiliary Surgery

Liver transplantation is associated with a high incidence of renal failure, in part from the chronic renal hypoperfusion that complicates liver failure and the nephrotoxicity of hyperbilirubinemia and calcineurin inhibitors. In a large prospective, controlled trial involving 48 patients, perioperative infusion of dopamine was not associated with lower BUN or an improved creatinine clearance at 24 hours after surgery or with isotope GFR measured at 1 month.⁶⁰ The incidence of ARF was similar in both groups, but was very low at 4% compared with 40% to 60% in some series.

Two trials have looked at the effect of dopamine on patients with obstructive jaundice and hyperbilirubinemia who were undergoing surgery. In a prospective, randomized, controlled trial involving 40 patients, Wahbah and colleagues⁶¹ concluded that administration of low-dose dopamine conferred no additional benefit over adequate hydration. Similarly, Parks and colleagues⁶² randomized 23 patients to dopamine or saline infusion during surgery for obstructive jaundice and found no benefit of dopamine infusion on creatinine clearance 5 days after surgery.

Renal Transplantation

Four studies have examined the role of perioperative low-dose dopamine infusion during renal transplantation, including three prospective studies^{63–65} and one retrospective study.⁶⁶ Endpoints measured included incidence of posttransplantation ARF, delayed graft function, requirements for dialysis, and allograft GFR at various points after transplantation. Three studies indicated no beneficial effects of perioperative dopamine infusion on allograft function. Indeed, dopamine-induced natriuresis and diuresis were often associated with fluid and electrolyte management problems in these patients. Carmellini and colleagues⁶⁴ reported a small but significantly higher GFR at 1 month in the dopamine-treated transplantation group. However, there were no significant differences in the rate of delayed graft function or in the requirement for dialysis between groups in this study.

Radiocontrast-Induced Nephropathy

Radiocontrast agents are a major cause of hospital-acquired ARF. Patients with diabetes, patients with preexisting renal impairment, and patients with intravascular volume depletion are most at risk of radiocontrast-induced nephropathy. In the majority of cases, radiocontrast-induced nephropathy is mild and reversible; however, contrast exposure may precipitate the need for permanent dialysis in patients with baseline chronic renal failure. The mechanism for this effect

is contrast-induced intrarenal vasoconstriction. The role of prophylactic dopamine to prevent radiocontrast-induced nephropathy has been assessed in six trials.^{67–72} Hans and colleagues⁶⁸ reported a significant reduction in ARF episodes (increase in creatinine >0.5 mg/dL) from 44% to 18% with dopamine infusion. Kapoor and colleagues⁶⁹ found similar results, although all cases of ARF were transient and not requiring acute dialysis. Four studies found no difference in the rate of ARF.^{67–72} It is difficult to justify the use of prophylactic dopamine, considering its potential significant side effects (see “Potentially Deleterious Effects of Dopamine”) including the need for central venous access, based on these studies.

Influence of Low-Dose Dopamine on Established Acute Renal Failure

Established acute tubular necrosis (ATN) is associated with a reduced GFR owing to several mechanisms, including (1) impaired glomerular perfusion secondary to preglomerular vasoconstriction, (2) back-leakage of glomerular filtrate through injured tubular epithelium, and (3) obstruction of the renal tubules by cellular debris.

Proponents of low-dose dopamine infusion argue that dopamine may improve the outcome of ATN by (1) improving renal perfusion, (2) inhibiting tubular transport processes and therefore improving the oxygen supply/demand relationship, and (3) “flushing out” renal tubules by inducing diuresis.

This presumption was strengthened by a small ($N = 23$) prospective, randomized, controlled trial (RCT) that looked at ARF in patients with falciparum malaria.⁷³ This study found that in patients with ARE, but with serum creatinine less than 400 $\mu\text{mol/L}$, dopamine reduced the recovery time from 17 days to 9 days.

Questions about the evidence base for dopamine began to be raised in a number of editorials and commentaries in the mid-1990s,^{74–76} but despite this, there remained a strong tradition of dopamine use for the treatment of ARF. For example, a survey in 2001 found that 17 of 24 ICUs in New Zealand were still using dopamine for the treatment of ARF or oliguria. There is now considerable evidence to suggest that dopamine is, at best, ineffective at reducing mortality or the need for renal replacement therapy in ARF. Recently, three systematic reviews^{77–79} and a large multicenter RCT⁷⁸ looked at the benefits of dopamine versus placebo in the treatment of ARF or the prevention of ARF in high-risk groups. The RCT from the Australian and New Zealand Intensive Care Society Clinical Trials Group looked at 328 patients in 23 ICUs. The inclusion criteria were two or more criteria for the systemic inflammatory response syndrome and one indicator of early renal dysfunction (urine output < 0.5 mL/kg/hr, serum creatinine > 150 $\mu\text{mol/L}$ in the absence of premonitory renal dysfunction, or an increase in creatinine > 80 $\mu\text{mol/L}$ within 24 hours). The patients were randomized to dopamine or placebo in a double-blind manner. The authors found no significant difference in primary outcome (peak serum creatinine) between the two groups, nor was there a difference in the increase in creatinine from baseline, the number of patients whose creatinine exceeded 300 $\mu\text{mol/L}$, the need for renal replacement therapy, the length of ICU stay, the length of hospital stay, or the number of deaths.⁷⁸

In an observational study, Chertow and colleagues⁸⁰ analyzed a subgroup of patients who received low-dose dopamine in the

placebo arm of a multicenter intervention trial. All patients in the placebo arm were adults with ARF (defined as an increase in the serum creatinine concentration of at least 1 mg/dL during 24–49 hours) and had a clinical history consistent with ATN. Dopamine had been administered to a portion of these patients at the discretion of the physician. A total of 86 patients received dopamine (<3 µg/kg/min) and 79 did not. Despite complex adjustment for treatment bias, low-dose dopamine treatment was not associated with a reduced risk of death or dialysis in patients with ATN.

Meta-analysis of Trials

Kellum and Decker⁷⁹ looked at 58 studies of 2149 patients, including 17 RCTs (854 patients). They included all studies looking at either the treatment or prevention of ARF and found no significant difference between dopamine and placebo in mortality or the need for renal replacement therapy. Marik⁸¹ looked at 15 RCTs of 970 patients that included studies looking at either the prevention or treatment of early renal dysfunction. It demonstrated no significant difference between the absolute change in serum creatinine or the incidence of ARF between those patients receiving low-dose dopamine and those receiving placebo. Friedrich and colleagues⁷⁷ looked at 61 trials with 3359 patients; they included patients with or at risk for ARF and who were patients having cardiac, vascular, and other surgery; receiving radiologic contrast or other nephrotoxins; or had miscellaneous indications. Their review included the Australian and New Zealand Intensive Care Society study, which was the second largest study and dominated the clinical outcomes data (with a weighting of 68.1% for mortality and 27.4% for renal replacement therapy). As well as looking at mortality and the need for renal replacement therapy, the authors of this review also looked at a variety of renal physiologic indices. Their findings mirrored those of the previous reviews, showing no evidence that dopamine offers any clinically important benefits to patients with or at risk for ARF. These results were similar when the Australian and New Zealand Intensive Care Society study was excluded from the analysis (to ensure that one large study did not skew the results extraordinarily). The physiologic analysis showed an increased urine output of 24% with dopamine therapy on day 1. This effect decreased and was no longer significant beyond the first day. The authors concede that the inevitable heterogeneity of the systematic review meant that the analysis might have been underpowered to detect any subgroup effects.

Summary

The conclusion that we draw from these studies is that there is no evidence that dopamine is of any benefit over placebo in reduction of mortality or the need for renal replacement therapy in patients with or at risk of ARF. These disappointing results may be due to several factors: (1) the renal hemodynamic effects of dopamine appear to be attenuated in critically ill patients, (2) dopamine may have a detrimental effect on the intrarenal distribution of blood flow, and (3) inhibition of proximal tubule solute reabsorption may enhance distal delivery of solute and increase the workload of distal nephron segments.

The three recent meta-analyses all included studies looking at the benefit of dopamine in the prevention of ARF in high-risk groups. These failed to show any benefit of dopamine over

placebo, and the authors concluded that low-dose dopamine should no longer be used for these indications. It could be argued that the obvious limitations of meta-analyses (i.e., the heterogeneous nature of the population studied) preclude extrapolation to individual subgroups. While there is a theoretical possibility that low-dose dopamine may be of benefit to one subgroup, this has not been indicated convincingly in any of a number of smaller trials. If this were to be the case, it would require a large prospective, randomized, controlled trial in one of the specific subgroups (for example, the study cited earlier that recruited 1100 patients undergoing coronary artery bypass grafting)⁵⁹ (ISRCTN 98672577, www.controlled-trials.com). Unless a future trial shows convincing evidence of benefit in a particular population, there should currently be no place for low-dose dopamine in the prevention of ARF in high-risk patients.

Potentially Deleterious Effects of Dopamine

Although proponents advocate the use of low-dose dopamine in ARF on the grounds that it may improve renal function and is unlikely to harm the patient, evidence is accumulating that the latter is a misconception. Table 2-3 outlines common adverse effects of low-dose dopamine. Administration of dopamine requires a central venous catheter. While this may be a routine procedure for patients undergoing cardiac surgery, for example, the additional risks of a central line for routine radiologic contrast procedures must be strongly considered. Local extravasation of dopamine adjacent to an artery may provoke distal ischemia and gangrene. Even at low doses, dopamine can, through β-receptor agonism, increase myocardial oxygen demand and precipitate tachyarrhythmias and myocardial ischemia.^{82–84} There is evidence to suggest that in patients undergoing cardiac surgery, dopamine may increase the risk of postoperative atrial fibrillation or flutter by 74%.⁸⁴

Neural dopamine is an inhibitory neurotransmitter in the carotid bodies, and dopamine infusion can suppress the respiratory drive induced by hypoxemia.⁸⁵ Dopamine can also lower blood Pao₂ by altering ventilation-perfusion matching within the lung, an effect arising from a shunt of blood away

Table 2-3 Deleterious Effects of Low-Dose Dopamine

Effect	Cause
Distal gangrene	Local extravasation of dopamine
Fluid and electrolyte imbalance	Inhibition of salt and water reabsorption
Tachyarrhythmias and myocardial ischemia	β-adrenoreceptor stimulation
Hypoxemia	Reduced respiratory drive; pulmonary shunting
Gut ischemia and bacterial translocation	Shunting of blood away from mucosal capillary bed
Catabolic	Inhibition of growth hormone release
Immunosuppression	Inhibition of prolactin release

from alveolar capillaries.^{18,82} Hypoxemia may worsen myocardial ischemia in susceptible patients and delay recovery from ischemic ATN.

Fluid and electrolyte imbalance is common and has been reported in several studies using dopamine, especially after renal transplantation. The natriuresis and diuresis induced by inhibition of tubular sodium reabsorption and antidiuretic hormone release can cause severe volume depletion unless close monitoring of the patient permits sufficient fluid replacement. Potassium depletion is also a common result of the increased delivery of sodium to the distal tubule. Hypophosphatemia and hypomagnesemia have also been reported.

Low-dose dopamine suppresses pituitary function and inhibits prolactin and growth hormone secretion and hence may exacerbate the catabolic state in critically ill patients.⁸⁶ Hypoprolactinemia suppresses T-cell proliferation.⁸⁷

Although low-dose dopamine increases total splanchnic blood flow, animal studies have shown that absolute intestinal mucosal flow is decreased as a result of dopamine-induced shunting of blood away from the mucosa.⁸⁸ This complication is of some concern, particularly in the critically ill patient in whom critical intestinal mucosal ischemia may lead to bacterial translocation and sepsis. When high-dose dopamine was compared with norepinephrine in patients with septic shock, dopamine was associated with a drop in gastric mucosal pH (an indicator of mucosal ischemia) compared with norepinephrine.⁸⁹

Finally, low-dose dopamine hastened the onset of gut ischemia in a porcine model of hemorrhagic shock as a result of shunting blood away from the bowel mucosa rather than an absolute reduction in mesenteric blood flow.⁹⁰

Fenoldopam

Fenoldopam mesylate is a selective DA₁ receptor agonist. It is currently being used for the treatment of hypertensive crises.⁵ It has been hypothesized that fenoldopam may be beneficial in the treatment or prevention of ARF.⁹¹ The reasons for this hypothesis, along with the evidence of its efficacy, are discussed in the following sections.

Rationale for Use of Fenoldopam

Dopamine receptors are expressed on the renal vasculature. DA₁ receptors are localized to the smooth muscle of the arterial beds, whereas DA₂ receptors are localized on the adventitia and probably on the sympathetic nerve terminals. It is the DA₁ receptor that mediates renal arterial vasodilation and natriuresis. DA₂ receptors cause vasoconstriction.⁹²

Fenoldopam mesylate is a benzapine derivative that is a potent short-acting DA₁ receptor agonist. It is slightly more active than dopamine on the DA₁ receptor, but has no action on DA₂ or β- or α-adrenoreceptors. This action means that fenoldopam has none of the adrenergic effects of dopamine and may cause more vasodilation in the outer renal medulla than in the cortex.⁹³ This may be important given that the outer medulla contains the pars recta of the proximal tubule and the medullary thick ascending limb, two highly metabolically active portions of the nephron. Therefore, at lower doses (0.03–0.1 μg/kg/min) it increases RBF without affecting systemic hemodynamics. At higher doses (>1 μg/kg/min) it causes dose-related hypotension, and it is at these doses that it is used in the treatment of accelerated hypertension. There is

a suggestion that fenoldopam may improve renal function in patients with severe hypertension.⁹⁴

Fenoldopam in the Prevention or Treatment of Acute Renal Failure

In the same way that the effects of dopamine have been studied in attempts to prevent ARF in high-risk populations, the same populations have been studied with respect to fenoldopam, although there is not yet the same volume of data as there is for dopamine. There is, however, at least one prospective RCT for most of the high-risk subgroups, as well as a large meta-analysis of all groups.

The meta-analysis reviewed 1290 patients in 16 RCTs.⁹⁵ The patients studied were all postoperative or in ICUs and were at risk of or had established ARF. They did not include patients at risk of contrast nephropathy. The authors of the meta-analysis found that the use of fenoldopam (versus placebo or usual care, including dopamine) significantly reduced the risk of acute kidney injury, the need for renal replacement therapy, and hospital mortality. In addition, the use of fenoldopam reduced the length of both ICU stay and total hospital stay. The authors did not find a significant incidence of hypotension or need for vasopressor use.

These findings are very promising in the search for a tool to help prevent or treat ARF. However, these findings should be interpreted with the caution that should accompany any meta-analysis. The limitations of this type of study include the heterogeneity of the population studied and the variation in definitive endpoints (for example, definition of acute kidney injury or parameters for commencing renal replacement therapy—only one study in the meta-analysis had predefined criteria indicating when a patient had reached a dialytic endpoint). These points are made by the authors as well as the acknowledgment that several of the studies were of suboptimal quality, increasing the risk of bias. They therefore conclude that their study supports the hypothesis that fenoldopam has renal protective effects, but given the limitations of meta-analyses, a larger multicenter RCT is required to confirm these results.

The benefits of fenoldopam in high-risk subgroups have, as with dopamine, been studied in a number of RCTs, some of which are listed in Table 2-4 (p. 24). Two studies have looked at fenoldopam in vascular surgery. Oliver and colleagues⁹⁶ compared fenoldopam with dopamine and nitroprusside in 60 patients undergoing elective aortic cross-clamping. They found no difference in urine output, serum creatinine, or creatinine clearance between the two groups. Halpenny and colleagues⁹⁷ also reviewed patients undergoing elective infrarenal cross-clamping, comparing fenoldopam with placebo in 28 patients. They found a decrease in creatinine clearance and an increase in serum creatinine in the control group compared with no change in the fenoldopam group. The relevance of this endpoint is unclear.

Three RCTs have looked at patients undergoing cardiac surgery. Bove and colleagues⁹⁸ randomized 80 patients to fenoldopam or dopamine. They found no difference in ARF, mortality, or length of ICU stay. The other two studies found an improvement in either creatinine clearance or serum creatinine.^{99,100} Two studies have looked at fenoldopam in liver transplantation. Della Rocca and colleagues¹⁰¹ compared fenoldopam with dopamine in 43 patients and found an improvement in serum creatinine and urea. Biancofiore and colleagues¹⁰² compared fenoldopam, dopamine, and placebo (N = 140) and found a similar improvement in

creatinine clearance. Neither study found a significant mortality benefit.

Four studies have reviewed fenoldopam in the prevention of contrast nephropathy. The first was a pilot study of 51 patients randomized to fenoldopam or placebo.¹⁰³ This study found an improvement in renal plasma flow, thus recommending further studies in this population. However, two of the other three trials showed no benefit of fenoldopam compared with either placebo or *N*-acetylcysteine,^{104,105} whereas the third found fenoldopam to be less effective than *N*-acetylcysteine in preventing contrast nephropathy.¹⁰⁶

There have been three RCTs of critically ill or septic patients with ARF. All three show promising trends in favor of fenoldopam, although none was able to confidently prove its value. In the largest of the three, 300 patients in ICUs with evidence of sepsis were randomized to fenoldopam or placebo.¹⁰⁷ The incidence of ARF (defined as an increase in serum creatinine > 150 $\mu\text{mol/L}$) was significantly lower in the fenoldopam group, although the incidence of severe ARF (creatinine > 300 $\mu\text{mol/L}$) failed to reach significance (10 in fenoldopam group versus 21 in control group; $P = .056$). Length of ICU stay was lower in the fenoldopam group, but mortality was not significantly different. The authors concluded that, although promising, their findings do not provide an adequate level of evidence to fully support the use of fenoldopam in this setting and they called for larger studies, adequately powered to assess endpoints such as mortality or the need for renal replacement therapy. Tumlin and colleagues¹⁰⁸ randomized 155 patients with early ATN to fenoldopam or placebo. There was a trend toward a benefit with fenoldopam, but it was not statistically significant. Certain subgroups reached statistical significance (nondiabetics and patients after cardiac surgery), but larger studies are required to confirm this. Brienza and colleagues¹⁰⁹ compared fenoldopam with dopamine in 100 patients in ICUs with early renal dysfunction. There was an improvement in serum creatinine levels at days 2, 3, and 4 in the fenoldopam group, although again the clinical significance of this finding is still not established.

Summary

Since its introduction into clinical use in the 1960s, low-dose dopamine became standard therapy for the treatment or prevention of ARF for three decades. Its use has diminished over the past 10 years as evidence suggesting a lack of benefit has grown. More recently, there have been three systemic reviews and one large, multicenter, randomized, controlled trial that have strengthened the argument against low-dose dopamine. Proponents of low-dose dopamine may argue that there remains a possibility of a subgroup of at-risk patients who may benefit from this therapy, although there are very few data to suggest that this is the case. Therefore, future use of dopamine for this purpose cannot be justified outside the confines of prospective RCTs, if at all. These recommendations should not preclude the use of dopamine for its systemic effects in heart failure or septic shock, when dopamine, like other inotropes or vasopressors, may afford a valuable increase in cardiac output and tissue perfusion.

Some of the properties of dopamine, which may contribute to its apparent lack of overall benefit, include DA_2 receptor agonism and β - and α -adrenoreceptor agonism. Fenoldopam is a selective DA_1 receptor agonist that does not share these other properties. It has therefore been suggested that low-dose

fenoldopam may be beneficial in the prevention or treatment of ARF. At present, the studies on fenoldopam, including one meta-analysis, have mostly been encouraging, although there is less evidence to support its protective properties against radiocontrast-induced nephropathy. However, while in previous years, a very promising meta-analysis would have been enough to provoke widespread use of this treatment, the legacy of three decades of dopamine use with no evidence base remains very prominent in our memories.¹¹⁰ Therefore, although fenoldopam remains a very encouraging prospect, the authors of these studies as well as other editorials have all been quite restrained in their conclusions and have called for further large, multicenter, randomized, controlled trials to support these promising findings.

VASOPRESSOR AGENTS IN ACUTE RENAL FAILURE

Volume depletion is by far the most common cause of renal hypoperfusion; if adequate fluid resuscitation has failed to improve arterial pressure, renal perfusion, and kidney function, it then becomes necessary to consider cardiogenic or distributive shock. Distributive shock is most likely to occur in the setting of severe sepsis, and in this case, one needs to consider the use of vasopressors. The vasopressors available for clinical use include norepinephrine, epinephrine, phenylephrine, dopamine, and vasopressin. Dopamine was covered in the previous section and is therefore not mentioned here. This section reviews the utility of vasopressors in improving renal perfusion and function in patients with sepsis-induced ARF.

Vasopressors promote vasculature smooth muscle contraction, increase systemic vascular resistance, and augment blood pressure in septic patients. By augmenting systemic blood pressure and renal perfusion pressure, they may improve renal function. However, renal failure in the setting of septic shock is not simply a consequence of systemic hypotension. Hypoperfusion of the kidney in sepsis may be exacerbated by concomitant renal vasoconstriction, and improving systemic blood pressure alone may not necessarily improve renal perfusion. Animal studies show variable changes in renal vascular resistance in sepsis-induced ARF.¹¹¹⁻¹¹⁴ A recent review by Langeberg and colleagues¹¹⁵ showed that of 137 studies published, 69 showed increased renal vascular resistance, 16 showed no change, and 52 showed a decrease. This has never been studied in humans.

Very few studies have been done to specifically assess the appropriate target blood pressure sought with vasopressors in patients with sepsis-induced ARF. There have been numerous trials in ICU patients comparing various blood pressure targets on outcome, but they have not looked at renal function as a primary endpoint. Hayes and colleagues¹¹⁶ chose a mean arterial pressure (MAP) target of 80 mm Hg when attempting to improve oxygen delivery, but showed no improvement in predicted outcomes. The early goal-directed therapy trial on which many guidelines of the surviving sepsis campaign are based used a target MAP of 65 mm Hg.^{117,118} Bougoin and colleagues¹¹⁹ randomized 40 patients with septic shock to a norepinephrine infusion to achieve a MAP of either 65 or 85 mm Hg. Endpoints were spot creatinine clearance, urine flow, and serum creatinine. They found no difference in any of these endpoints and therefore suggested that there was no

point in targeting a higher pressure. The study was limited in that it continued for only 8 hours, during which creatinine and, potentially, creatinine clearance would not normally change significantly. There was a significant reduction in the oxygen extraction ratio and serum lactate in the higher pressure group, suggesting that there may be some overall benefit. The problem with setting a specific target blood pressure is that higher doses of vasopressors can induce unwanted tissue vasoconstriction, and therefore the lowest dose possible that achieves adequate urine output is the optimum.

Norepinephrine

Norepinephrine is one of the most commonly used vasopressors and has by far the most evidence supporting its use in renal failure. It acts primarily on α -adrenergic receptors, although there is some β -adrenergic effect. This means that it is able to increase the MAP by vasoconstriction with little increase in cardiac output and myocardial oxygen demand. It is clinically proven to increase the MAP effectively, and in randomized, controlled trials comparing it with dopamine, it was more effective at increasing the blood pressure and had better effect on oxygen extraction ratios and splanchnic blood flow.^{120–123} Martin and colleagues¹²² compared 32 patients with vasoplegic shock who were treated with dopamine or norepinephrine and showed that there was adequate restoration of blood pressure or systemic vascular resistance in 31% and 98%, respectively.

There has long been concern over the use of norepinephrine in the setting of ARF because it was shown to cause renal vasoconstriction and ARF. This concern was raised by an animal model of ARF in which high doses of norepinephrine were infused directly into the renal artery. These animals were

normotensive and not septic and therefore far removed from the clinical situation.¹²⁴ In the face of hypovolemia, norepinephrine does worsen renal function and hence fluid resuscitation is imperative.^{124,125}

In septic animals and humans, there is evidence that norepinephrine infusion improves renal function. The proposed mechanisms are (1) an increased MAP and therefore perfusion pressure, (2) relatively greater efferent than afferent arteriolar vasoconstriction with consequent increased intraglomerular pressure, and (3) better regional blood flow.^{111,126,127} The details of these studies are outlined in the following.

Animal Studies

Table 2-5 (p. 28) summarizes some of the animal studies performed to determine the effects of norepinephrine infusion on renal hemodynamics and function in experimental models of sepsis induced ARF.^{112,127–130} Bellomo and colleagues¹¹³ looked at RBF with norepinephrine before and after treatment with lipopolysaccharide (LPS) in dogs. RBF was unchanged when norepinephrine was infused in nonseptic animals; however, once they had been given LPS, norepinephrine induced a marked increase in RBF from baseline. Similarly, in dogs injected with *Escherichia coli*, there was almost complete restoration of RBF to presepsis levels in those treated with norepinephrine.¹³⁰ Boffa and colleagues¹¹¹ injected LPS into mice and at 14 hours measured the MAP, RBF, renal vascular resistance, GFR, and urine flow. The animals were exposed to vasoconstrictors norepinephrine, angiotensin II, and N-nitro-L-arginine methyl ester both before LPS injection and then again 14 hours after LPS. They showed that norepinephrine did not decrease the GFR in control animals. In the animals with septic shock, all the agents increased the MAP to a similar degree, but there was a

FUNCTION		Significant Difference?	Comment

1.17	2.02	NS	Control = placebo
	29%	NS	
	27.5%	NS	
	16.3%	NS	
	-0.29	$P < 0.05$	
	16%	$P < 0.05$	
1.93	1.54		Control = dopamine 2 $\mu\text{g}/\text{kg}/\text{min}$

45% increase in the GFR in the norepinephrine group, which was not seen with the other agents. Di Giantomasso and colleagues^{131,132} showed in sheep treated with *E. coli* that norepinephrine was able to significantly increase creatinine clearance and urine flow 2 hours after the onset of sepsis.

Human Studies

There is a paucity of good studies assessing the benefit of norepinephrine in patients with septic shock. One concern with the use of norepinephrine is that it may worsen perfusion to some tissues due to its vasoconstrictive effect. However, these concerns have not been supported by most studies: Martin and colleagues¹²² compared norepinephrine and dopamine in septic shock and were able to show a significant reduction from baseline of serum lactate concentration with norepinephrine, suggesting improvement rather than worsening of tissue ischemia and that reduction of lactate correlates closely with survival in acute sepsis. Splanchnic blood flow is also improved or maintained in septic shock with norepinephrine.¹³³

Bourgoin and colleagues¹¹⁹ showed that in 28 patients randomized to receive norepinephrine to maintain an MAP of 65 or 85 mm Hg, there was improvement from baseline of both creatinine clearance and urine flow rate. There was no difference between the two groups, however. Desjars and colleagues¹³⁴ measured creatinine clearance and urine flow rates in septic patients before and 24 hours after starting norepinephrine. They showed an increase in both variables in all patients. Marin and colleagues¹²⁶ looked at 25 patients with septic shock who were treated with norepinephrine and showed improvements in urine flow, creatinine, and creatinine clearance in 20 patients. Redl-Wenzel and colleagues¹³⁵ looked at 56 patients who remained hypotensive despite dopamine and dobutamine. They were

then started on norepinephrine with a target blood pressure of 60 mm Hg. There was a significant improvement in creatinine clearance at 48 hours from 73 mL/min to 102 mL/min. Albanese and colleagues¹³⁶ performed a prospective, randomized, controlled trial in septic patients comparing norepinephrine and terlipressin. The renal parameters assessed were urine flow and creatinine clearance. Twenty patients were enrolled in this open-label study. There was no statistical difference between the two groups in both parameters; however, both groups did improve significantly from baseline.

Albanese and colleagues¹³⁷ also looked at two groups of ICU patients receiving norepinephrine. There were 14 patients with septic shock and 12 patients with head injuries. In the septic patients, there was an increase in urine flow rate from 14 mL/hr to 102 mL/hr. There was also a statistically significant increase in creatinine clearance. This is in contrast to those patients with head injuries who had no change in urine flow rate or creatinine clearance.

On the grounds of the above information, norepinephrine may well confer benefit in ARF in patients with distributive shock and can be recommended for this purpose. The recommended dose is 0.1 to 2 $\mu\text{g}/\text{kg}/\text{min}$.

Epinephrine

Epinephrine has both α - and β -adrenergic properties, with the former becoming more predominant at higher doses. It is able to increase the systemic arterial pressure by both increasing systemic vascular resistance and increasing cardiac output. This would appear at the outset to be the optimal way to treat patients with septic shock as they have both severe vasoplegia and myocardial dysfunction. Although it has been shown to improve blood pressure in a number of trials,¹³⁸⁻¹⁴¹ the major concern with its use has been that at clinically

Table 2-5 Effects of Norepinephrine Infusion on Renal Hemodynamics and Renal Function in Experimental Models of Sepsis

Study	Study Type	Animal Model	Norepinephrine Infusion Rate
Anderson et al ¹²⁸	Controlled trial of intravenous and renal-arterial norepinephrine infusion in nonseptic animals	Dog	0.1–0.4 µg/kg/min
Di Giantomaso et al ¹³⁰	Randomized, placebo-controlled animal trial using norepinephrine in experimental sepsis	Merino sheep	0.4 µg/kg/min
Peng et al ¹²⁹	Controlled trial of increasing doses of norepinephrine in experimental bacteremia	Dog	0.1–0.5 µg/kg/min
Bellomo et al ¹¹²	Controlled trial comparing response to norepinephrine before and after the induction of sepsis	Dog	0.3 µg/kg/min
Di Giantomaso et al ¹³¹	Randomized, placebo-controlled trial comparing renal response to norepinephrine and low-dose dopamine in experimental sepsis	Merino sheep	0.4 µg/kg/min
Boffa and Arendshorst ¹¹⁰	Placebo-controlled trial of norepinephrine versus placebo, then norepinephrine versus nitric oxide synthase inhibition or angiotensin II	Balb C mice	6 µg/kg/min
Di Giantomaso et al ¹¹³	Controlled trial assessing the effect of norepinephrine versus placebo on regional renal blood flow in sepsis	Merino sheep	0.4 µg/kg/min

N/T, not tested.

relevant doses, it impairs splanchnic perfusion and increases systemic lactate.^{138–140,142–144} The hyperlactatemia may not necessarily be due to tissue ischemia because in studies that looked over a longer period, the lactate increased transiently and then decreased progressively in survivors.¹³⁸

There is a paucity of experimental and clinical trials looking specifically at the use of epinephrine in renal failure. Di Giantomaso and colleagues,¹³⁹ using their septic sheep model, looked at renal hemodynamics with the use of epinephrine. It reduced RBF and increased renal vascular resistance in a manner similar to that seen previously with the use of norepinephrine. In contrast to norepinephrine, creatinine clearance actually decreased slightly. Krejci and colleagues¹⁴² showed an increase in RBF associated with epinephrine infusion that was greater than that seen with norepinephrine; however, there was no measurement of urine output or other renal function variables. Day and colleagues¹⁴⁰ performed an elaborate study using thermodilution catheters placed in the renal veins of patients with severe sepsis or malaria to measure RBF, lactate concentrations, and renal vascular resistance indices. Patients then received either dopamine or epinephrine in a crossover

manner. The trial was stopped early due to significant hyperlactatemia in the epinephrine group. Epinephrine did, however, result in an increase in renal vascular resistance and renal oxygen extraction ratios. There are, however, several limitations to the study. Only eight patients received epinephrine and only four received the full dose. There were a number of patients with malaria, which may respond differently due to different pathologic mechanisms in the kidney. These few studies are the main clinical trials looking specifically at epinephrine in sepsis-induced renal failure. Based on current evidence, epinephrine cannot be recommended for the initial management of patients with renal failure in the intensive care setting.

Phenylephrine

Phenylephrine is a specific α -adrenoreceptor agonist that is used in some ICUs to treat hypotension associated with septic shock. There is currently very little evidence of its use in patients with renal failure. Krejci and colleagues¹⁴² showed that phenylephrine increases RBF more than norepinephrine in septic pigs and the increase in RBF correlated with the in-

Effect of Norepinephrine on Renal Blood Flow	Effect of Norepinephrine on Renal Vascular Resistance	Effect of Norepinephrine on Urine Output	Effect of Norepinephrine on Glomerular Filtration Rate	Effect of Norepinephrine on Regional Blood Flow

crease in systemic pressure. It was postulated that, because phenylephrine constricts larger arterioles and not terminal ones, there may be better microvascular perfusion compared with norepinephrine. There was, however, no difference in splanchnic metabolic variables between the two agents. In the only study in humans to assess the effect of phenylephrine in septic shock, Gregory and colleagues¹⁴⁵ looked retrospectively at 13 patients and assessed response. Phenylephrine resulted in a marked increase in the MAP, systemic vascular resistance, and cardiac index. There was a significant increase in urine flow, but no change in creatinine.

Vasopressin

Vasopressin is a potent vasoconstrictive agent released by the posterior pituitary in response to baroreceptor stimulation caused by hypotension.¹⁴⁶ In septic shock, it has been shown that in the first 24 hours there is a significant (as much as 10-fold) increase in plasma levels; however, these then rapidly decrease to baseline levels. Exogenous administration of low-dose vasopressin in patients with septic

shock improves blood pressure significantly, and this effect is further augmented by catecholamines. Vasopressin 1 (V_1) receptors are present on vascular smooth muscle cells and through phospholipase C are able to increase intracellular calcium and sensitize the contractile apparatus to the calcium, thereby causing contraction. It therefore is able to overcome the mechanisms through which catecholamine resistance occurs.^{146–148}

The effects of vasopressin on the kidney in septic shock is becoming better understood. Vasopressin is able to elevate the MAP and therefore will increase renal perfusion pressure.^{149–154} Vasopressin may result in selective efferent arteriolar vasoconstriction. This was first suggested in 1956 by Wagener and Braunwald,¹⁵⁵ who looked at three patients with autonomic failure and showed that vasopressin caused a decrease in renal plasma flow using para-aminohippurate clearance; however, GFR remained constant (inulin clearance) suggesting that there was selective efferent arteriolar vasoconstriction. Using an in vitro model, Edwards and colleagues¹⁵⁶ showed that selective efferent arteriolar constriction was reversed by a V_1 receptor antagonist.

Animal Studies

Albert and colleagues¹⁵⁷ showed that vasopressin selectively enhanced renal cortical blood flow in endotoxin-treated animals. In rodents, Levy and colleagues¹⁵⁸ showed that vasopressin did not change RBF in endotoxin-treated animals, but it did significantly increase urine output and inulin-measured GFR. In contrast to these findings, two studies by Malay and colleagues¹⁵³ and Lefavre and colleagues¹⁵⁹ showed there was a decrease in RBF in endotoxemic pigs and rabbits, respectively.

Human Studies

Landry and colleagues¹⁶⁰ described the response to vasopressin in five patients with refractory shock unresponsive to standard vasopressors. In all the patients, there was a significant increase in the MAP. In three of the five patients, there was a marked increase in urine output. Another study randomized 48 patients with septic shock to receive either vasopressin (4 U/hr) with norepinephrine or norepinephrine alone. In the group randomized to vasopressin with norepinephrine, there were a significantly higher MAP and cardiac index. There was improved gastric pH in the vasopressin group, but also increased bilirubin and reduced platelets. Urine output was not reported; however, there was no change in creatinine after 48 hours.¹⁵⁰ Tsuneyoshi and colleagues¹⁵¹ also reported a prospective, case-controlled study on patients with septic shock treated with norepinephrine. Vasopressin was added to norepinephrine at a rate of 0.04 U/min in 16 patients. There was a significant improvement in blood pressure and a decrease in norepinephrine requirements. Urine output had significantly increased by 16 hours in the 10 patients who were oliguric but not anuric. Those patients who were anuric did not improve; however, this could be expected if ATN has already occurred.

Retrospective studies in larger numbers of patients have also been reported. These studies show that vasopressin decreases norepinephrine requirements¹⁶¹ and increases urine output.¹⁵² Albanese and colleagues¹³⁶ performed a randomized, open-label study of terlipressin (a synthetic vasopressin analogue) compared with norepinephrine. Twenty patients with septic shock and two with organ failure were randomized to receive either norepinephrine in incremental doses or terlipressin in a 1-mg bolus every 6 hours (equivalent to 0.03–0.04 U/min vasopressin). All patients achieved the target MAP of 60 to 70 mm Hg. Measurements at 6 hours showed significant reduction in lactate in both groups. Urine output and creatinine clearance significantly increased in both groups, and there was no difference between the two agents. Another randomized, controlled trial by Patel and colleagues¹⁵⁴ looked at 24 patients with septic shock and randomized them to a blinded infusion of either norepinephrine or vasopressin. All patients were on high-dose norepinephrine at the start of the study. The observation time was only 4 hours. During this time, there was no difference in blood pressure or cardiac index. Those patients in the norepinephrine group showed no change in urine output (25 to 15 mL/min) or creatinine clearance. In the vasopressin group, there was an increase in urine output from 32.5 to 65 mL/hr and a 75% increase in creatinine clearance. There was no difference in indirect markers of splanchnic blood flow, nor were there electrocardiographic changes

consistent with ischemia. This study is of great interest; however, it has the obvious limitation of being conducted over only a very short period of time.

Vasopressin and its analogue terlipressin appear to have a beneficial effect on renal function and are effective at increasing blood pressure in septic shock. The VASST study, a multicenter double-blind randomized controlled trial, randomized patients with septic shock to receive either vasopressin ($N = 397$) or norepinephrine ($N = 382$) in addition to open-label vasopressors. There was no difference in 28- or 90-day mortality between the two groups, but there was significantly reduced mortality in the vasopressin group, with less severe septic shock.¹⁶² A planned post-hoc analysis presented in abstract form looked at patients stratified by the RIFLE criteria for acute kidney injury.¹⁶³ The risk group treated with vasopressin had a significantly lower incidence of renal failure compared to the norepinephrine group (21.2% vs. 41.2%, $P = .02$), and this was associated with reduced mortality. There was no difference in renal outcomes between the injury and failure groups. When all patients in the study were included, there was a trend toward lower creatinine and increased urine output in the vasopressin group (personal correspondence). It is therefore recommended that vasopressin be added to norepinephrine in oliguric sepsis. The recommended dose of vasopressin is 0.01 to 0.04 U/min, and terlipressin is 1 to 2 mg every 6 hours. This should be titrated against blood pressure and not serum vasopressin levels.^{146,148}

There have been a number of concerns raised about the use of vasopressin. First is a hepatotoxic effect due to reduced hepatic blood flow and manifest by increased liver transaminases and bilirubin.^{150,164} Second is a detrimental effect on coronary blood flow highlighted by animal studies. In clinical studies, vasopressin use has not caused ischemic electrocardiographic changes or increased troponin I levels.¹⁵⁰ Third is a procoagulant side effect due to the presence of V_1 receptors on platelets resulting in platelet aggregation. This is of specific concern in patients who already have poor microvascular blood flow. Patients often become thrombocytopenic when treated with vasopressin.¹⁵⁰

SUMMARY

In shock states, fluid resuscitation is of prime importance. When fluid resuscitation does not adequately improve blood pressure and distributive shock has been confirmed, vasopressors should be used. In patients with ARF, current evidence suggests the use of norepinephrine at a dose of 0.01 to 2.0 $\mu\text{g}/\text{kg}/\text{min}$ in the first instance. This has been shown in both animal and human trials of sepsis to improve RBF and function. The aim is to increase the MAP to more than 60 mm Hg and potentially higher if there is significant underlying premorbid hypertension. Aiming for higher targets may in fact be detrimental due to vasoconstriction of both renal and splanchnic vascular beds, and therefore one must target the lowest MAP that achieves the endpoint of regional perfusion and improvement in renal function. The addition of vasopressin to norepinephrine is recommended in oliguric sepsis. High-dose dopamine, phenylephrine, and epinephrine are able to improve blood pressure in sepsis and do not appear to cause harm to renal function, but, due to a lack of evidence, their use cannot be recommended as first-line therapy to treat ARF associated with sepsis.

CONCLUSION 39

BACKGROUND

Acute kidney injury (AKI) remains a common problem with a prevalence of 5% in patients admitted to the hospital and 30% to 50% in those admitted to an intensive care unit. Despite significant advances in supportive care, the morbidity and mortality associated with AKI remain high. Multiple pathophysiologic factors contribute to renal injury in AKI, including vasoconstriction, reduced glomerular capillary permeability, tubular obstruction by casts and swollen epithelial cells, and back-leakage of filtrate through an altered epithelium.^{1,2} Over the past two decades, a variety of approaches have been explored by investigators to prevent or ameliorate AKI or accelerate the recovery of patients with AKI, of which the use of diuretics remains one of the most frequently used for this purpose. However, outcome data to support the use of diuretics remain sparse. Extensive data from animal studies suggest that diuretics given prophylactically before renal injury, or very early in so-called incipient AKI, may ameliorate the subsequent course of AKI, whereas their administration once AKI is established has generally been ineffective (see Conger³ for review). However, the data supporting a beneficial role for diuretics in human AKI are inconsistent. Evaluation of the available human studies is further complicated by the heterogeneity of AKI and varies widely in the definition of AKI, the underlying etiology of renal injury, the severity of disease, and the phase of AKI at which the diuretics were administered.

This chapter discusses the clinical data for the use of mannitol, loop diuretics, and natriuretic peptides in patients with AKI. Complications of diuretic therapy are considered, and recommendations are given for the use and dosing of diuretics. With the exception of a few small randomized, controlled trials, most of the data are from retrospective or case-control studies that are confounded by multiple factors. We focus on the recent prospective clinical trials and refer the reader to several excellent reviews⁴⁻⁸ for a summary of the earlier work.

USE OF DIURETICS IN THE PREVENTION OF ACUTE KIDNEY INJURY

Mannitol

The prophylactic use of mannitol began in the 1960s when it was introduced for use in patients undergoing cardiovascular surgery to maintain intraoperative urine flow.⁹ Since then, prophylactic mannitol has also been recommended for patients considered to be at high risk of AKI, such as those undergoing vascular (aortic aneurysm) surgery or cardiac surgery or patients developing obstructive jaundice; yet several small randomized, controlled trials have found no reduction in the incidence of AKI with mannitol administration.¹⁰⁻¹³ Over the past few decades, there have been several theoretical arguments favoring the use of mannitol. First, mannitol increases renal blood flow in both the renal cortex and medulla by reducing renal vascular resistance.¹⁴ Second, by increasing urine flow, mannitol could lead to relief of tubular obstruction by casts and cellular debris and to a reduction in the concentration of tubular toxins such as myoglobin or hemoglobin.¹⁵ Finally, mannitol may reduce epithelial cell swelling¹⁶ as well as scavenge harmful free radicals,¹⁷ thereby ameliorating hypoxic reperfusion injury. Although studies in animals have shown that mannitol helps to protect the kidney against ischemic injury, human studies fail to demonstrate the efficacy of mannitol in preventing AKI.^{5,18}

There are compelling data that mannitol causes a higher incidence of radiocontrast-induced nephrotoxicity as compared with saline plasma volume expansion alone in either diabetic or nondiabetic patients.^{19,20} Solomon and colleagues¹⁹ found that 25 g of mannitol before contrast administration plus plasma volume expansion with saline was not associated with any reduction in risk compared with saline alone; instead, there was a trend toward harm. A forced diuresis regimen that included intravenous crystalloid, mannitol, furosemide, and low-dose dopamine similarly exerted no effect on the overall incidence of contrast-induced nephropathy.²⁰ The

trial design allowed independent evaluation of the effects of mannitol, and the results demonstrated no additive benefit. In patients with both diabetes and chronic kidney disease receiving a radiocontrast agent, mannitol increased the incidence of nephrotoxicity.^{21,22}

Forced alkaline diuresis with intravenous fluids and mannitol has been advocated in the setting of rhabdomyolysis to create an osmotic diuresis,^{23,24} vasodilation of renal vasculature,²⁵ and free-radical scavenging.^{26,27} However, available evidence suggests that mannitol offers no benefit over and above aggressive fluid resuscitation.^{28–30} Furthermore, mannitol can be harmful if urine output cannot be maintained.

Mannitol may have a beneficial role in the prevention of AKI after renal transplantation. In small studies of patients undergoing kidney transplantation, mannitol administration appears to have salutary effects with regard to AKI. In these studies, 250 mL of 20% mannitol given immediately before vessel unclamping reduced the incidence of AKI, as determined by a decreased need for posttransplantation dialysis.^{31–38} However, no durable outcome difference at 3 months was found compared with patients who did not receive mannitol.³⁸ The practice of using mannitol in renal transplantation varies by center, and its potential benefit remains to be confirmed by larger multicenter trials.

Loop Diuretics

Loop diuretics have vasodilatory properties and, like mannitol, increase urine flow and could relieve tubular obstruction and reduce the concentration of tubular toxins.¹⁵ However, it has been postulated that the increased renal blood flow induced by loop diuretics may be maldistributed and potentially harmful.^{39,40} Furthermore, by inhibiting active solute transport, loop diuretics reduce the oxygen and adenosine triphosphate requirements of the tubular epithelium, thereby possibly improving tolerance of hypoxia.⁴¹ A

systematic review of seven randomized, controlled trials comparing fluids alone with diuretics in patients at risk of AKI from various causes found no evidence of improved survival, decreased incidence of AKI, or need for dialysis associated with diuretics.⁴²

Furosemide is widely used to prevent the development of AKI despite a lack of evidence of its efficacy in humans. In a double-blind, randomized, controlled trial ($N = 126$) examining the effectiveness of furosemide and dopamine in preventing AKI in patients with normal renal function after cardiac surgery, Lassnigg and colleagues⁴³ found that compared with 0.9% saline, furosemide was associated with an increased risk of the development of AKI. As the increased sodium and water excretion in the furosemide group was not fully replaced, these results could potentially be due to relative hypovolemia, although objective indices such as pulmonary capillary wedge pressures were not significantly different between the two groups.

Three prospective controlled studies have evaluated the role of furosemide in preventing AKI induced by radiocontrast material and found no benefit.^{39,44,45} In two of the studies, administration of furosemide before radiocontrast resulted in worsening of the decline in renal function that was associated with net loss of body weight,^{39,44} again suggesting that it had caused hypovolemia (Table 3-1).

USE OF DIURETICS IN ESTABLISHED ACUTE KIDNEY INJURY

Mannitol

There have been no controlled studies of the use of mannitol in early or established AKI. Although several uncontrolled studies performed before 1970 demonstrate that mannitol can restore urine flow when administered early in the course of

Table 3-1 Summary of Randomized, Controlled Clinical Trials of Diuretics in the Prevention of Acute Kidney Injury

Study	Patients	Control	Intervention	Effect of Intervention on Renal Recovery
Solomon et al ³⁹	78 patients with chronic kidney disease who underwent cardiac angiography	Saline	Mannitol and saline Furosemide and saline	Worse
Weisberg et al ⁷⁵	50 patients undergoing radiocontrast study	Saline	Mannitol and saline	None
Stevens et al ⁴⁵	98 patients undergoing radiocontrast study	Saline	Mannitol, furosemide, dopamine, and saline	None
Weinstein et al ⁴⁴	18 patients undergoing radiocontrast study	Saline	Furosemide	Worse
Van Valenberg et al ³¹	131 patients undergoing cadaveric renal transplantation	Saline	Mannitol and saline	Better
Lassnigg et al ⁴³	126 patients undergoing elective cardiac surgery	Saline	Furosemide and saline	Worse
Nicholson et al ¹⁸	28 patients undergoing abdominal aortic surgery	Saline	Mannitol	None

oliguric AKI, there is no evidence that it improves outcome in terms of renal function.^{46–49}

Loop Diuretics

Several retrospective studies, reviewed by Conger,⁵ have found no effect of furosemide on renal function or mortality in patients with AKI of various etiologies. A recent prospective observational study by Mehta and colleagues⁵⁰ found that diuretic use was associated with an increased risk of death and failure of renal function to recover in critically ill patients with established AKI. However, the increased risk was mainly in patients who were relatively unresponsive to diuretics. This suggests that the use of diuretics may be a marker of a sicker patient population (i.e., there was residual confounding by unobserved factors) rather than a direct cause of the poor outcome. This conclusion is supported by the recently reported results of an even larger, prospective, multinational, observational cohort study that found no association between the use of diuretics and mortality rate in critically ill patients with AKI.⁵¹ There have now been six randomized, controlled trials of loop diuretics in established AKI^{52–57} of which three were placebo-controlled trials,^{53,55,56} and in five of these studies,^{52–56} the use of loop diuretics failed to have a significant impact on renal function recovery or patient survival (Table 3-2). The recent study by Cantarovich and colleagues⁵⁶ is the largest prospective, randomized, double-blind, placebo-controlled study to date and the only one to be performed in the modern era. It was designed to have an 80% power to detect a 15% difference in the primary endpoint,

which was 1-month survival. Despite this, they found that furosemide had no effect on patient survival or renal recovery rate.

Natriuretic Peptides

Despite encouraging experimental data with the use of the atrial natriuretic peptide anaritide on ischemic AKI,^{58,59} results have been disappointing in humans. In two large, multicenter, prospective, randomized, placebo-controlled trials in patients with AKI due to acute tubular necrosis of various etiologies, atrial natriuretic peptide infusion for 24 hours had no effect on the need for dialysis, the rate of dialysis-free survival, and overall mortality rate.^{60,61} In both studies, however, approximately 90% of the patients in the anaritide group became hypotensive (systolic blood pressure < 90 mm Hg), which could have resulted in reduced renal perfusion.^{60,61} In a more recent single-center trial of patients ($N = 61$) with heart failure, recombinant atrial natriuretic peptide given for a longer period of time after cardiac surgery decreased the probability of dialysis and improved dialysis-free survival⁶² (see Table 3-2).

USE OF DIURETICS IN THE MANAGEMENT OF COMPLICATIONS OF ACUTE KIDNEY INJURY

Although there is no evidence that diuretics are effective at preventing or altering the course of AKI, they are very useful in the management of oliguria and volume overload in this setting.

Table 3-2 Summary of Randomized, Controlled Clinical Trials of Diuretics in the Setting of Established Acute Kidney Injury

Study	Patients	Control	Intervention	Effect of Intervention on Renal Recovery
Brown et al ⁵⁴	58 patients with postoperative AKI	Furosemide infusion × 4 hr	Furosemide infusion × 4 hr followed by IV bolus or oral furosemide 1 g tid	None
Shilliday et al ⁵⁵	92 patients with AKI of various etiologies	Placebo IV infusion, mannitol, and dopamine	Furosemide or torsemide, mannitol, and dopamine	None
Sirivella et al ⁵⁷	100 patients with postoperative oliguric or anuric AKI	Furosemide, bumetanide, or ethacrynic acid intermittent bolus	Furosemide, mannitol, and dopamine continuous infusion	Better
Kleinknecht et al ⁵³	66 with oliguric AKI	Placebo	Intervention: furosemide bolus every 4 hr	None
Cantarovich et al ⁵⁶	330 patients with AKI requiring renal replacement therapy	Placebo	Furosemide infusion or oral given after dialysis	None
Allgren et al ⁶¹	504 patients with oliguric and nonoliguric AKI	Placebo	ANP	None
Lewis et al ⁶⁰	222 patients with oliguric AKI	Placebo	ANP	None
Sward et al ⁶²	61 patients with postoperative AKI	Saline	ANP	Better

AKI, acute kidney injury; ANP, atrial natriuretic peptide.

Several studies have shown that diuretics administered early in the course of oliguric AKI, usually within 24 to 48 hours of onset,^{48,49,63} can induce a sustained diuresis in some patients, in some cases even after a single bolus dose. Although individuals who are successfully converted in this manner from oliguric to nonoliguric AKI have a better prognosis than those who are diuretic resistant,⁴⁹ this likely reflects the milder severity of their underlying renal injury and not any effect of the diuretic to alter the natural history of the disease. Thus, patients who are diuretic responsive had not only a shorter duration of oliguria, but also higher urine output and better urinary concentrating ability than diuretic-resistant patients.^{47,49,64} Successful reversal of oliguria, even in the initial absence of overt hypervolemia, might be expected to reduce the subsequent need for dialysis or ultrafiltration. Indeed this has been shown in some studies,⁵⁷ although not in others.⁵⁴ Our approach is to administer a single bolus of a diuretic within 24 hours of the onset of oliguria, once established AKI has been confirmed, to attempt to convert to nonoliguric AKI only after careful correction of the volume status and for a very limited time. We favor loop diuretics over mannitol because they appear to be safer and may also be more effective.⁶³ If there is no diuretic response to a maximally effective dose (see later), further doses should not be given as there is a significant risk of ototoxicity.^{53–56} If there is a diuretic response, but it is transient and not sustained, further doses of diuretic, given either as repeated boluses or as a continuous infusion, should be given only if required in a hypervolemic patient to maintain appropriate fluid balance.

PHARMACOLOGY AND DOSE RECOMMENDATIONS

Mannitol may be given in boluses of 12.5 to 25 g or as a continuous infusion of up to 200 g per 24 hours. It is rapidly distributed in the extracellular space, results in the onset of diuresis within 15 to 30 minutes, and has a half-life of 70 to 100 minutes in the setting of normal renal function. In the setting of renal dysfunction, mannitol may accumulate and cause plasma volume expansion as well as itself causing AKI.^{65,66} It should therefore be administered with caution, if at all, to anuric patients. Moreover, as with all diuretics, mannitol may induce AKI due to excessive osmotic diuresis in patients with hypovolemia, thereby exacerbating the renal injury.

The effectiveness of loop diuretics in patients with AKI is reduced due to decreased urinary excretion. This may be overcome by administering doses that achieve high enough serum concentrations to provide entry of sufficient amounts of diuretic into the urine. Treatment should be initiated with an intravenous bolus dose. A reasonable starting dose is 40 mg furosemide, 1 mg bumetanide, or 25 mg torsemide. If there is no response within 30 to 60 minutes, the dose should be increased by repeatedly doubling the dose until either diuresis is achieved or the maximum safe dose is reached. We consider a maximum single dose of 160 mg IV furosemide with a maximum total daily dose of 1 g to be safe or 6 to 8 mg IV bumetanide to be safe, and these will produce the upper plateau of the dose-response curve.⁶⁷ Higher doses may incur an unacceptable risk of ototoxicity.⁵⁴ In a recent meta-analysis, high-dose furosemide (1.0–3.4 g/day) was associated with an increased risk of temporary deafness and tinnitus, which resolved after treatment was stopped.⁶⁸

Some advocate maintaining a continuous infusion of intravenous loop diuretics in order to maintain a safe and constant plasma level. In two of these trials, continuous infusion was more effective at reversing oliguria.^{54,57} In the study by Sirivella and colleagues,⁵⁷ 90% of the patients receiving intermittent bolus diuretics required dialysis compared with only 6.7% of the patients receiving the continuous infusion of furosemide, dopamine, and saline. However, this study was flawed because there was no true control group. A recent meta-analysis (Cochrane review) comparing continuous infusion versus bolus injection of loop diuretics in patients with congestive heart failure showed greater diuresis and better safety profile when given as a continuous infusion.⁶⁹ In a small crossover, randomized study of eight patients with chronic kidney disease (mean creatinine clearance = 17 mL/min), continuous IV infusion of bumetanide was more effective (i.e., greater net sodium excretion) and less toxic when compared with conventional intermittent bolus.⁷⁰ Brown and colleagues⁵⁴ randomized 58 patients with established acute renal failure to receive either a one-time bolus of furosemide or a bolus followed by a continuous infusion. Although the continuous infusion was more effective at reversing oliguria, there was no difference in the need for dialysis, duration of renal failure, or mortality between the two groups. An infusion of furosemide may be given at 5 to 40 mg/hr after a bolus dose.⁷¹ The half-life of furosemide is intermediate, with bumetanide having a shorter half-life and torsemide having a longer half-life. Therefore, the benefits of continuous infusion may be greater for bumetanide and furosemide than for torsemide.

If the loop diuretic alone is ineffective, a thiazide diuretic may also be added (e.g., 250 or 500 mg IV chlorothiazide, given 30 minutes before a 200-mg IV bolus of furosemide). This combination has been studied in patients with chronic kidney disease,⁷² but can also be effective in patients with AKI. Thiazide diuretics alone are ineffective when the glomerular filtration rate is less than 30 mL/min, but may retain benefit when added to a regimen containing a loop diuretic. If no increase in urine output occurs in response to 200 mg furosemide given in combination with a thiazide diuretic, additional doses should not be administered until recovery of renal function is evident.

Several studies have looked into the use of albumin in conjunction with furosemide in hypoalbuminemic patients. In patients with severe hypoalbuminemia, the volume of distribution of furosemide, which in plasma is normally tightly protein bound, is markedly increased; thus, coadministration of furosemide with IV albumin could theoretically improve delivery of furosemide to the tubular lumen and thus improve the natriuretic effect of furosemide. One crossover, randomized, controlled trial (nine patients with nephrotic syndrome with a mean albumin of 2.9 g/dL) compared three interventions: furosemide alone, furosemide plus albumin, and albumin alone.⁷² It found that furosemide was superior to albumin alone, and furosemide plus albumin resulted in the greatest urinary sodium and volume excretion. The glomerular filtration rate was not significantly affected by either intervention. The clinical significance of this finding is unclear. In a randomized trial of 1126 cirrhotic patients with ascites not responding to bed rest or low-sodium diet,⁷³ patients assigned to receive diuretics plus albumin (12.5 g/day as inpatients or 25 g/wk as outpatients) had a shorter hospital stay, decreased recurrence of ascites during a 3-year follow-up period, and a

decreased number of hospital readmissions. There was no difference in the two groups with respect to survival and incidence of other complications. Mean albumin level was 3.1 g/dL. However, a more recent trial failed to show any convincing advantage to this approach.⁷⁴

CONCLUSION

In summary, although we would not discourage the use of diuretics in patients with AKI, we find insufficient evidence to support their use for prevention or treatment of AKI, and some evidence to suggest that they may be harmful if given intercurrently with an acute renal insult. Diuretics may safely be used to treat the complications of AKI and probably do not affect patient mortality or the rate of renal recovery.

Iodinated contrast media are commonly injected intravascularly, into either an artery or vein, to enhance images during diagnostic or interventional radiologic procedures. Most of the recent literature on contrast-induced nephropathy (CIN) has been in the setting of cardiac angiography and percutaneous coronary intervention. Estimates of risk, the mechanism of kidney injury, and the impact of preventive therapies may differ according to the population studied. There is no specific therapy for CIN once it occurs, with supportive measures applied as usual for acute kidney injury.

EPIDEMIOLOGY

Sensitive tests of kidney function commonly identify mild, transient reduction after contrast injection.¹ CIN has been reported to be the third most common cause of acute renal failure in hospitalized patients.² The reported incidence of CIN varies among studies due to differences in definition, background risk, type and dose of contrast, imaging procedure, and the frequency of other potential causes of acute renal failure. There is no specific diagnostic marker for CIN in humans, and contrast may be a contributory cause rather than a sole cause of acute kidney injury. Concomitant insults may include low blood volume, surgery, atheroembolic disease, and other nephrotoxins. In one study of patients having coronary angiography, serum creatinine increased by more than 25% in 14.5% (95% confidence interval: 12.9%–16.1%) of cases, whereas 0.77% required dialysis.³ The literature on risk after intravenous injection of modern contrast agents is sparse. The frequency of minor changes in serum creatinine after intravenous contrast appear to be many-fold less common than after cardiac angiography, and the importance of considering the background rate of acute change in kidney function has recently been re-emphasized.^{4,5} The presence or absence of risk factors and the type of imaging procedure are most relevant. Preexisting renal function is a major determinant of the risk of CIN.³ Although minor, usually transient changes in serum creatinine after contrast have been associated with prolonged hospital stay, adverse cardiac events, and higher

mortality both in hospital and in the long term.^{3,6–10} These associations may be explained at least in part by comorbidities, acuity of illness, or alternate causes of acute kidney injury such as atheroembolism.

PATHOGENETIC BASIS FOR PREVENTION

CIN likely results from both ischemic injury and direct tubular cell toxicity.¹¹ A reduction in medullary perfusion, possibly mediated by increased endothelin and adenosine together with reduced nitric oxide and prostacyclin, has been considered important.¹² The nature of the contrast including its physical properties such as viscosity and osmolality, associated ions, concentration, concomitant hypoxia, and oxygen free radical generation may each be related to the degree of cellular damage.^{11,13} Although controversy remains about the exact pathogenesis in humans and the relevance of animal models, pathogenetic considerations underlie most efforts to reduce contrast nephrotoxicity.

ASSESSMENT OF RISK

The first steps in preventing CIN are to identify risk factors and review the need for contrast. The most important risk factors are preexisting kidney disease, diabetes, poor cardiac function, hypotension, anemia, and older age. Most risk factors can be detected with a routine history and physical examination. It is not necessary to measure serum creatinine on every patient, but this should be done before intra-arterial contrast and in patients with a history of kidney disease, proteinuria, kidney surgery, diabetes, hypertension, or gout.¹⁴ Patients with reduced kidney function may be more accurately recognized if creatinine clearance or the glomerular filtration rate are estimated from the serum creatinine. Some risk factors such as volume depletion may be corrected before contrast. The risk of CIN increases exponentially with the number of risk factors present.^{7,9,15} Validated risk prediction models have been developed for those having percutaneous coronary intervention.¹⁶

Alternate imaging modalities not requiring contrast should be considered in those with any risk factors. High-dose gadolinium chelates should not be substituted for iodinated radiocontrast media in those patients at risk of CIN, as they have been shown to be at least as nephrotoxic as the latter media when used in this fashion.¹⁷ Serum creatinine should be measured again at 24 to 72 hours post-contrast in patients at risk of CIN.

SPECIFIC PROPHYLACTIC THERAPIES

Table 4-1 summarizes the most commonly used prophylactic measures supported by at least some evidence.

Fluid Administration

Administration of fluids is recommended to reduce the risk of CIN. However, data to support a specific fluid regimen are lacking and the optimal fluid regimen remains unclear. The trials evaluating prophylactic fluid therapy generally lack power. In two trials, prolonged IV saline was superior to an oral fluid regimen with or without a brief IV fluid bolus.^{18,19} No difference between fluid regimens was found in two other trials comparing IV saline with either oral salt and water or oral water and brief IV fluid.^{20,21} A final small trial, marred by excessive dropouts, showed a trend to less CIN with more prolonged precontrast IV fluid.²² Isotonic saline was slightly better than 0.45% saline in a large trial of patients with good kidney function.²³ Almost all participants in these trials received intra-arterial contrast. Based on this evidence, the recommendations for the present are to ensure that patients receiving contrast are in a state of optimal hydration as determined by clinical assessment. Fluid restriction before injection of contrast should be limited to when truly necessary. For those at risk of CIN, particularly those undergoing cardiac angiography, it is recommended that consideration be given to infusing 0.9% saline intravenously for at least 6 hours before and after contrast, in the absence

of data showing that shorter duration or oral fluid supplementation is comparable.

Bicarbonate

Alkalinization of tubular fluid has been proposed to reduce the rate of CIN. The mechanism of any benefit might include reduction in pH-dependent free radical generation in the kidney. In the only reported trial to date involving 119 patients, 81% of whom were undergoing cardiac angiography, isotonic sodium bicarbonate resulted in a lower frequency of CIN (defined as a 25% increase in serum creatinine within 2 days) compared with 0.9% saline infusion.²⁴ However, the trial was terminated early due to a lower than expected rate of events in the bicarbonate group, but the timing of the interim analysis and the stopping rules were not prespecified and the *P* value for the difference in event rates was higher than generally used to prematurely terminate a trial. It is also unclear whether any benefit from bicarbonate would be seen if patients were also treated with *N*-acetylcysteine (NAC). This question has not been properly addressed, but no additional benefit was seen in a retrospective analysis at one center.²⁵ Although it is reasonable to use bicarbonate infusion in an effort to reduce the rate of CIN, the results of this trial require replication before this can be recommended as the fluid of choice.

N-Acetylcysteine

NAC might reduce the nephrotoxicity of contrast through antioxidant and vasodilatory effects.²⁶ The results of an initial trial were dramatic, but the event rate in the controls was unexpectedly high for patients given low-dose IV low-osmolality contrast.²⁷ Subsequent trials have largely involved patients with reduced kidney function having cardiac angiography. Some have shown benefit and others not; many are limited by low power and a lack of blinding. The dose of NAC employed in most trials has not been chosen based on pharmacologic principles. Two trials comparing doses of NAC have suggested

Table 4-1 Therapies Commonly Used to Reduce the Risk of Contrast-Induced Nephropathy

Therapy	Dose	Route	Frequency	Comments
Fluid therapy	Varies from unrestricted PO fluids to 1 mL/kg/hr	IV or PO	Usually continuous from pre- to postcontrast. Some use bolus therapy pre-contrast	No one regimen proven best. IV 0.9% saline at 1 mL/kg/hr from 12 hr pre to 12 hr post most established. May increase risk of pulmonary edema
Isotonic sodium bicarbonate	3 mL/kg/hr × 1 hr, then 1 mL/kg/hr × 6 hr	IV	Infusion from 1 hr pre- and for 6 hr postcontrast	Only one supporting trial with caveats. May increase risk of pulmonary edema
<i>N</i> -acetylcysteine	Varies from 600–1200 mg bid PO to 150 mg/kg IV bolus	PO or IV	Varies, q12h for 4 doses beginning precontrast most common	Supporting study results heterogeneous
Theophylline and related	Varies 125–200 mg PO or 4–5 mg/kg IV bolus ± 0.4 mg/kg IV infusion	PO or IV	Varies from q12h PO to single IV bolus ± infusion for 24–72 hr	Limited evidence of efficacy, concern about potential cardiotoxicity

that higher doses may be required, especially if higher doses of contrast are being employed.^{28,29} Several meta-analyses of trials of NAC have been reported. The trials included in these analyses vary, but more recent and comprehensive meta-analyses suggest some benefit to NAC (pooled odds ratio ranged from 0.54 to 0.73 for contrast nephropathy defined variably as increases in serum creatinine).^{30–34} However, this estimate must be interpreted with caution, given the heterogeneous results of the individual trials and the possibility of publication bias, with small negative studies underrepresented. Also, the effect of NAC on outcomes other than minor changes in serum creatinine is largely unknown. Indeed, studies in healthy volunteers have suggested that NAC might have an effect on creatinine levels unrelated to an effect on the glomerular filtration rate.³⁵ However, in a recent trial involving patients undergoing primary angioplasty after myocardial infarction, NAC showed a dose-related improvement in CIN (defined as a serum creatinine increase), and there was a parallel beneficial effect on in-hospital death.²⁹

Theophylline

Theophylline and aminophylline have the potential to reduce CIN through antagonizing adenosine-mediated vasoconstriction. These drugs have been tested in several small trials. Recent meta-analyses found that the mean increase in serum creatinine was significantly, but only slightly, lower at 48 hours after contrast among those receiving active therapy compared with placebo. The clinical importance of this finding is not clear.^{36,37} There was heterogeneity among studies with regard to changes in serum creatinine. There is potential for adverse effects with theophylline. The optimal dose for prevention of CIN has not been established. Further studies are warranted.

Other Pharmacologic Agents

Several other interventions have been proposed to reduce the risk of CIN, but data are limited to support them. Forced diuresis with furosemide, mannitol, dopamine, or a combination of these given at the time of the contrast exposure has been associated with similar or higher rates of CIN when compared with prophylactic fluids alone.^{38–41} Negative fluid balance might underlie some of the detrimental effects.

Generally small randomized trials of vasodilation with dopamine, fenoldopam, atrial natriuretic peptide, calcium channel blockers, prostaglandin E₁, or a nonselective endothelin receptor antagonist failed to show a reduction in the rate of CIN compared with fluid therapy.^{41–46}

Two studies of captopril as a prophylactic agent yielded divergent results. In the first trial, serum creatinine increased by more than 0.5 mg/dL (44 μmol/L) in two (6%) patients given captopril for 3 days versus 10 (29%) given placebo ($P < .02$).⁴⁷ In the second study, CIN was reported as occurring in five (8.3%) patients given captopril versus one (3.1%) given placebo ($P = .02$).⁴⁸

Ascorbic acid as an antioxidant has been tested in a single randomized trial with patients undergoing cardiac angiography.⁴⁹ Serum creatinine increased by 25% or more than 0.5 mg/dL (44 μmol/L) within 2 to 5 days in 11 (9%) patients given ascorbic acid versus 23 (20%) given placebo ($P = .02$).⁴⁹ However, these results are difficult to interpret as the baseline serum creatinine level was lower in the placebo group and both groups reached a similar level post-contrast.

Prophylactic Renal Replacement Therapy

Hemodialysis during or shortly after contrast has not been shown to prevent CIN.^{50–52} In a trial of prophylactic hemofiltration in an intensive care unit before and after contrast involving patients with a mean creatinine clearance of 26 mL/min undergoing cardiac procedures, a 25% increase in serum creatinine was seen in three (5%) patients undergoing hemofiltration versus 28 (50%) given fluid alone ($P < .001$).⁵³ These results were replicated in a further trial by the same investigators, in which they also showed that hemofiltration limited to the post-contrast period was not significantly different from saline alone.⁵⁴ However, as changes in serum creatinine during and soon after hemofiltration are affected by creatinine removal, such changes in serum creatinine do not reliably reflect changes in kidney function. The mechanism of benefit, if any, to the kidney remains speculative. Marenzi and colleagues⁵⁴ suggest controlled high-volume administration as one possibility, but their hemofiltration protocol should lead to a neutral, not positive, fluid balance. In both trials, hemofiltration, especially pre- and post-contrast, was associated with reduced in-hospital cardiovascular mortality, but the mechanism by which this might occur is unclear. Given the resource implications and the problems with interpreting the true effect on kidney function, hemofiltration is not recommended at this time as a means to prevent CIN.

CONSIDERATIONS RELATED TO CONTRAST MEDIA

Contrast media can be classified in a number of ways including by osmolality, viscosity, and ionicity. High-osmolality agents such as sodium diatrizoate have been largely abandoned because of their greater general toxicities. In a meta-analysis of comparative trials, an increase in serum creatinine more than 0.5 mg/dL (44 μmol/L) after contrast in patients with reduced kidney function was less frequent with low- as opposed to high-osmolal media (odds ratio = 0.61, 95% confidence interval: 0.48–0.77).⁵⁵ Results in subgroups of trials were qualitatively similar, but statistical significance could only be shown for intra-arterial injection and in those with preexisting renal impairment. Due to the small number of events, no conclusion could be reached about the need for dialysis.

More recent trials have compared the nephrotoxicity of low-osmolal media such as iohexol or iopamidol with the iso-osmolal agent iodixanol. The results have not been totally consistent. A patient level meta-analysis of data from 16 trials in the database of GE Healthcare found that CIN defined as a 0.5-mg/dL increase in creatinine by 3 days post-contrast occurred in 1.4% after intra-arterial iodixanol versus 3.5% after low-osmolality agents.⁵⁶ The difference was more pronounced in those with existing kidney disease with or without diabetes. A further trial comparing iodixanol with iopamidol in 414 patients having cardiac angiography did not find any difference in the rate of CIN.⁵⁷ Similarly, comparative trials after intravenous injection of iodixanol versus low-osmolality agents have all shown similar rates of CIN with either agent.^{58,59} An analysis of the frequency of CIN before and after hospitals in Sweden switched to iodixanol suggested a higher rate of CIN with iodixanol.⁶⁰ Given the disparity in

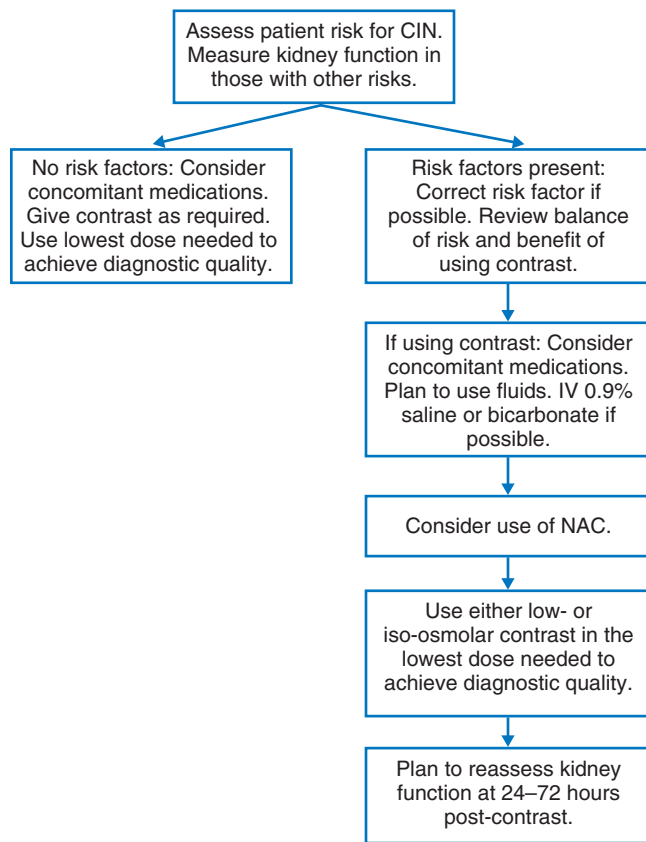

Figure 4-1 Algorithm for managing the risk of contrast-induced nephropathy (CIN). NAC, *N*-acetylcysteine.

the results, either low- or iso-osmolal media are acceptable at this time for patients at risk of CIN.

The nephrotoxicity of radiocontrast agents seems to be dose related. This has not always been clear when exposure to contrast has been measured as the volume injected (in milliliters). However, different contrast agents have varying concentrations of iodine and iodinated media are largely excreted through the kidney. It has been shown that the area under the curve as a measure of contrast exposure is closely estimated by dividing the grams of iodine injected by creatinine clearance.⁶¹ The related measure contrast volume (mL) × kg body weight ÷ serum creatinine in mg/dL has been associated with risk of CIN.^{62,63} Exceeding a value of 5 mL × kg body weight ÷ serum creatinine in mg/dL strongly predicts nephropathy requiring dialysis.⁶³ Therefore, the volume of contrast injected should be limited to the minimum required to complete the diagnostic or therapeutic procedure.

MANAGING CONCOMITANT MEDICATIONS

Because of the risk of lactic acidosis when CIN occurs in a patient with diabetes receiving metformin, it is recommended that this drug be stopped at least from the time of contrast injection and held until CIN has been excluded.^{5,64} The balance of risks and benefits associated with interrupting therapy with diuretics, angiotensin-converting enzyme inhibitors, and

angiotensin receptor blockers in cases at risk of CIN has not been thoroughly studied to date.⁶⁵ It is generally recommended that NSAID therapy be interrupted, but empirical data on which to base this are lacking.

RECOMMENDED OVERALL RISK MINIMIZATION STRATEGY

Figure 4-1 outlines an overall approach to minimizing the risk of CIN. The steps involved include an assessment of risk, review of the balance of risks and benefits associated with the use of contrast for the particular case, use of fluid prophylaxis, consideration of specific prophylactic drug therapy, management of concomitant drug therapy, choice of type and dose of contrast, and postcontrast follow-up.

MANAGEMENT OF TYPE 2 HEPATORENAL SYNDROME 53

General Measures	53
Specific Therapies	53
PREVENTION	53

Hepatorenal syndrome (HRS) is a systemic condition that usually occurs in patients with advanced liver disease and combines cardiovascular and kidney disturbances.^{1–5} Severe reduction in the glomerular filtration rate develops in the absence of significant renal lesions as a final consequence of an extreme splanchnic arterial vasodilation secondary to portal hypertension.^{6–11} Bacterial translocation probably plays a major role in the induction of the splanchnic arterial vasodilation responsible for decrease in systemic vascular resistances and arterial underfilling.^{12–20} The kidney perceives this decreased blood flow and initiates afferent arterial vasoconstriction and activation of the renin-angiotensin system.^{21,22} It also responds to sympathetic nervous system activation by increasing sodium retention and vasoconstriction in an attempt to improve kidney perfusion.^{23,24} Although initially compensated by the secretion of vasodilators within the renal circulation, vasoconstriction can progress to a severe reduction in the glomerular filtration rate, the so-called HRS. At this stage, patients constantly have alterations of renal solute-free water excretion as a consequence of increased vasopressin release and usually have a serum sodium lower than 130 mEq/L.^{25–29} Among patients with cirrhosis and ascites without renal failure, marked renal sodium retention and presence of hyponatremia have been identified as risk factors for the development of HRS.³⁰ Some triggering events can precipitate HRS, among them bacterial infections, particularly spontaneous bacterial peritonitis (i.e., the spontaneous infection of the ascitic fluid in the absence of an intra-abdominal source of infection).¹⁷ However, in other patients, HRS develops spontaneously without any apparent triggering event.

Besides vasoconstriction in the renal circulation, patients with HRS also have vasoconstriction in other nonsplanchnic vascular beds, including the lower and upper extremities, brain, and liver.^{17,31,32} Reduced blood flow in the latter two territories may play a role in some of the clinical features seen in patients with HRS, such as encephalopathy and worsening of liver function, respectively. A decrease in cardiac function may also contribute to arterial underfilling in patients with HRS. The cardiac dysfunction is likely due to cirrhotic cardiomyopathy, the origin of which is still under investigation.^{17,33–38}

Two different patterns of renal failure (steady and progressive) define two different clinical types of HRS: type 1 and type

2 HRS.^{39,40} The rate of progression used to define type 1 HRS has been arbitrarily set as a 100% increase in serum creatinine reaching a value greater than 2.5 mg/dL (221 μ mol/L) in less than 2 weeks. Patients not meeting these criteria of progression are considered to have type 2 HRS. There is consensus to establish the diagnosis of HRS when serum creatinine is greater than 1.5 mg/dL (133 μ mol/L),^{40,41} which corresponds approximately to a glomerular filtration rate lower than 30 mL/min.⁴² Because of the lack of specific diagnostic procedures for HRS, the diagnosis of HRS relies on the exclusion of other conditions that may cause renal failure in cirrhosis, particularly volume depletion, shock, treatment with nephrotoxic drugs, and parenchymal kidney diseases.^{40,43–45} Box 5-1 shows the diagnostic criteria of HRS proposed in a recent consensus workshop of the International Ascites Club.⁴¹ Reflecting the systemic nature of the disease, patients with type 1 HRS usually present signs of multiorgan failure. By contrast, in patients with type 2 HRS renal failure almost goes unnoticed, as the main clinical problem is refractory ascites and frequent need for repeated large-volume paracentesis due to poor response to diuretic therapy.^{40,41} Some patients with type 2 HRS eventually progress to type 1 HRS, often as a consequence of an acute event such as bacterial infections. Outcome is different for the two types of HRS, as patients with type 1 HRS have a median survival of only 1 month, whereas the median survival is 7 months for patients with type 2 HRS.^{39,46}

In recent years, major advances have been made in the field of HRS, particularly in its pathogenesis and management. The aim of the current chapter is to review the management of HRS in patients with cirrhosis, with particular emphasis on type 1 HRS. An update on the pathogenesis of HRS may be found in several recent reviews.^{4,47–49}

MANAGEMENT OF TYPE 1 HEPATORENAL SYNDROME

General Measures

Diuretics should be withdrawn in all patients with cirrhosis and renal failure, regardless of whether there is suspicion of HRS, and patients should be placed on a low-salt diet (<2 g/day). If

Box 5-1 Diagnostic Criteria for Hepatorenal Syndrome in Cirrhosis

1. Cirrhosis with ascites
2. Serum creatinine > 1.5 mg/dL (133 μmol/L)
3. No improvement in serum creatinine (decrease to a level <1.5 mg/dL after at least 2 days off diuretics and volume expansion with albumin 1 g/kg body weight up to a maximum of 100 g/day)
4. Absence of shock
5. No current or recent treatment with nephrotoxic drugs
6. Absence of signs of parenchymal renal disease, as suggested by proteinuria (>500 mg/day) or hematuria (>50 red blood cells per high-power field), and/or abnormal renal ultrasound scan

From Salerno F, Gerbes A, Ginès P, et al: Diagnosis, prevention and treatment of the hepatorenal syndrome in cirrhosis. A consensus workshop of the International Ascites Club. *Gut* 2007;56:1310–1318.

the patient presents with hyponatremia, which is usually the case, fluid intake should be restricted to 1.0 to 1.5 L/day to avoid a positive fluid balance and further decrease in serum sodium concentration. The administration of saline solutions may markedly increase ascites and edema due to the presence of severe renal sodium retention and therefore is not recommended. For this same reason and the lack of severe metabolic acidosis in most patients, the routine administration of sodium bicarbonate is not advisable. Early identification of infections and treatment with broad-spectrum antibiotics is fundamental because severe infections are very common and contribute to death in many of these patients. Considering that antibiotic prophylaxis is effective in the prevention of bacterial infections in other high-risk groups, such as patients with advanced cirrhosis and gastrointestinal bleeding,⁵⁰ it is possible that antibiotic prophylaxis is also effective in preventing bacterial infections in patients with type 1 HRS, but this has not been specifically investigated.

Specific Therapies

Several therapeutic approaches, which are discussed in the following sections, can be used in the management of type 1 HRS (Table 5-1).

Liver Transplantation

Liver transplantation is the treatment of choice for patients with cirrhosis and type 1 HRS without contraindications to transplantation because it allows the cure of both liver disease and associated renal failure.^{51–53} It is now well established that patients with HRS have a satisfactory long-term survival with liver transplantation alone (approximately 70% at 3 years after transplantation in most transplantation centers), yet slightly lower than that of transplant recipients without HRS.^{52,54–57} The main issue in liver transplantation for patients with type 1 HRS is the high mortality rate in the waiting list due to short survival expectancy in the setting of prolonged waiting times in most transplantation centers. This can be improved by assigning

Table 5-1 Treatment Options for Hepatorenal Syndrome and Mechanism of Action

Therapy	Mechanism of Action
Liver transplantation	Improvement in liver function and normalization of circulatory disturbances in the portal and systemic circulations
Transjugular intrahepatic portosystemic shunt	Reduction in portal pressure and suppression of the activity of vasoconstrictor systems
Vasoconstrictors (terlipressin, α-adrenergic agonists)	Vasoconstriction of the splanchnic circulation and suppression of the activity of vasoconstrictor systems
Albumin	Improvement in effective arterial blood volume? Improvement of endothelial function? Antioxidant activity?
Renal replacement therapy	Supplies renal detoxification functions
Albumin dialysis (MARS, Prometheus)*	Supplies liver detoxification functions. Improvement of circulatory function?

*Currently under clinical investigation.

patients with type 1 HRS a high priority for transplantation, which can be accomplished by using the MELD (Model for End-stage Liver Disease) score.^{58,59} This is a score of severity of cirrhosis used in many countries to allocate organs for liver transplantation, which includes three variables: two of liver function, serum bilirubin, and international normalization ratio (a standardized unit for Quick time) and one of renal function and serum creatinine (for calculation, please visit www.mayoclinic.org/meld/mayomodel6.html or www.unos.org). For the same degree of liver failure, MELD score values increase progressively as serum creatinine values increase (minimum value 6 points; maximum value 40 points). The maximum value of serum creatinine to be used in the calculation of MELD is 4 mg/dL. This value is also used for patients on renal replacement therapy. Patients with type 1 HRS usually have higher MELD scores than those of patients with type 2 HRS due to a greater impairment of liver and renal function. In patients with HRS, the MELD score is an excellent predictive factor of survival. Because patients with type 1 HRS have very high MELD score values, the use of this score as a system for organ allocation in liver transplantation may likely increase the applicability of liver transplantation in this patient population and help reduce waiting list mortality.

In addition to using the MELD score for organ allocation, patients with type 1 HRS awaiting liver transplantation may possibly benefit from treatment of HRS aimed at improving renal function before transplantation. Although not assessed

yet in prospective studies, the reversal of HRS before transplantation may help patients reach transplantation and improve posttransplantation outcome, and, in particular, reduce the frequent occurrence of chronic renal failure.^{52,55,60} A retrospective study including a small number of patients with HRS treated with vasoconstrictors before transplantation (see later) showed that patients with HRS who responded to therapy with an improvement in renal function had an outcome after transplantation that was not different from that of a control group of transplant recipients without HRS matched by age and severity of cirrhosis.⁶¹

The use of combined liver-kidney transplantation (CLKT) has also been suggested as an approach to therapy of HRS, but it is still a matter of debate. A clear benefit of CLKT on the evolution of renal function and patient survival compared with liver transplantation alone has not been demonstrated.^{54,56} Conversely, CLKT increases the use of kidneys for a group of patients in whom native kidney function may recover spontaneously after liver transplantation alone.^{51–53} Therefore, the use of CLKT in a scenario of growing lists for kidney transplantation in patients with permanent end-stage kidney disease remains very contentious. As a result, it appears that CLKT should not be recommended currently as standard therapy for patients with HRS. There remain doubts in the specific circumstance of patients with HRS who have been on dialysis for a prolonged period before liver transplantation and therefore have poor chances of regaining renal function after transplantation.^{56,62,63} It is currently unknown how much time on dialysis before liver transplantation prevents recovery from HRS in the posttransplantation period. A panel recently proposed guidelines to help select between liver transplantation alone or CLKT.⁶⁴ They recommended that patients with HRS requiring more than 6 weeks of dialysis should be evaluated for CLKT. For patients with HRS not on dialysis or with shorter duration of dialysis, prognosis was estimated to be good and liver transplantation alone was considered to be sufficient. Obviously, more studies are needed in this area.

Finally, kidney transplantation after liver transplantation was recently proposed as an alternative to CLKT for patients with HRS who needed dialysis for more than 30 days after liver transplantation.⁵⁷ This suggestion was based on findings of a 1-year survival rate 40% lower in patients who required dialysis for more than 30 days compared with patients who required dialysis for less than 30 days. Although kidney after liver trans-

plantation may be a reasonable approach in some patients, the information is still very limited.

Pharmacologic Therapy

Early studies assessed the use of vasodilators, such as dopamine and prostaglandins, with the aim of reversing the intense renal vasoconstriction characteristic of HRS. However, in addition to not improving renal function, these drugs may further impair systemic hemodynamics, which is already markedly altered in patients with advanced cirrhosis.^{65–68} Recent research on management of HRS has been directed toward reversal of major pathogenic events such as arterial splanchnic vasodilation and portal hypertension. This may be achieved by the administration of vasoconstrictor drugs or maneuvers aimed at reducing portal pressure. Several recent studies have shown that the administration of vasoconstrictor drugs is associated with an improvement in renal function in a significant number of patients with HRS (Table 5-2). The rationale of vasoconstrictor therapy is to improve circulatory function by causing vasoconstriction of the extremely dilated splanchnic arterial bed, which subsequently improves arterial under-filling, reduces the activity of the endogenous vasoconstrictor systems, and increases renal perfusion.^{69–71} Two types of drugs have been used: vasopressin analogues (mainly terlipressin) and α -adrenergic agonists (norepinephrine and midodrine), which act on V1 vasopressin receptors and α_1 -adrenergic receptors, respectively, present in vascular smooth muscle cells.

Vasopressin Analogues

The first analogue of vasopressin investigated was ornipressin (8-ornithin vasopressin), an agent with a predominant affinity for V1 receptors located in the vascular smooth muscle cells, particularly abundant in the splanchnic vessels. Ornipressin was initially given in studies of small numbers of patients as an IV infusion of 6 U/hr over 4 hours.^{69,72} During the infusion, the mean arterial pressure increased, cardiac output decreased, and renal blood flow and glomerular filtration rate improved as did sodium excretion. Following these positive findings, the effects of a more prolonged administration of ornipressin were investigated. Guevara and colleagues⁷³ treated eight patients for 3 days with a stepped-dose infusion of ornipressin (2–6 U/hr) plus albumin without observing any side effects but with only a slight improvement in the glomerular filtration rate. They subsequently treated eight additional patients for a longer period

Table 5-2 Vasoconstrictor Drugs Used in the Treatment of Hepatorenal Syndrome

Drug	Dose Range	Median Duration of Therapy	Response to Therapy (%) [*]	Severe Side Effects (%) [†]
Terlipressin	1–2 mg/4–12 hr IV bolus	15 days	52 [‡]	13
Norepinephrine	0.1–3 mg/hr IV perfusion	15 days	77 [§]	5
Midodrine	7.5–12.5 mg/8 hr PO	—	43	1

^{*}Response to therapy as defined by complete reversal of hepatorenal syndrome (serum creatinine < 1.5 mg/dL [133 μ mol/L] in most studies.

[†]Severe side effects include cardiac arrhythmia or ischemia, other ischemic events, dyspnea, and circulatory overload.

[‡]From references 77–81, 83–85, and 90. Total number of patients included is 255.

[§]From references 87 and 90. Total number of patients included is 22.

^{||}From references 86, 88, and 89. Midodrine was given in association with octreotide. Total number of patients included is 79.

(15 days) with the same regimen. Treatment was associated with a marked improvement in the glomerular filtration rate in four of seven patients treated. Ornipressin had to be discontinued in the remaining three patients because of severe ischemic complications (ischemic colitis and tongue ischemia). A good response rate (four of seven patients) with ornipressin (6 U/hr) plus low-dose dopamine, but without albumin, was also reported in a subsequent study performed by Gülberg and colleagues.⁷⁴ One of the patients developed severe intestinal ischemia. These studies confirmed the reversibility of HRS under pharmacologic therapy with a vasoconstrictor drug. However, due to the high incidence of adverse events related to ornipressin, the research was then focused on terlipressin, an analogue of vasopressin approved for the treatment of gastrointestinal bleeding caused by esophageal varices.^{75,76}

Terlipressin, a product of the cleavage of triglycyl-lysine-vasopressin, is the vasoconstrictor drug that has been used more frequently in HRS and thus far does not seem to share the high rate of ischemic complications observed with ornipressin. Moreover, its slow metabolism results in a prolonged half-life, which allows intermittent IV dosing. A preliminary crossover study demonstrated that terlipressin treatment for 2 days was more effective than placebo in improving renal function in patients with HRS without causing adverse effects.⁷⁰ However, improvement was very mild due to the short duration of treatment. A number of nonrandomized phase 2 studies using combined therapy of terlipressin (0.5–2 mg/4 hr for 15 days) plus albumin (1 g/kg of body weight on the first day and 20–40 g/day thereafter) including a total of 152 patients (87% with type 1 HRS) have shown a high response rate, ranging from 44% to 77%.^{77–81} In most studies, the definition used for response to therapy was a decrease in serum creatinine to less than 1.5 mg/dL (133 μ mol/L), although in some studies a decrease of 20% to 30% of serum creatinine from baseline was considered a response to therapy. The average survival rate of patients included in these phase 2 studies was 60% at 1 month. Recurrence of HRS after terlipressin withdrawal may occur in as many as 20% of patients, although some studies reported a higher rate, and treatment of recurrence is usually effective.^{77–79,81,82}

So far, only three randomized, comparative studies have been reported assessing the effects of terlipressin on renal function and survival in patients with HRS.^{83–85} One small trial from Solanki and colleagues⁸³ randomized 24 patients to either low-dose terlipressin (1 mg/12 hr) or placebo for 15 days in combination with albumin and fresh frozen plasma. Complete reversal of HRS was observed in 42% of patients treated with terlipressin. Survival was longer in patients treated with terlipressin compared with those treated with placebo, and transient cardiac arrhythmia was seen in three patients treated with terlipressin. The results of two larger randomized, controlled studies were reported recently.^{84,85} The Spanish trial⁸⁵ included 46 patients with HRS, 74% of them with type 1 HRS, and the American trial⁸⁴ included 112 patients, all with type 1 HRS. The two studies used very similar treatment regimens of terlipressin plus albumin for 2 weeks. The starting dose of terlipressin was 1 mg/4 to 6 hr IV and was increased to a maximum of 2 mg/4 to 6 hr after 2 to 3 days if there was no response to therapy as defined by a reduction in serum creatinine of greater than 25% to 30% of pretreatment values. Reversal of HRS, as defined by a decrease in serum creatinine to less than 1.5 mg/dL, was observed in 39% of patients in the Spanish study and 34% of patients in the

American study. In addition to a marked decrease in the high serum creatinine levels, response to therapy was characterized by an increase in arterial pressure, high urine output, and a marked increase in the low serum sodium concentration.⁸⁵ The latter could be due to improved glomerular filtration rate and/or suppression of antidiuretic hormone after improvement in effective arterial blood volume and is consistent with a predominant action of terlipressin on V1 over V2 antidiuretic hormone receptors. The frequency of ischemic side effects requiring the discontinuation of treatment was approximately 10%. Some patients developed transient pulmonary edema during the first few days of therapy, even with close monitoring of central venous pressure. In none of the studies was treatment with terlipressin and albumin associated with an improved survival compared with the control group of patients treated with albumin alone. However, both studies showed that responders in terms of improvement in renal function after therapy had a significant, albeit moderate, increase in survival compared with nonresponders (median survival > 90 days versus 13 days, respectively, in one of the studies).⁸⁵ Nevertheless, it is important to emphasize that despite the improved survival, responders still have a high risk of death in the short term, which is particularly important in patients awaiting liver transplantation. Further studies in larger patient populations are needed to definitively assess the effect of treatment with terlipressin on survival of patients with type 1 HRS.

There are two major shortcomings of the treatment with terlipressin: lack of availability in some countries and high cost, the latter being a major limiting factor for its use in some areas of the world. These two drawbacks have prompted the investigation of other vasoconstrictor drugs.

α -Adrenergic Agonists

α -Adrenergic agonists (norepinephrine, midodrine) represent an attractive alternative to terlipressin because of the low cost and wide availability compared with terlipressin.^{86–90} However, the information on the efficacy and side effects of α -adrenergic agonists in patients with type 1 HRS is still very limited. A small study from Angeli and colleagues⁸⁶ looked at the efficacy of midodrine in combination with octreotide, a somatostatin analogue used for gastrointestinal bleeding, and compared it with nonpressor doses of dopamine (both groups also received albumin 20–40 g/day). The rationale for the use of a somatostatin analogue is to suppress glucagon as well as other splanchnic vasodilator peptides. In the five patients treated with octreotide and midodrine, the authors observed an improvement in serum creatinine and glomerular filtration rate, as well as sodium excretion, and suppression of renin and aldosterone with a decrease in glucagon and nitric oxide levels. No changes or even a worsening of renal parameters were observed in a small control group of nonrandomized patients. In a retrospective study, patients treated with octreotide and midodrine had a higher rate of sustained response (40%) and a lower mortality rate (43%) compared with contemporaneous patients not treated (10% and 71%, respectively), although the study is limited by the retrospective design.⁸⁹ It appears that octreotide alone without the simultaneous use of vasoconstrictors does not improve renal function. In fact, a small placebo-controlled, crossover trial showed that octreotide plus albumin was not effective for the treatment of HRS.⁹¹

Norepinephrine in combination with albumin has been assessed because of its potent vasoconstrictor effect on both

arterial and venous circulation and its wide availability. Infusion of norepinephrine (0.5–3 mg/hr) together with administration of albumin and furosemide to keep central venous pressure in the range of 4 to 10 cm of water was shown to reverse type 1 HRS in 10 of 12 patients after a median of 7 days.⁸⁷ In addition to an increase in mean arterial pressure and a marked decrease in the activity of the renin-aldosterone system, sodium excretion also increased. The only adverse event reported was an episode of reversible myocardial hypokinesia probably related to cardiac ischemia. Three patients could undergo liver transplantation with a normal serum creatinine. A recent randomized study compared norepinephrine plus albumin with terlipressin plus albumin until reversal of HRS or 15 days of therapy.⁹⁰ The study randomized 22 patients with HRS (either type 1 or 2) and observed a reversal rate of 70% with norepinephrine and 83% (not significant) with terlipressin. Both groups had a significant improvement in circulatory function. The results of these two studies suggest that norepinephrine may be a good alternative to terlipressin. Nevertheless, larger studies are needed to confirm that α -adrenergic agonists are equally effective as terlipressin in the management of HRS.

Adjunctive Therapy to Vasoconstrictors

In most studies, vasoconstrictors have been given in combination with IV albumin with the aim of further improving the arterial underfilling. The rationale of the concomitant use of albumin is in part based on studies of head-of-water immersion in patients with ascites without HRS that showed that expansion of central blood volume (together with a vasoconstrictor) is necessary to overcome sodium avidity and achieve a negative sodium balance.⁹² In addition to its effects as plasma expander, albumin administration may also have beneficial effects related to its antioxidant properties or its ability to improve endothelial function, although this clearly needs further studies.⁹³ The possible role of albumin in improving response to vasoconstrictors for patients with HRS was investigated in two studies, the designs of which unfortunately limit their conclusions. Ortega and colleagues⁸¹ undertook a sequential observational study, in which the first 13 patients were given terlipressin (0.5 up to 2 mg/4 hr) plus albumin (1 g/kg of body weight for the first day followed by 20–40 g/day thereafter) and the subsequent eight patients received terlipressin alone. In the group receiving the combined therapy, 77% achieved a complete reversal of HRS (decrease in serum creatinine value to < 1.5 mg/dL) compared with significantly lower percentage (25%) in the group receiving terlipressin alone. The second study was a retrospective evaluation of a group of patients treated with terlipressin.⁸⁰ In the 68 patients who received terlipressin in combination with albumin, the response rate (decrease in serum creatinine $> 20\%$) was 62% compared with 48% in the 23 patients who were given terlipressin alone. This difference in response rate was not significant. Until further studies assessing the role of simultaneous albumin administration are done, the specific properties of albumin and its beneficial effect in combination with vasoconstrictor drugs on reversal of HRS remain controversial. However, as the majority of studies showing reversal of HRS have used albumin, its use as an adjunctive therapy to vasoconstrictors is currently recommended.^{41,77,81,83–85,93} Whether plasma expansion could be done with synthetic agents such as hydroxyethyl starch instead of albumin remains

to be assessed.⁹⁴ Nevertheless, accumulation of these agents and osmotic tubular damage reported in renal failure could be problematic.^{95,96}

Transjugular Intrahepatic Portosystemic Shunts

Only a few studies have reported on the effects of a transjugular intrahepatic portosystemic shunt (TIPS) in patients with type 1 HRS.^{97,98} A TIPS is a stent placed via the jugular vein in the liver parenchyma to create a direct communication between portal vein and hepatic veins aimed at reducing the increased portal pressure characteristic of advanced cirrhosis and HRS. In patients with type 1 HRS, a TIPS improves circulatory function and reduces the activity of vasoconstrictor systems. This is associated with a slow decrease in serum creatinine levels in approximately 60% of patients. Median survival after insertion of a TIPS in patients with type 1 HRS ranges between 2 and 4 months. The utility of a TIPS in patients with type 1 HRS is low because a TIPS is contraindicated in patients with severe liver failure, manifested by high serum bilirubin levels and/or high MELD scores and/or hepatic encephalopathy, which are common findings in the setting of type 1 HRS. Hepatic encephalopathy is particularly common after TIPS placement and is directly related to the shunting of the blood to the systemic circulation. In two studies including a small number of patients, TIPSs have been used as a sequential therapy in selected patients with HRS in whom renal function improved after treatment with vasoconstrictors (either terlipressin or midodrine plus octreotide).^{79,88} In both studies, a TIPS further improved renal function. In one of the studies, sodium excretion also improved, and there was a marked decrease in renin and aldosterone at 1 month post-TIPS insertion.⁸⁸ Although this approach (vasoconstrictors followed by TIPS insertion) appears promising, more information is needed before it can be generalized in clinical practice.

Other Therapeutic Methods

Renal replacement therapy (hemodialysis or continuous venovenous hemodiafiltration) has been used in the management of patients with type 1 HRS, especially in patients who are candidates for liver transplantation, in an attempt to keep patients alive until liver transplantation is performed or a spontaneous improvement in renal function occurs.^{99–103} Unfortunately, the potential beneficial effect of this approach has not been unequivocally demonstrated.¹⁰⁴ The clinical experience is that most patients do not tolerate hemodialysis well and develop major side effects, including severe arterial hypotension, bleeding, and infections, that may contribute to death during treatment. Some authors have suggested a better tolerance for continuous venovenous hemodiafiltration, but no study compared both therapies in patients with the same degree of liver impairment and studies done in the general intensive care unit population failed to demonstrate any superiority of one over the other.^{104–108} Conversely, findings that indicate the need for renal replacement therapy (severe fluid overload, acidosis, or hyperkalemia) are uncommon in type 1 HRS, at least in early stages. Therefore, the initial therapy for these patients should probably include measures aimed at improving circulatory function (particularly vasoconstrictors) before renal replacement therapy is started.

Extracorporeal albumin dialysis, such as the molecular adsorbents recirculation system, is a system that uses an albumin-containing dialysate that is recirculated and perfused through

a charcoal and anion-exchanger column, combined with a hemodialysis filter. It has been reported that the molecular adsorbents recirculation system improves renal function and survival in a small series of patients with HRS, but these results require confirmation in larger series of patients.¹⁰⁹ A multicenter European study (the Helios study) using a new extracorporeal adsorbent dialysis system, called Prometheus and based on recycling of patients' own albumin, is actually under way to specifically assess the efficacy of this device in patients with HRS. The use of albumin dialysis in the treatment of HRS should currently be restricted to investigational purposes.

Recommendations for Therapy of Type 1 Hepatorenal Syndrome

Given the limited information, particularly the low number of randomized, controlled studies on treatments of HRS, the following recommendations are based both on existing data and on the authors' experience (Fig. 5-1).

In patients who are candidates for liver transplantation, every effort should be made to include patients on the waiting list as soon as possible. Most patients with type 1 HRS will die while awaiting transplantation due to their extremely poor prognosis unless a system of prioritization of patients exists. In this regard, the use of MELD score as a system for organ allocation may increase the applicability of transplantation in patients with type 1 HRS by reducing waiting list mortality. Considering the relatively high morbidity and

mortality after liver transplantation in patients with type 1 HRS, patients should ideally be treated while awaiting transplantation in an attempt to improve renal function before transplantation. Among the different treatments available, the administration of vasoconstrictors plus albumin appears to be the method of choice because of its efficacy and easy applicability. Treatment with vasoconstrictors improves survival in responder patients and may also improve outcome after transplantation. However, given the limited survival effect, patients responding to therapy should probably be maintained on the waitlist with their pretreatment MELD score to avoid reducing their access to transplantation. Among the different vasoconstrictors available, terlipressin has been the drug most commonly used and should be considered the first choice of treatment. Norepinephrine or midodrine appear to be suitable alternatives if terlipressin is not available. Midodrine should be given in association with octreotide. Patients treated with vasoconstrictors should be hospitalized and closely monitored for adverse events, particularly ischemic complications and circulatory overload. Renal replacement therapy or insertion of a TIPS should be reserved for patients not responding to vasoconstrictors. Methods of albumin dialysis should be used only in the setting of prospective studies.

Recommendations for patients with type 1 HRS who are not candidates for liver transplantation are difficult to propose with the limited available information. In these patients,

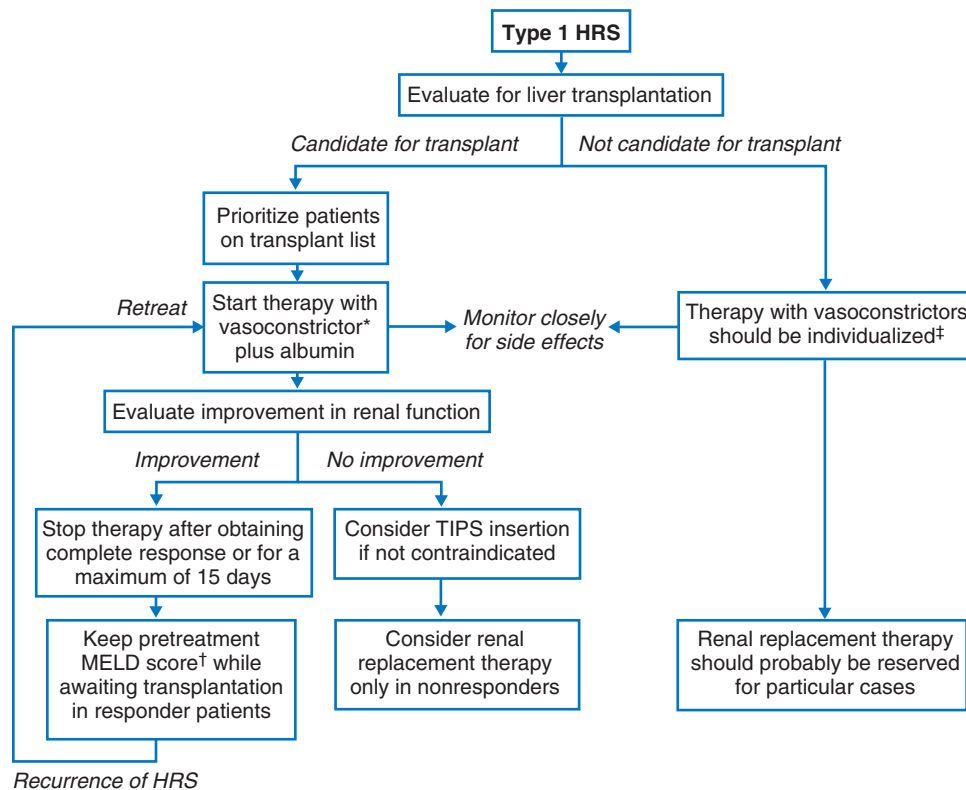

Figure 5-1 Proposed algorithm for the management of type 1 hepatorenal syndrome (HRS). *Either terlipressin, if available, or norepinephrine; therapy with a combination of midodrine and octreotide could also be an option. †MELD (Model for End-Stage Liver Disease) score (see text for details). ‡Patients for whom a limited survival advantage (in case of response) could be beneficial (e.g., alcoholic patients who could reach abstinence period sufficient to be placed on transplant list). TIPS, transjugular intrahepatic portosystemic shunt.

the appropriateness of a specific therapy for HRS should be evaluated in the context of the clinical characteristics of patients (e.g., age, severity of liver failure, possible improvement in liver disease). If treatment is considered appropriate, vasoconstrictors are probably the best option. A TIPS has a low utility and a high cost and is not available in many centers. Methods of renal replacement therapy should probably be used only in very specific cases, whereas albumin dialysis should be used only in the setting of prospective controlled studies.

MANAGEMENT OF TYPE 2 HEPATORENAL SYNDROME

General Measures

Unlike patients with type 1 HRS, patients with type 2 HRS can be managed as outpatients unless they develop complications that require hospitalization. The most frequent clinical finding of these patients is refractory ascites. Diuretics should be given only if they cause a significant natriuresis (i.e., urine sodium > 30 mEq/day).¹¹⁰ Care should be taken with the use of spironolactone and other potassium-sparing diuretics in these patients because of the risk of developing hyperkalemia. Repeated paracentesis with IV albumin is likely the method of choice for the treatment of large ascites in these patients.¹¹⁰ If hyponatremia is present, total fluid intake should be restricted to approximately 1000 to 1500 mL/day. Bacterial infections should be diagnosed and treated early due to the risk of precipitating type 1 HRS. Patients with low protein concentration in the ascitic fluid (<15 g/L) should receive prophylactic treatment with norfloxacin (400 mg/day) to prevent the development of

spontaneous bacterial peritonitis and reduce the risk of type 1 HRS (see later).¹¹¹

Specific Therapies

Liver transplantation is the treatment of choice for candidate patients. As for patients with type 1 HRS, the use of MELD score for organ allocation in liver transplantation is probably the best method to reduce mortality of those on the waitlist. Results from small studies suggest that the administration of vasoconstrictors improves renal function in these patients.^{79,81,85,90} Because of the paucity of data in patients with type 2 HRS, it is currently unknown whether all patients should be treated with vasoconstrictors. Candidates for liver transplantation should probably be treated to improve renal function before transplantation. The use of a TIPS in patients with type 2 HRS is associated with an improvement in renal function, better control of ascites, and decreased risk of progression from type 2 to type 1 HRS.¹¹² However, a TIPS does not improve survival in these patients compared with treatment with repeated paracentesis and IV albumin.^{112,113} Therefore, the beneficial effects of a TIPS in reducing ascites recurrence rate and progression to type 1 HRS in patients with type 2 HRS should be weighed against the lack of improvement in survival rate, increased risk of encephalopathy, and high costs. Recommendations for the management of patients with type 2 HRS are outlined in Figure 5-2.

PREVENTION

There is limited, yet important, information on the prevention of HRS. Two strategies are used to prevent the development of HRS in patients with cirrhosis. The first strategy is to use

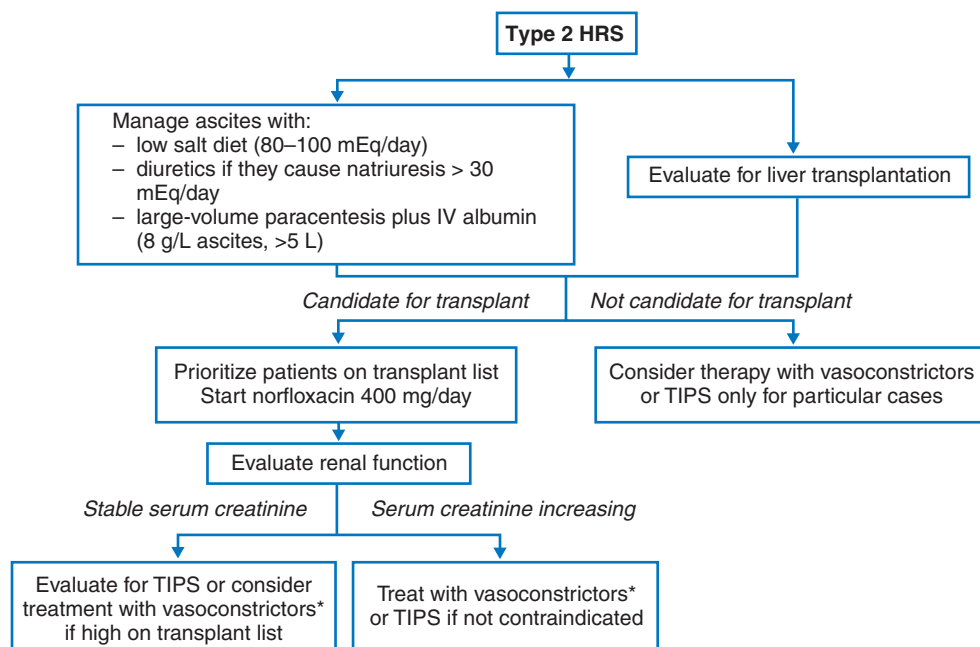

Figure 5-2 Proposed algorithm for the management of type 2 hepatorenal syndrome (HRS). *Terlipressin should be the preferred choice as information for norepinephrine and midodrine is lacking or limited. TIPS, transjugular intrahepatic portosystemic shunt.

Box 5-2 Key Concepts

1. HRS is a relatively common complication of cirrhosis and is characterized by a marked splanchnic arterial vasodilation leading to an extreme underfilling of the arterial circulation resulting in a marked renal vasoconstriction and reduction in glomerular filtration rate.
2. Liver transplantation is the definitive treatment for selected patients. However, waitlist mortality is high and posttransplantation outcome impaired in patients with HRS, particularly in those with type 1 HRS. Treatment of HRS before transplantation may help reduce waitlist mortality and improve posttransplantation outcome.
3. Specific treatments for HRS are aimed at improving the underfilling of the arterial circulation and include vasoconstrictors plus albumin and insertion of a TIPS. Both restoring effective plasma volume and improving vasodilation seem essential for the reversal of HRS.
4. The best treatment option for patients with type 1 HRS is terlipressin plus albumin because they improve renal function in as many as 40% of patients. Alternative drugs are norepinephrine and midodrine, but information is limited. A TIPS may be effective but has low applicability because it is contraindicated in patients with poor liver function.
5. Response to therapy (i.e., improvement in renal function) with vasoconstrictors is associated with an increased survival rate.
6. Hemodialysis should probably be used only in candidates for transplantation not responding to pharmacologic treatment. Extracorporeal albumin dialysis is promising, but requires further evaluation. CKLT should not be used in patients with type 1 HRS unless prolonged hemodialysis makes reversal of HRS unlikely.
7. Treatment of type 2 HRS with vasoconstrictors plus albumin is effective, but information is very limited. A TIPS improves renal function and management of ascites in these patients, but does not seem to improve survival, although more studies are needed.
8. Effective prevention of HRS in patients with spontaneous bacterial peritonitis is achieved by the administration of albumin together with antibiotics. The long-term administration of norfloxacin to patients with cirrhosis and ascites is associated with a reduced risk of developing HRS. Pentoxifylline reduces the risk of HRS in patients with alcoholic hepatitis.

albumin to prevent the deterioration of circulatory function that frequently occurs in patients with cirrhosis and spontaneous bacterial peritonitis.¹¹⁴ In patients with spontaneous bacterial peritonitis, the administration of albumin (1.5 g/kg IV at the diagnosis of the infection and 1 g/kg IV 48 hours later) together with antibiotics improves circulatory function and reduces markedly the occurrence of HRS compared with the standard treatment with antibiotics alone (10% in the albumin group versus 33% in the nonalbumin group).¹¹⁴ This effective prevention of HRS results in an improvement in survival.

The second strategy used for the prevention of HRS is either the inhibition of cytokines related to bacterial products, particularly tumor necrosis factor α , or selective intestinal decontamination to suppress the deleterious effects of bacterial translocation on cardiovascular function.^{20,115} In patients with alcoholic hepatitis, the administration of pentoxifylline (400 mg three times daily), a drug that inhibits tumor necrosis factor α , was shown to reduce the occurrence of HRS and mortality (8% and 24%, respectively) compared with a control group (35% and 46%, respectively).¹¹⁶ Finally, a recent study showed that long-term treatment with norfloxacin (400 mg/day) in patients with advanced cirrhosis and ascites was associated with a lower risk of developing HRS compared with a control group of patients receiving placebo.¹¹¹ In this study, the beneficial effect of norfloxacin in the prevention of HRS was not related to the effect of the drug in preventing the development of spontaneous bacterial peritonitis. More studies are needed to further evaluate these and other strategies for the prevention of HRS in cirrhosis.

The traditional concept of acute renal failure (ARF) has been recently redefined as acute kidney injury (AKI).¹ A collaboration of several societies has led to the creation of the Acute Kidney Injury Network (AKIN), which has proposed diagnostic and staging criteria for AKI based on the RIFLE criteria (Risk, Injury, Failure, Loss, End stage).² As is evident by these criteria, patients who suffer AKI may progress through various stages that correlate with outcomes. When renal replacement therapy (RRT)/support is required, there is a far worse prognosis than with lesser degrees of renal injury.^{3–5} Several dialysis techniques are now available for RRT to manage AKI. Acute intermittent hemodialysis (IHD), peritoneal dialysis, and continuous techniques are the mainstays of treatment modalities. This chapter reviews the indications, modalities, and administration guidelines for acute hemodialysis and peritoneal dialysis.

TECHNIQUE PRINCIPLES

Modalities

Dialysis modalities can be segregated by the type of clearance and duration of therapy. Variations in clearance technique include hemodialysis, hemofiltration, and hemodiafiltration (combining the former two). Therapy may be administered continuously, intermittently, or some combination of the two. Continuous modalities are discussed further in Chapter 7. Intermittent therapies all depend on diffusion-based transfer of solutes and use convection predominantly for fluid removal. The duration of therapy usually is short (3–6 hours) with sessions provided on a daily, alternate-day, or three times per week frequency. Alternatively, the duration can be prolonged (6–16 hours) with adjustments in the blood and dialysate flow rates. These hybrid modalities are termed slow low-efficiency dialysis (SLED), slow continuous dialysis, or extended daily dialysis (EDD).

Intermittent hemodialysis (IHD) is the procedure that has been widely used over the past four decades in patients with end-stage renal disease and those with ARF. The vast majority of IHD is performed using a single-pass of dialysate at flow rates greater than that of blood. Several important technological advances have made the procedure safer and more suited for the ARF patient. The availability of variable sodium concentrations in the dialysate, biocompatible membranes, bicarbonate-based dialysate, and volumetrically controlled ultrafiltration offer certain advantages that are particularly well suited to the ARF patient.^{6,7} Nevertheless, most centers use a fairly standard regimen for administration of the therapy. Because of limitations imposed by the use of dual-lumen catheters for vascular access, only moderate blood flow rates (200–250 mL/min) can be achieved. The standard dialysate flow rates used are 500 mL/min. IHD offers the advantage of providing for rapid correction of electrolyte and acid-base disturbances. A major disadvantage of IHD is the limited time (usually 3–4 hours) of total therapy per day. As a result, the patient will remain without renal support for the majority of the day during which fluid regulation, acid-base balance, and electrolyte homeostasis are not possible. Another important disadvantage of IHD is that patients with hemodynamic instability may not tolerate the higher blood flow rates needed to achieve an adequate level of diffusive clearance in the limited duration of the treatment. More important is the demonstration that intradialytic hypotension may contribute to delayed renal recovery.^{8,9} Of interest is the demonstration by Schortgen and colleagues¹⁰ that implementation of strict guidelines for the management and prevention of intradialytic hypotension helped reduce the incidence of such episodes, but did not affect overall mortality.

Sorbent system IHD is a system that regenerates dialysate by passing it through a sorbent cartridge that contains five distinct layers.^{11,12} The first layer contains activated carbon, the second contains urease, which converts urea to ammonium carbonate, and the third layer contains zirconium

phosphate in which cations such as potassium, calcium, and magnesium are adsorbed and exchanged for hydrogen and sodium ions. The fourth layer of the cartridge contains hydrated zirconium oxide to which phosphate and fluoride are adsorbed and exchanged for acetate. The fifth layer contains activated carbon, which removes creatinine and other waste products. Although this system is used only infrequently, it provides the advantage of eliminating the need for a source of pure water and providing a system that is highly portable. In addition, because of the unique characteristics of the regenerating system, sorbent IHD allows for greater flexibility in custom tailoring the dialysate. The greatest disadvantage of the sorbent system is that it is less efficient than single-pass IHD. The slower flow rate of dialysate and the overall adsorptive capacity of the sorbent cartridge impose the main limitations on efficiency of diffusive clearance. Previous sorbent-based systems (REDY) are also seeing a reemergence with the development of the Alliant System.¹³

Intermittent hemodiafiltration (IHF) uses convective clearance for solute removal. The main disadvantage of IHF is the need for large volumes of sterile replacement fluid. Therefore, the expense associated with IHF has limited its use in the United States. Proponents of the therapy claim that it offers greater hemodynamic stability and improved middle molecule clearance. Because of these advantages, IHF has been used extensively in Europe.¹⁴

Intermittent ultrafiltration uses the same device as with IHD, but differs in that the main use of IHD is in fluid removal. Typically, the procedure is used for treatment of pulmonary edema or severe cardiomyopathy with resistant fluid overload. Because the same machine used for IHD is also used for IUF, some centers use a combination of IUF and IHD in series. Such an approach provides greater hemodynamic stability and the ability to quickly treat volume overload. A major disadvantage is the loss of time available for diffusive solute clearance.

In 1999, Schlaepfer and colleagues¹⁵ reported the use of slow continuous dialysis in which blood flow rates were 100 to 200 mL/min and dialysate flow rates were 100 to 300 mL/min. Patients were treated for 12 hours during the day or evening. The procedure was thought to be safe, efficient, and relatively simple. Extended daily dialysis (EDD) was initially described by Kumar and colleagues.¹⁶ EDD or SLED differs from IHD in that blood flow (QB) and dialysate flow (QD) are intentionally kept low but the duration is extended to maintain the strength or intensity. Typical QB is 125 to 250 mL/min and QD is 200 to 400 mL/min. Typical run times are 8 to 12 hours. Furthermore, dialysis may be performed at night to avoid scheduling conflicts.^{17–24} Hybrid modalities have been run at night for 8 to 12 hours using intensive care unit (ICU) staff, thereby eliminating interruption of therapy and reducing staff requirements. Studies comparing hybrid modalities to continuous RRT (CRRT) have revealed favorable hemodynamic tolerance in critically ill patients while achieving dialysis adequacy and ultrafiltration targets.^{17,22,23,25} The use of standard IHD machines allows some cost savings by eliminating the need for specialized dialysate or replacement fluid. Anticoagulation use has also been shown to be less in SLED as compared with CRRT because SLED may be run without anticoagulation (saline flushes). Recently, a new system has been designed specifically for the hybrid modality. This system is called the Genius single-pass dialysis system (Fresenius).

Peritoneal dialysis was the first “continuous” form of dialysis therapy used in the acute setting. In peritoneal dialysis, the patient’s peritoneum acts as the semipermeable dialysis membrane. Dialysate consists of a sterile, lactate-based solution inserted via a peritoneal catheter into the abdominal cavity. Diffusion occurs from the blood perfusing the peritoneum to the fluid in the abdominal cavity across the peritoneum. Once the dialysate becomes saturated (3–4 hours), it is removed and fresh dialysate is instilled. Fluid removal is achieved by using an osmotic pressure mechanism in which varying dextrose concentrations in the dialysate provide an osmotic gradient for water flow from the patient’s blood to the peritoneum. The process of dialysate instillation and removal can be automated with cyclers. The main advantages of peritoneal dialysis are that it is less labor intensive than hemodialysis and does not require anticoagulation. The major disadvantage is that dialysis is relatively inefficient because total solute removal is limited by total peritoneal effluent. Moreover, transfer across the peritoneum is highly influenced by both the anatomy of the peritoneum and the underlying hemodynamic status of the patient. Another major disadvantage is that the procedure requires the placement of a peritoneal catheter into the abdominal cavity, which may add to the morbidity of the already compromised ICU patient.

Considerable debate has ensued over the choice of modality in the acute setting, especially for the critically ill. Over the years, continuous modes of renal replacement have become the preferred modality of treating physicians. In 1999, Mehta and Letteri²⁶ reported on a survey performed among U.S. nephrologists that revealed 70% of those responding used IHD as the acute renal replacement modality. A recent survey during the Third International Critical Care Nephrology Conference in Vicenza, Italy, revealed several changing trends. First, the care of patients with ARF has been accepted by multiple specialties. Thirty-six percent of respondents were intensivists; nephrologists represented 52% of the attendees. Second, the overwhelming majority of respondents preferred to use continuous modes of renal replacement. Intensivists preferred CRRT more than nephrologists, who preferred IHD. Acute peritoneal dialysis (PD) was listed as an option by approximately 20% of participants, although actual use was not addressed. If used, PD was considered solely by nephrologists.²⁷ The DOse REsponse Multicentre collaborative Initiative (DO RE MI) study is an ongoing multicenter study to examine current use and dosing patterns of renal replacement in the acute setting.²⁸ Preliminary data suggest that CRRT has become the preferred modality, especially for those patients who are hemodynamically unstable. A few, small randomized clinical trials have been unable to demonstrate a consistent overall survival benefit of CRRT over IHD; however, differences in renal recovery tend to favor continuous modalities over intermittent.^{29–34} At present, all the available modalities are viable options for managing patients with AKI; however, the choice of modality needs to be tailored to the clinical need.

Indications and Timing of Initiation for Dialysis

Hyperkalemia, severe hyperphosphatemia, severe hyperuricemia, severe acidemia, and uremia-related complications (coma, pericarditis, and seizures) are all accepted indications for starting dialysis. However, there is wide variability on the timing of initiation of dialysis even when these indications

are present. Aside from situations in which there are severe derangements, most nephrologists have a tendency to avoid dialysis for as long as possible. Two major factors contribute to the decision to delay dialysis. First, the dialysis procedure itself is not without risk. Hypotension, arrhythmias, and complications of vascular access placement are not uncommon.³⁵ Second is the concern that dialysis may delay recovery of renal function.^{9,36} Therefore, in general, dialysis in current practice is initiated when clinical features of significant volume overload and solute imbalance dictate a need for intervention. Common parameters used for defining the indications and timing of dialysis for AKI include the level of blood urea nitrogen and creatinine, presence of oliguria, evidence of heart failure and pulmonary edema, and an estimate of the catabolic state.^{37,38}

Continued debate ensues over the appropriate level of BUN above which one should always start dialysis. Underlying is the multitude of reasons that BUN may be elevated, as well as variability in the level at which complications arise. Liu and colleagues³⁹ examined the mortality associated with a high versus low starting BUN. In this prospective cohort analysis, patients with BUN less than 76 mg/dL (mean BUN, 46 mg/dL) had a trend toward higher mortality (14- and 28-day mortality: 0.80 and 0.69 in low BUN versus 0.75 and 0.54 for high BUN, respectively). In contrast, a randomized, controlled trial conducted in oliguric critically ill patients in the Netherlands revealed no significant difference in hospital mortality with early (mean BUN, 46 mg/dL) versus late (mean BUN, 105 mg/dL) hemofiltration initiation.⁴⁰

Oliguria and its associated complications are a serious contributor to morbidity of AKI. The use of diuretics to support urine flow has been debated in the literature with no clear indication that it either hurts or helps in oliguria.⁴¹⁻⁴³ Given the added comfort of volume control, maintenance of urine volume with or without diuretics may unnecessarily delay the onset of dialysis in select individuals. Liangos and colleagues⁴⁴ examined the relationship of urine volume to timing of initiation of dialysis and overall mortality. Nonsurvivors had significantly higher urine volumes and severity of illness than survivors (1.5 L/day versus 0.7 L/day). Nonsurvivors also had lower BUN at start of nephrology consult (42 versus 76 mg/dL, $P = .01$). What this study had demonstrated was the increasing complexity of the natural history of AKI. Seemingly mild clinical deterioration (as evidenced by lower APACHE [Acute Physiology, Age, and Chronic Health Evaluation] II score at consult) resulted in delayed initiation of therapy and ultimately poor outcomes. Neither laboratory nor clinical data alone seem to predict when dialysis should be initiated. The combination provides the basis for the decision-making process in initiating therapy with dialysis.

A key issue is the timing of involvement of the nephrologist in the care of individuals with AKI. Late consultation with a nephrologist was associated with lower BUN (mean 47 mg/dL versus 77 mg/dL in late versus early groups, respectively) and higher urine output (mean 1180 versus 608 mL in late versus early groups) was reported in a prospective observation trial conducted among ICU patients requiring a nephrology consultation.⁴⁵ Late nephrology consultation was also associated with higher in-hospital mortality and lower recovery of renal function in survivors (adjusted odds ratio = 1.5, although not statistically significant). AKI involves a

complex physiologic milieu that requires early aggressive collaborative management to provide appropriate therapy in a timely manner.

Despite the absence of standards for initiation of dialysis in the ICU, several important factors need to be considered when making the decision to provide RRT. An important distinction in the ICU patient is the recognition that ARF does not occur in isolation from other organ-system dysfunction. Consequently, providing dialysis can be viewed as a form of renal support rather than mere replacement.⁴⁶ For example, in the presence of oliguric renal failure, administration of large volumes of fluid to patients with multiple organ failure may lead to impaired oxygenation. In such a setting, early intervention with extracorporeal therapies for management of fluid balance may significantly affect the function of other organs irrespective of more traditional indices of renal failure, such as BUN. Several pieces of evidence point to the importance of fluid overload in determining outcomes of AKI. We showed in a randomized, controlled trial comparing intermittent therapies with continuous therapies that patients dialyzed for solute control had a better outcome than those dialyzed for volume control.³² Moreover, patients dialyzed for both solute and volume control had the worst outcome. Mukau and Latimer⁴⁷ showed that 95% of their patients with postoperative ARF had fluid excesses of more than 10 L at initiation of dialysis. Recent studies have suggested that achieving a negative fluid balance in the first 3 days of admission for septic shock was a predictor of better survival.⁴⁸ Foland and colleagues⁴⁹ have shown that pediatric patients receiving continuous venovenous hemofiltration (CVVH) with more than 10% fluid overload before initiation of CVVH have a poor prognosis. Consequently, fluid regulation seems to be an important consideration when deciding to initiate dialysis in the ICU patient with ARF. Moreover, such renal support provides volume "space," which permits for the administration of nutritional support without limitations.⁵⁰ Although there are currently no trials exploring the timing of intervention for acute dialysis, the availability of the Acute Kidney Injury Network staging system should permit an improved characterization of AKI. Ongoing analyses are being performed on the utility of RIFLE criteria as predictors of mortality as well as indicators for therapy initiation.^{4,51-53}

Prescription for Acute Dialysis

Acute Kidney Injury Patients

The acute dialysis prescription includes dialysis operational characteristics, duration, and frequency as the main parameters defining the dose of therapy. The operational characteristics are determined by the type of dialyzer, QB, and QD. QB is dependent on access type, with fistulas and grafts providing the highest flows and temporary polyurethane catheters providing the lowest flows before recirculation becomes an issue. The QD should be adjusted based on the QB to facilitate a maximal gradient with single-pass systems. In acute IHD, especially at high starting BUN, dialysis is initiated at half the target QB and QD. This is to prevent dialysis disequilibrium (DD) syndrome, which has been linked to rapid decreases in BUN in dialysis-naïve patients. The duration of each dialysis session determines the delivered dose per unit of time. Dialysis sessions of 4 to 5 hours are often

required to achieve adequate solute and fluid removal without significant hemodynamic disturbance.³³ Shorter sessions are typically used in dialysis initiation and then longer sessions are introduced gradually to meet adequacy goals. Daily hemodialysis has been proven to provide improved survival benefit in critically ill patients.⁵⁴ To address the need for prolonged therapy and accommodate the hectic schedule of the hospitalized patient requiring RRT, hybrid therapies have been designed. Table 6-1 compares IHD with different hybrid therapies.

Long-Term Dialysis Patients

Traditional guidelines for outpatient management of end-stage renal disease (ESRD) patients involve three times weekly dosing frequency of IHD. When these patients are hospitalized, the utility of continuing this regimen versus intensive therapy delivery has not been extensively studied. One recent observational study compared the mortality of patients who suffered AKI requiring RRT and had no history of renal insufficiency with ESRD patients requiring ICU admission.⁵⁵ This study demonstrated significantly higher hospital mortality among de novo AKI patients compared with ESRD patients (34% and 14%, respectively). Dialysis delivered to the ESRD population was every other day dosing (mean, every 1.95 ± 0.3 days). No comparison with less or more dosing was performed. A recent observational trial described the clinical characteristics of long-term hemodialysis patients admitted to the ICU.⁵⁶ This trial highlighted the influence of long-term phosphate management on ICU mortality in this population. No mention of dialysis dosing was given in this study. Until larger prospective cohort or randomized, controlled trials are conducted regarding dosing frequency in hospitalized ESRD patients, no specific recommendations can be made. Nevertheless, a thorough evaluation of the severity of illness and metabolic needs of the patient should serve as a general guide to dosing frequency.

Toxin/Drug Removal

Certain drug or toxin overdoses may be regulated by dialytic or adsorbent removal of the compound from circulation. This depends on the size and degree of albumin binding of the

compound of interest. Charcoal hemoperfusion techniques for toxin removal are rarely, if ever, used. The cartridges are expensive to purchase and have a very short shelf life, and hemodialysis or hemodiafiltration (intermittent or continuous) techniques provide adequate removal of toxins. A recent survey in New York City found that, of 34 hospitals that responded to a survey about charcoal hemoperfusion use, only 3 centers actually used the technique; the conditions for which it was used were theophylline toxicity and aluminum overdose.⁵⁷ The intensity and frequency of dialysis required for toxin removal depend largely on the individual drug/toxin pharmacokinetics. Table 6-2 lists common toxicities, indications, and prescriptions for hemodialysis.^{58,59}

Isolated Fluid Removal

Ultrafiltration has become a therapeutic maneuver in managing decompensated congestive heart failure with refractory volume overload. The UNLOAD trial group recently reported results from a randomized trial of ultrafiltration (using the Aquadex machine) compared with diuretics for acute decompensated heart failure. In this manufacturer-sponsored trial, patients with clinically determined heart failure decompensation (no EF in eligibility criteria) with no or only moderate renal disease (creatinine < 3 mg/dL) who received early ultrafiltration achieved greater volume removal and improved dyspnea score after 48 hours of treatment.⁶⁰ The Aquadex system is specifically designed to provide slow ultrafiltration using slow QB (10–50 mL/min). Traditional CRRT machines have also been used to provide IHD in congestive heart failure.⁶¹

Factors Influencing Acute Dialysis Delivery

Access

Acute hemodialysis access is a major factor in the delivery of an adequate dialysis dose. Modern dialysis catheters are composed of polyurethane, which is stiff at room temperature and then softens at body temperature; this facilitates access placement. Catheter length should be appropriate for the location of placement. Femoral catheters should be no shorter than

Table 6-1 Comparison of Intermittent Hemodialysis with Hybrid Therapies

	ACUTE IHD		SLED/EDD	
	Initiation	Maintenance	Initiation	Maintenance
Duration	2–2.5 hr	4–5 hr	8–12 hr	8–12 hr
Frequency	Daily for 2–3 days	Alternate day to daily depending on severity of illness	Daily	Daily
Filter	Synthetic or modified cellulose/small	Synthetic or modified cellulose/large	Synthetic or modified cellulose/small or large	Synthetic or modified cellulose/small or large
Q _B (mL/min)	200–250	250–350	150–250	150–250
Q _D (mL/min)/flow	400–500/counter- or syncurrent	500–800/countercurrent	16–20/countercurrent	16–20/countercurrent

EDD, extended daily dialysis; IHD, intermittent hemodialysis; QB, blood flow; QD, dialysate flow; SLED, slow-efficiency dialysis.

Table 6-2 Common Toxicities, Indications, and Prescription for Hemodialysis

Toxicity	Indications for HD	Dialysis Prescription ¹³⁰
Acetaminophen	Acute HD if concomitant renal failure (RIFLE criteria) requiring RRT; not for drug removal; N-acetylcysteine is still treatment of choice	Per general acute prescription section
Alcohols (ethylene glycol/methanol)	Refractory acidosis, visual impairments, renal failure, and pulmonary edema	Duration: typically long duration (6–8 hr); frequency: daily until serum levels undetectable; dialysate: high bicarbonate (e.g., 40 mEq/L) in the face of severe acidosis; QB/QD: high flows to maximize clearance; caution: hypophosphatemia with extended dialysis
Cyclic antidepressants (classic: carbamazepine)	Helpful in drug removal; no studies documenting aid in high bicarbonate dialysate to aid with blood alkalization for management of toxicity	Duration: typically shorter sessions given the high Vd, especially of TCA; frequency: daily until symptoms resolve or levels therapeutic or undetectable; dialysate: no specific recommendations; QB/QD: low initial flows and increase as needed/tolerated
Lithium	If levels > 4 mmol/L after acute ingestion or ≥ 2.5 mmol/L after long-term ingestion, renal failure, severe neurologic dysfunction; treatment may be needed daily and over extended periods of time (4–6 hr) as rebound levels are frequent problem	Duration: initially 6–8 hr and then subsequent sessions 3–4 hr; frequency: typically daily until lithium levels do not rebound to supratherapeutic levels; dialysate: bicarbonate based dialysate; QB/QD: high flows to maximize clearance
Salicylates	HD if levels > 100 mg/dL in acute ingestion, seizures, persistent electrolyte abnormalities, persistent altered level of consciousness, or refractory acidosis	Duration: initially 6–8 hr and then shorter as symptoms/levels permit; frequency: daily to alternate day; dialysate: bicarbonate based; QB/QD: high flows if severe acidosis present
Metformin	HD for severe lactic acidosis; may require prolonged daily therapy	Duration: longer sessions initially (some reports suggest 21–24 hr ¹³⁸ ; frequency: daily until acidosis resolves; dialysate: bicarbonate based (may need high levels, i.e., 40 mEq/L); QB/QD: high flows to maximize clearance of lactate

HD, hemodialysis; QB, blood flow; QD, dialysate flow; RRT, renal replacement therapy; TCA, tricyclic antidepressant; Vd, volume of distribution.

20 cm; right internal jugular placement requires anywhere between 13.5 and 16 cm depending on the size of the patient, and left internal jugular catheters necessitate approximately 16 to 20 cm catheters. Leblanc and colleagues⁶² showed that recirculation rates varied based on the site and length of the catheters. Subclavian catheters (13.5–19.5 cm) had recirculation rates of 4.1%, whereas femoral catheters had recirculation rates of more than 20% (13.5 cm) and 12.1% (19.5 cm). Subclavian vein insertion has been discouraged due to the finding of stenosis as a late complication. This is especially important in patients who will potentially require long-term hemodialysis access in the future.^{63,64} For these patients, subclavian catheters are contraindicated unless no other site is available.⁶⁵ Furthermore, unless done by trained individuals, subclavian catheter placement has high rates of complications including hemothorax and pneumothorax.⁶⁶ Femoral and right internal jugular arteries are the most common sites of insertion. Use of femoral catheters is associated with higher rates of recirculation and infection and less efficient dialysis

delivery.^{62,63,67} A recent study from France demonstrated the possibility of using tunneled silicone femoral catheters for acute hemodialysis.⁶⁷ Decreased recirculation, improved delivered Kt/V to prescribed Kt/V (where K = dialyzer urea clearance, t = dialysis time, V = urea volume of distribution) ratios, and decreased rates of infection were found compared with nontunneled femoral catheters. No comparisons with internal jugular catheters were made. This, along with the fact that few institutions have trained individuals available for placement of such catheters in the acute setting, limits the general applicability of this study.

A considerable amount of catheter hours are spent in nonuse. During these times, adequate patency must be ensured to prevent local complications (i.e., thrombosis) and obviate risks of reinsertion. Catheter lock solutions have traditionally been composed of heparin-containing saline solutions. Heparin carries the risk of hemorrhage if accidentally instilled into the patient and is contraindicated in those with heparin-induced thrombocytopenia (HIT).

Citrate (trisodium citrate) catheter locks compared with heparin locks have been studied with regard to catheter patency and complications. Catheter patency is equivalent, if not superior, to heparin.^{69,70} Furthermore, *in vitro* studies demonstrate protection against biofilm formation with citrate solutions compared with heparin solutions, although reduction in catheter-related bacteremia has been inconsistently shown in studies.^{69–72} Catheter lock solutions containing citrate are typically 4% to 49% citrate solutions.

Anticoagulation

Adequate system anticoagulation is paramount to achieving an optimally delivered dialysis dose. Heparin has been the mainstay of long-term and acute hemodialysis protocols. This is due to its ready availability, ease of administration, comfort among users with the agent, its monitoring, and its safety profile. There are several methods for administering heparin during dialysis. The standard method involves administering heparin systemically either as a continuous infusion or as repeated bolus units. The continuous infusion method is begun by giving a bolus, typically approximately 2000 U, waiting 3 to 4 minutes, and then continuous administration of 1200 U/hr. The therapeutic goal is to prolong the activated clotting time (ACT) to baseline plus 80%. Prolongation of ACT is directly proportional to the amount of heparin given. If the ACT is not prolonged to 180% of baseline after the initial bolus, then an additional amount should be given to reach the goal before the continuous amount is started. The repeated-bolus method involves administering approximately 4000 U of heparin as an initial bolus to prolong the ACT to well above the 180% target. This is repeated an hour later with a 2000-U bolus and then another hour later with 1000 U. The anticoagulation should be stopped approximately 1 hour before completion of therapy to prevent excessive residual anticoagulation.⁷³

In those patients at increased risk of hemorrhagic complications but not actively bleeding or immediately postoperative, a protocol of “tight” heparin or no anticoagulation may be followed. Tight heparin protocols are typically only given as single-bolus plus continuous-infusion administration. This is to prevent the large swings in ACT as seen by the repeated-bolus technique. The therapeutic goal for the tight heparin protocol is to prolong the ACT to no longer than 130% of baseline. This is typically achieved by giving 750 U as an initial bolus and then administering a continuous infusion of 600 U/hr. Again, adjustments should be made based on target ACT prolongation of 130%. This is the typical anticoagulation protocol followed for AKI patients. A no-anticoagulation protocol may also be followed, but is generally reserved for those who are at high risk of bleeding—notably, those who are actively bleeding, those who are immediately postoperative, or those in whom heparin is contraindicated (i.e., HIT patients). The system is primed with heparinized saline (1000 U/mL), unless HIT is present, in which case, normal saline alone is used. Once blood is circulating, rapid saline boluses administered prefilter every 30 minutes should provide adequate filter life in approximately 95% of cases. More frequent rinsing may be performed based on clinical inspection.

Citrate has been used as an anticoagulant for extracorporeal circuits for many years now. Its safety and efficacy have been demonstrated in numerous trials, but predominantly in the

CRRT literature. Regional citrate anticoagulation may also be used during IHD. Administration has traditionally been given in the presence of a calcium-free dialysate. Recent studies, however, have demonstrated the possibility of using low calcium dialysate with regional citrate anticoagulation and still achieving adequate dialysis with adequate filter life.⁷⁴ A summary of available anticoagulants and dosing strategies in IHD and SLED/EDD is given in Table 6-3.

Dialyzer

Several studies have examined the role of the dialyzer membrane itself in renal recovery after AKI. Biocompatibility refers to the degree to which complement is activated by blood-dialyzer contact. The traditional unsubstituted cellulose membranes (i.e., cuprophane) are considered bioincompatible due to the high degree of complement activation and leukodepletion. The new synthetic brands (polysulfone, acrylonitrile, polymethylmethacrylate) are considered biocompatible. Modified cellulose membranes have intermediate characteristics (i.e., meltspun cellulose diacetate). Dialyzer membranes have been further segregated based on the ability to remove mid- to large-size molecules (high versus low flux). Flux is measured based on the clearance of β_2 -microglobulin (>20 mL/min being high flux). In the long-term hemodialysis setting, high-flux synthetic or substituted cellulose membranes have become the norm due to decreased dialyzer reactions and improvements in clinical outcomes. In the acute setting, however, studies have not demonstrated a consistent benefit of synthetic high-flux membranes in terms of renal recovery or mortality. One meta-analysis did reveal that synthetic membranes conferred improved overall survival compared with cellulose acetate membranes, but there were no differences in renal survival.⁷⁵ As mentioned in this meta-analysis, the survival advantage may not persist when compared with modified cellulose membranes. In a randomized trial comparing synthetic with modified cellulose (meltspun cellulose diacetate) membranes, no differences in renal or patient survival were demonstrated.⁷⁶ Furthermore, there was no improvement in survival based on high- versus low-flux synthetic membranes. No definitive recommendations can be made regarding modified cellulose versus synthetic membranes for ARF at this time. Cellulose acetate membranes should be avoided as there is evidence of decreased survival with their use.

Dialysate (Bicarbonate/Acetate)

Bicarbonate-buffered dialysate solutions are the current standard in acute or long-term renal replacement. Lactate is the buffer base for PD solutions given its stability and conversion of lactate to bicarbonate by the liver. Thus, lactate-based dialysate is particularly avoided in those with decreased ability to metabolize lactate, such as those with liver failure or immediately after liver transplantation. If dialysis is emergently needed and lactate-based PD fluid is readily available, it may be used in acutely ill patients with preserved liver function.^{77,78} Acetate-based dialysate has also been used but has a tendency to exacerbate dialysis-induced hypoxemia (see later).

Sodium may be varied based on patient natremia or on the need to buffer intradialytic hypotension in susceptible patients (see “Preventing and Managing Complications of Acute Dialysis”). Potassium and calcium may likewise be altered based on patient needs.

Table 6-3 Summary of Available Anticoagulants and Dosing Strategies in Intermittent Hemodialysis and Slow-Efficiency Dialysis/Extended Daily Dialysis

Method	Filter Priming	Initial Dose	Maintenance Dose	Monitoring	Pro	Con	Overanticoagulation
No anticoagulation	None or with heparinized saline (5–8 IU/mL)	N/A	N/A	Filter thrombosis, filter pressure	No monitoring or risks associated with other anticoagulation regimens; adequate filter patency especially in high-risk patients (active bleeding or immediately post-operative)	Inadequate filter patency or dialysis adequacy due to decreased dialyzer performance over time	N/A
Heparin	Heparinized saline (5–8 IU/mL)	2000–5000 IU prefilter	3–15 IU/kg/hr prefilter	aPTT/ACT 1.5–2 times the upper limit of normal	Familiarity, effective anticoagulation, ease of monitoring in catheterized patient	Increased risk of hemorrhagic complications, HIT, adrenal insufficiency	Protamine administered 10 mg: 100 U heparin (dose should be sum of previous 2–3 hr of heparin administration)
Tight heparin	Heparinized saline	750–1000 IU prefilter	None, periodic bolus administration of 400–600 IU	Target ACT to 1.3–1.4 times the upper limit of normal	Same as above, may provide low bleeding risk in high-risk patients	Same as above	Same as above
LMWH (dalteparin)	Heparinized saline or 1.5–2.5 U/mL dalteparin	20-U/kg bolus	Prefilter administration at 10 IU/kg/hr	Recommendations are to monitor anti-Xa activity of 0.25–0.35 IU/mL	Similar patency rates as with heparin	More costly and pitfalls of heparin persist	Protamine may be tried as above; blood products may be required
LMWH (enoxaparin)		750 U	0.05 mg/kg/hr	Anti-Xa activity 0.25–0.35 IU/mL	Same as above	Same as above	Same as above

Argatroban	250 µg/kg	0.5–2 µg/kg/min	aPTT aiming for 1–1.4 times the upper limit of normal	Safe in renal failure; established as treatment for HIT	No antidote for bleeding and aPTT may not absolutely correlate with anticoagulation	No antidote available; blood products may be required
Citrate (TSC or ACD-A administered alone prefilter)	None or with heparinized saline if no HIT present	140–160 mL/hr of 4% TSC given prefilter (3%–8% of the blood flow rates) or ACD-A at 250 mL/hr	Vary rate of citrate in 5–10-mL/hr increments to maintain desired postfilter ionized calcium rates	Ease of administration, ease of monitoring, low incidence of adverse events, ease of discontinuation if complications arise; there may be improved biocompatibility with citrate ^{139,140}	Difficulty in obtaining appropriate dialysate and citrate solution (depends on pharmacy availability); potential for metabolic alkalosis, hypernatremia, hyperhypoalbuminemia, or citrate toxicity	Rarely, if ever occurs; if total calcium-to-ionized-calcium ratio > 2.1, then lower citrate rate or turn off citrate anticoagulation

ACD-A, acid citrate dextrose-A solution; ACT, activated clotting time; aPTT, activated partial thromboplastin time; HIT, heparin-induced thrombocytopenia; LMWH, low molecular weight heparin; N/A, not applicable; TSC, trisodium citrate.

Preventing and Managing Complications of Acute Dialysis

Hypotension

Intradialytic hypotension is a significant problem in both the long-term and acute dialysis setting. This is more of a problem in ARF as renal recovery has to be one of the goals of overall treatment. Manns and colleagues³⁶ showed that IHD was associated with a decrease in the glomerular filtration rate during and after the procedure compared with the preprocedure glomerular filtration rate. Conversely, a study by John and colleagues⁷⁹ examined the effects of intradialytic hypotension on splanchnic perfusion as represented by gastric intramucosal pH and Pco₂. Despite decreases in mean arterial pressure of more than 20% from baseline in IHD compared with CVVH, there was no significant impact on intramucosal acid-base status, nor was there a sustained impact on systemic hemodynamics. These findings were limited to a 24-hour period, and thus it is difficult to say whether repeated hypotensive insults would ultimately result in subtle organ damage. Two studies comparing the renal survival of patients undergoing CRRT versus IHD have demonstrated that there is a trend toward improved renal recovery in CRRT.^{29,30} Improvements in hemodialysis techniques have been put forth that aim to reduce the hemodynamic challenges of traditional IHD. Paganini and colleagues⁸⁰ have compared variable sodium and ultrafiltration modeling with a fixed scenario in critically ill patients with ARF requiring RRT. Variable sodium modeling (160 mEq/L to 140 mEq/L over the course of dialysis) and ultrafiltration (50% ultrafiltration in the first hour and 50% over the remainder of the dialysis session) afforded improved hemodynamic stability compared with fixed sodium and ultrafiltration. Furthermore, a randomized, controlled trial comparing IHD with continuous venovenous hemodiafiltration (CVVHDF) demonstrated significant adherence and hemodynamic tolerance in the IHD arm when a strict protocol for IHD administration was followed.³³ In this study, IHD was administered for 4 hours or longer, with high fixed sodium (150 mmol/L), low dialysate temperature (35°C), QB of 250 mL/min, and QD of 500 mL/min. Hypotension occurred no more frequently in the IHD arm than in the CVVHDF arm. Despite similar survival rates, no mention was made regarding renal survival. Dheenani and Henrich⁸¹ examined various techniques for hemodynamic buffering in ESRD patients and also demonstrated beneficial effects of high sodium, sodium modeling, and cool dialysate. They caution that fixed high sodium may result in net sodium gain and resultant intradialytic weight gains. The impact on AKI patients is not well described.

Hypoxia

Alveolar hypoventilation with resultant reductions in arterial oxygen tension during hemodialysis had been described during the use of acetate-buffered dialysate.^{82,83} Early comparison trials of bicarbonate-buffered dialysate had not demonstrated a significant difference in rates of intra- and postdialysis hypoxemia.⁸⁴ It is now recognized that a relative alkalosis, either by utilization of CO₂ in the conversion of acetate to bicarbonate or by diffusion from high bicarbonate dialysate, induces hypoventilation.^{85,86} Mildly elevated bicarbonate in the dialysate (~30 mEq/L) does not induce significant hypoventilation and resultant hypoxemia.⁸⁵ It is not clear, however, what, if any,

are the clinical consequences of dialysis-induced hypoxemia. Studies of long-term hemodialysis patients have revealed mild silent cardiac ischemic events and decreases in transcutaneous oxygen tension in patients with peripheral vascular disease.^{87,88} This would be expected to be pronounced in those with underlying lung pathology, although a study by Pitcher and colleagues⁸⁶ did not demonstrate significant differences in arterial O₂ changes in normals and those with chronic obstructive pulmonary disorder after hemodialysis. With the more commonplace use of bicarbonate-based dialysate, dialysis-induced hypoxemia has become a minor problem and one not likely to have significant clinical consequences for the majority of AKI patients requiring IHD.

Dialysis Disequilibrium Syndrome

DD syndrome occurs due to rapid urea removal and resultant brain edema. Urea is not an effective osmolar agent and thus should not result in significant fluid shifts regardless of the degree of urea gradient change. Biochemical profiles of urea transporters in the brain of chronic uremia have elucidated the mechanisms underlying this syndrome. Down-regulation of brain urea transporters and increased aquaporins (AQ4 and AQ9) in the brain have been demonstrated in chronic uremia in five of six nephrectomized rats.⁸⁹ This is more commonly seen in chronic kidney disease patients who are started on hemodialysis but has been reported in AKI as well.^{90,91} Patients with previous brain trauma or cerebrovascular events seem to be most susceptible to developing DD syndrome.⁹⁰ Symptoms may be mild such as headaches, dizziness, and blurry vision or more severe such as acute delirium and, in rare cases, brain death.⁹⁰ The ideal therapy for DD syndrome is prevention. As mentioned previously, reduced intensity of initial dialysis sessions affords more gradual removal of urea and time for osmotic gradient adjustment in the brain. SLED/EDD is administered in such a fashion as to eliminate the traditional difficulties of IHD with regard to DD. Slow QB and QD are the norm for the hybrid procedures and may confer protection against the development of DD syndrome. Mannitol may also be administered with initiating dialysis sessions to facilitate water egress from the brain.⁹¹

Bacterial Endotoxin–Related Pyrogenic Reactions

Dialysate provided for long-term hemodialysis is allowed 100 to 200 cfu/mL of bacteria or 0.25 to 2 EU/mL of endotoxin. This is based on decreased pyrogen response at these levels. However, evidence of chronic inflammation and downstream effects (malnutrition, decreased erythropoietin response, β_2 -microglobulin levels) related to systemic responses to these low levels of endotoxin has been mounting.^{92–94} Similar trials have not been conducted in the acute population.

Quality Assurance

Dose Monitoring and Goals

The simplest measure of dialysis adequacy is the urea reduction ratio. According to measured kinetics in the long-term hemodialysis setting, a delivered Kt/V of 1.0 corresponds to a urea reduction ratio of 60%.⁷³ Outcome studies in the ESRD population, most notably HEMO and the National Cooperative Dialysis Study (NCDS), have demonstrated correlations

between delivered single pool (sp) Kt/V and morbidity and mortality.^{95,96} The NCDS revealed that mortality was increased if delivered spKt/V was less than 1. The HEMO study, utilizing spKt/V of 1.2 as the standard arm, established that delivering higher doses in the conventional three times per week model conferred no additional survival benefit.⁹⁶ As such, the hemodialysis adequacy work group for the National Kidney Foundation (NKF) has recommended that the target for minimal dialysis adequacy, for ESRD management, be an spKt/V of 1.2.⁹⁷ Similar guidelines are lacking in acute hemodialysis, and thus considerable attention is being given to determining dose-outcome associations as well as appropriate dose delivery and quantification in recent years.

How does the dose of dialysis predict clinical outcomes in acute hemodialysis? A retrospective cohort analysis of acute hemodialysis and CRRT patients revealed little effect of Kt/V on mortality in patients with either high- or low-severity scores (Cleveland Clinic Foundation intensive care unit acute renal failure scores).⁹⁸ The severity score assessed critically ill patients requiring acute RRT on a 20-point scale based on select clinical variables (gender, mechanical ventilation, platelet count, surgical status, change in blood urea nitrogen, and serum creatinine). Those with scores less than 5 had the best survival rate and those with scores higher than 14 had the worst survival, regardless of the delivered dose of dialysis. The intermediate range was defined by a score between 5 and 14. Patients in this severity range who received a higher dose of dialysis ($Kt/V > 1$) demonstrated lower mortality than those patients who received a lower dose ($Kt/V \leq 1$).⁹⁹ A prospective analysis of alternate-day versus daily hemodialysis in ARF revealed that higher delivered Kt/V correlated with improved survival.⁵⁴ Higher Kt/V was accomplished by daily, rather than alternate-day, dialysis. The dependence of survival on dose appears to be a direct relationship up to a point, and a function of overall disease severity. Ronco and colleagues¹⁰⁰ describe this elegantly in a recent review regarding the dose of RRT in AKI.

The appropriate target of dose for acute IHD has not been clearly established. In CRRT, a high dose or the dose at which survival is affected has been demonstrated at 35 mL/kg/hr of ultrafiltration or effluent volume.¹⁰¹ This corresponds to a delivered Kt/V of 1.4 in a 70-kg man dialyzed for 24 hours.¹⁰² Prescribing acute dialysis sessions with the goal of 1.4 would deliver a Kt/V of approximately 1.2.¹⁰³ Reasons for the discrepancy between the prescribed and delivered dose of dialysis have been explored in several prospective studies.^{99,103,104} Reasons stated for this discrepancy include lack of a steady state of urea nitrogen appearance, variable function, and high recirculation with temporary catheters, decreased QB, multiple interruptions, and decreased dialyzer clearance, especially in anticoagulation-free dialysis.¹⁰⁵ Studies have examined alternate methodologies to calculate dose in acute hemodialysis. The concept of using only $K \times t$ has been put forth as an accurate measure of dialysis delivery in long-term hemodialysis patients.¹⁰⁶ Ridell and colleagues¹⁰⁷ studied Kt as measured by ionic dialysance compared with dialysate sampling. Kt ionic dialysance revealed acceptable correlation with Kt from dialysate sampling. No corresponding studies of outcome measures using Kt ionic dialysance as the therapeutic goal in AKI have been carried out to date.

The concept of equivalent renal urea clearance (EKRjc) has been suggested as an accurate and simple means of expressing dialysis dose in AKI.¹⁰⁸ Casino and Marshall¹⁰⁸ note that

the EKRjc meets several important criteria for acute dose quantification: independence from steady-state urea concentration, ease of calculation in the clinical setting that is applicable regardless of schedule (e.g., three times per week, alternate day, continuous), incorporating appropriate estimate of urea Vd in the acute setting, and allowing comparison with residual renal urea clearance. The first and third requirements are met in that urea removal (j) is used instead of urea generation and that minimal interdialytic periods are required to calculate interdialytic urea changes. With regard to inaccuracies in determinations of V in the acute setting, EKRjc as presented in their analysis is accurate within approximately 5% of their theoretical standard (dpEKRjc) when the estimated Vd is within 25% of the true Vd. EKRjc is proposed as a fair comparison of clearance across modalities. Studies have looked at EKRjc in SLEDD and CRRT.^{17,108–110} Further comparative studies will be required to determine the strength of EKRjc to predict outcomes in AKI.

In dose delivery, more seems to be better in much of medicine. However, this has not proven true in many well-designed randomized studies examining dose delivery in dialysis.⁹⁶ In the landmark study of Ronco and colleagues,¹⁰¹ no significant difference was noted between the 35- and 45-mL/kg/hr dose groups. One possible explanation for the potential for harm at higher doses of dialysis is that, in the critically ill patient, pro- and anti-inflammatory markers coexist in a delicate balance of activity.¹⁰² If the dose of dialysis is high enough, anti-inflammatory mediators may be removed at similar or greater rates as those of proinflammatory mediators. Caution needs to be taken in blanket prescriptions of high Kt/V (>1.2) until well-designed trials have indicated a clear benefit for AKI patients.

ACUTE PERITONEAL DIALYSIS

PD was first attempted in the acute setting in 1923, albeit unsuccessfully; it was not until the 1950s that the procedure became standardized and more commonplace.¹¹¹ Today, the use of acute PD has been limited to pediatric populations and in developing countries where access to blood purification techniques are severely limited. Given the higher clearances achieved with hemodialysis techniques when the technologies are available, these have been the preferred modalities for AKI requiring RRT. General indications for acute PD are similar to those for acute HD. Acute PD may be particularly useful in two clinical settings: cirrhosis and decompensated heart failure. Recent reports have suggested beneficial uses in cirrhotic patients with ascites requiring RRT, though this is better tolerated in the chronic population and less so in the acute population.¹¹² Heart failure, conversely, may benefit from less aggressive fluid removal that is afforded by PD.¹¹³ Additional indications include control of hyperthermia and treatment of necrotizing/hemorrhagic pancreatitis with concomitant renal failure when abdominal cavity washing is beneficial.⁷³ Contraindications to PD include recent abdominal surgery (especially when accompanied by drain placement), adynamic ileus, peritoneal fibrosis/adhesions, and emergency situations (i.e., flash pulmonary edema, poisoning, or drug intoxication).^{73,114} Although not proven, fears of uncontrolled fluid shifts have led people away from acute PD in acute brain injury individuals requiring RRT.¹¹⁵

Acute PD, although easy to perform in the acute setting, does not achieve clearances that approximate those with IHD or CRRT. The issue of adequacy of PD in the severely hypercatabolic patient has not been extensively studied, although small trials have looked at various PD modalities in hypercatabolic patients. Chitalia and colleagues¹¹⁶ examined two different types of PD (tidal PD and continuous exchange/equilibrium PD [CEPD]). In this randomized, controlled trial, tidal PD provided better clearances than CEPD. Using K/DOQI standards for long-term PD, tidal PD provided weekly creatinine clearance of 68.54 L/1.73 m² and weekly KtT/V of 2.43 versus 58.85 L/1.73 m² and 1.8 KtT/V for CEPD.¹¹⁶ In another recent trial of CEPD using a flexible Tenckhoff catheter and automated cycler, adequate metabolic control was achieved after 3 days.¹¹⁷ These patients had a mean APACHE II score of 32%, and 76.6% required ICU admission. Although both trials suggested adequate clearances for patients with AKI requiring RRT, no comparisons with blood purification modalities were carried out. This is especially important in that in the long-term setting PD, although providing lower clearances than IHD, affords adequate management of end-stage renal disease. This has not been officially compared in the acute setting.

Peritoneal access had been the limiting factor for therapy during the early years. Early access included such makeshift items as thermometer casing with a piece of tape attached to pull it out of the peritoneal cavity.¹¹⁸ It was not until the introduction of the flexible Tenckhoff catheter in the 1960s that PD became a more generally applicable process.¹¹⁹ Surgically inserted Tenckhoff catheters remain the most commonly used. Others such as the Cook Tenckhoff and Cook Mac-Lock multipurpose drainage catheter have been used without much proven benefit over the traditional Tenckhoff.^{119,120} There are acute peritoneal catheters that may be inserted at the bedside by trained individuals. Access is typically obtained in one of three locations on the abdominal wall: infraumbilical, right lower quadrant, or left lower quadrant. The left lower quadrant is generally preferred to avoid the cecum and the bladder. Rigid catheters that are used for acute PD tend to be more prone to kinking. This leads to increased alarms with the automated cyclers. Acute catheters should not remain in place for longer than 3 days as infection rates increase considerably after this time.

Dose calculation in PD involves consideration of dialysate composition and volume, session duration, and mode of exchange. Current PD fluids use lactate as the bicarbonate source. PD tends to remove significant amounts of calcium and magnesium, so replacement is typically added to the dialysate. Bicarbonate solutions cause precipitation of calcium and magnesium and are thus avoided in long-term PD. The obvious difficulty is that ARF patients may also be unable to adequately convert lactate to bicarbonate. Furthermore, patients with any form of shock may have worsening acidosis with lactate solutions. A randomized trial comparing bicarbonate with lactate-buffered dialysate in critically ill patients requiring RRT revealed excellent metabolic control with bicarbonate compared with lactate.¹²¹ Lactate-buffered solutions tended to correct acidosis more slowly and bicarbonate-buffered solutions tended to have lower calcium and magnesium levels; neither resulted in significant clinical consequences. If bicarbonate-based dialysate is to be used, it should be devoid of calcium and magnesium. A two-bag system designed to introduce bicarbonate at the time of fill is preferable.

Dextrose is used as an osmotic agent in PD fluids. Dextrose concentration is varied depending on the degree of fluid removal desired. Standard concentrations are 1.5%, 2.5%, and 4.25% dextrose. Icodextrins are alternative osmotic agents used in PD fluids in the long-term setting. These substances are polyglucose agents that have much lower transmission across peritoneal membranes (high reflection coefficient) and thus retain osmotic capability longer.¹²² Hyperglycemia may also be prevented with the polyglucose agents.^{123,124} Despite these potential benefits, the use of icodextrin in the acute setting has not been studied. Furthermore, icodextrins are associated with sterile hypersensitivity peritonitis.^{125,126} These may lead to unnecessary antibiotic exposure in the acutely ill patient. In the adult, average peritoneal capacity is approximately 2 L of dialysate. Smaller volumes should be used in smaller individuals and those with pulmonary disease or abdominal wall/inguinal hernias. In addition, smaller volumes (500–1000 mL) are very often used when PD is started to prevent leakage around the newly placed catheter. In pediatric populations, the issue of high-volume (20 mL/kg per exchange) versus low-volume (10 mL/kg per exchange) exchanges has been addressed in the literature.^{127,128} These trials suggest that low-volume exchanges provide adequate clearance without respiratory compromise or complications related to dialysate leakage. Low sodium dialysate (129 mmol/L) in association with high dextrose concentration (2.86%) has been studied in the pediatric AKI population with resultant enhanced sodium removal without sacrifice of ultrafiltration capacity.¹²⁹

Choice of modality (manual/autocycled) will depend on the patient's needs. Manual modalities may be chosen for those who are more stable with fewer volume management needs. Hypercatabolic patients with significant volume overload will need nearly continuous exchange that cannot be maintained via a manual modality. Such patients will be better served with an automated cycler. The dose of delivery should be individualized to the patient's needs. In CEPD, each fill lasts approximately 10 minutes (200 mL/min). The fluid should dwell for 30 minutes and then be drained for 20 minutes. Exchanges are performed every hour, giving the patients 48 L of dialysate exchanged on a daily basis.¹²¹ As the patient stabilizes, the dwells may be extended to 3 to 4 hours. Variations in dialysate flow have been introduced. Tidal PD is a modality in which a fraction of the dialysate cycles continuously throughout the dialysis period. Continuous-flow PD is a modality in which the entire volume of dialysate cycles through the abdomen in a continuous manner over several hours. This is facilitated by new techniques by which the dialysate is recycled and reinfused into the abdomen.¹³⁰

Aside from the trial by Chitalia and colleagues,¹¹⁶ few studies have examined the utility of adequacy guidelines for acute PD. Current long-term PD patient guidelines suggest a minimum weekly Kt/V of 1.7 for adequate delivery in anuric patients; however, there is considerable debate as to the appropriate level for the majority of patients.^{114,131} The dose in PD is determined by the 24-hour drain volume multiplied by the number of days per week of dialysis adjusted for urea Vd.¹¹⁴ Anthropometric formulas (i.e., Watson formulas) are typically used to determine urea Vd.¹³² Solute reduction index ($[(24\text{-hour urea removed (grams)})/(\text{predialysis BUN} \times \text{total body weight})] \times 100$) may also be used to determine PD adequacy in AKI.¹¹⁶ Goals for this have not been stringently established; Chitalia and colleagues¹¹⁶ put forth a solute reduction index of more than 20% compa-

rable with weekly Kt/V of more than 2.¹¹⁴ Studies are required to evaluate the efficacy of these models in acute patients, especially given the lack of urea generation and urea Vd steady state in acute patients as mentioned previously.

Complications related to acute PD are bowel perforations during catheter insertion, fluid leak around the catheter site, exit site infection, peritonitis, hemothorax, or hyperglycemia. A potentially life-threatening complication related to acute PD catheters relates to bowel incarceration after removal of the catheter.¹³³ This complication may be prevented by proper closure of the laparotomy incision after catheter removal. Pulmonary compromise has been one of the prime fears of using PD in critically ill patients. Patients on long-term PD have revealed minor alterations in pulmonary function without effects on acid-base status or oxygenation.¹³⁴ Significant complications (hydro-/hemothorax) are rare and typically managed with conservative measures.^{135,136} PD results in large protein and amino acid losses in the dialysate. Studies in critically ill patients receiving acute PD have demonstrated this as well; however, serum albumin levels were not altered significantly.^{117,121} Amino acid-supplemented dialysate has been shown to allow uptake and reduce losses in the dialysate in acutely ill children; however, serum albumin levels were not significantly altered from baseline.¹³⁷

In the past decade, the change in the epidemiology of acute renal failure has made critical care nephrology an emerging subspecialty of intensive care medicine. Dedicated literature and a series of physicians and nurses have made an effort to bridge the knowledge and experience from nephrology and critical care medicine in response to an increased incidence of acute kidney injury (AKI) in intensive care unit (ICU) patients.¹ The use of continuous renal replacement therapies (CRRTs) is constantly increasing, especially in the setting of intensive care and critically ill patients, as originally advocated by Kramer and colleagues.²

The kidneys remove water, various solutes, and nonvolatile acids, thereby maintaining homeostasis; they also metabolize inflammatory mediators and excrete administered drugs or their metabolites. Thus, the optimal treatment of acute renal failure should closely mimic the functions of the kidney. Different renal replacement therapy (RRT) strategies present advantages and disadvantages, and the application of a given technique should be decided based on specific indications and careful evaluation of patient's clinical conditions. In this setting, CRRTs are generally chosen for sicker patients for whom hemodialysis or peritoneal dialysis is contraindicated or even precluded.

EVOLUTION OF CONTINUOUS THERAPIES

The Birth of Continuous Renal Replacement Therapies

The origin of the new era of extracorporeal treatment of acute renal failure can definitely be found in the mid-1970s, when continuous arteriovenous hemofiltration (CAVH) appeared on the scene. Up to that point, AKI was treated with conservative measures: peritoneal dialysis or intermittent hemodialysis (IHD). All techniques had the limitations of low clearance rates, poor fluid management control, and many complications. CAVH was developed by Peter Kramer in 1977, and it immediately became an important alternative treatment for

AKI in those patients in whom peritoneal dialysis or IHD was clinically or technically precluded.³ This opened the doors of ICUs to a dedicated dialysis technology that experienced a flourishing evolution in subsequent years. In the mid-1980s, the technology of CAVH was extended to infants and children, and newly designed hemofilters permitted the application of the technique even to newborns. CAVH presented important advantages over IHD. These were particularly apparent in the areas of hemodynamic stability, control of circulating volume, and nutritional support. However, CAVH also had serious shortcomings that included the need for arterial cannulation (or construction of a Scribner arteriovenous shunt) and the limited solute clearance that could be achieved even under optimal operating circumstances (10 ± 12 mL/min for small solutes such as urea). Initial technical modifications, such as predilution (i.e., the infusion of the replacement solution before the filter instead of after it), did improve creatinine clearance, but the next major technical advance was the creation of an additional side port to the hemofilter. Through this port countercurrent dialysate could be infused at slow flow rates (i.e., 1 L/hr) to achieve additional diffusive solute clearance: this modified technique was named continuous arteriovenous hemodiafiltration or hemodialysis (CAVHDF or CAVHD). With the arrival of CAVHDF-CAVHD, IHD was used even less because uremic control could be achieved in all patients irrespective of their weight or catabolic state simply by increasing the countercurrent dialysate flow rates to 1.5 or 2 L/hr as necessary.

Venovenous Pumped Techniques

Arteriovenous therapies were simple because they did not require a peristaltic blood pump, but the morbidity associated with arterial cannulation was substantial. For this reason, venovenous techniques using a double-lumen central venous catheter for vascular access were considered preferable and safer. Thus, within a few years, continuous venovenous hemofiltration (CVVH) replaced CAVH because of its improved performance and safety. The advance was made possible by the use of blood pumps, calibrated ultrafiltration control

systems, and double-lumen venous catheters. In this setting, improved safety and reliability were then offered by CVVH or continuous venovenous hemodiafiltration or continuous venovenous hemodialysis. These treatments started to be widely used at the end of the 1980s and achieved excellent uremic control using high blood flows (≥ 150 mL/min) and large membrane surface areas (≥ 0.8 m²). To facilitate nursing care, ultrafiltration was soon controlled by devices with reasonable precision. Thus, for clinical purposes, ultrafiltration and reinfusion could be fully regulated to achieve the desired therapeutic goals. In the late 1980s, specific machines for CRRTs were designed and a new era of renal replacement in the critically ill patient began.⁴ The therapy started to be standardized and clear indications began to be defined. The evolution of technology did not stop, however, and the recent demand for higher efficiency and exchange volumes has spurred new interest in a further generation of machines with better perfor-

mance, integrated information technology, and easy-to-use operator interfaces.

Recent Advances in Continuous Renal Replacement Therapies

The latest generation of machines available on the market today, representing the evolution of the past decade of research and development, is shown in Figure 7-1. Specific machines have now been designed to permit safe and reliable performance of the therapy. These new devices are equipped with a user friendly interface that allows for easy performance and monitoring. The apparent complexity of the circuit is made simple by a self-loading circuit or a cartridge that includes the filter and the blood and dialysate lines. Priming is performed automatically by the machine and pre- or postdilution (reinfusion of substitution fluid

Figure 7-1 The latest generation of continuous renal replacement therapy machines. **Top**, The Fresenius Multifiltrate, The Bellco Lynda, The B. before or after the filter) can easily be performed by changing the position of the reinfusion line. These new machines permit all CRRTs to be performed by programming the flows and the total amounts of fluid to be exchanged or circulated as a countercurrent dialysate at the beginning of the session.

A schematic drawing of different techniques available today for the therapy of the critically ill patient with renal and other organ dysfunction is given in Figure 7-2. An important advance in the past decade has been the use of either increased exchange volumes in hemofiltration or the combined use of adsorbent techniques.⁵ Early data suggest that high-volume hemofiltration (HVHF) and continuous plasma filtration coupled with adsorption may have a beneficial effect on clinical outcome in patients with severe sepsis and septic shock (see following discussion).

The effect of different modalities of CRRT on length of stay and recovery of renal function in the general population is still under evaluation, since the case mix is changing

in every study and the populations treated are not homogeneous. In this field, further research is needed. Adequate technical support becomes mandatory, therefore, to fulfill all these expectations. The evolution of understanding of the above-mentioned concepts has led to the improvement of technology and the generation of new machines and devices compatible with the demand for increased efficiency, accuracy, safety, performance, and cost/benefit ratio. At present, almost all CRRTs can be delivered in a safe, adequate, and flexible way, thanks to devices specifically designed for critically ill patients, to a point that multiple organ support therapy is envisaged as a possible therapeutic approach in the critical care setting.⁶ Nevertheless, CRRTs cannot be considered simple therapies that can be prescribed and administered by everybody. Thorough education and training are quintessential for the personnel dealing with these techniques. Dedicated nurses and knowledgeable specialists are required to administer a therapy with optimal features of safety and efficacy.

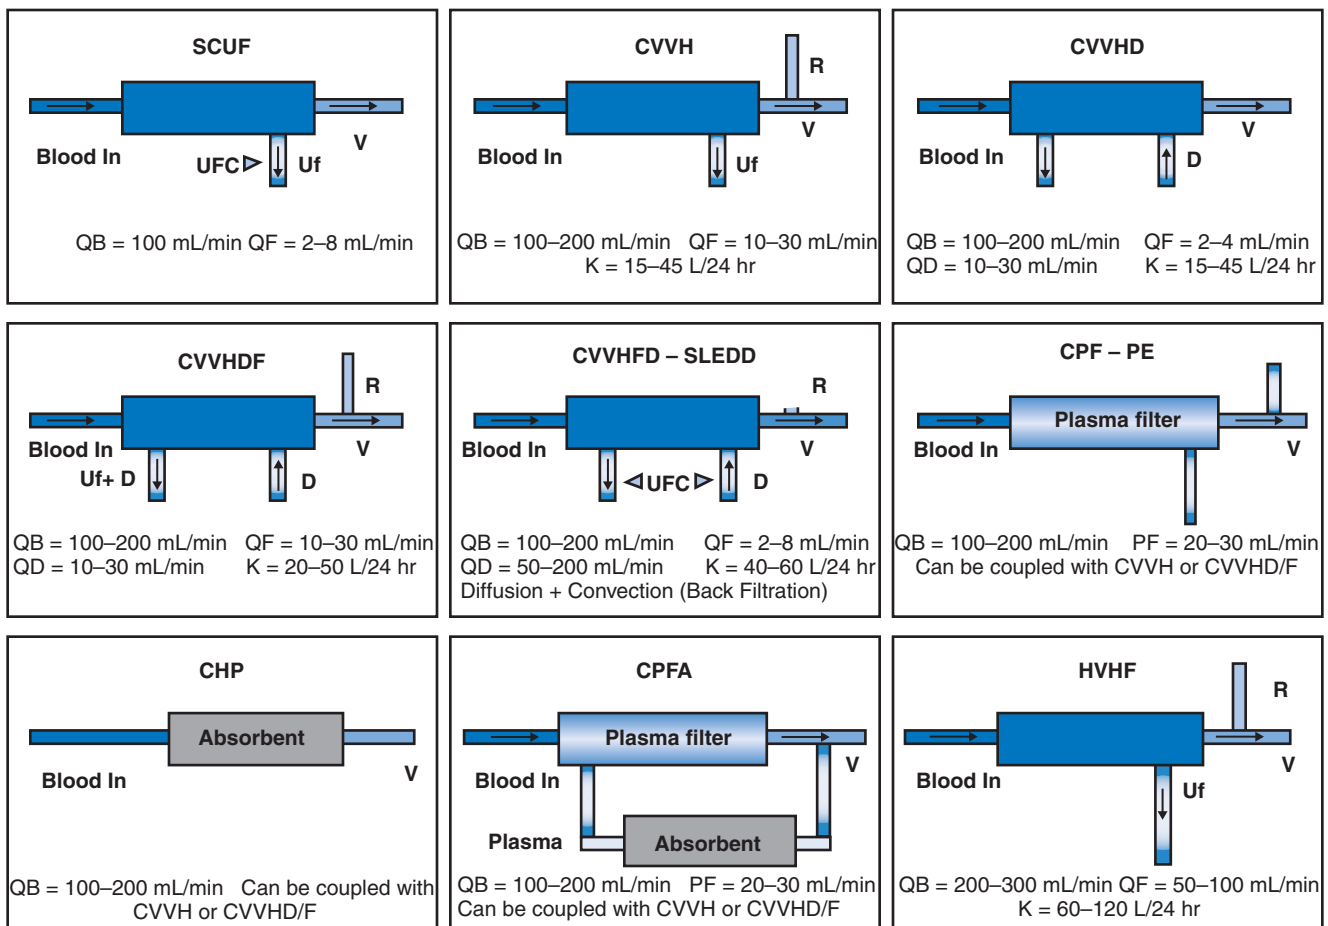

Figure 7-2 Techniques available today for renal replacement in the intensive care unit. CAVH, continuous arteriovenous hemofiltration; CHP, continuous hemoperfusion; CPFA, continuous plasmafiltration coupled with adsorption; CPF-PE, continuous plasmafiltration–plasma exchange; CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; CVVHFD, continuous venovenous high-flux dialysis; D, dialysate; HVHF, high-volume hemofiltration; K, clearance; PF, plasma filtrate flow; QB, blood flow; QD, dialysate flow; QF, ultrafiltration rate; R, replacement; SCUF, slow continuous ultrafiltration; SLEDD, sustained low efficiency daily dialysis; UFC, ultrafiltration control system; V, venous return.

CLINICAL ASPECTS OF CONTINUOUS RENAL REPLACEMENT THERAPIES

Fluid Removal

CRRT slowly and continuously removes fluid, mimicking the urine output, whereas IHD must extract up to 2 days worth of administered fluid plus excess body water, which may be pathologically present in the anuric patient. The intravascular volume depletion associated with IHD is due to both the high rate of fluid removal required and the transcellular and interstitial fluid shifts caused by the rapid dialytic loss of solute.⁷ The major consequence of rapid fluid removal is hemodynamic instability. Critically ill patients need continuous volume infusions: blood and fresh frozen plasma, vasopressors and other continuous infusions, and parenteral and enteral nutrition, which must be delivered without restriction or interruption even in hypercatabolic patients. In the clinical picture of an anuric patient, this means a constant risk of fluid overload and high daily ultrafiltration requirements. The extreme example of the patient who cannot afford intravascular volume shifts is the patient with acute respiratory distress syndrome, the septic patient who is becoming refractory to vasopressors, or the patient with cerebral edema. Furthermore, all critically ill patients tolerate hypotension poorly, with a definite risk of cardiac arrest, particularly if they are already inotropic dependent. Indeed, the damaged kidneys, which have temporarily lost pressure-flow autoregulation, may also be threatened with fresh ischemic lesions occurring with each episode of IHD,⁸ leading to a delay in renal recovery. Interestingly, recent reports have suggested a benefit of CRRTs with respect to recovery of renal function (see following discussion).

The importance of fluid balance management is enhanced in the specific category of patients with decompensated heart failure. In fact, it is just such patients who may well respond positively to continuous ultrafiltration with an increase in cardiac index, while avoiding a decrease in arterial pressure, due to a change in the preload optimizing myocardial contractility on the Starling curve.⁷ Many patients with congestive cardiac failure nonresponsive to conventional therapy are now successfully treated in this way.⁹

In critically ill children, the correction of water overload is considered a priority: it has been shown that restoring an adequate water content in small children is the main independent variable for outcome prediction.^{10,11} This concept is even more important in critically ill neonates in whom a relatively larger amount of fluid must be administered to deliver an adequate amount of drug infusion, parenteral/enteral nutrition, and blood derivatives.

Solute Removal and Electrolyte Balance

An attribute of IHD often quoted by proponents is that it is highly efficient at clearing solutes such as urea. In fact, this is both a false argument and a disadvantage. The primary rationale of using continuous therapy is to maintain a more physiologic constant removal of fluid and solute, among other things. In the process, the cumulative clearance of urea and creatinine by a continuous method is significantly superior to that achieved by IHD administered as often as four times per week, even in septic patients. Indeed, IHD six times per week would be required to achieve the same uremic control.¹²

The detailed physiologic impact of better uremic control has not been fully elucidated. Uremia causes immunosuppression with impaired phagocytosis and defective lymphocyte and monocyte function, which could well be important in the ICU setting. Extrapolating from data established in patients with end-stage renal disease, better uremic control is clearly advantageous. In the National Cooperative Dialysis Study, there was a higher morbidity, including cardiovascular events and hospitalization rate, in patients with end-stage renal disease hemodialyzed to a target average urea concentration of 100 mg/dL (36 mmol/L) compared to the group whose target was 50 mg/dL (18 mmol/L).¹³ There is, however, uncertainty regarding the relative contributions of uremia, malnutrition, and bioincompatible membranes in these older studies.¹⁴ Furthermore, work needs to be done specifically on patients with AKI.

A landmark study by Ronco and co-workers¹⁵ is at present the only randomized trial in AKI that showed that a high (adequate) dialytic dose (metabolic control) improved survival: in this study, continuous venovenous postdilution hemofiltration at 35 mL/kg/hr or 45 mL/kg/hr was associated with improved survival when compared with 20 mL/kg/hr in 425 critically ill patients with AKI.¹⁵ This suggests that 35 mL/kg/hr should be considered the minimum adequate CRRT dose in patients with AKI.

One specific comment must be made concerning the difference between CVVH and all other techniques, including dialysis and the use of diuretics. In all pharmacologic and dialytic techniques, the removal of sodium and water cannot be dissociated and the mechanisms are strictly correlated. In particular, the diuretic effect is based on natriuresis, while ultrafiltration during dialysis may result in hypo- or hypertonia, depending on the interference with diffusion and removal of other molecules such as urea and other electrolytes. In such circumstances, water removal is linked to other solutes in proportions that are dependent on the technique used. In CVVH, the mechanism of ultrafiltration produces a fluid that is substantially similar to plasma water except for a minimal interference due to Donnan effects. In such a technique, ultrafiltration is basically iso-osmotic and isonatremic and water and sodium removal cannot be dissociated, with sodium elimination linked to the sodium plasma water concentration. However, the sodium balance can be significantly affected by the sodium concentration in the replacement solution. Sodium removal can be dissociated from water removal in CVVH, thus obtaining a real manipulation of the sodium pool in the body. This effect cannot be achieved with any other technique. The advantage is that one can normalize not only plasma concentrations but also the electrolyte content in the extracellular and possibly intracellular volume.¹⁶

Immunomodulatory Effects

One of the most active areas of research in intensive care in recent years involves the modulation of the septic response to reduce the persistently high mortality in sepsis syndrome and the potential benefit of CRRT. Although there is skepticism that any improvement might be due to nonspecific changes such as fluid removal or lowering the core temperature in febrile patients, there is evidence that cytokines and complement, among other mediators, are cleared from the blood by convection and/or adsorption onto high-flux synthetic hemofilter membranes. There is little doubt that it is important to

use biocompatible membranes, and if mediator removal is to be effective, it needs to be continuous and convective, not intermittent and diffusive.¹⁷

HVHF or continuous plasma filtration coupled with adsorption (CPFA) has been investigated as potent immunomodulatory treatments in sepsis. Since sepsis and systemic inflammatory response syndrome are characterized by a cytokine network that is synergistic, redundant, autocatalytic, and self-augmenting, the control of such a nonlinear system cannot be approached by simple blockade or elimination of some specific mediators. Therefore, nonspecific removal of a broad range of inflammatory mediators by HVHF and CPFA may be beneficial, as recently suggested based on the peak concentration hypothesis.¹⁸ The high dose that characterizes HVHF can be delivered by using either a constantly high exchange rate or delivering a pulse (for 6–8 hours) of very high-volume hemofiltration (85–100 mL/kg/hr) followed by standard doses.¹⁹ In both cases, cytokine half-lives and concentrations are affected, the first by the continuous modality and the second by the nonspecific decapitation of peaks. Therefore, rather than a detailed analysis of each molecule involved, we envisage as much more interesting and useful a teleologic analysis of the impact of HVHF on more integrated events such as monocyte cell responsiveness, including apoptosis, neutrophil-priming activity, and oxidative burst.^{18,20} Whether these effects translate into significant changes in end-organ damage by inflammatory mediators or result in a reproducible reduction in mortality and/or morbidity is still being elucidated.

Side Effects of Continuous Renal Replacement Therapies

Although considerable attention has focused on the perceived benefits of CRRTs, there has been less emphasis on the possibility that CRRT might confer increased risk. As a continuous extracorporeal therapy, CRRT often requires continuous anticoagulation, which can increase bleeding risk. Conversely, clotting of the extracorporeal circuit also occurs frequently with CRRTs, which might contribute to blood loss and could exacerbate anemia in critically ill patients. The increased solute transfer associated with the use of CRRTs might enhance removal of amino acids, vitamins, catecholamines, and other solutes with a beneficial function in critically ill patients. Continuous therapies must be continuous to work: how many treatments really last more than 18 to 20 hours per day? Downtime due to filter-circuit-catheter clotting, circuit change, frequent replacement solution bag substitution, and patient mobility (surgery, diagnostics) should be carefully monitored and might significantly affect dialysis dose.²¹ Also of concern are recent reports that technical problems with the delivery of CRRTs, including machine malfunction, medication errors, and compounding errors, might contribute to increased patient morbidity and mortality. Detection of safety problems and/or adverse events is particularly difficult when there are high rates of expected morbidity and mortality in the population undergoing a procedure, as is the case with CRRTs in critically ill patients with AKI. Currently, few available studies in the nephrology literature provide substantive information on the safety or adverse effects of CRRTs or IHD in the critically ill population. After the introduction of new technology and devices into medical practice, there is a natural tendency to assume that the novel therapeutic approach is

providing benefit. This is especially the case when a therapy is administered to a critically ill patient 24 hours per day and becomes part of the typical equipment of an ICU bed: the level of attention is probably superior when a dedicated dialysis nurse administers the treatment for few hours during a day shift. Nonetheless, a new generation of dedicated CRRT machines has been recently released with strict safety features and the possibility of a high range of prescriptions. In any case, the ideal therapy still does not exist and specific ICU staff training is mandatory before the routine use of such modern monitors: there will never be a solution to the unwise use of a perfect system.²²

Clinical Trials Focusing on Mortality

Four recently published randomized clinical trials and one multicenter observational study tested the hypothesis that outcomes with CRRTs are superior to those with IHD.^{23–27} None of these studies showed a superior outcome for CRRTs compared with IHD. The results of these studies are surprising and, in some cases, strongly criticized for methodology and group randomization.²⁸ Nevertheless, they certainly do not support the belief that CRRTs provide better outcomes than IHD. One of the common key points of these recent trials can be that IHD has become safer and more efficacious with contemporary dialytic techniques. Furthermore, a liberal and extended use of CRRTs might have become less safe and/or efficacious than previously considered or expected. The concept that CRRTs can provide more hemodynamic stability, more effective volume homeostasis, and better blood pressure support than IHD has been the basis for the assumption that CRRTs are superior therapies. Over the past two decades, however, technical advances in the delivery of IHD have dramatically decreased the propensity of IHD to cause intradialytic hypotension. These advances include the introduction of volume-controlled dialysis machines, the routine use of biocompatible synthetic dialysis membranes, the use of bicarbonate-based dialysate, and the delivery of higher doses of dialysis. In an important study, Schortgen²⁹ demonstrated that there were a lower rate of hemodynamic instability and better outcomes after implementation of a clinical practice algorithm designed to improve hemodynamic tolerance to IHD. Recommendations included priming the dialysis circuit with isotonic saline, setting dialysate sodium concentration at more than 145 mmol/L, discontinuing vasodilator therapy, and setting dialysate temperature to below 37°C. Thus, the original rationale for the widely held assumption that CRRTs are superior therapies may have dissipated over time. Examining the results of recently published observational studies and randomized trials reveals no convincing evidence to support superiority of CRRTs over IHD in terms of mortality in the management of most critically ill patients with AKI.³⁰

Clinical Studies and Renal Recovery

However, is mortality the only relevant endpoint to examine? There is a certain tendency to neglect the kidney once it has failed, based on the misconception that one can do no further harm to an organ that has already failed. However, renal recovery is an equally important clinical endpoint. Long-term dialysis is not only associated with significant impairment in health-related quality of life,³¹ it is also an expensive therapy,

costing on average U.S. \$69,751 per year.³² Moreover, chronic kidney disease of milder severity (stage 2 or 3) is likewise associated with adverse patient outcomes and high health care costs, suggesting that the presence of any sustained renal impairment is potentially significant.³³ Therefore, treatment of all patients with intermittent hemodialysis on the presumption of equipoise based on mortality outcomes may be inappropriate from both clinical and economic standpoints because it disregards potential downstream effects. Better rates of renal recovery might save significant resources and affect long-term well-being among survivors.

Three observational studies and one randomized, controlled study reported renal-related outcomes.^{23,34–36} In a single-center observational study, dialysis independence was significantly higher among patients initially treated with CRRTs (87%) versus IHD (36%).³⁵ Similar results were seen in a Swedish multicenter study in which 91.7% of patients treated with CRRTs were dialysis independent at 3 months compared with 83.5% of IHD patients.³⁴ A large international multicenter database confirmed these findings.³⁶ Unadjusted dialysis dependence at hospital discharge was higher after CRRTs (85.5%) than after IHD (66.2%). Last, the randomized, controlled trial by Mehta and colleagues,²³ often quoted as a “negative” trial, found CRRTs to be beneficial regarding renal recovery. Chronic renal insufficiency at death or hospital discharge was diagnosed in 17% of patients whose therapy was IHD versus only 4% of those whose initial therapy was CRRTs ($P = .01$). For patients receiving an adequate trial of monotherapy, recovery of renal function was 92% for CRRTs versus 59% for IHD ($P < .01$). A pathophysiologic explanation for this observation can be easily found. In at least one study, a significantly higher incidence of hypotension was seen among patients treated with IHD as opposed to CRRTs.³⁷ The gentle but effective correction of metabolic and fluid derangements and the maintenance of a steady correction of homeostasis by CRRTs may influence the process of recovery of the kidney during and after the acute injury has occurred. When seen in this light, CRRT is a potentially valuable tool to aid renal recovery.

Clinical Effects of Hybrid Techniques

Hybrid techniques have been given a variety of names, such as sustained low efficiency daily dialysis (SLEDD), prolonged intermittent daily RRT, extended daily dialysis (EDD), or simply extended dialysis,^{38–41} depending on variations in schedule and type of solute removal (convective or diffusive). Theoretically speaking, the purpose of such therapy would be the optimization of the advantages offered by either CRRTs or IHD, including efficient solute removal with minimum solute disequilibrium, reduced ultrafiltration rate with hemodynamic stability, optimized delivered-to-prescribed ratio, low anticoagulant needs, decreased cost of therapy delivery, efficiency of resource use, and improved patient mobility. Initial case series have shown the feasibility and high clearances that potentially are associated with such approaches. The arrival of technology that can be used in the ICU by ICU nurses to deliver SLEDD with convective components offers further options from a therapeutic point of view. One can now easily use technology in the ICU to generate ultrapure replacement fluid and administer it as in CRRTs, but at lower cost, in greater amounts, and for shorter periods of time, or combine such hemofiltration with diffusion, or use pure diffusion at any

chosen clearance for a period of time that can encompass a given nursing shift, the 9 to 5 maximum staff availability period, or the nighttime period.

A recent randomized trial comparing CVVH and EDD with filtration (EDDf) found that both techniques achieved correction of several electrolyte abnormalities present before intervention.⁴² The potential risk of hypophosphatemia in CVVH patients suggests the need for vigilance and frequent serum phosphate monitoring. Importantly, in all patients, hypo- or hyperkalemia/-magnesemia were avoided with the prescriptions used. Although the serum sodium was maintained within the normal range and was similar in both groups, there were significant differences in the chloride concentration. The relative hyperchloremia in the EDDf patients was almost certainly due to the greater concentration of chloride in the fluids used for EDDf (111.8 mmol/L) than in the fluids used for CVVH (100.75 mmol/L). The authors found that the two therapies affected metabolic acid-base variables differently. First, the concentration of lactate was lower with EDDf throughout the study period. This difference was likely explained by the use of lactate as buffer during CVVH, compared with bicarbonate during EDDf. Second, despite the increase in lactate with CVVH, median pH, bicarbonate, and base excess values were all less acidotic with continuous treatment. These findings are consistent with both the lower amount of buffer in EDDf fluids (26 mEq/L) than in CVVH (45 mEq/L) and the relative hyperchloremia of these fluids. The effect of hyperchloremia is also likely to explain the difference in mean apparent strong ion difference between the two groups. A decrease in CO₂ in response to this metabolic acidosis accounted for the lower effective strong ion difference values observed during EDDf. Conversely, the strong ion gap was similar for both treatments, in keeping with likely equivalent clearance of unmeasured acids. Although the clinical significance of these differences is uncertain, a higher bicarbonate concentration in EDDf fluids may be desirable.

CONCLUSIONS

Comparing intermittent and continuous therapies can be misleading. Besides the difficulty of conducting a well-designed, adequately powered, randomized trial (requiring at least 1200 patients), continuous and intermittent therapies represent a continuum in the management of AKI; thus, sicker patients would derive greater benefit from CRRTs, whereas less severely ill patients might take advantage of daily extended or intermittent treatments.

The choices today are almost limitless: Should the therapy be 3 or 4 hours of IHD with standard settings? Or should it be CRRT at 35 mL/kg/hr effluent flow rate? Or should it be SLEDD at blood and dialysate flow rates of 150 mL/min for 8 hours during the day? Or should we apply SLEDD for 12 hours overnight? Or should we add a convective component to SLEDD and make it SLEDD with filtration? Or should we combine CRRT for the first 2 or 3 days when the patient is in the hyperacute phase, with SLEDD thereafter as recovery takes place? Indeed, from the point of view of the intensivist, the modes of RRT are beginning to resemble the modes of mechanical ventilation, with ventilator settings seamlessly being changed to fit into the therapeutic goals and patient needs and phases of illness. Just as stereotyped approaches to ventilation

are anachronistic and inappropriately try to fit the patient into a fixed therapy rather than tailoring the therapy to the patient, so should RRT be adjusted to fulfill the needs of the individual and his or her illness. Just as the concept of showing that one mode of ventilation is better than another seems a lost cause, the same might happen with RRT. In the light of current knowledge, it is prudent to say that the best RRT for a patient is the safest, the simplest, and the more efficient that the center can provide. Until definitive data become available, be it about mortality or renal recovery, personal experience and local circumstances remain major determinants in the selection of a given RRT mortality.

		SUMMARY	89

Nutritional support is a cornerstone in the complex therapeutic strategies designed to care for the patient with acute renal failure (ARF). ARF is a hypermetabolic, proinflammatory, and pro-oxidative clinical syndrome.¹ Metabolism and nutrient requirements for ARF patients are affected not only by the acutely uremic state per se, but also by the type and intensity of renal replacement therapy and by the underlying disease process and associated complications. Any nutritional program for an ARF patient must take into consideration this complex metabolic environment and must be coordinated with renal replacement therapy.

ARF is associated with an excess attributable mortality being interrelated with the systemic immunologic and metabolic consequences of ARF, and these factors are aggravated by malnutrition.^{1,2} The objectives of nutritional therapy are to maintain lean body mass and to stimulate immunocompetence and repair functions and are aimed at mitigating the inflammatory state while improving oxygen radical scavenging system and endothelial functions. Despite the difficulty of demonstrating clear-cut benefits of nutritional interventions in the prognosis of critically ill patients, an increasing number of investigations have led to the conclusion that nutrition improves the course of disease and prognosis.³

The principles of nutritional support for ARF differ fundamentally from those for patients with chronic kidney disease (CKD) because diets or infusions that satisfy minimal require-

ments in CKD will not necessarily be sufficient for acutely ill ARF patients. Specifically, it is not renal dysfunction that principally determines nutrient needs. Instead, the severity of diseases/conditions associated with hypercatabolism, the nutritional state, and the type and frequency of renal replacement therapy determine nutrient requirements.

For many years, parenteral nutrition was the preferred route of nutritional support in patients with ARF. During the past decade, enteral nutrition has become the primary type of nutritional support for ARF patients who can tolerate enteral/oral feeding.⁴ It is an unfortunate fact that few systematic studies have been conducted of nutritional support in ARF; most recommendations thus are necessarily based on expert opinion rather than on controlled studies.

METABOLIC ALTERATIONS AND NUTRIENT REQUIREMENTS IN ACUTE RENAL FAILURE

ARF is associated with a broad pattern of disturbances of physiologic functions that exert a pronounced impact on morbidity and mortality. In many cases, ARF is not an isolated event but a complication of sepsis, trauma, or multiple organ failure so metabolic changes in such patients will be determined by the acute uremic state plus the underlying disease process and/or

complications (severe infections and organ dysfunction) and by the type and intensity of renal replacement therapy. The acute loss of excretory renal function affects water, electrolyte, and acid-base metabolism and has a profound effect on the *milieu interieur*. There are specific alterations in protein, amino acid, carbohydrate, and lipid metabolism.⁵

As noted, the optimal intake of nutrients in ARF patients is influenced more by the nature of the illness causing ARF, the extent of catabolism, and type and frequency of dialysis rather than renal dysfunction per se.⁶ ARF patients present as a heterogeneous group of subjects with widely differing nutrient requirements, and in individual patients, requirements can vary considerably (Box 8-1).

Energy Metabolism and Energy Requirements

In contrast to experimental animals, in which ARF is associated with decreased oxygen consumption (uremic hypometabolism), energy expenditure is normal in patients with uncomplicated ARF. However, sepsis or multiple organ failure will increase oxygen consumption by 30% on average,⁷ so energy metabolism is determined more by the underlying disease process than by ARF. There are well-defined complications of administering excessive energy substrates; thus, feeding should not exceed actual rates of energy expenditure. Complications, if any, from slightly underfeeding are less deleterious than those arising from overfeeding. For example, increasing energy intake from 30 to 40 kcal/kg body weight (BW)/day in ARF patients was shown to increase metabolic complications, such as hyperglycemia and hypertriglyceridemia, and had no beneficial effects.⁸ Since basal energy expenditure cannot be measured easily, it should be estimated from standard formulas such as the Harris-Benedict equation plus corrections for the degree of hypermetabolism (i.e., a stress factor). Please note that in most clinical situations, energy requirements are 20 to 25 kcal/kg BW/day and rarely higher than 130% of basal energy expenditure.

Amino Acid/Protein Metabolism

A hallmark of ARF is excessive protein catabolism and sustained negative nitrogen balance. It is impossible to block or compensate for protein losses by nutritional strategies. Hyper-

Box 8-1 Important Metabolic Abnormalities Induced by Acute Renal Failure

- Activation of amino acid and protein catabolism (especially in muscle)
- Peripheral glucose intolerance/increased gluconeogenesis
- Inhibition of lipolysis and altered fat clearance
- Depletion of the antioxidant system
- Induction of a proinflammatory state
- Impairment of immunocompetence
- Complex endocrine abnormalities: hyperparathyroidism, insulin resistance, erythropoietin resistance, resistance to growth factors, etc.

catabolism causes excessive release of amino acids from skeletal muscle, and there is also defective utilization of amino acids in the synthesis of muscle protein.^{9,10} Hepatic gluconeogenesis (and ureagenesis) and synthesis of a number of proteins including acute phase proteins are all increased. ARF also causes an imbalance in amino acid pools in plasma and in the intracellular compartment; the utilization of amino acids after intravenous infusion is also defective.¹¹

Release of inflammatory mediators (e.g., tumor necrosis factor α , interleukins), endocrine factors (catabolic hormones, hyperparathyroidism), circulating proteases, and catabolism stimulated by renal replacement therapy each contribute to accelerated protein breakdown in ARF (Box 8-2). A major catabolic factor is insulin resistance, which interrupts the control of protein turnover.¹² In muscle, both insulin-mediated stimulation of protein synthesis and inhibition of protein degradation are depressed in ARF. Metabolic acidosis has been identified as one important factor that stimulates protein breakdown.¹³ Nitrogen losses in ARF patients are augmented if stressful factors such as inadequate nutrition, infection, trauma, sepsis, and thermal injury are present.

Protein and amino acid metabolism is also impaired by the loss of renal tissue since several amino acids are synthesized and/or metabolized by the kidney.¹⁴ Indeed, the loss of kidney function can make several amino acids (e.g., tyrosine, arginine, serine, cysteine) conditionally indispensable. Moreover, the renal degradation of peptides is retarded in ARF, so catabolism of peptide hormones and inflammatory cytokines is retarded, a mechanism by which the inflammatory response in ARF is augmented.¹⁵

Anticatabolic Strategies in Acute Renal Failure

Anticatabolic strategies can be aimed at various targets (see Box 8-2). Nutrition is of paramount importance in mitigating catabolism. However, hypercatabolism in ARF can only be reduced and is not completely suppressed by conventional nutritional substrates (including branched-chain

Box 8-2 Protein Catabolism in Acute Renal Failure: Contributing Factors

- Impaired metabolic functions caused by accumulating uremic toxins
- Endocrine factors
 - Insulin resistance
 - Increased secretion of catabolic hormones (catecholamines, glucagon, glucocorticoids)
 - Hyperparathyroidism
 - Suppression of release/resistance to growth factors
- Acidosis stimulation of amino acid and protein catabolism
- Acute phase reaction: systemic inflammatory response syndrome (activation of cytokine network)
- Release of proteases
- Inadequate supply of nutritional substrates
- Renal replacement therapy
 - Loss of nutritional substrates
 - Activation of protein catabolism

amino acids). Whether specific nutrients such as glutamine or lipids can exert a more pronounced benefit for protein balance remains to be shown. Further therapeutic targets include hormones (especially the use of insulin and growth factors) and mediators (anti-inflammatory strategies) (see later). Finally, the enzyme systems that catalyze protein breakdown (e.g., the ubiquitin-proteasome system) potentially can be blocked. Obviously, inhibiting protein catabolism systems should not present a primary target of therapy because many metabolic pathways would be impaired. It appears that more upstream therapeutic interventions aimed at mitigating the underlying inflammatory process will be required.

Anti-inflammatory strategies using anticytokines have been reported to limit the release or action of inflammatory mediators in animal experiments. Unfortunately, they have not been successful in clinical trials of patients with critical illnesses. However, it should be recognized that several nutritional factors such as amino acids (glutamine, glycine, arginine), ω -3 fatty acids and selenium can modify inflammatory responses and the release of mediators and can mitigate oxidative injury, presenting a promising field in nutritional intervention in patients with ARF.

There is hope that the use of growth factors in ARF patients (e.g., recombinant human growth hormone or insulin-like growth factor I) would be beneficial. In sharp contrast to findings from animal experiments, available clinical results from treating acutely ill patients have been disappointing: a multicenter study of insulin-like growth factor I administration to ARF patients was prematurely terminated because of a lack of benefit; recombinant human growth hormone was even associated with increased mortality in critically ill patients, many of whom had ARF.^{16,17}

Protein/Amino Acid Requirements

The most controversial question in nutritional support of patients with ARF concerns the optimal intake of amino acids/protein. Unfortunately, few studies have attempted to define requirements. The optimal daily protein or amino acid requirement seems to be above the minimum level of 0.6 g of protein/kg BW/day recommended for CKD patients or the recommended allowance (RDA) of 0.8 g/kg BW/day for normal subjects. Even for noncatabolic patients during polyuric recovery phase of ARF, an amino acid intake of 1 g/kg BW/day was found to be necessary to achieve a neutral nitrogen balance.¹⁸ Some studies have tried to evaluate protein/amino acids requirements in critically ill patients with ARF on continuous renal replacement therapy (CRRT). In these patients, a protein catabolic rate of 1.4 to 1.7 g/kg BW/day was observed,^{6,19,20} and there was an inverse relationship between protein and energy provision and protein catabolic rate. Overall, the nitrogen deficit was less in patients receiving nutritional support. A protein intake of about 1.5 g/kg BW/day was recommended.

Thus, unless renal insufficiency will be brief and there is no associated catabolic illness, the intake of protein or amino acids should not be lower than 1.0 g/kg BW/day. It should be emphasized that hypercatabolism cannot be overcome by increasing protein or protein/amino acid intake to more than 1.5 g. This level is in accordance with general recommendations for critically ill patients. Any exaggerated protein intake,

as recently suggested by some authors,^{21,22} has not proven to be beneficial and simply stimulates the formation of urea and other nitrogenous waste products, can induce hyperammonemia, and may aggravate uremic complications. For patients treated by hemodialysis/continuous hemofiltration/peritoneal dialysis, extra protein/amino acid intake of 0.2 g/kg BW/day (again to a maximum of 1.5–1.7 g/kg BW/day) should be provided to compensate for losses occurring during therapy.

Carbohydrate Metabolism in Acute Renal Failure

ARF is characterized by an insulin-resistant state that is closely related to the prognosis of the patients.²³ Maximal insulin-stimulated glucose uptake by skeletal muscle is lower, whereas the insulin concentration causing half-maximal uptake is normal, indicating the presence of a postreceptor defect rather than impaired sensitivity.²⁴ A second feature of abnormal glucose metabolism in ARF is accelerated hepatic gluconeogenesis from the amino acids released during catabolism. Hepatic extraction of amino acids and their conversion to glucose and urea production all are increased by ARF. In contrast to healthy adults, hepatic gluconeogenesis from amino acids and thus protein catabolism cannot be completely suppressed by exogenous infusions of glucose.²⁵

The metabolism of insulin is grossly abnormal in ARF; endogenous insulin secretion is decreased in the basal state and during a glucose infusion. Renal insulin catabolism is blunted and, surprisingly, insulin catabolism by the liver is consistently decreased in ARF.²⁶ As a consequence, many ARF patients express hyperglycemia. This is relevant because hyperglycemia in critically ill patients is recognized as an important determinant of the evolution of complications such as infections (but also of kidney injury) and prognosis.²⁷ Normoglycemia must be strictly maintained during nutritional support in ARF patients.

Lipid Metabolism in Acute Renal Failure

Profound alterations in lipid metabolism occur in patients with ARF; the triglyceride content of plasma lipoproteins is increased, whereas total cholesterol and, in particular, high-density lipoprotein cholesterol are decreased.²⁸ The major cause of lipid abnormalities is impaired lipolysis. The activities of both lipolytic systems, lipoprotein lipase and hepatic triglyceride lipase, are decreased to less than 50% of normal.²⁹ Whether increased hepatic synthesis contributes to hypertriglyceridemia in ARF remains unsettled. In contrast to CKD, carnitine deficiency does not participate in the development of lipid abnormalities in ARF. Plasma carnitine levels in ARF patients are increased due to both increased release from muscle tissue and activated hepatic synthesis.³⁰ The nutritional relevance of abnormal lipid metabolism is that lipid particles of artificial fat emulsions are metabolized like very low density lipoprotein lipids; their elimination is delayed in ARF. The delayed lipolysis in ARF contrasts with other acute illnesses such as surgery, trauma, and sepsis, in which fat elimination and utilization are enhanced to cover increased energy requirements via the oxidation of free fatty acids.³¹ Moreover, intestinal absorption of lipids is retarded in renal failure.

Micronutrients

Requirements for water-soluble vitamins in patients with ARF are increased, mainly because of losses induced by renal replacement therapies. Caution should be used in prescribing vitamin C because it is a precursor of oxalic acid and an excess (>250 mg/day) can result in secondary oxalosis.³² In contrast to CKD, the requirements of vitamins A, E, and D (but not vitamin K) are increased in patients with ARF, and a daily supplement should be provided.³³ This is possible because most multivitamin preparations for parenteral infusions contain the RDA of vitamins.

Requirements of trace elements are poorly defined for ARF patients. Parenteral infusions carry the risk of inducing toxic effects because the regulation of trace element homeostasis, including gastrointestinal absorption and impaired renal excretion is impaired in ARF. Nevertheless, selenium concentrations in plasma and erythrocytes are consistently decreased in patients with ARF and CKD. Selenium supplementation can reduce the evolution of organ dysfunctions and ARF and potentially improve prognosis in critically ill patients with sepsis.³⁴ Several micronutrients are part of the organism's defense mechanisms against oxygen free radical-induced injury. This is relevant because ARF is a pro-oxidative state and profound depression in antioxidant-status has been documented in patients with ARF.^{35,36} Repletion of the antioxidative system is an important aim in nutritional support of renal failure patients.

Electrolytes

Derangements in electrolyte balance in patients with ARF are extremely variable, so no standard recommendations can be given. Electrolyte requirements not only vary considerably among patients, but it must be noted that abnormalities can fundamentally change during the course of the disease.³⁷ Notably, hypokalemia, hypophosphatemia, and hypomagnesemia are frequently present in ARF patients, especially those with nonoliguric ARF and the patients treated by CRRT. Nutrition support, especially parenteral nutrition with a low electrolyte content, can induce hypophosphatemia and hypokalemia, respectively (the refeeding syndrome).³⁸ Thus, electrolyte requirements have to be evaluated in patients with ARF on a day-to-day basis.

METABOLIC IMPACT OF EXTRACORPOREAL THERAPY

The impact of renal replacement therapies on metabolism is manifold. Protein catabolism is caused not only by substrate losses, but also by activation of protein breakdown mediated by release of leukocyte-derived proteases and inflammatory mediators.³⁹ Potentially, dialysis induces also an inhibition of muscular protein synthesis.⁴⁰ Several water-soluble substances, such as vitamins and carnitine, are lost during hemodialysis, and it has been suggested that generation of reactive oxygen species is augmented during dialysis treatment (Box 8-3).

Recently, CRRT (continuous hemofiltration and/or continuous hemodialysis) have been widely used to manage critically ill patients with ARF. The metabolic consequences of these modalities reflect the continuous mode of therapy and the recommended high fluid turnover.⁴¹

One major effect of CRRT is the elimination of small- and medium-sized molecules. Amino acid losses can be estimated from the volume of the filtrate and the average plasma concentrations. Usually, amino acid loss accounts for 5 to 15 g of amino acid per day, representing approximately 10% to 15% of amino acid intake.⁴² Water-soluble vitamins, such as folic acid and vitamins B₁, B₆, and C are also eliminated during CRRT, so their intake should be higher than the RDA to maintain plasma concentrations.⁴³ There are also relevant losses of selenium during CRRT accounting for as much as twice the daily RDA.⁴⁴

CLINICAL EXPERIENCES WITH NUTRITIONAL SUPPORT IN ACUTE RENAL FAILURE

Unfortunately, only a limited number of controlled trials on nutritional support in ARF have been done. Few are prospective and fulfill minimal requirements in study design with respect to patient numbers, definition of endpoints, and stratification of groups. Early investigations compared nutritional support with amino acids plus glucose versus glucose alone.⁴⁵ Pooled results of the four best studies reveal a mortality rate of 64% with glucose infusion only compared with a 42% mortality rate when a more complete parenteral nutrition solution was provided.⁶ Combining these results with other retrospective investigations, the data are consistent with the conclusion that nutritional support is effective and that sicker patients with more complications will derive benefit from nutritional therapy. Other investigations have evaluated the optimal type of amino acid solution and the quantity of amino acids/protein to be used. These studies have not generated conclusive results with regard to an improved survival rate or an improvement in

Box 8-3 Metabolic Effects of Renal Replacement Therapy in Acute Renal Failure

Intermittent Hemodialysis

- Loss of water-soluble molecules
 - Amino acids
 - Water-soluble vitamins
 - L-carnitine, etc.
- Activation of protein catabolism
 - Loss of amino acids
 - Loss of proteins
 - Cytokine release (tumor necrosis factor α , etc.)
- Inhibition of protein synthesis
- Increase in reactive oxygen species production

Continuous Renal Replacement Therapy

- Heat loss
- Excessive load of substrates (lactate, citrate, glucose, etc.)
- Loss of nutrients (amino acids, vitamins, selenium, etc.)
- Loss of electrolytes (phosphate, magnesium)
- Elimination of (short-chain) proteins (hormones, potential inflammatory mediators but also albumin)
- Metabolic consequences of bioincompatibility (induction/activation of mediator cascades, of an inflammatory reaction, stimulation of protein catabolism)

nitrogen balance, but the numbers of patients studied is small or no matched control group or patients were not hypercatabolic.^{37,46} This includes some recent investigations using high amounts of protein/amino acids in nutritional support in patients with ARF on CRRT (see previously).²² Most of these studies have evaluated parenteral nutrition in patients with ARF, but enteral nutrition is now the first line of nutritional support. Unfortunately, few systematic studies of the potential benefits of enteral nutrition in ARF patients are available.^{4,47,48}

In some ways, the ongoing controversy over the efficiency of nutritional support in ARF reflects a basic misunderstanding of the objectives of nutritional therapy. Nutritional support presents just one element of a complex pattern of therapeutic interventions, so it can be argued that patient survival should not be the sole endpoint of a nutritional evaluation. Nevertheless, there are reports demonstrating a beneficial effect of timely instituted and qualitatively/quantitatively adapted nutritional support on the course of acute disease states and patient survival.³

IMPACT OF NUTRITIONAL INTERVENTIONS ON RENAL FUNCTION AND/OR RECOVERY FROM ACUTE RENAL FAILURE

Starvation accelerates protein breakdown and impairs protein synthesis in the kidney, whereas refeeding exerts the opposite effects. In the experimental animal model, provision of amino acids or total parenteral nutrition accelerates tissue repair and recovery of renal function. In patients, however, this has been much more difficult to prove; only one study has reported a positive effect of nutrition on the resolution of ARF.⁴⁵ Available evidence, however, suggests that the provision of substrates may enhance tissue regeneration and, potentially, renal tubular repair. Conversely, high doses of amino acids can induce toxic damage to renal tubules subjected to ischemic or nephrotoxic insults.⁴⁹ In part, this “therapeutic paradox” in ARF is related to an increase in metabolic work occurring when oxygen is limited (similar observations have been made with glucose infusions during renal ischemia). In summary, during the insult phase of ARF (similar to the ebb phase after trauma, major operations, etc.), exaggerated amounts of nutritional intake can aggravate tissue injury and must be avoided. In contrast, certain amino acids may be renoprotective. Glycine and, to a lesser degree, alanine have been shown to limit tubular injury in ischemic and nephrotoxic experimental models of ARF. Arginine (possibly by producing nitric oxide) also is reported to preserve renal function (but may also accentuate tubular injury) in experimental models of ARF.⁵⁰ In a nephrotoxic model, protein-rich nutrition was shown to limit tubular injury.⁵¹ Clinically, high amino acid intake was shown to preserve water balance while increasing diuresis and reducing the need for diuretic therapy in patients with nonoliguric ARF.⁵²

Various other endocrine-metabolic interventions (e.g., thyroxine, human growth hormone, epidermal growth factor, insulin-like growth factor I) can accelerate regeneration in experimental ARF. In the rat, insulin-like growth factor I accelerates recovery from ischemic ARF and improves nitrogen balance. Unfortunately, these approaches have not been effective in clinical studies of ARF patients (see previously). Nevertheless, a prominent goal in studies of ARF is to stimu-

late renal regeneration by several mechanisms, including growth factors, stem cells, and erythropoietin.

PATIENT CLASSIFICATION

Ideally, a nutritional program should be designed for each ARF patient because these patients are extremely heterogeneous. In practice, it is advisable to distinguish at least three levels of dietary requirements according to the severity of disease and the extent of protein catabolism associated with the underlying disease (Table 8-1). The first group includes patients without excess catabolism; they will have a urea appearance rate of less than 5 g of nitrogen more than nitrogen intake. ARF is usually caused by nephrotoxins (e.g., aminoglycosides, contrast media, mismatched blood transfusions). In most cases, these patients can be fed orally, and the prognosis for recovery of renal function and for survival is excellent. A second group includes patients with moderate hypercatabolism as signified by a urea appearance rate exceeding nitrogen intake by 5 to 10 g of nitrogen per day. These patients frequently suffer from complicating infections, peritonitis, or moderate traumatic injuries associated with ARF. Nutritional support and dialysis are often required. In the third category of patients, ARF occurs in association with severe trauma, burns, or overwhelming sepsis. Urea appearance is markedly elevated (>10 g/day above nitrogen intake). Treatment strategies are complex and include enteral/parenteral nutrition, hemodialysis, and blood pressure or ventilatory support (see Table 8-1). Insulin is often required to maintain blood glucose concentrations within acceptable levels. Dialysis/continuous hemofiltration is recommended as necessary to maintain fluid balance and a blood urea nitrogen less than 80 mg/dL. The mortality rate in this group exceeds 60% to 80%, and in addition to the severity of the underlying illness, ARF is a major independent contributor to poor prognosis.^{2,53}

NUTRIENT ADMINISTRATION

Important questions are which patients require nutritional support and when should it be initiated? Both decisions are influenced by the nutritional state of the patient as well as the type and degree of hypercatabolism associated with the underlying illness. During the acute phase of ARF (i.e., within the first 24 hours after trauma, surgery, etc.), nutritional support should be avoided because infusion of large quantities of amino acids or glucose during this ebb phase will increase oxygen requirements and aggravate tubular injury and the degree of renal function loss. If the nutritional status of the patient is normal (e.g., based on plasma protein concentrations, anthropometric measurements, and, most importantly, clinical judgment) and if the patient will resume a normal diet within 5 days, no specific nutritional support is necessary. However, if there is evidence of lost protein and energy stores, nutritional therapy should be initiated regardless of whether the patient is likely to eat within 5 days.

For all patients, some estimate of the type and severity of complicating diseases should be made. For patients with evidence of protein catabolism (see Table 8-1, groups 2 and 3), nutritional support should be instituted early and dialysis used to keep the blood urea nitrogen less than 80 mg/dL. Since metabolic

Table 8-1 Patient Classification and Nutrient Requirements in Patients with Acute Renal Failure

	EXTENT OF CATABOLISM		
	Mild	Moderate	Severe
Excess urea appearance (above N intake)	<5g	5–10 g	>10 g
Examples of clinical settings	Drug toxicity	Elective surgery ± infection	Severe injury or sepsis
Mortality	20%	60%	60%–80%
Dialysis/hemofiltration frequency	Rare	As needed	Frequent
Route of nutrient administration	Oral	Enteral and/or parenteral	Enteral and/or parenteral
Energy recommendations (kcal/kg BW/day)	20–25	20–30	25–30 (35)
Energy substrates: Glucose/fat (g/kg BW/day)	Glucose 3.0–5.0	Glucose + fat (3.0–5.0 glucose, 0.5–1.0 fat)	Glucose + fat (3.0–5.0 glucose, 0.8–1.2 fat)
Amino acids/protein (g/kg/day)	0.6–1.0 EAA (+ NEAA)	1.0–1.4 EAA + NEAA	1.2–1.5 (1.7) EAA + NEAA
Nutrients used			
Oral/enteral	Food	Enteral formulas	Enteral formulas
Parenteral		EAA + specific NEAAs (general or “nephro” solutions) Glucose 50%–70% + fat emulsions 10% or 20% Glucose 50%–70% Multivitamin and multitrace element preparations*	

*Consider increased micronutrient requirements
BW, body weight; EAAs, essential amino acids; NEAAs, nonessential amino acids.

abnormalities associated with ARF generally occur when creatinine clearance decreases to less than 50 mL/min, nutritional regimens should be designed to counteract specific metabolic abnormalities if renal function is below this threshold. Therapeutic attention must focus on methods that provide an optimal nutritional regimen to prevent both the loss of lean body mass and hospital-acquired malnutrition and to stimulate immunocompetence while supporting patients to survive the acute illness. Nutritional support should be started early and must be both quantitatively and qualitatively sufficient (Fig. 8-1).

Oral Feedings

Oral feedings should be encouraged in all patients who can tolerate them. This is required because of the beneficial effects of food on the function of the intestine (see later). Initially, 40 g/day of high-quality protein (e.g., egg protein) should be given to provide a daily protein requirement of approximately 0.6 g/kg BW/day. Protein intake should be increased to 0.8 to 1.0 g protein/kg BW/day if the BUN is maintained at less than 100 mg/dL, but patients treated by hemodialysis will require a protein intake of 1 to 1.2 g/kg BW/day, whereas those treated by peritoneal dialysis will need 1.4 g/kg BW/day of protein to counteract losses of both amino acids and protein during peritoneal dialysis. Because water-soluble vitamins in such diets might be insufficient, a supplement is recommended.

Enteral Nutrition

Whenever possible, enteral feeding, providing at least a portion of nutritional needs, should be performed.^{4,47} Even small amounts of nutrients serve to maintain normal intestinal structure and function and limit bacterial translocation from the gut. Enteral feeding also may help prevent the development of infections. It also may exert beneficial effect on kidney function; in experimental ARF, enteral compared with parenteral nutrient administration was found to improve renal function.⁵⁴ In two clinical studies, enteral nutrition was a factor associated with an improved prognosis in ARF patients.^{22,53} Despite the fact that this practice is used in most critical care units, there are few systematic studies on enteral nutrition in ARF patients.⁴⁸

Enteral diets are given through a small (8–10 French) soft feeding tube positioned with the tip in the stomach or jejunum, and nutrients are administered by pump either intermittently or continuously. The gastric contents should be aspirated every 2 to 3 hours until adequate gastric emptying and intestinal peristalsis are established. This will prevent vomiting and bronchopulmonary aspiration and is required because ARF is associated with a profound impairment of gastric and intestinal motility. Enteral nutrition should be started slowly, and the infusion gradually increased over several days until nutritional requirements are satisfied. Potentially treatable side effects include nausea, vomiting, diarrhea, abdominal distention, and cramping.

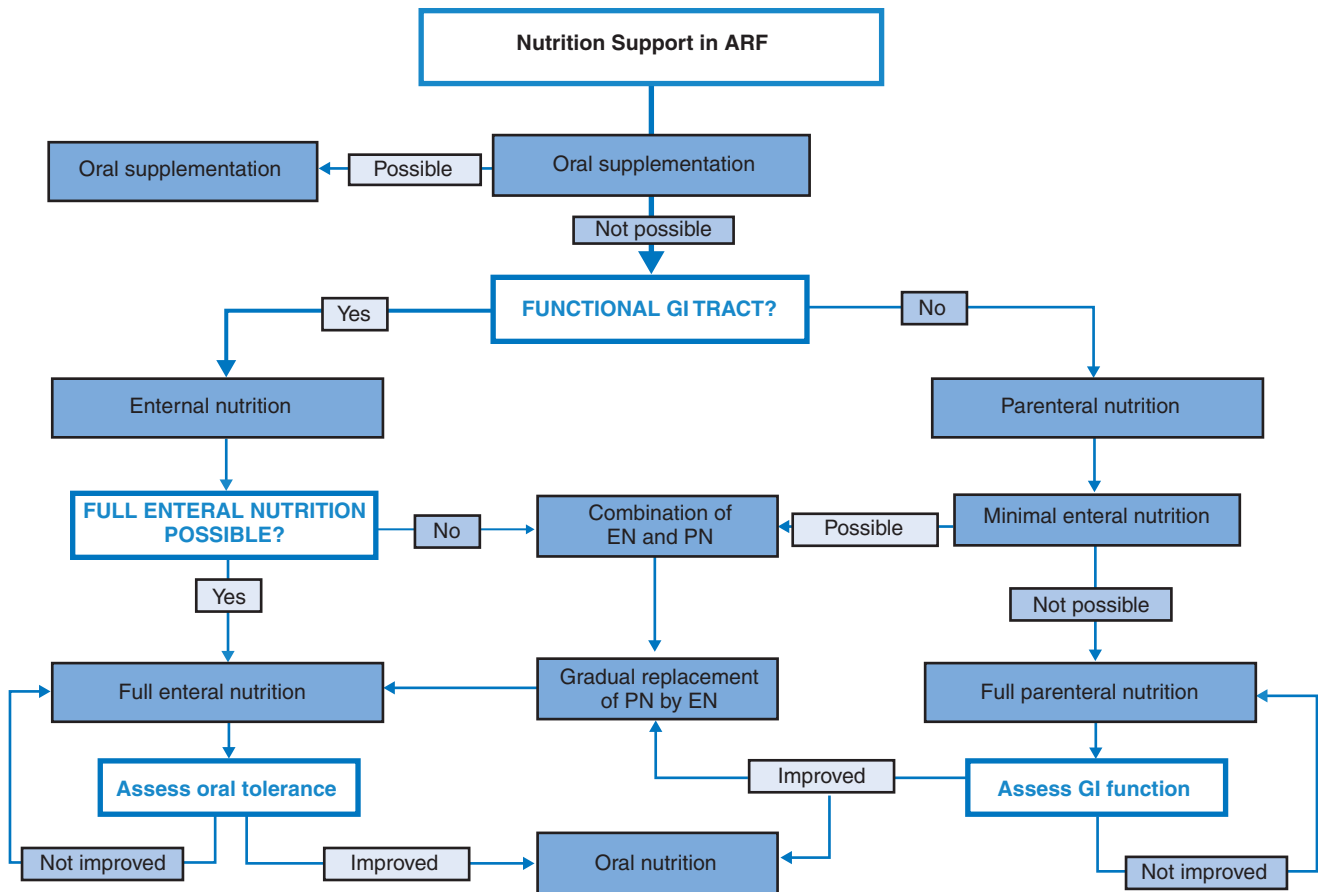

Figure 8-1 Flow chart for nutritional support in patients with acute renal failure (ARF). EN, enteral nutrition; GI, gastrointestinal; PN, parenteral nutrition. (Adapted from Druml W, Jadrna K, for the AKE. Recommendations for enteral and parenteral nutrition in the adult. Vienna: Austrian Society for Clinical Nutrition, 2008, p 14).

Enteral Feeding Formulas

No commercially available enteral diets have been specifically developed for patients with ARF. The use of conventional tube feeding formulas designed for subjects with normal renal function can be limited by the fixed composition of nutrients and high content of protein and electrolytes (especially potassium and phosphates). Specialized ready-to-use liquid diets developed for CKD patients or for hemodialysis patients can be used for ARF patients. In those patients who do not require extracorporeal therapy, preparations with a reduced protein content (high-quality proteins provided in part as oligopeptides or free amino acids) but with a restricted electrolyte concentration can be given. For catabolic ARF patients, preparations with a moderate protein content and a reduced electrolyte content present the optimal diet currently. Whether enteral diets containing specific nutrients such as glutamine, arginine, ω -3 fatty acids, and nucleotides (immunonutrition) will exert advantages in patients with ARF remains to be shown.

Parenteral Nutrition

Parenteral nutrition should not be viewed as alternative but rather complementary nutritional support because many ARF patients are not able to meet their nutritional requirements by enteral infusions alone. Moreover, ARF frequently occurs in

patients with gastrointestinal dysfunction (e.g., pancreatitis) or in hypercatabolic patients with multiple organ dysfunction; thus, a total or supplementary parenteral nutrient supply may become necessary.⁵⁵

Substrates for Parenteral Nutrition in Acute Renal Failure

Amino Acid Solutions

Amino acid solutions containing exclusively essential amino acids should no longer be used. There is controversy whether parenteral nutrition for ARF patients should consist of general amino acid solutions containing essential amino acids plus nonessential amino acids in standard proportions or should be limited to nephro solutions that contain essential amino acids in modified proportions and specific nonessential amino acids that might be conditionally essential. For example, tyrosine is regarded as a conditionally essential amino acid in ARF patients, but tyrosine has a low water-solubility index. Consequently, tyrosine is supplied as tyrosine dipeptides such as glycyl tyrosine in modern nephro solutions because the conjugates increase tyrosine solubility. Glutamine has been termed a conditionally essential amino acid in catabolic illness because it may exert beneficial effects on renal function and can improve survival in critically ill patients. These benefits were

found to be most pronounced in ARF patients (4 of 24 survivors without, 14 of 23 with glutamine, $P < .02$).⁵⁶ Since free glutamine is not stable in aqueous solutions, glutamine-containing dipeptides can be given as a glutamine source for parenteral nutrition. Despite considerable investigation, there is no persuasive evidence that mixtures enriched with branched-chain amino acids exert significant blunting of protein catabolism and loss of muscle mass.

Energy Substrates: Carbohydrates

Glucose is the main energy substrate in total parenteral nutrition. However, when glucose intake is increased to more than 3 to 5 g/kg BW/day, the extra glucose is not oxidized but instead increases lipogenesis.⁵⁷ This is undesirable because it induces fatty infiltration of the liver and excessive carbon dioxide production, yielding hypercarbia. The amount of glucose that can be infused is also often limited by impaired glucose utilization, a complication of ARF. In this case, insulin is needed to maintain normoglycemia. Consequently, energy requirements cannot be met by glucose alone unless excessive amounts of insulin are infused; thus, a portion of the energy requirement should be covered by lipid emulsions. The most suitable means of providing energy substrates to critically ill patients is not with glucose or lipids, but with glucose plus lipids. Other carbohydrates including fructose, sorbitol, and xylitol are available in some countries (but not in the United States). They should not be used in patients with ARF because they exert adverse metabolic effects.

Fat Emulsions

The advantages of intravenous lipids include their high energy content per gram of lipids and low osmolality, being a source of essential fatty acids, and having a low frequency of hepatic side effects compared with glucose (i.e., less fatty infiltration of the liver and hyperbilirubinemia) and less carbon dioxide production (especially important for patients with compromised respiratory function). Altered lipid metabolism caused by ARF should not prevent lipid emulsion use; the amount infused should be adjusted to the patient's

capacity to use lipids. Usually, 1 g of fat/kg BW/day will not increase plasma triglycerides substantially, so approximately 20% to 30% of energy requirements can be met by lipid infusion. Lipid emulsions are not hyperosmolar and can be infused into a peripheral vein.

Conventional lipid emulsions contain large amounts of triglycerides with polyunsaturated fatty acids (mainly from soy oil). Because of the potential generation of proinflammatory and vasoconstrictor eicosanoids from polyunsaturated fatty acids, these lipid preparations are increasingly exchanged for emulsions in which soy oil is replaced by coconut oil (containing medium triglycerides) and/or olive oil or fish oil (containing ω -3-fatty acids). For critically ill patients, these novel formulas have been associated with a mitigation of the inflammatory state, a reduction in the length of hospital stay, and potentially an improved prognosis.^{58,59} This is speculative because systematic investigations of these newer emulsions in patients with ARF are not available. For medium triglyceride-containing emulsions, metabolic advantages include a faster elimination from plasma, complete carnitine-independent metabolism, and a triglyceride-lowering effect. Unfortunately, the defect in lipolysis characteristic of ARF cannot be circumvented by using medium triglycerides.³¹ Lipids should not be administered in the presence of hyperlipidemia (e.g., plasma triglycerides > 350 mg/dL) or when there is activated intravascular coagulation, acidosis ($\text{pH} < 7.25$), or impaired macro-/microcirculation.

Parenteral Solutions

Standard solutions are composed of amino acids, glucose, and lipids with vitamins, trace elements, and electrolytes added as required (see Table 8-2). Recently, all-in-one solutions (in three-chamber bags) in which all nutrients are present have proven efficacious and gained wider acceptance. If hyperglycemia is present, insulin can be added or administered separately. To ensure optimal nutrient utilization and to avoid creating metabolic derangements (such as hyperglycemia, hypertriglyceridemia, an excessive increase in the blood urea nitrogen, and a mineral unbalance), the infusion should be started at a low

Table 8-2 Parenteral Nutrition in Acute Renal Failure: Renal Failure Fluid (All-in-One Solution)*

Component	Quantity	Remarks
Glucose 30%–70%	500 mL	In the presence of severe insulin resistance, use glucose 30%
Fat emulsion 10%–20%	500 mL	Start with 10%, switch to 20% if triglycerides are < 350 mg/dL
Amino acids 6.5%–10%	500 mL	General or special nephro amino acid solutions including EAAs and NEAAs
Water-soluble vitamins [†]	2 × RDA	Limit vitamin C intake to < 250 mg/day
Fat-soluble vitamins [†]	RDA	Increased requirements of vitamin E
Trace elements [†]	RDA	Plus selenium 100–300 μg /day
Electrolytes	As required	Caution: hypophosphatemia or hypokalemia after initiation of TPN
Insulin	As required	Added directly to the solution or given separately

*"All-in-one solution" with all components contained in a single bag, infusion rate initially 50% of requirements, to be increased over a period of 3 days to satisfy requirements

[†]Combination products containing the recommended daily allowances (RDA)

EAAs, essential amino acids; NEAAs, nonessential amino acids; TPN, total parenteral nutrition.

Table 8-3 A Minimal Suggested Schedule for Monitoring of Nutritional Support

Variables	PATIENT METABOLICALLY	
	Unstable	Stable
Blood glucose, potassium	4–6 times/day	Daily
Osmolality	Daily	Once weekly
Electrolytes (sodium, chloride)	Daily	Three times per week
Calcium, phosphate, magnesium	Daily	Three times per week
BUN/BUN increase/day	Daily	Daily
UNA	Daily	Once weekly
Triglycerides	Daily	Twice weekly
Blood gas analysis/pH	Daily	Once weekly
Ammonia	Twice weekly	Once weekly
Transaminases + bilirubin	Twice weekly	Once weekly

BUN, blood urea nitrogen; UNA, urea nitrogen appearance rate.

rate (providing approximately 50% of requirements) and gradually increased over several days. Optimally, the solution should be infused continuously over 24 hours to avoid marked changes in substrate concentrations and to achieve maximal utilization for anabolism. Because fluids are restricted in ARF patients, the parenteral nutrition solutions are hyperosmolar and hence must be infused through a central venous catheter to avoid damage to peripheral veins. The use of special venous catheters both as infusion ports and for temporary dialysis access is possible, but they carry a significant risk of infection.

COMPLICATIONS AND MONITORING OF NUTRITIONAL SUPPORT

Complications and side effects of nutritional support in ARF patients do not differ fundamentally from those observed in other patient groups. Hypervolemia and electrolyte imbalances, however, can develop rapidly, and altered utilization of several nutrients make it unwise to give an exaggerated intake of protein or glucose (see previously). If an excess is given, metabolic derangements and waste product accumulation will occur. Most complications of nutritional support are related to an excess intake of substrates (e.g., hyperglycemia, hypertriglyceridemia, hyperkalemia, an accelerated increase in BUN or in carbon dioxide production). More rare is the development of deficiencies (e.g., minerals, vitamins, essential fatty acids). Thus, nutritional therapy in ARF patients requires more frequent monitoring than in other patient groups (Table 8-3).

SUMMARY

Acute loss of renal function causes complex metabolic abnormalities affecting not only water, electrolyte, and acid-base balance but also amino acid, carbohydrate, and lipid metabolism. Moreover, the critically ill ARF patient presents a hypercatabolic, proinflammatory, and pro-oxidative state. The excess attribut-

able mortality of ARF is tightly interrelated with the systemic immunologic and metabolic consequences of ARF, factors that are aggravated by malnutrition. Knowledge about the pathophysiology of these metabolic changes, understanding the metabolic side effects of renal replacement therapies, and improved definitions of nutritional requirements plus advancements in nutritional techniques have improved the success of nutritional therapy in ARF. Dietary restrictions based on the principles of treating CKD patients have been largely abandoned in favor of an approach that is directed at meeting nutrient requirements. There is no longer doubt that enteral nutrition is the preferred route of meeting nutritional requirements in ARF patients. Even small amounts of food can help support intestinal functions (and potentially improve renal function). Nevertheless, many ARF patients have severe limitations to enteral nutrition and require supplementary or even total parenteral nutrition.

Unfortunately, nutritional support has not convincingly reduced the morbidity and mortality associated with ARF. We believe that future advances in nutritional therapy will not be based on a quantitative approach to provide nitrogen and energy requirements. Instead, the developments will move toward a more qualitative type of metabolic support taking advantage of specific pharmacologic effects of nutrients.

EXPERIMENTAL APPROACHES FOR EARLY DIAGNOSIS OF ACUTE KIDNEY INJURY 95

EXPERIMENTAL STRATEGIES FOR PREVENTION OR TREATMENT OF ACUTE KIDNEY INJURY 95

The high incidence and lack of specific early diagnostic tools and effective therapeutic approaches to acute kidney injury (AKI)/acute renal failure underlie the importance of exploration of novel experimental strategies to make advances in the care of patients with this syndrome. This overview is divided into four sections. The first section reviews experimental models of AKI. The second section discusses general advances in the pathophysiology of AKI using current experiment models. The third focuses on novel diagnostics and the fourth on experimental therapeutics that are promising for clinical translation. Owing to space limitations, we have had to be selective and focus on recent advances. For more in-depth review, we refer the reader to previous editions of this chapter as well as to the updated comprehensive AKI chapter in the parent textbook.¹⁻³

EXPERIMENTAL MODELS OF ACUTE KIDNEY INJURY

Experimental models of AKI can be divided into two categories: in vivo and in vitro. Studies can be further subdivided according to how AKI is simulated: ischemia-reperfusion injury (IRI), sepsis, or nephrotoxic agents.

In Vivo

A large number of studies of AKI have been conducted in rodents, especially rats. More recently, because of the opportunity to apply genetic approaches to change the expression of proteins in mice, this species has increased in popularity as a model. IRI models have been established in mice.⁴ Mice can be genetically engineered with specific deficiencies in cytokines, surface markers, or certain cell populations. When dealing with mice, however, it is important to recognize that different background strains have strain-specific responses to

AKI, highlighting the importance of using appropriate strain controls.⁵ Age and sex of the animal used also have to be considered because the susceptibility to AKI can vary according to age or sex.⁶ Female mice are known to be resistant to IRI-induced AKI but more sensitive to cisplatin-induced AKI.⁷ The weaknesses of rodent models include unique physiology, size difference from humans, and key immunologic differences that limit applicability to humans. Large mammals such as dogs,^{8,9} pigs, and sheep¹⁰ have been used, but less commonly than rodents. The pig kidney has many similarities to the human kidney, both anatomically and physiologically,¹¹ and may be well suited to simulate the hemodynamic changes encountered during AKI. However, the high costs involved in developing and maintaining large mammalian models and also ethical issues have limited their use. A few newer animal models, such as zebrafish¹² for nephrotoxic drug-induced AKI or *Caenorhabditis elegans*¹³⁻¹⁵ for understanding cellular response to hypoxia are promising. Hentschel and Bonventre¹⁶ recently reviewed novel nonrodent models of AKI.

IRI-induced AKI models are widely used to simulate both native kidney and transplant injury. In mice, IRI is usually performed using microvascular clamps on renal pedicles, occluding the artery and vein while sparing the ureter. Clamping the renal artery alone followed by reperfusion is more often used in larger animals. Unilateral renal pedicle clamp followed by contralateral nephrectomy is also widely used as a variant of this model to study IRI-induced AKI to simulate transplant injury more closely. Strict attention to temperature during ischemia and surgical technique are required for reproducibility in the clamp model. A major limitation is that most patients with native kidney AKI do not undergo IRI in the same manner; the period of ischemia is usually not accompanied by abdominal surgery, and it is usually in the context of whole-body ischemia. Sepsis-induced AKI models are usually induced by administration

of lipopolysaccharide or cecal ligation and puncture (CLP). Although the CLP model may be closer to the clinical situation, some laboratories have had difficulty achieving a reliable and reproducible increase in serum creatinine with this model. Star and colleagues¹⁷ recently refined this model in aged mice and found that ethyl pyruvate inhibited renal and multiple organ damage, even when the ethyl pyruvate was administered 12 hours after CLP. Key to this model was employing a fluid resuscitation and antibiotic strategy after CLP. The model results in a two- to threefold increase in serum creatinine concentration, which is less than the increases frequently seen in patients with sepsis, but it does embody many components of similarity to the multiorgan disease state of patients with sepsis and AKI. The same group subsequently reported a CLP model in aged rats,¹⁸ demonstrating that this rat model has more inconsistency with development of AKI, defined as a doubling of serum creatinine. The heterogeneity of response was taken advantage of by the authors as they performed proteomic analysis on collected urine from rats that developed AKI and compared patterns with those obtained on urine from rats that did not develop AKI.

Many nephrotoxics pertinent to human disease can be reproduced in rodent models. Cisplatin, a common chemotherapeutic agent, has many pathophysiologic features that overlap with IRI. Other nephrotoxics such as gentamicin have been studied for many years, whereas recently much more attention is being devoted to environmental nephrotoxics such as cadmium.¹⁹ Dosing with various nephrotoxics in animals may differ considerably from what it takes to produce toxicity in humans. Although some models exist for radiocontrast nephropathy, these models are generally multicomponent and difficult to reliably reproduce as well as difficult to translate from one species to another.²⁰ Thus, given its importance to human exposure, this represents an important opportunity to develop more clinically oriented disease models *in vivo*. The recently recognized strong association between gadolinium and nephrogenic systemic fibrosis during CKD and during AKI represents a new opportunity for development of models to study gadolinium effects during AKI.

In Vitro

Most *in vitro* studies of AKI have been performed with cell culture methods. Hypoxic chambers or chemical anoxia are commonly used. Strengths of *in vitro* approaches are the ability to tightly control the environment and evaluate the specific cellular response. However, *in vitro* conditions are quite different from *in vivo* conditions, and single cells in isolation do not represent the true complex milieu in which a kidney cell population responds to injury and repair. Use of immortalized cells in culture, which increases the ease of obtaining cells, further distances the cell of study from the human kidney. It is important to recognize that cells placed in culture change their metabolic characteristics quite dramatically; to the extent that metabolism is linked to function, many functional characteristics would also be expected to change. There are, however, situations in which *in vitro* approaches nicely complement *in vivo* ones, because the mechanism at the cellular level can often be dissected more effectively *in vitro*. As an example, cell culture methods have been very useful in reveal-

ing the molecular mechanisms of apoptosis or regeneration of tubular epithelial cells.

ADVANCES IN PATHOPHYSIOLOGY OF ACUTE KIDNEY INJURY

In AKI models, there have been at least six main pathophysiologic themes: (1) imbalance between vasoconstrictive and vasodilatory factors, (2) inflammation, (3) tubular dysfunction and intratubular obstruction, (4) cell death by necrosis or apoptosis, (5) preconditioning, and (6) organ cross talk.

Imbalance between Vasoconstrictive and Vasodilatory Influences

Although total renal blood flow reaches 25% of cardiac output, the majority of that flow is directed to the renal cortex²¹ and the distribution of renal blood flow may be abnormal after ischemia even though total renal blood flow after ischemia may be close to normal.²² The outer medulla is hypoxic under normal conditions and is particularly sensitive to further decrements in blood flow.²³ There have been a number of studies exploring the balance between renal vasoconstrictive and vasodilatory influences in AKI and many therapeutic attempts to increase renal blood flow and ameliorate abnormal redistribution. Nitric oxide, endothelin, atrial natriuretic peptide, angiotensin II, dopamine, eicosanoids, and platelet-activating factors are candidate mediators of the intrarenal balance between vasoconstriction and vasodilation in postischemic kidneys.¹ Recently, renal endothelial dysfunction and impaired autoregulation during AKI from excess nitric oxide were reported.²⁴ Although atrial natriuretic peptide, dopamine, calcium channel blockers, and eicosanoid products of phospholipase A₂ enzymes, including prostaglandins, have been reported to be implicated in the pathophysiology of AKI, there is no convincing evidence of protective effects in humans.²

Inflammation

Inflammation is thought to be of greatest importance for AKI at the level of the microvasculature. The flow of leukocytes through capillaries and small venules can be adversely affected by cell-cell interactions, such as platelet plugging, or blood cell-endothelium interactions resulting in leukocyte adhesion and transmigration through the endothelial layer. The important role of leukocyte-endothelium adhesion molecules, particularly CD11/CD18, intercellular adhesion molecule (ICAM)-1, E-selectin, P-selectin, and tissue-type plasminogen activator in IRI-induced AKI, has already been demonstrated.^{4,25-30} However, clinical trials with a CD11a/CD18 or ICAM-1 monoclonal antibody did not demonstrate any protective effect.^{31,32} Several studies have elucidated significant pathophysiologic roles for T cells during the initiation phase of IRI-induced AKI.³³⁻³⁷ A "hit-and-run" hypothesis regarding T cells was proposed to explain that few T cells were detected in the kidneys during the insult phase of IRI-induced AKI.³⁸ Isolation and assessing phenotypes of lymphocytes from the postischemic kidneys³⁶ and confirmation of the existence of T cells in the kidneys within 1 hour of IRI³⁹ directly support the "hit-and-run" hypothesis. It was

demonstrated that the CD4⁺ T cells have an important pathophysiologic role in IRI-induced AKI,³⁴ that CD4 cells of the Th1 phenotype are pathogenic, and that the Th2 phenotype can be protective.⁴⁰ The role of T cells, however, is more complex than initially expected. Although T-cell depletion with thymectomy followed by T cell-depleting antibody administration improved the course of experimental IRI,⁴¹ mice deficient in both T and B cells were not protected from IRI.⁴² The role of T-cell receptor in IRI is another important question to be solved. The T-cell receptor appears to play a role in the full injury response to IRI, although alloantigen-independent activation in IRI could also participate.³⁶ The role of B cells in AKI has had limited study, but there may be a role for these cells.⁴³ Natural killer T (NKT) cells are another lymphocyte population that can respond to nonprotein antigens and have been implicated in experimental AKI.⁴⁴ Macrophages are well established to migrate to the kidney during AKI and likely play an important role in the cellular inflammatory cascade.⁴⁵ Interleukin-1-dependent inflammatory cascades⁴⁶ and alternative complement pathway⁴⁷ were also implicated to have some role in pathogenesis of IRI.

The severity of tubular damage in the outer medulla could increase with increasing distance from vascular bundles, which is also consistent with the important role of local oxygen gradients.^{48,49} In experimental AKI models in which vascular changes are induced by inactivation of prostaglandin and nitric oxide synthesis in the setting of contrast medium administration, medullary thick ascending limb of the loop of Henle oxygen consumption appears to correlate with tubular damage since furosemide, which inhibits NKCC2 in the medullary thick ascending limb of the loop of Henle, confers structural and functional protection.⁵⁰

Tubular Cell Dysfunction and Intratubular Obstruction

Coexistence of renal tubular dysfunction and down-regulation of tubular sodium transporters, especially NHE3, Na⁺/K⁺-ATPase, and NKCC2 after IRI, has been reported.⁵¹⁻⁵⁴ More recently, NHE activation, followed by renal endothelin-1 overproduction, seems to play an important role in the pathogenesis of IRI-induced AKI, as demonstrated by administering pre- and post-treatment of 5-*N*-ethyl-*N*-isopropyl amiloride in mice IRI model.⁵⁵ Renal tubular dysfunction in sepsis-associated AKI is associated with a marked down-regulation of ROMK, NKCC2, ENaC, Na⁺/K⁺-ATPase, and NHE3, with attenuation of these effects by glucocorticoid treatment.⁵⁶ Peritubular capillary dysfunction and renal tubular epithelial cell stress were also found after lipopolysaccharide administration in mice using intravital video microscopy.⁵⁷ Reactive nitrogen species were implicated as an important mediator in sepsis-induced peritubular dysfunction.⁵⁸ Protein C may play a role in sepsis-associated AKI: a rapid decrease in protein C after sepsis was reported with an increase in blood urea nitrogen and expression of known markers of renal injury, including neutrophil gelatinase-associated lipocalin, CXCL1, and CXCL2 in a CLP model of sepsis.⁵⁹ In experimental settings mimicking hyperdynamic sepsis, a marked increase in renal blood flow with severe renal vasodilatation was observed in a sheep model.¹⁰ Caspase-1,⁶⁰⁻⁶² Toll-like receptor 4,⁶³ myeloid differentiation factor 88,⁶⁴ heme oxygenase-1,⁶⁵ thromboxane

receptor,⁶⁶ and T-cell modulation of neutrophils via the CD28 pathway⁶⁷ have been implicated in the pathogenesis of sepsis-induced AKI.

Cell Necrosis and Apoptosis

Proteins such as prostate apoptosis response-4,⁶⁸ a leucine zipper protein linked to apoptotic cell death in prostate cancer and neuronal tissues, and calpain,⁶⁹ an intracellular Ca²⁺-dependent cysteine protease that is released in the extracellular milieu by tubular epithelial cells, were also recently proposed as novel and early mediators of renal tubule cell injury following IRI. Various mediators have been shown to be involved in cisplatin-induced AKI: T cells,⁷⁰ Fas and tumor necrosis factor (TNF) receptor 1,⁷¹ TNF receptor 2,⁷² caspase-1,⁷³ p53,⁷⁴ and p21,⁷⁵ a cell cycle-inhibitory protein. Prostaglandin E₂ has been implicated in mercury chloride-induced AKI,⁷⁶ caspases in glycerol-induced AKI,⁷⁷ and A₁ adenosine receptor in acute radiocontrast nephropathy.⁷⁸ Fas-associated death domain, an adaptor protein required for the transmission of the death signal from lethal receptors of the TNF superfamily, and TNF-like weak inducer of apoptosis (TWEAK), a member of the TNF superfamily, were found to play an important role in apoptosis of renal tubular cells in culture.^{79,80} Extracellular signal-regulated kinase can elicit apoptosis in epithelial cells by activating caspase-3 and inhibiting Akt pathways, leading to nuclear condensation through caspase-3 and histone H₂B phosphorylation in H₂O₂-induced renal proximal tubular cell apoptosis during IRI.⁸¹ Although Bid, a proapoptotic Bcl-2 family protein, was shown to be involved in the pathogenesis of ischemic injury,⁸² apoptosis-antagonizing transcription factor, a leucine zipper domain-containing protein, was reported to protect renal tubule cells against apoptosis induced by IRI.⁸³

Preconditioning

Over a number of years, it has been appreciated that the kidney can be preconditioned by previous toxin or ischemic exposure so that it is more resistant to subsequent toxins or ischemia.⁸⁴ The mechanisms of this protection are not completely understood. Inducible nitric oxide synthase is an important contributor but does not account for all the protection.⁸⁵ A complex pattern of hypoxia-inducible transcription factor activation appears to play an important role in tissue preservation in response to regional renal hypoxia,⁸⁶ and preconditioning activation of hypoxia-inducible transcription factor ameliorates ischemic injury.⁸⁷ A recent study demonstrated that activation of heat shock protein-70 by heat preconditioning also attenuated ischemic renal injury via inhibition of NF-κB-mediated inflammation.⁸⁸

Organ Cross Talk

Given that many patients die during AKI of distant organ effects, a new area of investigation has been the mechanisms of distant organ effects of AKI. A major inflammatory and proapoptotic response occurs in the lung, heart, and brain during AKI.⁸⁹⁻⁹¹ An increase in lung vascular permeability occurs during AKI, more severe than the change associated with the same increase in serum creatinine caused by an acute removal of kidneys, implicating reperfusion products in addition to

uremia as the cause. The time after AKI can have an important influence on the type of extrarenal response because lung responses can be proinjurious or protective.⁸⁹ It is also important to recognize that pathophysiologic processes in distant organs can also influence kidney function.⁹² Further specific pathophysiologic targets for therapy are discussed later in the section on future preventive and therapeutic strategies.

EXPERIMENTAL APPROACHES FOR EARLY DIAGNOSIS OF ACUTE KIDNEY INJURY

The increase in serum creatinine or decrease in urine output is not sensitive enough to reveal early injury events in the kidney. There is an important need for novel biomarkers of AKI, much like serum troponin can be used to detect early acute myocardial injury. Many novel biomarkers such as urinary Toll-like receptor 4,⁹³ malondialdehyde,⁹⁴ keratinocyte-derived chemokine,⁹⁵ neutrophil gelatinase-associated lipocalin,⁹⁶ spermidine/spermine (N_1 -acetyltransferase),⁹⁷ and kidney injury molecule-1,⁹⁸ a type 1 membrane protein with extracellular immunoglobulin and mucin domains, can increase well before an increase in serum creatinine occurs in AKI models (Box 9-1). The cyclin-dependent kinase inhibitor p21, a kind of stress-induced gene, and mouse telomerase reverse transcriptase could serve as a novel marker for estimating the ischemic period.⁹⁹ However, the jury is still out on the best approach to use one or several urinary or serum tests in diagnosing or classifying AKI.¹⁰⁰ This topic is covered in much greater detail in a review.¹⁰¹

Newer technologies have been embraced to detect novel biomarkers: proteomics using special techniques such as difference in-gel electrophoresis¹⁸ and 1H-nuclear magnetic resonance spectroscopy.¹⁰² Novel imaging approaches are also promising for the detection and staging of AKI. A new radiometric measurement technique has been developed based on

Box 9-1 Some Novel Biomarkers and Imaging Techniques That Deserve Increased Evaluation for Early Diagnosis of Acute Kidney Injury

Novel Biomarkers

Urine

- Kidney injury molecule-1
- Neutrophil gelatinase-associated lipocalin
- Toll-like receptor 4
- Malondialdehyde
- Keratinocyte-derived chemokine (Gro- α)
- Cytokines and chemokines
- Urine epigenetics/DNA methylation

Gene

- Cyclin-dependent kinase inhibitor p21
- Spermidine/spermine (N_1 -acetyltransferase)
- Mouse telomerase reverse transcriptase

Novel Imaging Techniques

- Ultrasound superparamagnetic iron oxide-enhanced MRI
- MRI with dendrimer-based contrast
- ApoSense technique

MRI, magnetic resonance imaging.

intravital fluorescence microscopy that allows rapid evaluations of renal function in rodent models.¹⁰³ By using this technique, plasma clearance rates of a fluorescent glomerular filtration rate marker can be measured in less than 5 minutes following a bolus infusion of a fluorescent dye mixture into the bloodstream. Ultrasound superparamagnetic iron oxide-enhanced magnetic resonance imaging,¹⁰⁴ magnetic resonance imaging with dendrimer-based contrast,^{105,106} and ApoSense,¹⁰⁷ a family of small-molecule compounds capable of selectively targeting and accumulating within apoptotic/necrotic cells, have been proposed as imaging techniques for diagnosing early renal injury before azotemia develops.

EXPERIMENTAL STRATEGIES FOR PREVENTION OR TREATMENT OF ACUTE KIDNEY INJURY

The major experimental approach in this field involves the application of novel pharmacologic and cell-based therapy (Box 9-2). Another approach, although performed by limited groups but with great promise, is to use novel devices or innovative use of existing approaches, taking advantage of advances in bioengineering and tissue engineering.

Growth factors have shown great promise in experimental models, but a small study in humans with insulin-like growth factor I was not protective.¹⁰⁸ That does not exclude, however, the possibility for other growth factors to have therapeutic potential. There has been recent interest in applying agents that prevent lymphocyte infiltration into the kidney, such as the sphingosine-1-phosphate type 1 receptor agonists FTY720¹⁰⁹ and SEW2871,³⁹ which were successful in mice IRI models. Although FTY720 will likely not be used in human transplantation, similar agents with better side effect profiles have promise. Erythropoietin (EPO) and similar agents could have potential for human AKI. EPO has been shown to decrease mortality in experimental AKI¹¹⁰ and can also provide renoprotection at a

Box 9-2 Experimental Preventive or Therapeutic Agents for Acute Kidney Injury

- Stem cell therapy
- Renal tubule assist device or bioartificial kidneys

In IRI Models

- Sphingosine-1-phosphate type 1 receptor agonists
- Erythropoietin
- Trimetazidine
- Caspase inhibitors
- Selectin ligand inhibitors
- Antiapoptotic agents
- CD4⁺ T cells of the Th2 phenotype
- New molecules identified by subtraction/array/proteomic techniques

In Sepsis-induced AKI Models

- Activated protein C
- Levosimendan
- Ethyl pyruvate

AKI, acute kidney injury; IRI, ischemia-reperfusion injury.

high dose,¹¹¹ a low dose,¹¹² and after pretreatment with EPO.¹¹³ Endothelial cells are a potential target of the cytoprotective effects of EPO.^{114,115} However no significant change in renal outcome was observed in human studies in which EPO was administered to acutely ill patients.¹¹⁶ Darbepoetin, a clinically used variant of EPO, was reported to have a renoprotective effect in IRI-induced AKI.¹¹⁷

Using current immunosuppressive drugs for AKI has been limited to date by their nonimmune side effect profile. Cyclosporine or rapamycin were reported to aggravate damage in ischemic organs, negatively affecting posttransplantation recovery in a concentration-dependent fashion.¹¹⁸

Cyclosporine also delayed tubular regeneration after IRI. Rapamycin delayed but did not prevent renal recovery after AKI in rats undergoing renal artery occlusion likely due to acquired tubular cell resistance to rapamycin.¹¹⁹ By contrast, pretreatment with mycophenolate mofetil led to reduced IRI in rats by decreasing the expression of ICAM-1 and infiltration of macrophages and lymphocytes, and this is a relatively well-understood agent with an acceptable toxicity profile in humans.¹²⁰

Trimetazidine, an anti-ischemic metabolic agent that inhibits fatty acid metabolism, enhanced hypoxia-inducible transcription-1 α expression and reduced tubulointerstitial fibrosis in a pig IRI model.¹²¹ Other novel potential therapeutic agents include olprinone,¹²² L-carnosine,¹²³ inhibitory monoclonal antibody to mouse factor B¹²⁴ and CD55/CD59¹²⁵ for targeting complement system, fructose-1,6-diphosphate,¹²⁶ ghrelin,¹²⁷ peroxisome proliferator-activated receptor β/δ ,¹²⁸ geranylgeranylacetone,¹²⁹ the oxygen radical scavenger edaravone,¹³⁰ apotransferrin,¹³¹ nitric oxide precursor L-arginine,¹³² α_1 -acid glycoprotein,¹³³ and the tyrosine kinase inhibitor typhostin AG126.¹³⁴ For each of these agents, a rationale can be developed for why they might be effective.

Granulocyte colony-stimulating factor was reported to attenuate renal injury in IRI-induced AKI,^{135,136} cisplatin-induced AKI,¹³⁷ and folic acid-induced AKI,¹³⁸ but to worsen renal injury in another setting of IRI-induced AKI.¹³⁹ Activated protein C,¹⁴⁰ levosimendan,¹⁴¹ and ethyl pyruvate¹⁷ hold promise for sepsis-induced AKI. Several conventional agents such as 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor,¹⁴²⁻¹⁴⁴ mineralocorticoid receptor blocker,^{145,146} minocycline,¹⁴⁷ docosahexaenoic acid (all cis 4,7,10,13,16,19 docosahexaenoic acid C22: n-3),¹⁴⁸ and magnesium supplementation combined with N-acetylcysteine¹⁴⁹ have had beneficial effects in animal models and are candidates to test in humans.

Fibrate,^{150,151} MEK inhibitor,¹⁵² peroxisome proliferator-activated receptor α ligand,¹⁵³ and antioxidants¹⁵⁴ can ameliorate renal injury in experimental cisplatin-induced AKI. Kallikrein/kinin was reported to have renoprotective effects by inhibiting inflammatory cell recruitment and apoptosis through suppression of oxidative stress-mediated signaling pathways in gentamicin-induced nephrotoxicity.¹⁵⁵

It is important to consider why many pharmacologic agents have demonstrated renoprotective effects or therapeutic potentials in animal models, but have failed in human clinical trials. Dose and timing of pharmacologic agents could be an important factor. In most animal studies, supraphysiologic doses, not tolerated by patients, were usually administered prior to or very early during the renal insult, whereas much smaller doses were administered, usually after established AKI, in clinical trials. The difference in physiologic and

immunologic characteristics and responses between humans and animals also has to be considered.

Stem-cell therapy is a novel and promising approach for mitigating tissue damage or hastening the healing process after AKI. Hematopoietic stem cells and mesenchymal stem cells were beneficial in experimental AKI, and the mode of actions was initially thought to be from directly repopulating and repairing renal tubules.^{135,156-158} However, more recent reports have proposed that the restoration of tubular epithelial cells relies on replication of intrinsic tubular cells more than exogenous cells.¹⁵⁹⁻¹⁶¹ Recent reports have demonstrated that mesenchymal stem cells ameliorated tissue damage after IRI in mice,¹⁶² and exogenous mesenchymal stem cells trafficked into the kidneys injured by glycerol.¹⁶³ It is very likely that paracrine mechanisms play a key role in the healing effect of exogenously administered stem cells. This topic has recently been reviewed much more extensively.¹⁶⁴

The bioartificial renal tubule assist device (RAD) was introduced as a therapeutic approach that combined cell therapy and hemodialysis or hemofiltration.¹⁶⁵ The RAD is a cartridge containing living renal proximal tubule cells isolated from deceased donor kidneys, grown in confluent monolayers along the inner surface of the hollow fibers in a conventional hemofiltration cartridge.^{166,167} The bioartificial kidney, consisting of a filtration device (a conventional high-flux hemofilter) followed in series by the RAD, showed promise in acutely uremic dogs after bilateral nephrectomies^{168,169} and also in septic shock models using dogs and pigs.^{170,171} Continuous bioartificial kidney therapy was recently tested on a porcine multiple organ dysfunction syndrome with AKI model, with measured decrements in serum TNF- α , increment of serum interleukin-10, and consequently prolonged survival.¹⁷² Although controlled trials with a small number of patients failed to demonstrate that the RAD could confer a survival advantage in sepsis-induced AKI, recent phase I/II clinical trials were promising.^{173,174}

In summary, there have been many advances in our understanding of AKI over the past few years. The current focus is to translate findings from the laboratory into improved diagnosis, prevention, and treatment for our patients. There is a great need and many candidates to evaluate more completely.

Chapter 10

Immunosuppressive Agents for the Therapy of Glomerular and Tubulointerstitial Disease

Alice Sue Appel and Gerald B. Appel

CHAPTER CONTENTS

OVERVIEW OF THE IMMUNE RESPONSE AND IMMUNOSUPPRESSIVES 105

IMMUNOSUPPRESSIVE AGENTS 106

Glucocorticoids 106

Azathioprine 106

ALKYLATING AGENTS 106

Cyclophosphamide 106

Chlorambucil 107

CALCINEURIN INHIBITORS 107

SIROLIMUS 107

MYCOPHENOLATE MOFETIL 108

RITUXIMAB 108

OTHER POTENTIAL IMMUNOSUPPRESSIVE AGENTS 108

Mizoribine 109

INTRAVENOUS IMMUNOGLOBULIN 109

OTHER MODULATORS OF THE IMMUNE RESPONSE 109

Many glomerular and a number of tubulointerstitial diseases are the result of immunologic processes that damage the kidney. A variety of immunosuppressive agents have been used in the treatment of these diseases and many more are currently undergoing study. Only a few of these agents have been studied in controlled, randomized trials in any parenchymal renal disease and virtually none of them are approved by the U.S. Food and Drug Administration for the treatment of glomerular diseases. Many medications have been adopted after proving effective as immunosuppressives in transplantation. Others have been studied in rheumatologic and other immunologic disorders. Most have been used in combinations with other drugs blocking the immune system, thus making the specific role of any one agent less clear. Since many are broad-spectrum blockers of the immune response, attributing efficacy in reducing proteinuria or prolonging renal survival to one specific blocking action in the immune cascade is often impossible. In this chapter, we present a brief overview of the mechanism of the immune responses and then discuss the current and potential future medications used for immunosuppressive therapy for glomerular and tubulointerstitial diseases.

OVERVIEW OF THE IMMUNE RESPONSE AND IMMUNOSUPPRESSIVES

Self-tolerance refers to a lack of immune responsiveness to the tissues of one's own body. Two main mechanisms explaining self-tolerance deal with central tolerance and peripheral tolerance.¹ Central tolerance is the process of the deletion of self-reactive lymphocytes (B and T cells) during their maturation process in bone marrow for the former and thymus for the latter. Peripheral tolerance is the process of backup tolerance in peripheral tissues to self-reactive T cells that have escaped deletion in the thymus.

Autoimmune disease is believed to result from the bypass of at least one of the mechanisms of self-tolerance, and the mechanism differs from disease to disease. Often there is an interaction among immunologic, genetic, and even microbial factors. Classically, the immune system has been divided into two classes: humoral, mediated by soluble antibody proteins, and cellular, mediated by lymphocytes. Immune complex-mediated glomerulonephritis is a classic humoral response, whereas alterations in T-cell function may underlie the pathogenetic defects in minimal change disease. However, in some glomerular diseases such as antineutrophilic cytoplasmic antibody (ANCA)-positive glomerulonephritis, there is evidence of involvement of both humoral and cell-mediated limbs of the immune system. This chapter deals with current and possibly future immunosuppressive treatments for glomerular disease in terms of their mechanisms, efficacy, and toxicities. Although much is known about the mechanisms of actions of many immunosuppressive drugs, it is clear that most have multiple effects in blockade of the immune response. Even monoclonal antibodies may have pleiotropic effects. Thus, understanding synergistic immunomodulation requires adequate study in animal models and in humans with glomerular disease.

Moreover, there is no immunosuppressive agent that does not have the potential to produce serious side effects. Some adverse reactions are relatively specific to a given drug such as hair growth and gum hyperplasia with cyclosporine or alopecia and hemorrhagic cystitis with cyclophosphamide. However, it is important to note that along with use of virtually all immunosuppressive agents there exists the potential for a marked increase in both infection and neoplasia. These factors must always be taken into account when one is treating with immunosuppressive agents. In treating any individual patient, the risks versus benefits of the immunosuppressives must be weighed.

IMMUNOSUPPRESSIVE AGENTS

Glucocorticoids

Glucocorticoids (e.g., prednisone, methylprednisolone) have been used for many decades as both immunosuppressive and anti-inflammatory agents. They suppress both cell-mediated immunity, by inhibiting genes that code for important cytokines including interleukins 1 through 6 and 8 and interferon- γ , and humoral immunity, by diminishing B-cell clonal expansion and antibody synthesis. At high doses, they also directly kill T and B cells, which could account for the powerful immunosuppressive effects of pulse steroids.

As long ago as the 1950s, they were used for the treatment of idiopathic nephrotic syndrome and lupus nephritis. Currently, they are commonly used in numerous glomerular diseases including minimal change disease, focal glomerulosclerosis, membranous nephropathy, lupus nephritis, and rapidly progressive glomerulonephritides, as well as in acute interstitial nephritis. They may be used alone or in conjunction with other immunosuppressants.²

Unfortunately, these agents are associated with many potential adverse effects, and close monitoring for side effects is crucial. Toxicities include an increased susceptibility to infection, impaired glucose metabolism, sodium retention and hypertension, accelerated bone loss with accompanying osteoporosis (which may be diminished by the use of calcium, vitamin D supplements, and bisphosphonates),³ cataracts, and cushingoid appearance and other cosmetic effects. The latter complication must be strongly considered when treating young people and others who are especially concerned about their appearance since these patients often discontinue the use of these drugs rather than tolerate the social consequences of cosmetic changes.

Azathioprine

Azathioprine has been used in humans as an immunosuppressant since the early 1960s. It is actually a prodrug, which is converted in the body to its active metabolite 6-mercaptopurine, which acts by inhibiting the formation of phosphoribosyl pyrophosphate, an intermediate in purine formation.

Azathioprine has been used to treat many immunologic glomerular diseases including lupus, IgA nephropathy, and vasculitis. It is the focus of many ongoing studies dealing with maintenance of remission in severe proliferative glomerulonephritides such as lupus nephritis and ANCA-positive disease.⁴

Acute myelosuppression with resulting leukopenia, megaloblastic anemia, and thrombocytopenia can be caused by azathioprine therapy due to the incorporation of azathioprine-derived 6-thioguanine nucleotides into DNA.⁵ The metabolite of azathioprine, 6-mercaptopurine, is deactivated by the enzyme thiopurine S-methyltransferase, and those with a genetic polymorphism for thiopurine S-methyltransferase are particularly susceptible to such toxicity.⁵ This genetic abnormality occurs in approximately 1 per 220 individuals, and screening for it before starting azathioprine therapy has been recommended, although rarely practiced clinically.⁶ Other side effects include nausea, vomiting, diarrhea, and hepatotoxicity, although liver function tests usually return to normal after discontinuation of the drug. Another concern is the interaction between azathioprine and allopurinol,⁷ which results in potentiating the bone marrow

suppression caused by the azathioprine. This results because allopurinol impairs the metabolism of the azathioprine. Both drugs should not be used together unless absolutely necessary and then only with very great caution. Although it was previously believed that there was no significant teratogenicity attributable to azathioprine,⁸ leukopenia and/or thrombocytopenia have been reported in neonates whose mothers had taken azathioprine throughout pregnancy.⁹

ALKYLATING AGENTS

Cyclophosphamide

Drugs of the nitrogen mustard alkylating agent class of which cyclophosphamide is the most commonly used have been known to be immunosuppressants since the 1950s.¹⁰ Cyclophosphamide is actually a prodrug, converted in the liver by mixed-function oxidase enzymes to the active metabolites 4-hydroxy-cyclophosphamide and phosphoramidate mustard. The result is the binding of these agents to and the cross-linking of DNA, thus inhibiting cell proliferation and function. This frequently results in dose-dependent neutropenia and lymphopenia with reductions of both B cells and CD4⁺ and CD8⁺ T cells.¹¹

Cyclophosphamide has been used to treat autoimmune glomerular diseases, both as intravenous pulses and in an oral form. For many years, it was the first-line therapy for severe lupus nephritis, and it remains the drug of choice for most patients with severe crescentic rapidly progressive glomerulonephritis whether related to ANCA-positive disease or antiglomerular basement membrane disease.^{4,12-14} Cyclophosphamide has also been used to treat steroid-resistant minimal change disease and focal glomerulosclerosis, IgA nephropathy, and membranous nephropathy.^{15,16} Because of its toxicity (see "Mycophenolate Mofetil"), newer immunosuppressants with fewer adverse side effects, such as mycophenolate mofetil, are now becoming the alternate treatments.

The adverse effects of cyclophosphamide can be severe. There is significant dose-dependent bone marrow depression with granulocytes, lymphocytes, erythrocytes, and platelets all affected. The effect on leukocytes is most pronounced, and the aim should be to keep the total white blood cell count greater than 3000/mm³. Infections are especially common in those who are neutropenic, but major bacterial and fungal infections can also occur without neutropenia, especially in the presence of concomitant treatment with glucocorticoids.

Another important adverse effect of oral cyclophosphamide, although rare with intravenous dosing, is hemorrhagic cystitis with the increased risk of developing bladder cancer.¹⁷ A small percentage of the cyclophosphamide metabolite aldophosphamide is converted to acrolein, which is toxic to bladder epithelium. Aggressive hydration should be encouraged to prevent this complication. Infertility in both males and females may also occur with the use of cyclophosphamide. Clearly, the patient's age and desire to have children must be taken into consideration before using this agent. If cyclophosphamide remains the drug of choice, a suggestion would be to have the patient's ova or sperm banked before initiation of therapy. Also, pregnant women should not be given cyclophosphamide unless absolutely necessary because of teratogenicity. Other common adverse effects include nausea, hair loss, mouth sores,

and hyponatremia due to increased secretion of antidiuretic hormone.

Because of the major toxicities of the alkylating agents, a strategy that should be strongly considered is induction therapy with cyclophosphamide and then maintenance therapy with a less toxic drug such as mycophenolate mofetil and azathioprine. Studies are now under way to determine the effectiveness of this strategy.^{4,18}

Chlorambucil

Like cyclophosphamide, chlorambucil is a nitrogen mustard alkylating agent. It has been used to treat steroid-resistant minimal change disease and focal glomerulosclerosis, as part of an alternating monthly regimen with corticosteroids to treat membranous nephropathy, and for several other immune renal diseases.¹⁹ Its mechanism of action is primarily binding to and cross-linking of DNA, resulting in apoptosis or defective cellular function with reductions in both B and T cells (CD4⁺ and CD8⁺).

The major adverse side effect of chlorambucil is bone marrow suppression, causing anemia, neutropenia, and thrombocytopenia. Other toxicities include gastrointestinal disturbances, central nervous system side effects including seizures and tremors, hepatotoxicity, and infertility. In some studies, it was found to have greater toxicity than cyclophosphamide and hence it is used infrequently in clinical nephrology at this time.²⁰ Chlorambucil should never be used during pregnancy due to its strong teratogenic potential.

CALCINEURIN INHIBITORS

This class of immunosuppressive drugs includes cyclosporine and tacrolimus (previously known as FK506). The immunosuppressive activity of cyclosporine was first noted in 1972, and tacrolimus was discovered in 1984.²¹

Originally used to prevent transplant rejection, the use of both drugs as immunosuppressive agents has widely expanded. Both cyclosporine and tacrolimus have been used to treat minimal change disease, focal glomerulosclerosis, membranous nephropathy, and as an adjunct to treatment of many proliferative glomerulonephritides.^{22,23}

Cyclosporine is a cyclic polypeptide consisting of 11 amino acids and tacrolimus is a macrolide lactone. Both exhibit similar immunosuppressant mechanisms in their effects on both humoral and cell-mediated responses. They act chiefly by inhibiting calcineurin. Cyclosporine first binds to the cytoplasmic protein cyclophilin; the cyclosporine-cyclophilin complex then binds to and competitively inhibits the calcium-sensitive phosphatase calcineurin,^{24–26} an enzyme that normally dephosphorylates the nuclear factor of activated T cells. T cells are especially sensitive to calcineurin inhibition because of their low calcineurin content. Tacrolimus binds to FK binding protein, an immunophilin, and forms a new complex (FK binding protein-12–FK506) that interacts with and inhibits calcineurin.^{24,25} The result of both agents is the inhibition of a number of transcription factors, leading to decreased production of various cytokines, especially interleukin-2. In addition, both cyclosporine and tacrolimus inhibit the activation of the T-cell transcription factors AP-1 and NK-κB.²⁶ Fortunately, unlike many other immunosuppressive drugs, neither cyclosporine nor tacrolimus is myelosuppressive.²⁶

Both cyclosporine and tacrolimus exhibit similar adverse side effects. First, both drugs are nephrotoxic and may cause acute renal insufficiency (usually reversible after lowering or discontinuing the medication) or chronic renal insufficiency (often irreversible).^{27,28} The acute manifestations may result from both renal vasoconstriction (affecting both afferent and efferent glomerular arterioles) and tubular toxicity. Rarely, hemolytic uremic syndrome may also occur. Hypertension is also a common side effect of both drugs, usually appearing within weeks of beginning treatment. Reduction in the dose often ameliorates the hypertension, but antihypertensive therapy is often required.

Neurological toxicity, particularly with tremor, is also not uncommon, especially with tacrolimus at high doses.^{29–31} Gastrointestinal side effects, including loss of appetite, nausea and vomiting, and diarrhea, occur and are also more frequently noted with tacrolimus.³² On the other hand, both gingival hyperplasia and hirsutism occur with cyclosporine but not with tacrolimus.³³ Tacrolimus may cause alopecia.^{34,35} Both the cosmetic effects of hirsutism and alopecia should be taken into account when treating patients who are highly concerned with their appearance. Both tacrolimus and cyclosporine are associated with an increased risk of developing diabetes. Although the data are somewhat conflicting, in general, this is more common with tacrolimus than cyclosporine.^{36–38} Hyperkalemia and hypomagnesemia are associated with the use of both medications due to renal tubular malfunction. Hyperuricemia with resulting gout also may occur with both drugs.

Cyclosporine and tacrolimus are both metabolized by the cytochrome P-450 3A enzymes in the liver. Therefore, one must be aware that other drugs metabolized by the same system, including diltiazem, verapamil, ketoconazole, allopurinol, erythromycin, and numerous others, can result in an elevation of cyclosporine and tacrolimus blood levels. Patients should also be informed that they should not drink grapefruit juice while they are taking cyclosporine or tacrolimus for the same reason.^{39,40} Conversely, certain medications, such as rifampin and phenobarbital, may reduce the level of cyclosporine or tacrolimus by induction of cytochrome P-450. Certain statins (simvastatin, lovastatin, and atorvastatin) are metabolized by the cytochrome P-450 3A4 system. Concomitant use of these lipid-lowering agents with cyclosporine may increase their plasma concentrations and increases the risk of myopathy with possible accompanying rhabdomyolysis.⁴¹ (Note that rosuvastatin and pravastatin are excreted mainly unchanged so that cytochrome P-450 3A inhibitors do not significantly increase their plasma concentrations.⁴¹) However, because of the major cardioprotective effects of the statins, many believe that the benefits of statin therapy for patients on cyclosporine far outweigh the risk of rhabdomyolysis as long as the patients are carefully monitored.^{42–44}

To avoid nephrotoxicity and other side effects, serial levels of cyclosporine and tacrolimus should be obtained. Trough levels are commonly measured just before the next dose of the drug.

SIROLIMUS

Sirolimus (rapamycin) is produced from the bacteria *Streptomyces hygroscopicus*. It was first discovered in a soil sample from Easter Island (or Rapa Nui Island, hence the name rapamycin).⁴⁵

It is a lipophilic macrolide like tacrolimus but is not a calcineurin inhibitor. Like tacrolimus, it first binds to the immunophilin FK binding protein-12. However, the sirolimus–FK binding protein-12 complex then binds directly in mammals to cytosolic protein kinases known as mammalian targets of rapamycin or mTOR, resulting in the inhibition of the growth of hematopoietic and lymphoid cells. The mechanism by which it does this is thought to be regulation of the cell cycle through inhibition of growth factor–related signal transduction,^{46,47} which results in blockade of the G1 to S phase transition. Thus, the major immunosuppressive activity of sirolimus is to inhibit proliferation of T cells. Therefore, sirolimus acts at a later stage in the immune response than the calcineurin inhibitors and may act synergistically with the latter.

Initial enthusiasm for the use of sirolimus in the treatment of glomerular diseases has been tempered by reports of acute renal failure in such patients as well as the potential induction of focal glomerulosclerosis in patients with renal allografts.^{48–50} Nevertheless, there are reports of successful use of this agent in steroid-resistant focal glomerulosclerosis.⁵¹

Unlike cyclosporine and tacrolimus, sirolimus does not appear to be nephrotoxic. The drug, however, is certainly not benign in terms of other side effects. These include hyperlipidemia and especially hypertriglyceridemia, nausea and diarrhea, elevated liver function tests, and myelosuppression. Sirolimus may also impair wound healing so that some prefer to avoid its use in the immediate postoperative period.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (MMF), derived from the fungus *Penicillium stoloniferum*, is metabolized to its active form mycophenolic acid in the liver. Its mechanism of action is to inhibit the enzyme inosine monophosphate dehydrogenase, crucial for the de novo synthesis of guanosine nucleotides.^{52,53} Since lymphocytes do not have a salvage pathway for purine synthesis but rely entirely on de novo synthesis, MMF selectively blocks T- and B-cell proliferation. Unlike alkylating agents such as cyclophosphamide, mycophenolic acid has little impact on tissues with high proliferative activity that possess a salvage pathway for nucleotide synthesis (e.g., skin, intestine, bone marrow). This provides a more favorable tolerability and toxicity profile than many other commonly used immunosuppressants. MMF may also limit glomerular injury and prevent progressive renal scarring and fibrosis by inhibiting proliferation of mesangial cells and by decreasing lymphocyte migration into renal tissue by altering adhesion molecule function with impaired glycosylation.^{52–57} Moreover mycophenolic acid seems to lessen the expression of the inducible form of nitric acid synthase in the renal cortex⁵⁸ and may slow the development of atherosclerosis.

MMF has been used as a standard component of modern immunosuppressive regimens for transplantation. It has been shown to be effective in several induction and maintenance studies of severe lupus nephritis and is currently being studied in focal glomerulosclerosis, IgA nephropathy, membranous nephropathy, and as maintenance therapy for ANCA-positive glomerulonephritides.^{18,59–61} It has also proven successful in the therapy of steroid-resistant or intolerant acute interstitial nephritis.⁶²

The most common adverse effect of MMF is gastrointestinal upset including nausea, abdominal cramps, and diarrhea. This can often be ameliorated by dividing the daily amount of the drug into three or four doses. Leukopenia, which is often responsive to dose reduction, may be seen. As with all other immunosuppressant medications, there is an increased risk of infectious complications.

RITUXIMAB

Rituximab was first approved in 1997 for the treatment of B-cell lymphoma. It is a chimeric (mouse-human) antibody, 60% to 65% human, that binds to the CD20 antigen, a phosphoprotein found commonly on B cells but not on stem cells or mature plasma cells. Rituximab is composed of the variable region of a murine anti-human CD20 monoclonal antibody fused to the human IgG1 κ constant region. Rituximab binds to a conformational epitope on CD20 and deletes CD20⁺ B cells, by a combination of mechanisms, including direct complement-mediated cytotoxicity, antibody-dependent, cell-mediated cytotoxicity via binding to the Fc γ receptor on cytotoxic cells, and deregulation of survival pathways with resulting apoptosis.^{63–65} Among the B cells deleted are those responsible for the production of self-reactive antibodies.⁶⁶

Although originally used for the treatment of B-cell lymphoma, the use of rituximab has spread as a possible treatment choice for numerous autoimmune diseases. In nephrology, it is being actively studied as an immunomodulator in lupus and lupus nephritis, Wegener's granulomatosis, and other ANCA-positive rapidly progressive glomerulonephritides.⁶⁷ It has also been used in membranous nephropathy and isolated cases of minimal change disease and focal glomerulosclerosis (see Chapters 19 and 21 for details).

As with other immunosuppressive drugs, rituximab is not without adverse side effects. Rituximab is given weekly for four consecutive doses of 375 mg/m² or two doses of 1000 mg given 2 weeks apart. Infusion more rapidly than over 4 hours or without concomitant methylprednisolone can result in allergic phenomena with wheezing, shortness of breath, pulmonary reactions, and hypotension. Other side effects include reactivation of hepatitis B and other viral infections. In several lupus patients, immune toxicity resulting from the loss of B cells has led to activation of JC virus and fatal progressive multifocal leukoencephalopathy.⁶⁸ The efficacy of rituximab may be abrogated by the development of antichimeric antibodies. It is still unclear how commonly such antibodies will develop in response to this chimeric, partially murine antibody. The development of fully humanized anti-B cell monoclonal antibodies is already under way.

OTHER POTENTIAL IMMUNOSUPPRESSIVE AGENTS

T lymphocytes require two signals for activation. The first signal occurs with presentation of antigen to the T-cell receptor, while the second signal is an interaction of costimulatory molecules on T lymphocytes and antigen-presenting cells. Blockade of this second costimulatory signal interrupts the immune response. A number of agents have been developed to modulate the immune system based on this mechanism.

CD40, a member of the tumor necrosis factor receptor family, is expressed on antigen-presenting cells including B cells and macrophages.⁶⁹ The ligand of CD40 is CD154 (CD40 ligand), which is expressed on activated CD4⁺ T cells and some CD8⁺ T cells. Although a murine anti-CD154 analogue was successful in murine lupus, results with two different humanized anti-CD40 monoclonal antibodies (BG9588 and IDEC-131) have not been successful in human lupus nephritis.^{70,71} BG9588 (ripilimumab) was associated with unacceptable thromboembolic phenomena, and IDEC-131 was ineffective in reaching stated endpoints of therapy.

Another costimulatory pathway involves CD28 and CD80/86. CD28 is present on T cells and binds to CD80 (B7-1) and CD86 (B7-2) on antigen-presenting cells. CTLA-4 competes with CD28 for the same B7 ligands and antagonizes CD28-dependent costimulation.⁶⁹ CTLA4-Ig is a recombinant fusion molecule that combines the extracellular domain of human CTLA4 with the constant region (Fc) of the human IgG1 heavy chain. Two preparations of CTLA4Ig have been used clinically to modulate costimulation.⁷² Abatacept binds CD80 more avidly than CD86 while belatacept (LEA29Y) binds even more avidly to both CD80 and CD86 and provides more potent inhibition of T-cell activation. Both agents have been studied in transplantation, and trials are ongoing in lupus nephritis. Similar costimulatory blockade could prove useful in a number of other immune-mediated glomerulonephritides.

Mizoribine

Mizoribine, an immunosuppressant agent not approved yet in the United States, has been used in Japan for the treatment of lupus nephritis and glomerulonephritis. Its active form, mizoribine-5-P, selectively inhibits inosine monophosphate synthetase and guanosine monophosphate synthetase, resulting in blocking synthesis of guanine nucleotides. There is inhibition of T-cell activation and proliferation associated with a decrease in intracellular guanosine triphosphate.⁷³ In Japan, mizoribine, in addition to preventing transplant rejection, has been used in the treatment of rheumatoid arthritis, steroid-resistant nephrotic syndrome, and systemic lupus nephritis.^{74–76}

The safety profile of mizoribine has been reported to be as safe or safer than that of other immunosuppressant agents. Adverse effects have been reportedly less severe with mizoribine than with other such drugs, especially azathioprine.⁷³ There is one report of rhabdomyolysis in a patient also treated with a fibrate, and there is warning against the use of both drugs together.⁷⁷ Also, at the highest doses, mizoribine has been reported to increase uric acid levels.⁷⁸

INTRAVENOUS IMMUNOGLOBULIN

Intravenous immunoglobulin (IVIG) has been used to treat lupus nephritis, Henoch-Schönlein purpura, and a number of other glomerulonephritides.^{79–81} Almost all studies have been small in size, and most have been uncontrolled and combined with other therapies. IVIG has a variety of immune-modulating actions including acceleration of IgG catabolism. Thus, the role of IVIG remains unclear in any glomerular disease. Since these agents possess a number of potential adverse side effects including acute renal failure,

especially seen with sucrose-based IVIG, they should be used cautiously until their precise role has been clarified.

OTHER MODULATORS OF THE IMMUNE RESPONSE

Another area of potential interest is in designer molecules that modulate a specific element of the immune response. For example, LPJ 394, a complex of four oligonucleotides, was designed to induce B-cell anergy by binding surface immunoglobulin without T-cell help.⁸² Despite effectively reducing anti-double-stranded DNA antibody levels in murine and human lupus, this agent has not yet been established as clinically effective in humans. Antagonists of tumor necrosis factor α are clinically available for the treatment of rheumatoid arthritis. They have been associated with severe infections including activation of tuberculosis in some patients and the induction of systemic lupus in some rheumatoid patients. They have not proven effective in maintaining remissions in ANCA-positive vasculitis.⁸³ As the effector limb of the immune system becomes better studied, there will clearly be a variety of new targets for the prevention of glomerular damage. Potential therapeutic targets include cytokines (i.e., interleukin-6, interleukin-10,⁸⁴ IL-18) B-lymphocyte stimulator,^{85–87} interferons (i.e., type I)^{88–90}, Toll-like receptor (TLR9 blockade),^{91,92} adhesion molecules, and complement components. Agents to modulate these factors will probably be combined with conventional therapy to induce remission in glomerular diseases as well as to maintain patients in remission. A major challenge will be understanding the interactions between newer immunomodulator drugs and currently used immunosuppressives.

INFLAMMATION AND POINTS OF ATTACK FOR ITS MODULATION

Inflammation can be classically defined as the reaction of a living vascularized tissue to localized damage,¹ and it plays a role in both normal repair reactions and the pathogenesis of disease. The inflammatory reactions are usually defined as acute or chronic based on both their temporal duration and the prevailing phenomena occurring. Acute inflammation, lasting minutes to hours, has its main features in fluid and plasma protein exudation (edema) and leukocyte (mainly neutrophil) migration.² Chronic inflammation lasts longer, is less stereotyped, and is associated histologically with the presence of lymphocytes and macrophages as well as with the proliferation of small blood vessels and of connective tissue.³ Inflammatory phenomena are at the basis of a number of disease processes of either systemic or organ-specific nature, ranging from classic rheumatic diseases to bronchial airway hyperresponsiveness, inflammatory bowel disease, kidney diseases, psoriasis, and atopic eczema. Tissue phenomena occurring in inflammation include modification of blood flow and vessel diameter, changes in vascular permeability, leukocyte exudation and phagocytosis, remodeling of the extracellular matrix, and cell proliferation. Each phase of the inflammatory reaction is sustained by the local production of mediators, including vasoactive amines, plasma and tissue proteases, arachidonic acid metabolites, cytokines, chemokines and growth factors, lysosomal components, and reactive oxygen species, each of which may be a theoretical target for drugs or therapeutic interventions. It has recently been appreciated that many of these phases may be modulated by diet. Dietary modulation of

the inflammatory reaction is thus now achievable as a therapeutic option in the treatment of a variety of human diseases. Selected dietary components can also be supplemented in amounts not easily achieved through the diet, thus configuring truly pharmacologic modalities based on dietary components. This chapter reviews the main options currently available for these interventions, their proposed rationale and mechanism of action, clinical results, and some current therapeutic recommendations. Most of these are currently based on manipulation of fatty acid (FA) intake, but important new notions in this area deal with the link of obesity and inflammation with the consequent target of weight loss through restriction of dietary calorie intake and the link with salt sensitivity, inflammation, and hypertension.

HIGHLY UNSATURATED AND N-3 FATTY ACIDS

Present mainly in seafood, and therefore better known as fish oils, highly unsaturated FAs of the n-3 series (ω -3 FAs) are probably the best example of how diet may affect inflammation. These compounds exert a remarkable variety of biologic effects^{4,5}; because of this, they are currently being tested in a variety of clinical situations as disparate as coronary artery disease,^{6,7} hypertension,^{8,9} some dyslipidemias,¹⁰ cancer,¹¹⁻¹³ diabetes,¹⁴ renal diseases,¹⁵ and a number of inflammatory states.¹⁶ The reader is referred to the cited reviews covering their use in these conditions, whereas this section focuses on their use in inflammatory states and renal disease.

Biologic Properties and Effects of N-3 Fatty Acids and Their Potential Relevance to Inflammation

Current medical interest in n-3 fatty acids stems from observations of the different prevalence of some chronic diseases in the Greenland (Eskimo) population relative to Western populations.¹⁷ Diseases with lower prevalence in Inuit compared with control Danes include myocardial infarction, from which the main source of interest for these compounds as preventive agents in coronary artery disease has derived, but also conditions such as psoriasis, bronchial asthma, diabetes mellitus, and thyrotoxicosis,¹⁷ which share a background of inflammation or a derangement of immunity. Increased nutritional intake of fish and marine mammals, providing an increased supply of n-3 FAs, was pointed out as the main factor responsible for such differences.^{18,19} Mammals in general cannot synthesize FAs with double bonds distal to the ninth carbon atom (starting counts from the methyl end of the carbon chain), although they are able, to some extent, to elongate (increase carbon chain length) and further desaturate (increase the number of double bonds) the aliphatic chain. Two main families of long-chain polyunsaturated FAs exist, biologically derived from the shortest nonsynthesizable precursors linoleic acid (C18:2 n-6)

and α -linolenic acid (C18:3) (Fig. 11-1). Linoleic acid is abundant in oils from most vegetable seeds such as corn and safflower. α -Linolenic acid is found in the chloroplasts of green leafy vegetables. Humans can desaturate and elongate α -linolenic acid to eicosapentaenoic acid (EPA) and, further, to docosahexaenoic acid (DHA). However, the elongation and desaturation processes are likely to be slow and possibly further limited by aging²⁰ and disease conditions.²¹ For these reasons, EPA and DHA are considered, to a large extent, nutritionally essential and nearly exclusively derived from fish. Fish increase their membrane content by eating the phytoplankton rich in either the precursor α -linolenic acid or the more elongated compounds EPA and DHA. Fatty fish living in cold seas (e.g., mackerel, salmon, herring) are particularly rich in these compounds, which may give them a selective advantage in preventing low temperature-related loss in membrane fluidity in cell membranes.²⁰ Concentrated formulations of EPA and DHA are now available from industrial processing of the body fat from fish and are undergoing clinical trials as dietary supplements or pharmacologic agents.

The n-3 FAs exert a remarkable variety of biologic effects, many of which may affect inflammation and clinical conditions related to their presence (Fig. 11-2). The most important of these are now discussed in greater detail.

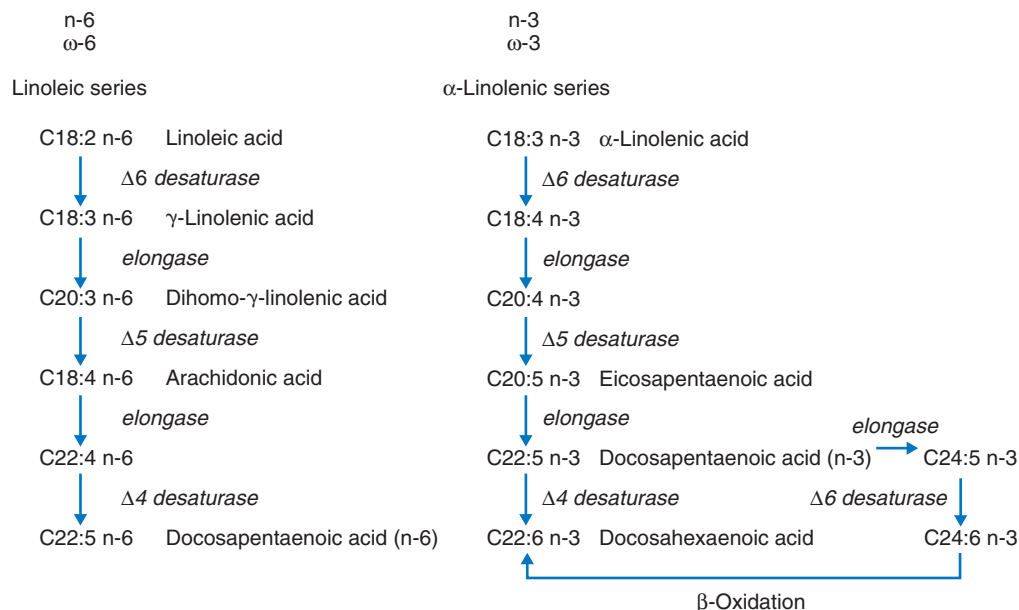

Figure 11-1 Metabolism and nomenclature of the main polyunsaturated fatty acid (FA) of the linoleic series (*left*) and the α -linolenic series (*right*). The two metabolic pathways, although largely using the same enzymes without appreciable substrate specificity, are entirely distinct and not interconvertible in animals and humans. Regulation of elongase and desaturates is largely unknown. Both pathways use the same enzymes for chain elongation and desaturation. Recent findings, however, have indicated that formation of docosahexaenoic acid (DHA) from 22:5 n-3 occurs through an initial chain elongation to 24:5 n-3 (in either mitochondria or peroxisomes), which is in turn desaturated in microsomes at position 6 to yield 24:6 n-3. The chain is then shortened via β -oxidation to yield DHA. This novel biosynthetic pathway is commonly referred to as Sprecher's shunt.¹²² Dihomo- γ -linolenic acid is the precursor of prostaglandins of the 1 series. Arachidonic acid is the most common eicosanoid precursor; eicosapentaenoic acid is the most common precursor of the prostaglandins of the 3 series and of leukotrienes of the 5 series, and the most abundant polyunsaturated FA present in fish oil concentrates; DHA is the most abundant n-3 FA accumulated in tissues (especially in the central nervous system) and in fish, and can exert its effects partially by retroconversion to eicosapentaenoic acid and partially by itself. See text for further details. (Modified from De Caterina R, Endres S, Kristensen S, Schmidt E: n-3 Fatty acids and renal diseases. *Am J Kidney Dis* 1994;24:397–415.)

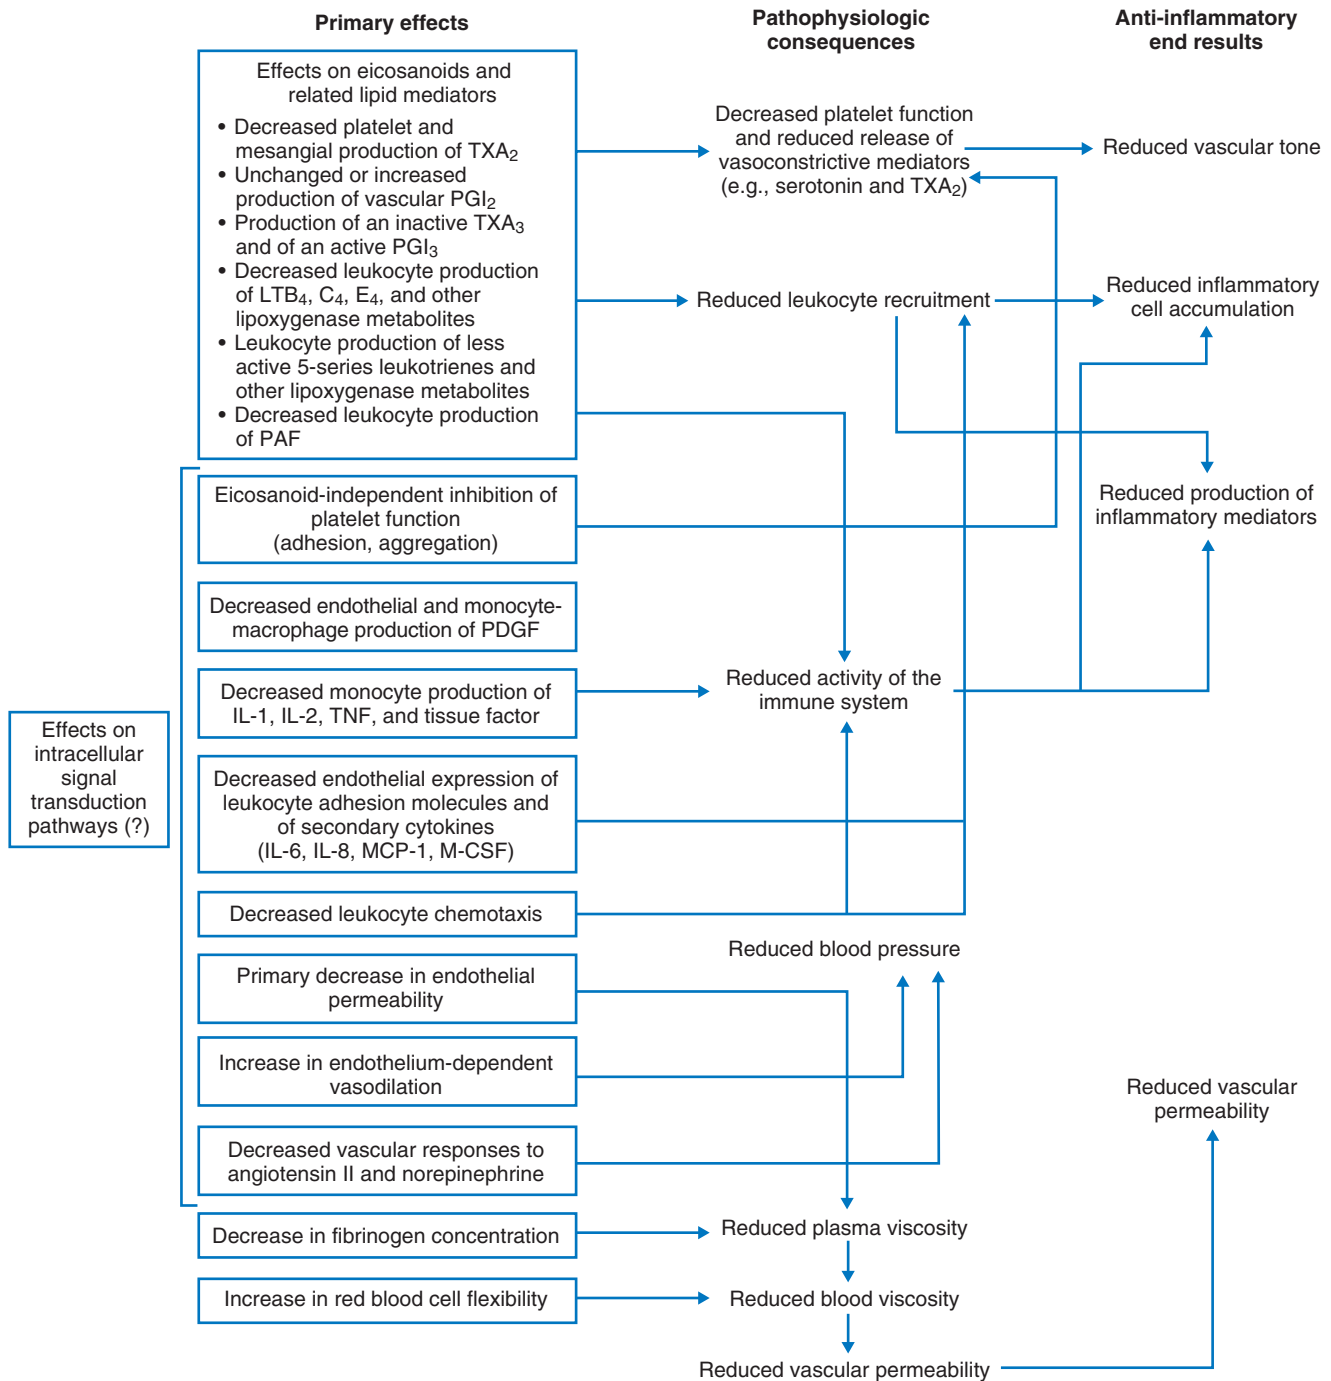

Figure 11-2 Biologic effects of n-3 fatty acids (FAs) and the rationale for their anti-inflammatory use. IL, interleukin; LT, leukotriene; MCP-1, monocyte chemoattractant protein-1; M-CSF, macrophage colony-stimulating factor; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PG, prostaglandin; TNF, tumor necrosis factor; TX, thromboxane. See text for details and references.

Production of Eicosanoids and Related Lipid Mediators

Until recently, the prevailing hypothesis to explain the protean effects of n-3 FAs was that their action could be related to the different profile of activities of neosynthesized, soluble lipid mediators derived from EPA as opposed to those derived from the normally more abundant arachidonic acid (AA) (Fig. 11-3).

Both AA and EPA are FAs with 20 (in Greek, *eicosa*) carbon atoms and four or five *cis* double bonds, each one inducing a bending of the otherwise linear aliphatic chain. These bendings allow the occurrence of a hairpin configuration and the subsequent enzymatic transformation of the FA precursor in a variety of compounds commonly designated eicosanoids. This term now encompasses a number of classes of related compounds, named prostaglandins, thromboxanes (TXs), leukotrienes (LTs), hydroxy- and epoxy-FAs, lipoxins, and isoprostanes.

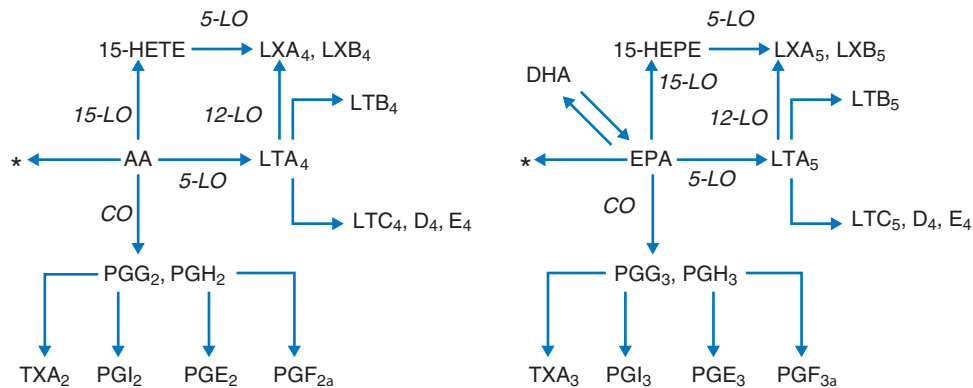

Figure 11-3 An updated schema for the origin of the main eicosanoids deriving from the linoleic series (metabolites of arachidonic acid [AA]) and of the α -linolenic series (metabolites of eicosapentaenoic acid [EPA]) with relevance to inflammation physiology and pathophysiology. The best characterized metabolic pathway, catalyzed by the enzyme prostaglandin (PG) H synthase (cyclooxygenase [CO], of which a constitutive form and an inducible form are now known), leads to the formation of prostanoids (PGs⁸²) and thromboxanes (TXs) of the 2 series from AA and of the 3 series from EPA. AA and EPA also can be metabolized in leukocytes and some connective tissue cells via the enzyme 5-lipoxygenase (5-LO) to leukotrienes (LTs) A₄ and A₅, respectively. These labile intermediates can be converted to the more stable LTB (endowed with potent chemotactic properties) or by the addition of a peptide residue to the sulfidopeptide LTs (LTC, LTD, LTE), which are powerful vasoconstrictors and able to increase vascular permeability. The schema also outlines the possible complex metabolism of both AA and EPA toward lipoxins (LXs), which are also endowed with vasoactive properties. Lipoxins arise through the combined action of 5-LO and other LOs (15-LO and 12-LO). Cell-cell interactions, including exchanges of substrates and of intermediate metabolites, are thought to be particularly relevant to the generation of LO metabolites. On the average, metabolites derived from EPA are less active than the corresponding species derived from AA, potentially explaining the reduction in many cellular responses occurring when n-3 fatty acids are added to the diet. More importantly, EPA is a worse substrate for the metabolizing enzymes than AA, leading to a net absolute reduction in the amount of metabolites generated. The schema also outlines the bidirectional relationship of EPA and DHA, by which the latter compound may serve as a storage compartment for EPA. The asterisk denotes other potential metabolic conversions of AA and EPA to bioactive compounds, which have been recently appreciated in particular organ systems. These include the generation of isoprostanes, ω -3 hydroxylation, epioxygenase, and cytochrome P-450/allylic oxidation products. 15-HEPE, 15-hydroxypentaenoic acid; 15-HETE, 15-hydroxytetraenoic acid. (Modified and updated from De Caterina R, Endres S, Kristensen S, Schmidt E: n-3 Fatty acids and renal diseases. *Am J Kidney Dis* 1994;24:397–415.)

The initial step in the biosynthesis of these compounds is thought to be a receptor- or physical perturbation-mediated influx of Ca²⁺ ions, causing translocation of a cytoplasmic phospholipase A₂ to the cell membrane.^{22,23} The enzyme then catalyzes the hydrolysis of the esterified AA in the sn-2 position.^{24,25} A variety of phospholipase A₂ have now been identified, differing in molecular weight, calcium sensitivity, and the specificity for AA.²⁶ The activity of these enzymes appears to be increased by a phospholipase A₂-activating protein, which is activated by cytokines such as interleukin (IL)-1 and tumor necrosis factor (TNF).²⁷ A secretory phospholipase A₂ present on the surface of mast cells and other cells may also be involved in the liberation of AA.^{28,29}

Physical stimuli—or agonist-induced activation of cytoplasmic phospholipase A₂ leads to a liberation of free AA. When EPA partially replaces AA as the polyunsaturated FA in the sn-2 position of glycerophospholipids, free EPA is produced. AA or EPA then becomes available for a variety of enzymes able to drive their further metabolism in directions depending on the cell type where such activation processes occur (see Fig. 11-1). Thus, in platelets and a few other tissues (including the kidney), AA is metabolized to TXA₂, a powerful vasoconstrictor and inducer of platelet activation. The replacement of EPA leads to the production of a much weaker TXA₃. On the other hand, in endothelia, products of AA and EPA are the almost equally active

prostaglandins I₂ and I₃, both vasodilators and inhibitors of platelet activation. In leukocytes, which are pivotal cells in inflammation, the main metabolism of AA is toward the production of LTs, endowed with chemotactic (LTB₄) or vaso- or bronchoconstrictive and endothelium-permeabilizing properties (LTC₄, LTD₄, and LTE₄). EPA also acts as a poor substrate for AA-metabolizing enzymes, leading to a decreased net production of derived compounds (reviewed in De Caterina and Zampolli³⁰). Lipoxygenase products of EPA are the weaker corresponding LTs of the 5 series (LTB₅, C₅, D₅, E₅) (see Fig. 11-3), although, in this regard, the most relevant property of n-3 FA incorporation in membrane phospholipids appears to be the reduced production of such mediators.³¹ As a result, a shift in the relative abundance of AA and EPA leads to a new balance of eicosanoids, favoring vasodilating, antiplatelet, and less proinflammatory compounds. Elevated TXA₂ (by urinary assays of metabolites of its hydrolytic product TXB₂) has been found in patients with systemic lupus erythematosus³² and in a variety of renal diseases including chronic glomerular disease,³³ diabetic nephropathy,³⁴ renal damage caused by cyclosporine,³⁵ renal transplant rejection,³⁶ and proteinuric syndromes.^{37–40} Substitution of EPA for AA reduces platelet^{41–45} as well as renal production of TX.⁴⁰ In addition, n-3 FAs have been found to reduce the gene expression of cyclo-oxygenase-2,⁴⁶ leading to the net reduction in the output of proinflammatory prostanoids. In

addition, some of the anti-inflammatory effects of n-3 FAs may derive from their conversion, mainly through a cytochrome P-450-mediated pathway, to oxygenated products that carry potent protective bioactions present in resolving inflammatory exudates and therefore termed resolvins.^{47–49} Resolvin E₁ is biosynthesized *in vivo* from EPA via transcellular biosynthetic routes during cell-cell interactions, and thus resolvin E₁ is formed *in vivo* during multicellular responses such as inflammation and microbial infections. Resolvin E₁ protects tissues from leukocyte-mediated injury and counterregulates proinflammatory gene expression. These newly identified resolvins may underlie the beneficial actions of n-3 polyunsaturated FAs, especially in chronic disorders where unresolved inflammation is a key mechanism of pathogenesis.

Overall, these changes may be an explanation for some of the anti-inflammatory, antihypertensive, and renal effects of n-3 FAs.

Modulation of Cell Activation and Cytokine Production

In addition to changes in eicosanoid metabolism, increased attention is being now paid to n-3 FAs as possible modulators of cytokine production. When administered to healthy volunteers, n-3 FAs decrease bacterial lipopolysaccharide-induced production of the proinflammatory cytokines IL-1 and TNF- α from peripheral blood mononuclear cells.^{50,51} In cultured human endothelial cells, the membrane enrichment of n-3 FAs, by supplementation of culture medium with DHA, reduces the ability of endothelial cells to respond to stimulation with bacterial lipopolysaccharide, IL-1, IL-4, or TNF in terms of surface expression of the leukocyte adhesion molecules vascular cell adhesion molecule-1, intercellular adhesion molecule-1, and E-selectin, as well as release of soluble mediators of endothelial activation, such as IL-6 and IL-8, which are able to provide positive feedback for the amplification of the inflammatory response.^{52–55} Similarly, n-3 FAs also inhibit the gene expression of cyclooxygenase-2,⁴⁶ thereby providing another negative interference on inflammation. This provides a basis for a reduced responsiveness of cells to inflammatory stimuli, probably due to the ability of n-3 FAs to modulate the activation of transcription factors (nuclear factor κ B),^{46,52–55} which can coordinate the concerted activation of a variety of genes involved in acute inflammation, atherosclerosis, and the modulation of the immune response.^{55–57} Other reported properties of n-3 FAs, including the ability to modulate the expression of tissue factor by stimulated monocytes,^{58,59} or of platelet-derived growth factor-like proteins in endothelial cells⁶⁰ or monocytes⁶¹ could be due to the same or a similar underlying mechanism of action.

Other Biologic Properties of N-3 Fatty Acids Related to Modulation of Inflammation

Other effects of n-3 FAs include reduction of monocyte and neutrophil chemotaxis^{62–65} and leukocyte inflammatory potential,⁶⁶ possibly by modulating cytokine and chemokine production. Total blood viscosity is reduced by n-3 FAs,^{67–69} most probably through a combined effect on red blood cell deformability²⁰ and plasma viscosity, the main determinant of which, concentration of fibrinogen, is favorably reduced by these compounds.^{70–72} In addition, n-3 FAs have been reported to increase endothelium-dependent vasodilation^{73,74}

and to decrease vasoconstrictive responses to angiotensin II.^{75,76} At least some of these effects may be due to a modulation of intracellular signal transduction pathways, partly due to the function of FAs as intracellular second messengers themselves in cell activation⁷⁷ (see Fig. 11-2). In general, n-3 FAs have been found to reduce the increase in intracellular calcium in response to agonists. In particular, the enrichment of cellular phospholipids with DHA inhibits calcium transients.^{78–80} In cardiac myocytes, this may occur through a modulation of the L-type calcium channel.⁸¹ Alternatively, changes in agonist-induced increase in intracellular calcium may occur through an alteration of the agonist-receptor affinity⁸² or cell membrane physicochemical characteristics.^{83,84} Postreceptor signaling pathways and the formation of second messengers involved in the mobilization of intracellular calcium may be inhibited by reductions of the production of inositol trisphosphate^{85,86} or by conversion of FAs to cytochrome P-450 epoxygenase metabolites.^{87,88} By some of these mechanisms, fish oil has been reported protective against proteinuria in animal models⁸⁹ as well as in humans with glomerular kidney diseases.⁴⁰

ESSENTIAL FATTY ACID DEFICIENCY

More than 25 years ago, it was established that essential FA (EFA) deficiency was able to prevent the lethal glomerulonephritis that occurs in the New Zealand black \times New Zealand white model of murine lupus.⁹⁰ The original report was followed by others showing similar results for supplementation with n-3 FAs in both the New Zealand black \times New Zealand white and MRL1pr models of murine lupus.^{91–93} A proximal step in the pathogenesis of the glomerulonephritis in murine lupus is the formation of autoantibodies. Suppression of such an event did not appear to be involved in these protective effects. Dietary polyunsaturated FA manipulation was found to be effective even when started late in the disease, after a full-blown autoantibody response.⁹² Also, investigations on the mechanism of action of EFA deficiency were not able to show clear results of suppression of lymphocyte responses.⁹⁴ Therefore, it was reasoned that FAs had to act distally to the deposition of immune complexes in glomeruli. The original hypothesis entertained at that time was that the efficacy of dietary polyunsaturated FA manipulation was through diminished levels of active cyclooxygenase metabolites.⁹³ However, several lines of evidence subsequently argued against such a simplistic explanation. These were mainly that (1) pharmacologic inhibition of cyclooxygenase in murine lupus did not reproduce the beneficial effects of FA manipulation⁹⁵ and that (2) EFA deprivation was not inevitably accompanied by a decrease in tissue AA or the production of cyclooxygenase metabolites.⁹⁶ Subsequent studies in normal glomeruli showed that EFA deficiency has the unique ability to modulate macrophage migration, dramatically depleting the resident population of glomerular and renal interstitial macrophages.⁹⁷ The specific deficiency of n-6 FAs was responsible for these effects because the administration of linoleic acid (18:2 n-6), but not that of α -linolenic acid (18:3 n-3), reversed the decrease in macrophage population.⁹⁷ These changes were interpreted as due to an attenuated ability of glomeruli from EFA-deficient animals to generate LTB₄.⁹⁸ More recently, it was observed

that EFA deficiency attenuates the immunologic, metabolic, and functional alterations accompanying nephrotoxic nephritis, a model of immune-mediated glomerulonephritis.^{99,100} In this model, multiple mechanisms appear operative in different phases, including an early role for neutrophil-platelet interactions, causing increased glomerular LTB₄ and TX synthesis and consequent proteinuria and involving complement and possibly fibrinogen, P-selectin, and eicosanoids.¹⁰¹ EFA deficiency does not alter neutrophil influx in the glomeruli, but affects the acute increase in glomerular LTB₄ and TX⁹⁹ and other neutrophil functions, such as the generation of superoxide anion,¹⁰² similarly to what occurs with n-3 FA supplementation.⁶² A role for the generation of platelet-aggregating factor, the production of which is also impaired by EFA deficiency¹⁰³ as well as by n-3 FA supplementation,¹⁰⁴ has been postulated.¹⁰⁵ In later phases of nephrotoxic nephritis, the critical cellular effector system is the monocyte macrophage, which appears to mediate the increase in glomerular TX production, proteinuria, and the decline in renal function.^{106,107} EFA deficiency dramatically inhibits the elicitation of monocyte macrophages into the glomerulus in this model of renal inflammatory disease, and this effect is not attributable to either platelet-aggregating factor or LTB₅ because it is not inhibited by platelet-aggregating factor receptor blockade or 5-lipoxygenase inhibition.¹⁰⁸ Because no defect in *in vitro* sensitivity to chemotactic agents in monocyte/macrophages from EFA-deficient animals is also demonstrable,⁹⁹ it is likely that glomerular production of a monocyte-specific chemoattractant or monocyte adherence is impaired, similar to what was demonstrated with n-3 FA supplementation.^{52,54} FA manipulation with EFA deficiency has also been shown to be effective in decreasing the late glomerulosclerosis,^{109,110} which is a consequence of glomerular injury and inflammation regardless of the initiating insult.¹¹¹

STUDIES IN HUMANS WITH DIETARY MANIPULATION OF FATTY ACID INTAKE

Along with the elucidation of their many biologic properties, studies have been performed to explore the potential usefulness mostly of dietary supplementation with n-3 FAs in a number of pathologic conditions in which inflammation is either the most prominent or an essential component. Such conditions include rheumatoid arthritis,¹¹² systemic lupus erythematosus¹¹³ and other rheumatic diseases,¹¹⁴ ulcerative colitis,^{115–117} Crohn's disease,^{118–120} and bronchial asthma.¹²¹ Results of the vast majority of these trials have been critically reviewed.^{122,123} Several well-controlled, double-blind trials of the effects of n-3 FAs in rheumatoid arthritis have reported statistically significant beneficial effects, which were, however, of a small magnitude and modest clinical impact. Such studies were conducted with doses in the range of 5 to 6 g/day, with minimal side effects, justifying the hypothesis that larger doses might possibly have a greater clinical efficacy. Inconsistent results, possibly for similar reasons, have also been reported in inflammatory respiratory diseases (i.e., allergic asthma)^{124,125} and inflammatory skin diseases.^{126–128} Promising, yet not definitive, studies have been reported in systemic lupus erythematosus.¹²⁹ A double-blind, placebo-controlled clinical trial in patients with Crohn's disease at high risk of relapse showed

that 59% of patients kept on 2.7 g/day of n-3 FAs remained in remission compared with 26% in the placebo group.¹²⁰ This is the most promising result obtained so far in this disease category. Compared with previous less favorable results obtained by others,^{118,119} the authors hypothesized a better compliance in the last study due to a special coating that enhances protection of the n-3 FA capsules against gastric acidity and the consequent occurrence of gastric side effects.¹²⁰ Also, four double-blind, placebo-controlled trials in ulcerative colitis, with doses of n-3 FAs ranging between 2.7 and 5.4 g/day, have documented moderate clinical improvements, mostly in remission induction.^{115–118} The variable results obtained by dietary supplementation with n-3 FAs in different inflammatory conditions can possibly be explained by the variable nature of inflammation in these conditions. A unitary explanation of these discrepancies is, however, lacking at present.

Studies with Supplementation of N-3 Fatty Acids in Renal Disease

Against a background of older literature indicating promising effects in slowing down the progression of glomerular sclerosis and reducing proteinuria in various forms of renal diseases (reviewed by De Caterina and colleagues¹⁵), more recent human studies fall in the following two main categories: (1) studies with intermediate mechanistic endpoints showing that in patients on hemodialysis, n-3 FAs may ameliorate the lipid profile by reducing plasma levels of triglycerides, remnant lipoproteins, and, contrary to common expectations, lipid peroxidation¹³⁰; increase high-density lipoprotein cholesterol¹³¹; synergize the lipid-lowering effects of statins¹³²; reduce LT formation¹³³; and increase heart rate variability, a prognostic marker of arrhythmic death in these patients,¹³⁴ and showing that in patients after renal transplantation, n-3 FAs may have, like in other clinical conditions,^{8,44} favorable effects on blood pressure¹³⁵ and improvement in cyclosporine absorption and metabolism¹³⁶ and (2) studies with clinical endpoints, mostly confined to the setting of IgA nephropathy.¹³⁷ In this disease, a prospective, double-blind trial had originally shown beneficial effects of n-3 FAs.¹³⁸ This was confirmed in a follow-up of the original cohort of longer than 6 years.¹³⁹ A more recent study in IgA nephropathy has confirmed positive effects.¹⁴⁰ Possible differences between animal and human studies using fish oils are the larger doses generally used in animal studies and the different background diet, whereby in experimental studies the animals are usually placed on a n-3 enriched diet without exposure to competing n-6-containing food, whereas human studies have usually involved n-3 supplements, with patients usually eating a regular diet rich in competing n-6 FAs. Future studies in patients will have to address the issues of the background diet and of the achieved ratio of n-3/n-6 FAs.

VITAMINS AND OTHER NUTRIENTS

There are scanty and occasional reports in the literature of other nutrients able to modulate selected examples of inflammation. Thus, plasma levels of pyridoxal-5'-phosphate (vitamin B₆) have been found to be reduced in patients with rheumatoid arthritis, and this reduction is in some way correlated with an increased production of the inflammatory mediator TNF- α by peripheral

blood monocytes.¹⁴¹ Antioxidant vitamins, mostly vitamin E¹⁴² and β -carotene (vitamin A),¹⁴³ have occasionally been reported to modulate the inflammatory response in a variety of experimental models and some clinical conditions. Their effects, although with a clear biologic rationale in interfering with redox-mediated intracellular signal transduction pathways activated by cytokines, are weak at best, and their clinical impact appears to be minor.

OBESITY AS AN INFLAMMATORY STATE

An effective immune response to infectious agents and the capability of repairing tissue damage and storing energy to be spent in situations of environmental food deprivation, such as during long famine periods, are fundamental functions of living organisms. In an evolutionary perspective, it is not unexpected that metabolic and immune pathways evolved in an interdependent manner and that the immune response and metabolic control systems in part share the same cellular mechanisms.¹⁴⁴ Cytokines, transcription factors, and some lipids represent regulatory signals both for the metabolic and the immune response to infection. Stimulation of the immune system activates metabolic pathways that mobilize stored body fuels and in parallel suppresses pathways conducive to energy storage, such as the insulin signaling pathway.¹⁴⁵ This adaptive response serves to provide the energy input required to mount and sustain the inflammatory response (Fig. 11-4). Starvation suppresses the immune system, whereas overfeeding and fat excess have an opposite influence on the immune response. For millennia, starvation and malnutrition have been recognized as major risk factors for infection and death. In this scenario, the integrated functioning of the inflammatory and the metabolic responses aimed at generating an appropriate response to infectious agents emerged as a trait advantageous for survival. Although famine still remains a problem of considerable dimensions in less economically developed countries, in most Western countries the major threat to human health is now represented by the epidemics of obesity-driven diseases such as diabetes, hypertension, and dyslipidemia and to related atherosclerotic complications,¹⁴⁶

that is, to a set of diseases and complications causally related to altered metabolic and immune mechanisms.

TNF- α was the first biochemical link discovered between the adipose tissue and immune mechanisms/inflammation. TNF- α alters insulin sensitivity, as shown by the observation that the obese TNF- α knockout mouse has better insulin sensitivity than the obese wild-type mouse.¹⁴⁷ Beyond TNF- α , fat cells are endowed with the ability to express a large series of inflammatory genes. These cells produce a series of compounds involved in adaptive and innate immunity. These include leptin, a hormone central to immunosuppression associated with starvation, and the large, continuously expanding repertoire of adipokines, now including, among others, adiponectin, resistin, and visfatin, all identified as fundamental factors in the regulation of insulin sensitivity as well as in the innate immune response.¹⁴⁸ The prototypical innate immunity cell, the macrophage, has similarities with the adipocyte because it expresses gene products typical of the adipocyte, such as the cytoplasmic FA-binding protein, adipocyte lipid-binding protein 2, and peroxisome proliferator activated receptor- γ .^{149–152} Macrophages have lipid-storage capabilities, and the lipid-overloaded macrophage is a key factor in the processes leading to atherosclerotic plaque formation. Conversely, preadipocytes may differentiate into fully functional macrophages.¹⁵³ It is important to note that in obese patients, these two cell types, the macrophage and the adipocyte, colocalize in adipose tissue,¹⁵⁴ thus forming an integrated system participating in the innate immune response and in metabolic regulation.

Weight Loss and Inflammation in Obesity

There is substantial evidence that circulating levels of major cytokines such as TNF- α , IL-6, and IL-1 β as well as C-reactive protein (the main inflammatory pentraxin synthesized in the liver) are associated with measures of adiposity, such as the waist circumference, the waist-to-hip ratio, and body mass index.¹⁵⁵ The causal nature of this link has been tested in a variety of intervention studies of weight loss in obese patients. Weight loss, no matter whether achieved through diet, exercise, or a surgical intervention, is accompanied by a decline in the level of C-reactive protein (CRP) and other circulating cytokines. The magnitude of the association between body fat and inflammation as well as the dose-response relationship between changes in weight loss and changes in CRP have been recently examined in a thorough meta-analysis encompassing the full series of medical and surgical interventions currently applied to induce weight loss.¹⁵⁶ Reduction in body weight was consistently associated with a decline in CRP level across a wide range of weight loss. In the combined analysis of the various interventions, the strength of the association was quite high because as much as 72% of the variance in CRP change was explained by concomitant weight loss, and each kg of weight loss corresponded to a decrease in CRP of 0.13 mg/L. The largest decreases in CRP level (by 5–10 mg/L) were observed in surgical intervention studies, which achieved the most pronounced weight changes (by 30–45 kg). The consistent association between decreases in inflammatory markers and weight loss, observed in diverse lifestyle-related interventions and in surgical studies, supports the hypothesis that inflammation represents one of the relevant mechanisms transducing the risk of vascular complications in obesity.

Figure 11-4 Mechanisms linking sodium-sensitive hypertension to inflammatory signals. See text for further explanations. NF- κ B, nuclear factor κ B.

Collectively, these studies document that weight loss is probably the most effective intervention for reducing inflammation in obese patients.

INFLAMMATION AND HYPERTENSION

Although still overlooked, it is well demonstrated that hypertension per se (i.e., independent of excess weight, obesity, and other risk factors) is closely linked to inflammation. Plasma concentrations of IL-6 are significantly associated with blood pressure levels in apparently healthy men.¹⁵⁷ The propensity at mounting amplified inflammatory responses to hypertensive stimuli in hypertensive patients is epitomized by the observation that in vitro monocytes of these patients show an amplified synthesis of IL-1 β in response to angiotensin II.¹⁵⁸

Mechanistically, inflammation may be an integral part of the very same process leading to arterial damage in hypertensive patients. Activation of resident cells in the media or the adventitia may produce a variety of inflammatory compounds influencing the vascular tone. This hypothesis is supported by the consistent link between plasma CRP, IL-6, and TNF- α and indexes of arterial rigidity.¹⁵⁹ Of note, in the Women's Health Study cohort, CRP predicts the future development of hypertension.¹⁶⁰ CRP may play a direct role in arterial damage because it is associated with impaired endothelial function¹⁶¹ and because it activates monocytes, vascular smooth muscle, and endothelial cells, thereby generating a proatherogenic milieu.

A major regulator of vascular tone, angiotensin II, has now also emerged as a major determinant of inflammation. Macrophages express high levels of angiotensin-converting enzyme (ACE). In addition, in experimental atherosclerosis, there is a close association between macrophages in the intima-media and angiotensin II.¹⁶² Angiotensin II, through nuclear factor κ B, activates the major cytokine cascade, including TNF- α , IL-6, and monocyte chemoattractant protein-1.^{163,164} Increased vascular superoxide anion (O₂⁻) production and altered vascular relaxation are hallmarks of angiotensin II-induced hypertension.¹⁶⁵ The association between inflammation and cardiovascular damage in experimental models and in humans seems to be causal in nature because a variety of studies with angiotensin-converting enzyme inhibitors or angiotensin II type 1 receptor blockers demonstrated that these drugs not only improve target organ damage and the clinical outcome,¹⁶⁶⁻¹⁶⁹ but also reduce the plasma levels of a variety of inflammation markers.¹⁷⁰ Thus, inflammation is not only a hallmark of established hypertension, but also an alteration that may precede and predict the development of hypertension.

Sodium and Inflammation in Hypertension

It is now well established that sodium may induce hypertension by mechanism(s) beyond the expansion of extracellular volume. High sodium concentration induces cardiac myoblast and smooth muscle cell hypertrophy¹⁷¹ and up-regulates the angiotensin II type 1 receptor,¹⁷² that is, the receptor that triggers vasoconstrictive and also proinflammatory responses. In cells of the proximal tubule, high sodium concentrations per se activate nuclear factor κ B, which is, as highlighted previously, a transcription factor for a variety of proinflam-

matory cytokines, chemokines, and adhesion molecules. This phenomenon is of relevance for intrarenal inflammation, a process now considered a fundamental pathogenetic step in salt-sensitive hypertension (see later). Conversely, sodium has a direct effect on the production of transforming growth factor- β in the kidney cortex of Dahl rats within just 1 day of increasing salt intake,¹⁷³ a phenomenon that may be implicated in the progression of renal disease in this model. Apart from its profibrotic effects, transforming growth factor- β may have a direct effect on blood pressure. Indeed, mice lacking emilin-1, an endogenous inhibitor of transforming growth factor- β , have reduced vessel diameter, increased peripheral vascular resistance, and hypertension.¹⁷⁴

Inflammation appears to be a central mechanism in salt-sensitive hypertension. Activation of nuclear factor κ B and up-regulation of TNF- α correlate with hypertension in the Dahl salt-sensitive rat,¹⁷⁵ and this effect seems to be causally implicated in salt-sensitive hypertension because immunosuppression by mycophenolic acid ameliorates blood pressure in this model.¹⁷⁶ Importantly, oxidative stress, a feature of inflammation, enhances the Na/K/2Cl cotransport and luminal Na/H exchange,¹⁷⁷ thus favoring salt retention. Furthermore, high salt intake triggers oxidative stress by stimulating a fundamental enzyme in the control of superoxide anion generation at the cellular level, reduced nicotinamide adenine dinucleotide phosphate oxidase.¹⁷⁸ Overall, there is therefore coherent, substantial evidence that, in experimental models, salt-induced hypertension is a process characterized by intrarenal inflammation and that inflammation is a key factor mediating the effect of salt on blood pressure and on renal damage in these models.

Salt Sensitivity and Inflammation in Human Hypertension

Salt sensitivity in humans is recognized as an independent driver of cardiovascular events.¹⁷⁹ Salt-sensitive patients frequently do not show the physiologic nocturnal blood pressure decrease¹⁸⁰ and exhibit a greater prevalence of left ventricular hypertrophy,¹⁸¹ and clear-cut endothelial dysfunction.¹⁸² The nondipping pattern of blood pressure¹⁸³ and left ventricular hypertrophy¹⁸⁴ are both well-known correlates of a systemic low-grade inflammatory state in essential hypertensive patients, and salt-induced endothelial dysfunction, a likely consequence of a salt-induced systemic and renal inflammation, is the most probable link between salt sensitivity and atherosclerotic complications in these patients. Soluble intercellular and vascular cell adhesion molecules and E-selectin are elevated in salt-sensitive hypertensive patients.¹⁸⁵ Recent observations indicate that levels of metalloproteinase-9, an enzyme involved in plaque stability, are lower in salt-sensitive than in salt-resistant patients, whereas type 1 tissue inhibitor of metalloproteinases shows an opposite pattern, suggesting that the balance between the two is skewed toward enhanced collagen deposition in the vascular wall in salt-sensitive patients.¹⁸⁶ Thus, findings in salt-sensitive forms of human hypertension appear consistent with data in experimental models. However, there is very little information on the effects of manipulating salt intake on inflammation in salt-sensitive patients. In the only study performed so far, no change in serum CRP, serum intercellular adhesion molecule-1, serum vascular adhesion molecule-1, or IL-6 was observed in either salt-sensitive or

salt-resistant hypertensive patients 2 weeks after switching from a high (250 mmol/day) to a low (50 mmol/day) salt intake.¹⁸⁶ It should be noted, however, that 2 weeks may be too short a time to allow the effect of high salt intake on inflammation to dissipate. Indeed, studies exploring the effect of pharmacologic interventions on the main inflammatory biomarker CRP suggest that a substantially longer treatment period is needed for the effect of statins on CRP to be fully manifest in patients with primary and secondary forms of dyslipidemia, coronary heart disease, and renal diseases.¹⁸⁷

CONCLUSIONS

Modulation of long-chain polyunsaturated FA intake, mostly by increasing the relative proportions of n-3 versus n-6 FAs, is probably the clearest example of how diet may modulate inflammation. It is possible that many of the epidemiologic differences in the incidence of inflammatory diseases among different populations can be tracked back to different nutritional intake of selected, quantitatively minor nutritional components such as n-3 FAs. An additional important notion in the past years has been the role of inflammation in explaining the link between obesity and cardiovascular risk, whereby dietary restriction of calorie intake exerts remarkable anti-inflammatory effects likely intervening in the pathogenetic events linking excess body weight to cardiovascular risk. Finally, the link between dietary sodium intake, salt sensitivity, and hypertension has been highlighted by recent research. The clarification of the mechanisms of action of these dietary components and a better documentation of the spectrum of clinical possibilities offered by dietary manipulation of the intake of such compounds, linking together classic nutritional science, molecular biology, epidemiology, and clinical medicine, are a frontier for nutritional research in the years to come and are likely to gain a place for these compounds in the therapy of inflammatory disorders.

CONCLUSIONS	136

Plasma exchange is the removal of plasma from a patient and replacement with fresh frozen plasma or a substitute for plasma. The procedure is frequently termed *plasmapheresis* when solutions other than plasma (e.g., isotonic saline) are used as replacement fluid. *Pheresis* is derived from the Greek word for “to take away.” The terms *plasma exchange* and *plasmapheresis* are interchangeable, and current literature does not distinguish between them.

Plasmapheresis was first introduced to nephrology for the removal of cryoglobulins in 1967, of alloantibodies in transplantation in 1970, and of antiglomerular basement membrane (GBM) antibodies in anti-GBM disease in 1976.¹⁻³ It has become increasingly employed in renal diseases in which circulating factors, especially antibodies, are believed to contribute to disease pathophysiology. The strength of the theoretical rationale for plasmapheresis varies among indications and is complicated by the nonspecific nature of plasma exchange when potential unidentified pathogenic agents are also removed. Plasmapheresis is an invasive and expensive procedure that carries some risk to the patient. The evidence base for plasmapheresis remains relatively weak, with only a small number of randomized trials with more than 100 patients, and no trials in renal disease have been blinded.

MECHANISM OF ACTION

By removal of plasma, plasmapheresis removes any substance that exists in the plasma compartment. The rational use of plasmapheresis requires identification of the circulating factor to remove and the serial measurement of the factor to guide plasmapheresis dosing. Plasmapheresis is often combined with other treatments to control the target disease. For example, in anti-GBM disease, plasmapheresis rapidly

reduces levels of circulating pathogenic anti-GBM antibodies; renal inflammation is reduced with steroids and cyclophosphamide suppresses further antibody production.⁴ Other indications include the removal of components other than immunoglobulins, such as the removal of prothrombotic von Willebrand’s factor (vWF) multimers by plasmapheresis in thrombotic thrombocytopenic purpura (TTP).⁵ In this setting plasma infusion is also beneficial by replacing a deficient vWF cleaving metalloprotease. Thus, the nature of the replacement fluid may contribute to the therapeutic mechanism of the procedure (Table 12-1).

There are many other potential secondary mechanisms of plasma exchange that are less understood and will be of different relevance in different disease settings. For example, the pathology of small-vessel vasculitis includes inflammatory cytokines and chemokines and microthrombosis. The removal of these factors along with fibrinogen and other coagulation factors may be relevant to the therapeutic effect of plasma exchange. In autoimmune settings, prolonged immunoregulatory effects of plasmapheresis on lymphocyte activity and antibody production have been demonstrated, and plasmapheresis improves immune complex clearance.⁶⁻⁸ Until these other mechanisms of plasmapheresis are better understood, they cannot be used to support its use in the absence of an identified circulating factor or secure clinical evidence.

TECHNICAL CONSIDERATIONS

Plasmapheresis involves withdrawal of venous blood, separation of plasma from blood cells, and reinfusion of cells plus donor plasma or another replacement solution. Plasma and blood cells may be separated by centrifugation or membrane filtration (Fig. 12-1).

Table 12-1 Possible Mechanisms of Action of Plasmapheresis

Mechanism	Example of Disease
Removal of Circulating Pathologic Factors	
Autoantibodies	Anti-GBM antibody disease, ANCA-associated vasculitis
Donor-specific antibodies	ABO-incompatible transplantation, HLA sensitization
IgA immune complexes	Crescentic IgA nephropathy, Henoch-Schönlein purpura
Cryoglobulin	Cryoglobulinemia
Myeloma protein	Myeloma cast nephropathy
Prothrombotic factors	Thrombotic microangiopathy
Replacement of Deficient Plasma Factors	
Antithrombotic or fibrinolytic factor	Thrombotic microangiopathy
Effects on the Immune System	
Removal of complement products	Lupus nephritis
	Transplantation
Effect on Immunoregulation	
Improvement in reticuloendothelial system function	SLE, cryoglobulinemia

ANCA, antineutrophil cytoplasmic antibody; GBM, glomerular basement membrane; HLA, human leukocyte antigen; IgA, immunoglobulin A; SLE, systemic lupus erythematosus.

Centrifugation Technique

The use of centrifugal force causes whole blood to separate into various components according to their specific gravity, and the separation is monitored by sensors on the centrifuge or by computer algorithms.⁹ Centrifugation can be intermittent or continuous. With intermittent centrifugation, blood is drawn in successive batches and separated. The cycle is repeated as often as necessary to remove the desired volume of plasma (usually, the equivalent of 1.0–1.5 plasma volumes or 2.5–4.0L during a session). The advantages of intermittent centrifugation include relative simplicity of operation, portability of the machines, and adequacy of a single-needle peripheral venipuncture. The disadvantages are slowness (typically > 4 hr) and the relatively large extracorporeal blood volume required (>225 mL). With continuous-flow equipment, blood is fed continuously into a rapidly rotating bowl in which red cells, leukocytes, platelets, and plasma separate into layers. Any layer or layers can be removed, and the remainder is returned to the patient with replacement fluid (see Fig. 12-1A). Continuous-flow centrifugation is faster and most operations (anticoagulation, collection procedures, fluid replacement) are automated. Disadvantages include higher cost, relative immobility of the equipment, and the requirement of either two venipunctures or insertion of a dual-lumen catheter.

Membrane Filtration Technique

Membrane filtration technology provides an alternative to centrifugation. The patient's blood is pumped through a parallel-plate or hollow-fiber filter at a continuous flow rate, typically 50 to 200 mL/min (see Fig. 12-1B). The membranes usually have

pores of 0.2- to 0.6- μ m diameter, sufficient to allow passage of plasma while retaining cells. Plasma is collected and weighed regularly, and the infusion rate of replacement fluid is adjusted manually or automatically to maintain intravascular volume. Membrane filtration can be performed using conventional hemodialysis equipment, but with increasing automation, specifically designed machines are safer and more convenient. Patients with acute renal failure can receive hemodialysis and plasmapheresis sequentially, using the same machine. In general, plasma can be removed at a rate of 30 to 50 mL/min (at a blood flow rate of 100 mL/min), and the average time required for a typical membrane filtration is less than 3 hours. The potential disadvantages of membrane filtration include activation of complement and leukocytes on the artificial membrane and the need for a large-vein catheter to obtain adequate blood flow rates.¹⁰

Membrane filtration is as safe and efficient as centrifugal plasmapheresis.¹¹ Automated continuous-flow centrifugal devices are more expensive than membrane-based filtration devices; however, the major costs of plasmapheresis relate to blood products, disposable blood lines, filters or centrifuge bowls, and staff time. In 2007, reimbursement rates for plasmapheresis in the United States were more than \$1800 per procedure.

Selective Plasmapheresis Techniques

More sophisticated approaches achieve selective removal of immunoglobulins or other specific molecules. They have the joint aims of more efficient removal of the target factor and avoidance of the need for blood factor replacements and their associated cost and adverse reactions. In double-filtration apheresis following conventional plasmapheresis, separated

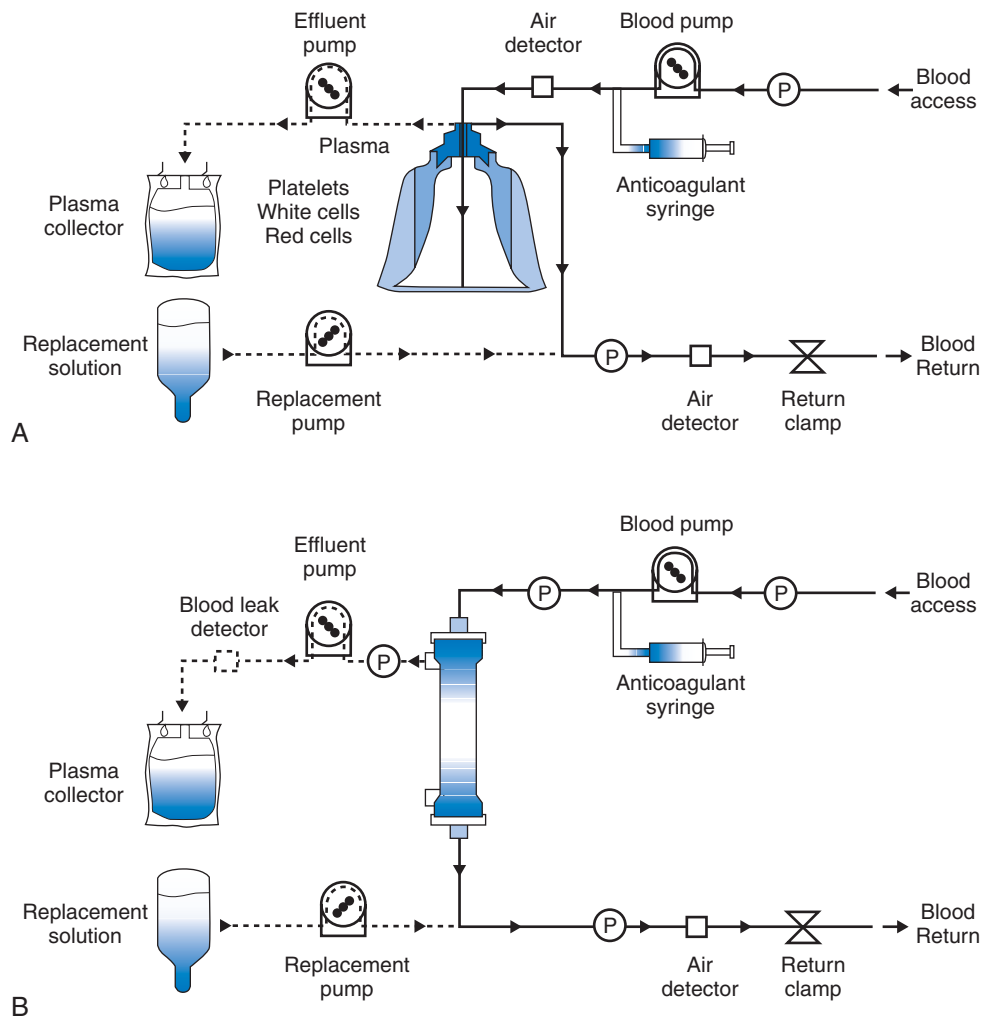

Figure 12-1 Centrifugal separator (**A**) and membrane filtration (**B**) systems for plasma exchange. **A**, Blood is pumped into the separator container. As the centrifuge revolves, different blood components are separated into discrete layers, which can be harvested separately. Plasma is pumped out of the centrifuge into a collection chamber. Red cells, leukocytes, and platelets are returned to the patient, along with replacement fluid. **B**, Blood is pumped into a biocompatible membrane that allows the filtration of plasma while retaining cellular elements. P, pressure monitor.

plasma is passed through a second filter for which the pore size can be selected according to the indication. The remaining plasma is then returned to the patient.¹¹ More than one plasma volume can be treated in one procedure, allowing more complete removal of the target factor. This is of potential use for the removal of donor-specific antibodies for immediate pre-transplantation desensitization, for the removal of pathogenic antibodies in a seriously ill patient, for patients who cannot tolerate plasmapheresis, or for patients in whom conventional plasmapheresis provides inadequate target factor removal.

Modifications to the double-filtration process combine ligands for the target protein in the secondary column, so-called immunoabsorption. Examples include staphylococcal protein A to remove IgG antibodies, blood protein antigens A and B to remove anti-A and anti-B antibodies, and L-tryptophan or phenylalanine to remove autoantibodies.^{12–15} These procedures have been used in case series in renal diseases; however, a prospective, randomized trial in 44 patients with rapidly progressive glomerulonephritis (RPGN) found no difference in outcome between plasmapheresis and protein A immunoabsorption.^{16,17}

The high cost of secondary columns and complexity of double plasma treatment systems is currently limiting their availability, but with the increasing costs of blood products, they will become more attractive in the future.

Anticoagulation

Both centrifugation and membrane plasmapheresis require anticoagulation to prevent activation of the clotting mechanisms within the extracorporeal circuit. The most frequently used anticoagulant for centrifugation procedures is citrate. Acid-citrate dextrose is infused continuously at a rate adjusted according to the blood flow rate. Citrate chelates the divalent cations calcium and magnesium and may result in symptomatic hypocalcemia, especially with albumin replacement solutions that contain no calcium or magnesium. Standard unfractionated heparin is the most frequently used anticoagulant for membrane plasmapheresis. The required dose of heparin is approximately twice that needed for hemodialysis because a substantial amount of the infused heparin is removed along with the plasma.

Replacement Fluids

The typical replacement fluids are fresh frozen plasma, 5% albumin or other plasma derivatives (e.g., cryosupernatant), and crystalloids (e.g., 0.9% saline or Ringer's lactate). The choice of fluid has implications for the efficacy of the procedure, oncotic pressure, coagulation, and spectrum of adverse effects. Albumin is usually preferred to plasma because of the risk of hypersensitivity reactions and transmission of viral infections with the latter. When directly compared for the treatment of autoimmune disease, there was no difference in efficacy of plasmapheresis between albumin or plasma replacement.¹⁸ Albumin (5%) is either used as 100% volume replacement or diluted 50:50 (volume/volume) with 0.9% saline. The exact composition of replacement fluids is tailored to the needs of the patient. For example, plasma is the replacement fluid of choice in patients with thrombotic microangiopathy (TMA) because the infusion of normal plasma may contribute to the replacement of a deficient plasma factor.⁵ Plasma or a plasma derivative dosed at 6 to 12 mL/kg is used toward the end of the procedure in patients at risk of bleeding (e.g., after renal biopsy or those with liver disease or disseminated intravascular coagulation) or requiring intensive therapy (e.g., daily exchanges for several weeks). Alternatively fibrinogen levels can be monitored and plasma protein replacement dosed against fibrinogen levels. Albumin replacement and plasma replacement are equally effective at reducing plasma viscosity.¹⁹

EFFICACY OF PLASMAPHERESIS IN SPECIFIC RENAL DISEASES

General Comments

Clinical application of plasmapheresis was based initially on anecdotal or uncontrolled studies. The past two decades have witnessed a more rigorous reexamination of the efficacy of therapeutic plasma exchange.^{20–23} However, for many disorders, there are few prospective, controlled clinical trials with adequate statistical power to allow definitive conclusions to be reached regarding the efficacy of plasmapheresis. In addition, other factors complicate the interpretation of published literature. First, the natural history of many diseases under investigation (e.g., lupus) is characterized by spontaneous exacerbations and remissions, making it difficult to evaluate whether any improvement is attributable to plasmapheresis. Second, treatment protocols vary widely between centers, making the comparison between

published studies hazardous. Finally, plasmapheresis is often combined with other therapies, making it harder to determine the value of the intervention. The therapeutic use of plasmapheresis in specific renal conditions is reviewed with reference to the pathogenesis when known, the strength of clinical trial evidence, and details of specific plasmapheresis regimens. Renal diseases in which plasmapheresis has been used include the various causes of RPGN, systemic lupus erythematosus, the TMAs, multiple myeloma, cryoglobulinemia, and renal transplantation.

Antiglomerular Basement Membrane Antibody Disease

Anti-GBM antibody disease (see also Chapter 18) typically presents as RPGN with or without pulmonary hemorrhage (Goodpasture's syndrome). Circulating anti-GBM antibodies are detected in more than 90% of patients, and, in general, disease activity correlates with the level of circulating anti-GBM antibodies.²⁴ Before 1975, anti-GBM-induced nephritis had a very poor prognosis, and more than 85% of patients treated with steroids and cytotoxic drugs progressed to end-stage renal disease (ESRD).⁴ Against this background, the results of more than 20 uncontrolled studies including more than 250 patients, published over the past 20 years, suggest that survival rates greater than 80% and renal preservation rates greater than 45% may be obtained with therapeutic regimens combining plasmapheresis and immunosuppressive drugs.⁴ These results compare favorably with historic data suggesting a patient survival rate of 45% and progression to ESRD in 85%. The largest published series involved 71 patients, and the outcome is detailed in Table 12-2. The chance of renal recovery was particularly poor for the most common subgroup, which is those presenting with a serum creatinine greater than 500 $\mu\text{mol/L}$ and an immediate dialysis requirement due to oliguria or anuria. Less than 10% recovered renal function, and none of those in this subgroup who had 100% crescents on renal biopsy recovered. Several other centers have also reported that patients with a serum creatinine level greater than 500 $\mu\text{mol/L}$ are unlikely to respond to therapy and regain renal function.

The specific role of plasmapheresis in anti-GBM disease has never been properly assessed by prospective, randomized, controlled trials. Only two controlled studies have evaluated the efficacy of plasmapheresis as an adjunct to conventional immunosuppressive therapy in this disease.^{25,26} Although small (17 and 20 patients), both studies suggested a benefit as evidenced by faster decrease in anti-GBM antibody titers, lower serum creatinine after therapy, and fewer patients progressing

Table 12-2 Renal Outcome and Survival of 71 Patients with Anti-GBM Disease

Renal Function at Presentation	No. of Patients	PATIENT SURVIVAL		RENAL SURVIVAL	
		12 Mo	90 Mo	12 Mo	90 Mo
Creatinine < 500 $\mu\text{mol/L}$	19	19 (100%)	16 (84%)	18 (95%)	18 (95%)
Creatinine > 500 $\mu\text{mol/L}$	13	11 (83%)	8 (62%)	9 (82%)	4 (50%)
Dialysis dependent	39	26 (65%)	14 (36%)	2 (8%)	2 (5%)
Total	71	55 (77%)	38 (54%)	29 (53%)	25 (35%)

Data from Levy JB, Turner AN, Rees AJ, Pusey CD: Long-term outcome of anti-glomerular basement membrane antibody disease treated with plasma exchange and immunosuppression. *Ann Intern Med* 2001;134:1033–1042.

to renal failure. However, the authors were cautious about concluding that plasmapheresis had been responsible for the improved outcome because the groups receiving plasmapheresis had milder disease than the control groups.

Thus, there is good evidence based on an understanding of the pathogenesis and from nonrandomized trials with historic comparison that plasmapheresis in combination with steroids and immunosuppressive drugs improves renal outcome in patients with anti-GBM disease but without an immediate dialysis requirement. Plasmapheresis can accelerate disappearance of anti-GBM antibody and improve renal function if instituted promptly. Patients with oliguria/anuria and serum creatinine greater than 500 $\mu\text{mol/L}$ (5.8 mg/dL) are unlikely to recover renal function, especially if the renal biopsy specimen demonstrates 100% crescents. Plasmapheresis is hard to justify in this setting unless lung hemorrhage is present. Lung hemorrhage is a life-threatening manifestation of anti-GBM disease and is more common in cigarette smokers. Urgent plasmapheresis is required to rapidly reduce anti-GBM levels with attention paid to replacement of coagulation factors, without which hemorrhage may be exacerbated.

Daily plasmapheresis involving 60 mL/kg phereses is usually continued for 10 to 12 days with measurement of anti-GBM levels. The target is to continue plasmapheresis until pretreatment levels fall into the normal range. Once this is achieved, plasmapheresis may be stopped but anti-GBM measurement should continue because an antibody rebound may occur in the days following its withdrawal. Late relapse of anti-GBM disease is rare.

One third of patients with RPGN and anti-GBM antibodies also have antineutrophil cytoplasm antibodies (ANCA) and features of systemic vasculitis.²⁷ Such patients present with severe nephritis and are more likely to have pulmonary hemorrhage and are generally older than those with anti-GBM alone. The chances of renal recovery appear similar to those in patients with anti-GBM alone, and initial management is similar.²⁸ This subgroup differs from those with pure anti-GBM disease in that relapse may occur during long-term follow-up. Anti-GBM is negative at the time of relapse, but ANCA is usually positive.

Antineutrophil Cytoplasm Antibody–Associated Vasculitis

The renal lesion in Wegener's granulomatosis and microscopic polyangiitis is a focal, necrotizing glomerulonephritis in association with circulating ANCA with specificity for proteinase 3 (proteinase 3–ANCA) or myeloperoxidase (myeloperoxidase–ANCA).²⁹ When disease is limited to the kidney, the term renal-limited vasculitis has been used. These syndromes are grouped under the term ANCA-associated vasculitis (AAV) (see also Chapter 17). The majority of cases have few or no immune deposits (pauci-immune), but 30% have appreciable immunoglobulin deposition. The pathogenicity of ANCA has been demonstrated in vitro and in experimental animals.³⁰ In human disease, ANCA appear likely to contribute to the pathogenesis, but other mechanisms are important and ANCA are not detectable in 5% of pauci-immune crescentic glomerulonephritis.³¹ Plasmapheresis reduces levels of circulating ANCA and adhesion molecules in vasculitis but has little effect on the high cytokine levels.³² The typical clinical presentation is with RPGN, but an earlier phase with hematuria, proteinuria, and preserved renal function is often found when extrarenal manifestations dominate the presentation.

Conventional therapy employs the combination of high-dose corticosteroids and cyclophosphamide.³³

Early randomized, controlled trials evaluated the efficacy of plasmapheresis as an adjunct to immunosuppressive therapy in patients with pauci-immune RPGN and varying degrees of renal failure, mostly before the availability of ANCA testing (Table 12-3).^{22,34–40} Two studies randomly assigned patients to receive immunosuppressive agents with or without plasmapheresis and found no statistically significant difference between the two groups as judged by serum creatinine or dialysis dependence.^{35,37} Three other studies demonstrated better renal outcomes in subgroup analyses of those presenting with severe disease.^{36,38,39} Nonrandomized, controlled studies and other case series have indicated a recovery rate of 75% in those presenting in renal failure with a creatinine level greater than 5.8 mg/dL (500 $\mu\text{mol/L}$); this appears superior to that reported in series not using plasmapheresis in which recovery rates of 40% to 50% were seen.^{41–43}

A recent study focused on 137 AAV patients presenting with a creatinine level greater than 5.8 mg/dL (500 $\mu\text{mol/L}$) who were randomized to either seven plasmapheresis sessions of 60 mL/kg within 14 days or three daily infusions of 1000 mg of methylprednisolone.²² All patients received oral cyclophosphamide and the same oral corticosteroid regimen. Renal recovery occurred in 69% of the pheresis group and 49% of the control group. Risk of progression to ESRD was reduced by pheresis by 24%.⁴⁴ Thus, this study confirmed the benefit of pheresis seen earlier for the subgroup of patients presenting in renal failure, and plasmapheresis can now be routinely recommended for this indication. In a multivariate analysis studying predictive factors for renal recovery in this subgroup, the use of plasmapheresis remained associated with an improved outcome even in the presence of severe histologic features.⁴⁵

Uncertainty remains regarding the role of plasmapheresis in AAV with RPGN and serum creatinine less than 500 $\mu\text{mol/L}$. Studies that have reported on this varied in the number of plasmapheresis sessions, and there is no established measure by which to judge how many sessions are needed. There also are no data to support or refute using ANCA levels in this setting; however, persistence of ANCA, lack of renal improvement as judged by urine output and serum creatinine, and activity of extrarenal vasculitis suggest that prolonged plasmapheresis may be required.

Pulmonary hemorrhage occurring with RPGN is termed pulmonary renal syndrome. AAV is the cause in 80% of cases, and it has been suggested that the pathogenesis of alveolar capillaritis is similar to that occurring in the glomeruli. Lung hemorrhage can be life threatening, and plasmapheresis is frequently used for this indication, but no randomized trials have addressed this presentation.^{46,47} Whether plasmapheresis has a role for the treatment of other severe extrarenal manifestations of vasculitis is unknown, with inconclusive randomized trials providing conflicting evidence.^{34,48}

Lupus Nephritis

Nephritis (see also Chapter 15) occurs in one third of patients with systemic lupus erythematosus and implies a poor prognosis with mortality rate of 12% and risk of progression to ESRD of 12% at 10 years with poorer outcomes in black populations.^{49,50} The pathogenesis is complex with dysregulation of cellular, antibody, and cytokine/chemokine immune components. A belief in

the pathogenicity of circulating anti-double-stranded DNA antibodies or immune complexes developed from animal models inspired interest in plasmapheresis, and case reports and uncontrolled case series indicated a potential role in human disease.

The Lupus Nephritis Collaborative Study Group assessed the value of plasmapheresis as an adjunct to prednisone and cyclophosphamide in 86 patients with severe lupus nephritis.⁵¹ Patients underwent plasmapheresis three times weekly for 4 weeks and were followed for an average of 136 weeks. Plasmapheresis caused a rapid reduction of serum anti-double-stranded DNA antibodies and cryoglobulins, but did not influence renal function or mortality. Importantly, patients receiving plasmapheresis tended to have a worse outcome. Four smaller randomized, controlled trials of plasmapheresis have been reported, although some patients included in these trials had mild disease (Table 12-4).⁵¹⁻⁵⁵ Plasmapheresis produced significant reduction in circulating immune complexes and anti-DNA antibodies, but the frequency and degree of partial or complete remission were the same in both plasmapheresis and control groups. Experimental evidence suggesting increased autoantibody production after plasmapheresis led to a theory that autoreactive lymphocytes might become more sensitive to cyclophosphamide in this setting.⁵⁶ Despite encouraging results in an uncontrolled study, a randomized, controlled trial found no additional benefit of sequential plasmapheresis and high-dose cyclophosphamide when compared with

conventional cyclophosphamide dosing without plasmapheresis, and the sequential group had more severe adverse events.⁵⁶⁻⁵⁸

The results of the randomized trials do not exclude a beneficial role for plasmapheresis in defined subgroups, and no good studies have examined its role in lupus nephritis with RPGN, refractory lupus nephritis, or lupus nephritis with TMA. The evidence from TMA in other disease settings suggests an indication for plasmapheresis, and case series of catastrophic antiphospholipid syndrome also support its use.^{59,60} Furthermore, there are uncommon extrarenal lupus manifestations associated with pathogenic autoantibodies, such as secondary diabetes with insulin receptor antibodies, in which plasmapheresis has been helpful.⁶¹ Therefore, although plasmapheresis cannot be recommended for the routine treatment of severe lupus nephritis, it retains a potential role in certain subsets of patients.^{62,63} Infection is the major cause of early mortality in SLE, and the possible increased infective risk of immunoglobulin removal by plasmapheresis in addition to high-dose corticosteroids and immunosuppression should be considered.

Cryoglobulinemia

Mixed (type II) cryoglobulinemia (see also Chapter 14), reflecting immune complexes containing monoclonal IgM rheumatoid factor and polyclonal IgG that precipitate within the glomerular

ESRD, end-stage renal disease; GFR, glomerular filtration rate.

capillary lumen, is often associated with a proliferative or membranoproliferative glomerulonephritis and a variable but sometimes rapidly progressive course. The majority of cases of type II cryoglobulinemia occur in association with chronic hepatitis C virus infection.⁶⁴ It may also be associated with non-Hodgkin's lymphoma or occur in isolation, that is, mixed essential cryoglobulinemia. Circulating cryoglobulins can be directly measured, and the level of monoclonal IgM, rheumatoid factor activity, and complement levels also reflect disease activity. Proteinuria is often of nephrotic range and extrarenal manifestations of systemic vasculitis are typically present.

Because cryoglobulins are restricted to the plasma compartment, their levels are rapidly and predictably reduced by plasmapheresis. Although case series have shown improved renal function in 55% to 87% of patients and improved survival (~25% mortality rate) compared with historic data (~55% mortality rate), the efficacy has never been subjected to a prospective, randomized, controlled clinical trial despite 30 years of experience.⁶⁵

Management of cryoglobulinemia should address the underlying cause as well as the inflammatory manifestations. In hepatitis C–associated cryoglobulinemia, control of viral replication with interferon- α and ribavirin will abolish cryoglobulin production. Plasmapheresis increases the clearance of interferon- α and dosing may need to be adjusted.^{66,67} Uremic patients tolerate interferon- α poorly and have a high frequency of *Staphylococcus aureus* sepsis. Plasmapheresis and corticosteroids may be required in the acute presentation or for the management of disease flare, but prolonged therapy is unnecessary if viral replication is controlled. In contrast, for mixed essential cryoglobulinemia, chronic intermittent plasma exchange may be required to control cryoglobulin levels, which are usually refractory to conventional immunosuppressives, including cyclophosphamide.⁶⁸ After an intensive course of three to five plasmaphereses, measurement of sequential cryoglobulin levels will allow the rate of synthesis to be assessed. A return of cryoglobulins does not necessarily imply return of glomerulonephritis or other inflammatory disease, and long-term therapy with corticosteroids and immunosuppression may dissociate cryoglobulin levels from disease activity. However, in those cases in which active inflammation persists, long-term intermittent plasmapheresis may be required.⁶⁷ Intravenous immunoglobulin may precipitate a cryoglobulinemic crisis but can be administered more safely immediately after plasma exchange. Rituximab and other therapeutic monoclonal antibodies are showing promise in a proportion of cryoglobulinemic patients but will be cleared by plasmapheresis, and their administration should also be planned to follow the procedure.⁶⁹

The requirement for plasmapheresis should be determined by clinical severity. In subacute presentations with preserved renal function, corticosteroids with antiviral therapy in hepatitis C–associated disease or corticosteroids with an immunosuppressive in mixed essential disease may be sufficient. Plasmapheresis is indicated for persistent nephrotic syndrome, progressive renal failure, and severe extrarenal features, such as polyneuropathy. The frequency of plasmapheresis should be guided by the cryocrit, rheumatoid factor and complement levels, proteinuria, and serum creatinine. Volume should be replaced with albumin and saline and not plasma. Patients should be treated in a warm room with all infusions heated to 37°C to avoid cold precipitation of cryoglobulins. Despite optimal therapy in this subgroup of

patients, adverse events, including severe infection, are common and the risk of progression to ESRD is high.

IgA Nephropathy and Henoch-Schönlein Purpura

IgA nephropathy and Henoch-Schönlein purpura (HSP) (see also Chapter 16) represent a spectrum of manifestations of the same disease and are characterized by production of aberrantly glycosylated IgA1, circulating IgA rheumatoid factors, and IgA-containing immune complexes and mesangial deposition of IgA. Although serum total IgA concentration is elevated in 33% to 55% of patients, circulating IgA levels do not correlate with the severity or activity of disease. IgA nephropathy has a benign course in 50% to 70%, but those with proteinuria, hypertension, and glomerular or interstitial scarring follow a slowly progressive course with an appreciable risk of ESRD at 20 years. Less frequently, IgA nephropathy has a rapidly progressive course with glomerular necrosis, crescents, and deteriorating renal function. This also occurs in 24% of children and 31% of adults with HSP, accompanied by extrarenal features of systemic vasculitis.⁷⁰ Plasmapheresis has been employed in this setting in small case series.^{71,72} Roccatello and colleagues⁷¹ reported on their experience in treating six adults with crescentic IgA disease using plasmapheresis in addition to steroids and cyclophosphamide. All patients improved in the short term, but subsequent deterioration in renal function was observed in more than half of these patients. Sixteen children with HSP and severe renal involvement were treated with plasmapheresis alone; 15 recovered and one, referred late, developed ESRD.⁷³ Reversal of renal histologic activity and prevention of chronic changes was observed in six children who underwent biopsy before and after plasmapheresis plus immunosuppression.⁷⁴ Unfortunately, the uncontrolled nature of these observations does not permit definitive conclusions about the efficacy of plasmapheresis.

There is no consensus or randomized, controlled trials to guide either the use of corticosteroids or immunosuppressive drugs or plasmapheresis for the treatment of RPGN in IgA nephropathy or HSP. A rationale exists for the use of plasmapheresis to remove circulating IgA, and existing data are supportive but not conclusive.⁷⁵

Focal Segmental Glomerulosclerosis and Relapsing Nephrotic Syndrome

A circulating pathogenic factor has been partly identified in focal segmental glomerulosclerosis (FSGS) that indicates plasmapheresis may be an effective treatment.⁷⁶ Small case series of patients with primary FSGS or relapsing nephrotic syndrome have reported benefit with prolonged plasmapheresis in a proportion of patients.^{77–79} Reduction of proteinuria was used to determine the efficacy of plasmapheresis and the need for further treatment. The use of plasmapheresis for recurrent FSGS is discussed in the following section.

Thrombotic Microangiopathy

TMA (see also Chapter 26) is the renal lesion seen in hemolytic-uremic syndrome (HUS) and TTP and is found in conjunction with consumptive thrombocytopenia, microangiopathic hemolytic anemia, renal failure, and extrarenal organ involvement.⁸⁰ The pathogenesis may involve the accumulation

of vWF multimers as a result of a deficiency of a vWF cleaving metalloprotease, ADAMTS 13, or the presence of an inhibitor to ADAMTS 13.⁵ The vWF multimers cause endothelial cell and platelet activation and consequent microvascular thrombosis. An autoantibody blocking the activity of ADAMTS 13 is present in some spontaneous cases and when TMA occurs in association with systemic lupus erythematosus.⁸¹ Infection-associated TMA results from a circulating toxin that causes direct endothelial injury and platelet activation. The rationale for therapy is the removal of pathogenic autoantibody, vWF multimers, or other pathogenic factors and the replacement of deficient antithrombotic and fibrinolytic factors with normal plasma. Plasmapheresis will also remove other circulating procoagulant and inflammatory factors. Therapeutic plasma exchange has been suggested mainly for adult HUS-TTP, although some studies have also included cases with childhood diarrhea-associated HUS.

Most of the evidence in favor of the role of plasmapheresis in HUS-TTP originates from uncontrolled or retrospective studies and from comparison with historical data.^{80,82} Before the introduction of plasma infusion and plasmapheresis, TTP typically progressed rapidly and was almost uniformly fatal (93% fatality rate; 79% within 90 days). With plasmapheresis using fresh frozen plasma, remission rates of greater than 75% and survival rates greater than 85% have been consistently reported.⁸² The underlying cause of TMA influences the outcome with idiopathic or autoimmunity-associated cases having a superior outcome when compared to those associated with malignancy or bone marrow transplantation.⁸³

Two randomized, controlled trials compared plasma exchange with plasma infusion (Table 12-5).^{84,85} Rock and colleagues⁸⁴ randomized patients with TTP to either plasma exchange or plasma infusion with fresh frozen plasma and observed that patients receiving plasma exchange had a better response rate and superior survival. Although the authors concluded that plasma exchange is superior to plasma infusion, interpretation should be guarded because patients undergoing plasma exchange received three times as much plasma as patients undergoing plasma infusion. Indeed, a smaller multicenter controlled trial did not observe a difference in outcome when patients were randomized to receive either daily infusions of 15 mL/kg of fresh frozen plasma or plasma exchange with a mixture of 15 mL/kg of fresh frozen

plasma and 45 mL/kg of 5% albumin as replacement fluid (see Table 12-5).⁸⁵ Thus, the exact role of plasma removal and plasma infusion in the beneficial effect of plasma exchange remains controversial. A retrospective analysis has found that mortality in TMA is related to low plasmapheresis dosing.⁸⁶ Predictive factors for mortality were age older than 40 years, hemoglobin less than 9 mg/dL, and fever; the authors suggested that those with a more severe prognosis should receive more plasmapheresis, but this has not been prospectively examined. A further retrospective review of idiopathic TTP found a mortality of 11%, a response to plasmapheresis rate of 80%, and an association of low hemoglobin with response to plasmapheresis; elevated lactate dehydrogenase levels after therapy predicted relapse.⁸³ Persistence of low ADAMTS 13 activity or high inhibitor levels after plasmapheresis is associated with a poor outcome, and these assays may be useful to titrate therapy.⁸¹

Plasmapheresis in combination with plasma infusion is now widely recommended for TMA regardless of its cause. Therapy aims to restore a platelet count to more than 150×10^9 L, with a low hemoglobin and elevated lactate dehydrogenase levels indicating a need for a longer treatment course. Typically, daily plasmapheresis of 60 mL/kg is required for 7 to 14 days with whole plasma or cryosupernatant plasma replacement.⁸²

Renal Failure Associated with Multiple Myeloma

See also Chapters 23 and 40.

Renal failure complicates 3% to 9% of cases of multiple myeloma, of which 80% to 90% develop ESRD, and their survival is poor. Renal impairment can be caused by a variety of factors, including precipitation of free light chains within renal tubules and direct toxicity to tubule epithelium. Other factors frequently implicated include hypercalcemia, hyperuricemia, amyloidosis, hyperviscosity, infections, and chemotherapeutic agents. Measurement of circulating free light chains has shown that plasmapheresis is relatively inefficient at their removal, whereas hemodialysis with protein-leaking dialyzers is more effective.^{87,88} Randomized, controlled trials have evaluated plasmapheresis in multiple myeloma but preceded the availability of free light chain assays (Table 12-6).^{89,90} Johnson and colleagues⁸⁹ randomized patients to either chemotherapy and

forced diuresis with or without plasmapheresis and could detect only a small and nonsignificant benefit on renal function despite lowering of plasma concentration of myeloma protein. There was no difference in patient survival. In contrast, Zucchelli and colleagues⁹⁰ randomized patients to receive steroids and cyclophosphamide with or without plasmapheresis and observed significant improvements in renal outcome and patient survival. A similar trend was noted in at least three other nonrandomized studies and case series. The Canadian Apheresis Group study found no superior outcome of five to seven plasmaphereses in 104 patients with acute renal failure at the onset of myeloma.²³

A decision to use plasmapheresis in multiple myeloma with renal failure should be preceded by attention to reversible factors including volume depletion and hypercalcemia. The role of plasmapheresis remains controversial, and the role of free light chain assays and their removal by hemodialysis requires further attention. While plasmapheresis dosing can be guided by renal recovery, existing data suggest that substantial free light chain removal requires prolonged therapy.

Renal Transplantation

Investigations of plasmapheresis in renal transplantation have focused on desensitization, treatment of rejection, and prevention and treatment of recurrent glomerular disease. Comparison of studies is complicated by different background immunosuppressive regimens and variable combination of plasmapheresis with therapeutic antibodies and intravenous immunoglobulin.

Plasmapheresis is increasingly employed to permit desensitization for ABO incompatibility or remove anti-HLA antibodies in sensitized patients. ABO incompatibility is a barrier to live kidney donation in 30% to 50% of cases, and removal of alloantibodies before and immediately after transplantation in combination with immunosuppression, rituximab, intravenous immunoglobulin, or splenectomy has led to graft survival rates similar to those of ABO-compatible transplants.¹⁵ Procedures have involved conventional plasmapheresis or semiselective removal of immunoglobulin by double-filtration pheresis, staphylococcal protein A immunoabsorption, or selective removal of anti-A and anti-B antibodies using a blood group A and B antigen column. The dosing of plasmapheresis before

and after transplantation is titrated against circulating anti-A/B antibodies.

Approximately 20% of patients waiting for cadaveric transplantation have high titers of preformed cytotoxic antibodies that render them at high risk of hyperacute and acute allograft rejection. Plasmapheresis and immunoabsorption are also effective in the removal of cytotoxic anti-HLA antibodies before transplantation, permitting successful transplantation.¹² Prophylactic plasmapheresis of highly sensitized patients in the immediate postoperative period has not shown a major benefit over conventional antirejection prophylaxis.

Evidence supporting removal of donor-specific cytotoxic antibodies and inflammatory mediators in humoral rejection with prominent vascular injury by plasmapheresis in combination with other strategies has been controversial, with older studies reaching conflicting conclusions and more recent, uncontrolled studies reporting benefits on long-term graft function.^{91,92} In a comparison with historic controls, the combination of plasmapheresis and intravenous immunoglobulin led to superior graft outcomes in humoral rejection than the additional use of intravenous immunoglobulin alone.⁹³ The recent identification of antibodies targeting the angiotensin II receptor type I in association with humoral rejection provides a further target for plasmapheresis.⁹⁴ Circulating antiendothelial antibodies have been identified in certain cases of humoral rejection associated with a high risk of graft failure; their removal by plasmapheresis is advocated according to the results of several small studies.^{91,92} Where donor-specific or other pathogenetic antibodies are identified, dosing of plasmapheresis can be titrated against their levels.⁹⁴ Four randomized, controlled trials have been conducted on the efficacy of plasmapheresis in the treatment of established acute rejection (Table 12-7).^{95–98} Blake and colleagues⁹⁵ randomized 85 patients to receive conventional antirejection therapy with or without plasmapheresis for treatment of all episodes of acute rejection occurring within the first 3 months after transplantation. There was no statistically significant difference in 5-year actuarial graft survival, although there was a trend toward superior graft survival in patients undergoing plasmapheresis. Two of these studies^{96,97} did not observe a significant difference in graft survival, whereas the third study⁹⁸ suggested a benefit. Thus, all the data published to date do not support the use of therapeutic plasmapheresis for the prevention or

treatment of acute rejection. The literature on therapeutic plasmapheresis in chronic allograft nephropathy is limited to a few uncontrolled series, and the results in general have been disappointing, with improvement in graft function being, at best, modest and usually transient.⁹⁹

The presence of a circulating pathogenetic factor and the high rate of recurrent disease have provided a rationale for plasmapheresis in posttransplantation FSGS. Several small studies have reported success both in the prevention of recurrent disease by pre- and posttransplantation plasmapheresis or immunoabsorption and in its treatment, as judged by a reduction in proteinuria, after transplantation.^{77,100–104} Further work is required to enable better prediction of the risk of recurrent disease, an understanding of plasmapheresis failure when it is ineffective, and a guide to plasmapheresis dosing in the absence of an accessible biomarker. TMA with or without associated HUS occurs de novo post-transplantation or as recurrent disease; plasmapheresis has been used in both its treatment and prevention.^{82,105} The role of plasmapheresis in other glomerulopathies with a high risk of recurrence, such as dense deposit disease, is unclear.

Other Indications

Other indications included hepatitis B–associated polyarteritis, serum sickness, and toxin removal. Polyarteritis nodosa associated with hepatitis B infection has been effectively treated in an observational study by corticosteroids, plasma exchange, and lamivudine. All patients had remission of vasculitis and the majority lost hepatitis B early antigen and hepatitis B virus DNA from the circulation. Randomized trials have not shown a benefit in polyarteritis nodosa without hepatitis B infection.⁴⁸

Serum sickness reactions after polyclonal or monoclonal antibodies, such as antithymocyte globulin, that fail to respond rapidly to corticosteroids, have improved after one or two plasmapheresis procedures.¹⁰⁶ With increasing use of therapeutic monoclonal antibodies, there is a need for a study of the role of plasmapheresis in the management of severe infusion reactions associated with an antiglobulin

response or unintended effects of the primary therapeutic antibody.

The removal of toxic substances by plasmapheresis is indicated when those substances are not readily removed by hemodialysis or charcoal hemoperfusion due to high levels of protein binding.¹⁰⁷ Examples include amanita toxin of *amanita phalloides*, digoxin in combination with antidigoxin antibodies, tricyclic antidepressants and heavy metals in combination with chelation agents.¹⁰⁸ Plasmapheresis dosing can be guided by plasma levels, the volume of distribution of the toxin, and clinical parameters.

COMPLICATIONS OF PLASMAPHERESIS

Plasmapheresis is an invasive procedure with potential complications relating to vascular access, the extracorporeal procedure itself, the removal of coagulation factors and other plasma proteins, and the use of large volumes of pooled plasma products. Adverse events of the procedure occur in one third of patients, are usually mild, and rarely lead to discontinuation or hospital admission.¹⁰⁹ They comprise fever, urticaria, pruritus, hypocalcemic symptoms, and hypotension and are more common with fresh frozen plasma volume replacement than with albumin/saline. More severe reactions include anaphylaxis, thrombocytopenia, and hemorrhage and occur in 0.5% to 3.1% of treated patients.¹¹⁰ The risk of hemorrhage after plasmapheresis is increased in the presence of uremia, coagulopathy, and thrombocytopenia or after a surgical procedure including renal biopsy. Complications of vascular access include hematomas, pneumothorax, thromboses, and catheter infections. Transmission of chronic viral infections through the use of blood products is now very rare, and there is a theoretical risk of other infections, including prions. Symptomatic hypocalcemia resulting from infusion of citrate (either as the treatment's anticoagulant or in fresh frozen plasma) complicates 1.5% to 9% of treatments. Hypotensive episodes occur in 4% to 7% of patients and can be triggered by vasovagal episodes, delayed or inadequate volume replacement, hypo-oncotic

fluid replacement, or anaphylaxis. Repeated plasmapheresis depletes immunoglobulins and other immune reactants, which potentially increases the infective risk, especially in immunosuppressed or uremic patients. However, infection rates reported from randomized trials in the treatment of lupus nephritis and ANCA-associated vasculitis do not support this contention.^{22,111,112} Intravenous immunoglobulin therapy has been used in the intensive care setting to reduce infective risk of immunosuppressed patients, including those treated with plasmapheresis, but there is no evidence that routine immunoglobulin replacement after a course of plasmapheresis is justified.

CONCLUSIONS

Use of plasmapheresis has changed in recent years reflecting the availability of evidence largely obtained from controlled, prospective studies. This evidence supports its use for anti-GBM disease, ANCA vasculitis with severe renal failure, refractory cryoglobulinemia, thrombotic microangiopathy, and desensitization before renal transplantation. In contrast, there is no role for plasmapheresis in the routine treatment of lupus nephritis or allograft rejection. More evidence is required to determine whether plasmapheresis is beneficial in other forms of ANCA vasculitis, certain severe lupus subgroups, crescentic IgA nephropathy and HSP, FSGS, multiple myeloma, and humoral transplant rejection. Plasmapheresis remains an expensive and nonspecific therapy in which side effects are common. Newer techniques, such as double filtration and immunoadsorption, offer the opportunity of equal or greater efficacy and reduced toxicity and merit further evaluation.

An association between glomerulonephritis and infectious disease has long been recognized. Glomerular damage occurs in infection-associated glomerulonephritis as a result of three pathogenic pathways: the direct renal effects of the invading microorganism, the sepsis-induced dysregulation of systemic circulation and homeostasis, and, most importantly, the innate and adaptive host immune responses to microbial antigens. Current clinical therapies actively target the invading organism and provide support for host homeostasis, whereas the aberrant host immune response is not directly addressed.

The epidemiology of infectious disease and the problems in producing reliable and accurate animal models make infection-associated glomerulonephritis a difficult condition to study. Despite some advances in our understanding of the immunopathogenesis, little impact has been made on specific immunotherapy, and the treatment of infection-associated glomerulonephritis remains largely empirical rather than evidence based. With these limitations in mind, this chapter briefly reviews recent conceptual advances in the understanding of this form of glomerulonephritis and then discusses current therapeutic strategies associated with specific organisms and sites of infection. Approaches to management are provided and avenues amenable to future research highlighted. Renal diseases caused by infections

with human immunodeficiency virus (HIV) and hepatitis B virus are covered in Chapter 24 and hepatitis C virus in Chapter 14. Drug doses, including correction factors for renal dysfunction, are listed in Chapter 91.

RECENT DEVELOPMENTS IN INFECTION-ASSOCIATED GLOMERULONEPHRITIS

The epidemiology of infection-associated glomerulonephritis has changed. Classic poststreptococcal glomerulonephritis (PSGN) remains the most common cause of the nephritic syndrome in some communities.^{1,2} Staphylococcal infection has, however, become a far more frequent precipitant of glomerulonephritis in developed countries.³ Infective endocarditis is now the bacterial infection most frequently associated with glomerulonephritis in developed countries and is predominantly caused by staphylococci introduced via needles or surgery.^{3,4} In Europe and North America, hepatitis C is a common cause of cryoglobulinemia and membranoproliferative glomerulonephritis, whereas on a worldwide scale, hepatitis B and malaria persist as dominant causes of the nephrotic syndrome.⁵

As the epidemiology has evolved, the classification of glomerulonephritis resulting from infection has broadened. As the

incidence of PSGN in developed countries has decreased, infection with an increasing number of other microorganisms has been associated with glomerular disease. The glomerular lesions induced include classic postinfectious exudative endocapillary changes, but also mesangioproliferative, mesangiocapillary, crescentic, and membranous lesions. The time course varies such that clinical glomerulonephritis may become apparent during the acute or chronic infective phase or during convalescence. Accordingly, the term *postinfectious glomerulonephritis* is best used with specific reference to poststreptococcal disease, whereas the broader term *infection-associated glomerulonephritis* is the more appropriate nomenclature to apply to the entire spectrum of glomerulonephritis that results from infection.

The importance of host immune status is increasingly recognized as being central to the development of infection-associated glomerulonephritis and to the patient's prognosis. Alcoholism is prevalent throughout the world and is now well recognized as conferring both an increased susceptibility to infection-associated glomerulonephritis and a poor prognosis for this condition.^{3,6} In addition, the immune dysregulation induced by chronic viral infections may enhance patient susceptibility to glomerulonephritis, particularly in the case of infections with hepatitis B, hepatitis C, and HIV.

Progress in molecular biologic technology has facilitated new insights into the pathogenesis of glomerulonephritis.⁷ Infectious organisms may produce glomerular damage via several mechanisms:

1. Direct cytopathic effects, e.g., staphylococcal antigens may induce glomerular damage in the absence of immunoglobulin
2. Engagement of innate immune receptors by microorganisms, such as Toll-like receptor 4 engagement by bacterial lipopolysaccharide, causing activation of inflammatory cells and intrinsic kidney cells
3. Host cell-mediated damage due to the presence of the organism within renal cells, with subsequent cell surface antigen expression serving to attract cytotoxic T cells
4. Deposition of circulating immune complexes or cryoglobulins within the glomerulus
5. Formation of in situ immune complexes to planted infective antigens
6. Induction of autoimmunity via the development of cross-reactive antibodies
7. Indirect effects of infection mediated by cytokines and growth factors^{8,9}

Various infections have been shown to induce glomerular damage via these mechanisms, although one major discrepancy exists. Humans incur infection many times a year during every year of their life, yet only a minority develop clinical nephritis. The reason that only some individuals develop glomerulonephritis in response to infection with particular organisms remains an enigma. Certainly some strains of organism are more nephrogenic than others (e.g., nephritogenic versus nonnephritogenic streptococci). Patient susceptibility factors have also been identified, such as complement deficiency, whereas others remain unidentified but inferred, such as familial susceptibility to PSGN. It appears likely that several infection-dependent and host-dependent factors must interact to produce infection-associated glomerulonephritis.

The diagnosis of infection-associated glomerulonephritis should be considered in three broad clinical settings. First, the patient who develops renal dysfunction or an abnormal urinary sediment in the context of an infectious illness may have infection-associated glomerulonephritis. This should be differentiated from renal tract infection, interstitial nephritis (due to infection or therapy), preexisting or concurrent renal disease, and the indirect effects of fever on urinary protein and red cell content. Second, infection-associated glomerulonephritis remains underdiagnosed as a cause of glomerulonephritis in the general community and should therefore be considered in all patients presenting with glomerular abnormalities.¹⁰ Risk factors for infection with potentially nephritogenic organisms should be sought in the patient history. Examination for signs of infection such as skin rash, needle tracks, and stigmata of endocarditis should be performed. Specific serologic investigations, tailored to the epidemiology of infectious disease relevant to the patient, should be undertaken. Percutaneous renal biopsy should be performed in all cases in the absence of significant contraindications.¹⁰ Finally, an infection-related exacerbation should be considered in patients with preexisting glomerulonephritis who develop an unexplained flare of their disease.⁷

The likelihood of renal and patient recovery depends on host status, control of infection, and the degree of kidney damage as assessed by both clinical and biopsy parameters. Drug and alcohol withdrawal, malnutrition, immunosuppression, and concurrent infection (both preexisting and hospital acquired) are major contributors to the high rates of morbidity (50%) and mortality (11%) seen in patients with infection-associated glomerulonephritis.³ Additionally, screening tests for concurrent disease, such as HIV and viral hepatitis, should be undertaken to avoid diagnostic confusion and to optimize management. Cases in which severe crescentic disease has been present on a renal biopsy sample or in which renal dysfunction has persisted or evolved despite clinical eradication of infection have prompted the use of immunosuppressive therapy: 35 cases of infection-associated glomerulonephritis (including 11 cases of classic PSGN) treated with immunosuppressants have been reported^{3,11-19} (Table 13-1). Endocarditis was the most frequently associated infection. One controlled trial of prednisolone, cyclophosphamide, dipyridamole, and azathioprine in children with crescentic PSGN showed no benefit over placebo.¹⁸ All other reports involved uncontrolled therapeutic trials of corticosteroids (100%), cyclophosphamide (44%), azathioprine (4%), heparin (4%), dipyridamole (8%), and plasmapheresis (20%), used either singly or in various combinations and always in conjunction with antibiotics. Indices of renal function improved in 52% of cases. No specific reports of therapy-related morbidity or mortality were made; however, 12% of patients progressed to terminal renal failure and 8% of patients died of multiple complications including renal failure. Thus, based on these uncontrolled data, the role of immunosuppressive therapy for infection-associated glomerulonephritis is difficult to determine. Bearing in mind the potential for positive publication bias, these results clearly highlight the need to mount a prospective, controlled clinical trial to examine the safety and efficacy of immunosuppression in this setting. Until then, this form of treatment cannot be broadly recommended, except for consideration in cases of severe renal failure unresponsive to documented clearance of infection.

Table 13-1 Immunosuppressive Treatment of Glomerulonephritis Associated with Bacterial Infection: Published Reports and Trials

Ref.	Infection	No. of Patients	Histology	Treatment	Outcome
Montseny et al ³	Various, unspecified	17	Crescents (12), Endo (5)	Prednisone (17), cyclophosphamide (8)	5 resolved, 8 CRF, 2 ESRD, 2 deceased

Kupari and Teerenhovi ¹⁷	Dental abscess	1	Crescents, 80%	Plasmapheresis, prednisone, cyclophosphamide	Resolved
Roy et al ¹⁸	PSGN	5 treated, 5 controls	Crescents, 70%; crescents, 65%	Prednisone, azathioprine, cyclophosphamide, dipyridamole	Resolved*
Fairley et al ¹⁹	PSGN	1	Crescents, 83%	Plasmapheresis, prednisone, cyclophosphamide, dipyridamole	Resolved

*All patients showed resolution of clinical indicators of renal damage; however, two patients died of causes thought to be unrelated to therapy.¹⁸

CRF, chronic renal failure; Endo, endoproliferative glomerulonephritis; ESRD, end-stage renal disease; PSGN, poststreptococcal glomerulonephritis.

The prognosis for recovery from infection-associated glomerulonephritis remains linked to the interaction between host factors, the infecting organism, and the amount of kidney damage that is incurred. Recent therapeutic developments have made little impact, with the exceptions of antibiotic prophylaxis for at-risk populations during epidemics of nephritogenic streptococcal infection² and the use of antiviral agents for the treatment of glomerulonephritis associated with hepatitis C and B viruses (see Chapters 14 and 24). Thus, the prognosis has changed in line with the epidemiology. In areas where infection-associated glomerulonephritis remains primarily streptococcal, the prognosis remains generally favorable, at least in the short to medium term.^{1,20} However, in communities where the majority of cases of infection-associated glomerulonephritis are due to staphylococcal infection occurring in alcoholics or intravenous drug abusers, the prognosis is relatively poor for both patient and renal survival.^{3,21}

Is resolution of the clinical episode of acute infection-associated glomerulonephritis all that matters? Long-term follow-up studies of survivors of PSGN have revealed evidence of chronic kidney disease on clinical grounds and on kidney biopsy in a significant proportion and renal failure in a minority.^{20,22} Whether these findings are applicable to all forms of infection-associated glomerulonephritis is

unknown. Also unknown is whether such asymptomatic abnormalities indicate a significant increase in the lifetime risk of renal failure, cardiovascular disease, or overall mortality for these patients.⁷ This information is required in order to provide accurate prognostic information for both the patient and caring physician and to facilitate the development and use of renoprotective strategies during the acute and recovery phases of infection-associated glomerulonephritis (see Chapter 62).

BACTERIAL INFECTIONS

Streptococcus

Poststreptococcal Glomerulonephritis

The management of classic PSGN involves three phases: (1) the prompt treatment of streptococcal infections in the community, (2) the management of the patient with nephritis, and (3) the prevention or detection of streptococcal disease and PSGN among the patient's contacts.

Animal data have demonstrated that penicillin given within 3 days of the onset of streptococcal infection is able to prevent the development of nephritis, and although there is no conclusive evidence that antibiotic treatment of pharyngitis or impe-

tigo in humans is effective in preventing the development of PSGN, such treatment seems logical to reduce the streptococcal antigenic load. Additionally, antibiotics may prevent the development of suppurative complications in the individual and hopefully reduce the prevalence of pathogenic streptococci in the community. Thus, as the cost and adverse-effect profile of penicillin is favorable, it should be given to patients with clinically probable and/or culture-positive streptococcal pharyngitis or impetigo. The appropriate dose for adults is 1.2 million units of benzathine benzylpenicillin as a single intramuscular injection or 250 mg phenoxymethyl penicillin every 6 hours PO for 10 days. Children should receive half doses, and erythromycin should be given to individuals who are allergic to penicillin.

The diagnosis of PSGN is made in a patient who has historical and/or laboratory evidence of antecedent streptococcal infection, which was followed by a latent period before the development of nephritis. The laboratory finding of decreased C3 is a sensitive, but not specific, supporting feature. Renal biopsy is often required for the diagnosis in endemic cases, although less so in the epidemic situation, to differentiate PSGN from other causes of the nephritic syndrome.

Once the diagnosis is made, patient management involves three phases. First, penicillin is given in an attempt to eliminate streptococcal antigenemia. Second, features of the nephritic syndrome are treated supportively. If hypertension or signs of volume overload are present, sodium intake should be minimized and fluid intake restricted to 1000 mL/day in mild cases and 500 mL/day in moderate to severe cases. Loop diuretics should be used to manage edema. Therapy should be guided by the maintenance of strict fluid balance records including daily weights. In cases of severe volume overload with imminent or actual hypertensive encephalopathy or pulmonary edema, morphine, oxygen, sedation, ventilation, intravenous nitrates, and hydralazine may be required. In this setting, urgent hemodialysis including ultrafiltration is often the most effective and physiologic therapeutic maneuver. With good supportive care, attention to nutrition, and the treatment of intercurrent infection, an acute mortality of less than 1% can be expected.²⁰ Resolution is spontaneous and generally complete within several months. Patients with adult-onset, nephrotic-range, or persistent proteinuria; extensive crescent formation; and heavy capillary IgG/C3 deposition on biopsy are an exception to this rule and commonly exhibit an incomplete renal recovery. A minority will progress to end-stage renal failure.^{20,22}

Combined immunosuppressive and anticoagulant therapy has been tried in severe PSGN in children and was not found to be of benefit.¹⁸ Persisting hypertension should be treated, preferably with an angiotensin-converting enzyme inhibitor. Acute PSGN recurs only rarely, due to the development of type-specific, long-lasting, and protective immunity to streptococcal M protein.

Management of the patient in the long term is less clearly defined. Studies of patients up to 20 years after an episode of acute PSGN reveal conflicting results but clear trends in terms of renal outcome. The vast majority of patients recover acutely, but 5% to 60% will show features of subclinical renal dysfunction (proteinuria or decreased creatinine clearance, fibrosis, and glomerulosclerosis on biopsy) or hypertension during the next 10 to 20 years,^{20,22} and almost all patients with resolved PSGN can be shown to have a decreased renal functional reserve. Asymptomatic abnormalities are more common sequelae of

PSGN in adults than in children. Whether such abnormalities indicate a significant increase in the lifetime risk of the development of progressive renal failure remains to be determined. It would seem prudent to monitor all patients who recover from PSGN with annual assessment of blood pressure, urinary protein excretion, and creatinine clearance. Hypertension should be treated aggressively, and the development of proteinuria or decreased creatinine clearance should prompt the adoption of general measures for the preservation of renal function (see Chapter 62).

Epidemics of PSGN continue to occur in communities that have relatively poor hygiene and overcrowding. The administration of penicillin (2.4 million units IM for adults, half dose for children) to all community members during such outbreaks appears to be of benefit.²

Other Streptococcal Infections

Streptococcus viridans has classically been implicated as the major cause of subacute bacterial endocarditis, whereas *Streptococcus faecalis* (enterococcus) is an increasingly recognized cause of acute endocarditis. These and other groups of streptococci have been documented as causes of proliferative glomerulonephritis, both focal and diffuse, in the setting of infectious endocarditis and other visceral infections. Principles of diagnosis and management are similar to those detailed here for staphylococcal endocarditis. Antibiotic resistance is becoming problematic. The emergence of penicillin-resistant streptococci requires the use of penicillin plus an aminoglycoside until bacterial sensitivities are defined. Enterococci are generally penicillin insensitive and require combination therapy with ampicillin and low-dose gentamicin, which act synergistically. Vancomycin is indicated if enterococci with high-level penicillin resistance are prevalent or are isolated; however, the development of vancomycin-resistant enterococci is a major concern and requires consultation with an antimicrobial expert.²³ Vigilant monitoring of aminoglycoside and vancomycin levels are required to avoid toxicity.

Staphylococcus

Staphylococcal Endocarditis

Staphylococcal endocarditis may occur on normal, damaged, or prosthetic valves on either the left or the right side of the heart. Infection of a previously normal tricuspid valve is particularly commonly seen in intravenous drug abusers. The presentation may be acute, particularly in the case of *Staphylococcus aureus* infection, or chronic, as is typically seen with coagulase-negative staphylococcal endocarditis.

Glomerulonephritis occurs in 20% to 80% of cases of infective endocarditis and may be recognized at any stage of the illness.⁴ In cases of infective endocarditis complicated by glomerulonephritis, circulating immune complexes (90% of cases), rheumatoid factors (10%–70%), and cryoglobulins (84%–95%) are present, whereas C3 is frequently reduced in serum. No serologic marker has consistently been shown to have predictive value in identifying the presence or absence of glomerulonephritis in patients with endocarditis. Serology may be more useful for monitoring therapy, as the persistence of circulating immune complexes and C3 depletion, despite antibiotic treatment, has been shown to indicate the failure of therapy and a high probability of persistent infection and

glomerulonephritis.⁴ Microbiologic identification, including the determination of antibiotic sensitivities, is crucial in establishing a therapeutic plan. Renal biopsy is also crucial to both confirm the diagnosis and provide prognostic information. Biopsy specimens may reveal either focal or diffuse proliferative changes, often accompanied by an exudate of neutrophils. Crescents are less commonly seen. Immunostaining reveals granular C3 deposition, which is often but not always accompanied by IgG or IgM. Staphylococcal antigens have frequently been reported within damaged glomeruli in the absence of immunoglobulin and rarely in the absence of C3, suggesting that staphylococci may induce either direct or complement-mediated renal injury, independent of immunoglobulin.²⁴

Treatment involves the intravenous administration of bactericidal antibiotics at dosages appropriate for renal function (see Chapter 91). The role of surgery is to restore valve function and remove foci of infection where necessary. This requires an ongoing evaluation of the patient in consultation with the involved infectious disease and cardiac teams. The persistence of glomerulonephritis, despite the apparent resolution of infection, is an additional indication to reassess the affected heart valve with a view to surgery because the surgical removal of a sterile vegetation has been associated with improvement in renal function.¹⁷ Supportive measures for renal and cardiac function and the optimization of host nutrition and immune status are important components of therapy. As summarized in Table 13-1, the use of immunosuppression after apparent eradication of infection has been reported; however, this approach incurs significant risk of infective relapse and further cardiac decompensation.^{3,11,13-15}

Staphylococcal Septicemia

Proliferative glomerulonephritis was documented in 35% of cases of fatal staphylococcal septicemia at autopsy.²⁵ Treatment is similar to that for infectious endocarditis, in addition to a rigorous search for primary (e.g., skin, bone, joint) and secondary (e.g., heart, lung) sites of infection.

Visceral Abscess

Abscesses within abdominal viscera, bone, joint, lung, and other tissues have been associated with infection-associated glomerulonephritis. *S. aureus*, and, less commonly, other organisms, have been cultured from the abscess fluid. Although blood cultures have frequently been negative in reported cases, bacterial antigens have been identified within glomerular deposits accompanied by immunoglobulin and complement components. Thus, an immune-mediated, infection-associated glomerulonephritis occurs that produces a proliferative renal lesion associated with a nephritic clinical presentation frequently accompanied by severe acute renal failure.²⁶ Successful eradication of the antigen via surgical evacuation and appropriate antibiotic therapy has resulted in clinical resolution of nephritis in the majority of reported cases.

Shunt Nephritis

Ventriculoatrial shunts, inserted for the treatment of hydrocephalus, may rarely become colonized by coagulase-negative staphylococci or other organisms of low virulence such as *Propionibacterium acnes*.²⁷ Such colonization is associated with the development of membranoproliferative glomerulonephritis, manifest by heavy proteinuria, hematuria, and renal impairment. The diagnosis may be confirmed by positive culture of

blood, cerebrospinal fluid, or the shunt itself. Removal of the shunt, combined with appropriate antibiotic therapy, leads to an improvement in renal function in the majority of cases and is recommended; however, treatment of the infection with antibiotics alone with clearance of infection and restoration of renal function has been reported.²⁸

Pneumococcus

Pneumococcal pneumonia, endocarditis, and other infections have been associated with glomerulonephritis. Immune-mediated renal disease is induced via mechanisms similar to those described for staphylococcal infection, although pneumococcal capsular antigen has additionally been detected within a cryoprecipitate obtained from one patient with infection-associated glomerulonephritis. Treatment involves the same principles as discussed for staphylococcal infections. Penicillin is the antibiotic of choice, except in areas of drug-resistant pneumococci, for which initial treatment with vancomycin plus penicillin is advisable pending antibiotic sensitivity determination.²⁹

Gram-Negative Bacteria

Salmonella

Although uncommon in typhoid fever, a diffuse proliferative infection-associated glomerulonephritis may occur and is generally associated with a relatively mild nephritic clinical presentation. Glomerulonephritis must be differentiated from cystitis, pyelonephritis, and acute tubular necrosis, all of which may occur in the context of this illness. In contrast, acute infection with various species of *Salmonella* has been associated with the onset of the nephrotic syndrome in patients with coexistent hepatosplenic schistosomiasis. Nephrosis has been found to resolve on the eradication of *Salmonella* carriage by treatment with cotrimoxazole or ampicillin.³⁰

Other Bacterial Infections

Glomerulonephritis has been reported following enteritis caused by *Yersinia enterocolitica*. Pneumonia or lung abscess due to *Klebsiella pneumoniae*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Pseudomonas aeruginosa*, *Chlamydia psittaci*, and *Legionella pneumophila* have rarely been reported to cause glomerulonephritis. Diarrhea-associated hemolytic-uremic syndrome from *Escherichia coli* O157:H7 is discussed in Chapter 26. *E. coli*, meningococci, and other gram-negative, gram-positive, and anaerobic bacteria causing septicemia, peritonitis, subphrenic abscess, osteomyelitis, meningitis, and septic abortion have also been linked to infection-associated glomerulonephritis. As a generalization, this rare complication of infection has been found to resolve after the eradication of infection with antibiotic treatment and/or surgery.

Mycobacteria

Leprosy

Approximately 10 million people worldwide have leprosy; of these, 6% to 8% can be expected to have glomerulonephritis.³¹ Most commonly, a mesangioproliferative lesion has been found on biopsy, with evidence of IgG and C3 deposition on

immunofluorescence microscopy; mycobacterial antigens within glomeruli have been documented. Nephritis is generally clinically mild, with low-grade proteinuria and minimal impairment of renal function. Cases of rapidly progressive glomerulonephritis have been reported, generally in the context of an episode of erythema nodosum leprae, in which spontaneous or treatment-associated systemic immune complex disease occurs, superimposed on the course of previously indolent lepromatous leprosy. Standard treatment for erythema nodosum leprae, consisting of 1 mg/kg/day prednisone PO, was reported to produce a rapid resolution.³¹ In general, glomerulonephritis due to leprosy responds clinically to bacteriologic cure, although drug treatment may be complicated by the development of erythema nodosum leprae or drug adverse effects.³² Interstitial nephritis and renal amyloidosis are also documented in patients with leprosy. As opposed to glomerulonephritis, amyloid produces more severe proteinuria and renal impairment and consequently carries a poor prognosis. A recent study with eprosinate, a sulfonated, low molecular weight compound similar to heparan sulfate, has shown promise in slowing the progression of AA (secondary) amyloidosis of the kidney.

Tuberculosis

Tuberculosis may produce direct renal infection and cavitation or glomerular involvement through the development of amyloidosis, but has only rarely been reported as a cause of glomerulonephritis. Treatment involves antituberculous chemotherapy and possibly eprosinate³³ (see Chapter 37).

SPIROCHETES

Syphilis

The prevalence of syphilis is increasing worldwide. As congenital, secondary, and tertiary syphilis have been associated with various forms of glomerulonephritis, renal gumma formation, and amyloidosis, the incidence of renal presentations of syphilis may also be anticipated to increase. Congenital syphilis may result in membranous nephropathy. Acquired secondary and tertiary syphilis in adults may also produce a nephrotic presentation in association with minimal change or membranous features on biopsy. A nephritic presentation may also occur, with typical proliferative glomerular changes of infection-associated glomerulonephritis seen on biopsy. Granular deposition of IgG and C3 is generally demonstrable by immunofluorescence, suggesting an immune complex basis. Treatment of syphilis with penicillin, 2.4 million units by weekly IM injection for 3 weeks, has led to the resolution of proteinuria in the majority of cases.³⁴

Leptospirosis

Leptospirosis has been associated with a mesangioproliferative glomerulonephritis, but far more commonly induces acute interstitial nephritis or acute tubular necrosis in the setting of Weil's syndrome. Regardless of the renal lesion produced, treatment involves intensive supportive care and antibiotic treatment, which is of proven benefit if started within the first 5 days of infection. Doxycycline 200 mg/day PO is effective in mild cases. Penicillin, 1.5 million units every 6 hours for 7 days,

is preferred for severe disease. Exchange transfusion may have a role in reducing hyperbilirubinemia, which may contribute to the renal toxicity in Weil's syndrome. The renal lesion is entirely reversible on resolution of the infection.³⁵

VIRAL INFECTIONS

Viruses in General

Viral infection is almost ubiquitous in humans. However, clinically relevant infection-associated glomerulonephritis due to viral infection is rare. Circulating immune complexes may be found in the serum of patients at some stage in the course of nearly all acute viral infections. Indeed, glomerulonephritis in the setting of viral infection is associated with the glomerular deposition of immune complexes. This is accompanied by endothelial and/or mesangial cell proliferation and rarely by extracapillary crescent formation. Why only a minority of people develop glomerulonephritis on infection with virus is unknown. The probable explanation is that multiple virus-dependent factors (nephritogenicity, virulence, capacity for immunomodulation and chronicity) and host-dependent factors (immune competence, profile of cytokine response, intrinsic kidney cell response) interact to determine the glomerular consequences of infection.^{7,36} The management of acute virus-associated glomerulonephritis is directed at clearance of the viral infection, which generally occurs spontaneously, and the provision of supportive care when required. The management of chronic virus-associated glomerulonephritis additionally involves the use of specific antiviral or immunomodulatory therapies, as discussed in Chapter 14 for hepatitis C virus and in Chapter 24 for hepatitis B virus and HIV.

Viral Hepatitis

Hepatitis A has been reported to cause immune complex mesangioproliferative glomerulonephritis. The management of this uncommon complication of hepatitis A virus infection is supportive, and nephritis resolves with recovery from the infection.

Hantaan Virus

Hantaan and related viruses induce an illness known as nephropathia epidemica or hemorrhagic fever with renal syndrome, which is endemic in areas of Southeast Asia and southern Europe and appears in epidemics worldwide.³⁷ Spread by the inhalation of aerosolized virus-containing particles formed from the excreta of infected mice, these viruses induce a spectrum of disease that ranges from a mild febrile illness to a life-threatening disorder. Severe disease is characterized by several phases. Initially high fever and myalgias dominate, while facial and truncal flushing and petechiae develop in association with thrombocytopenia. Fever suddenly subsides after several days, but profound hypotension develops, associated with oliguric acute renal failure. Systemic hypotension, derangements of intrarenal vasomotor tone, coagulation, and associated interstitial nephritis contribute to renal injury. Membranoproliferative glomerulonephritis has been reported; however, glomerular involvement is generally minor.

The diagnosis is confirmed by an increase in titer of specific antibody to Hantaan virus between serum samples taken 1 week apart. Leptospirosis and scrub typhus should be excluded, also on serologic grounds, because these agents may produce a similar illness but are amenable to treatment with tetracyclines. Treatment of hemorrhagic fever with renal syndrome is supportive only.³⁷ A specific vaccine is currently under trial in Korea.

Herpes-Type Viruses

Generally mild and spontaneously resolving acute nephritis has been reported as a rare complication of various infections, including infectious mononucleosis, pneumonitis, encephalitis, and congenital infection with Epstein-Barr virus, cytomegalovirus, varicella, and herpes simplex virus. Specific antiviral therapy is indicated for critical organ infection rather than for glomerulonephritis, which tends to resolve after control of the infection.

Other Viruses

Smith and colleagues³⁸ reported a 3.8% incidence of glomerulonephritis after nonstreptococcal upper respiratory tract infection in American army recruits. Presumably, the majority of these infections were viral in etiology. Recovery was spontaneous and clinically complete (except in one patient with a history of PSGN) but took up to 12 months in some cases. In nephrologic practice, virus-associated glomerulonephritis is a far less frequently encountered cause of glomerulonephritis than these figures would indicate.³⁶ This is probably due to underdetection. Given the apparently benign clinical course of infection-associated glomerulonephritis after viral upper respiratory tract infection, biopsy does not appear to be indicated except in cases of diagnostic uncertainty. However, the degree of renal functional impairment, as documented above, does indicate a need for follow-up for evidence of chronic kidney disease in such patients. Whether the long-term prognosis of patients with virus-associated glomerulonephritis is similar to that for patients with PSGN is unknown.

Human parvovirus B19 has recently been identified as a possible cause of non-HIV-associated collapsing glomerulopathy. This virus is common and typically causes a mild nonspecific illness, but has been associated with red cell aplasia in a minority of patients. Parvovirus B19 DNA was identified within glomeruli in the majority of cases of supposedly idiopathic collapsing glomerulopathy in one study.³⁹ The clinical presentation is similar to HIV-associated collapsing glomerulopathy, and progression to renal failure is frequent.

Cases of glomerulonephritis have been reported in association with mumps, measles, and enteroviral infections (Coxsackie B5 virus and echovirus). Generally, these have produced only a mild nephritic illness that resolved spontaneously.

RICKETTSIAL INFECTIONS

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever, in severe cases, results in a multiorgan vasculitis involving the central nervous system, myocardium, and kidney. Renal involvement is predominantly

tubulointerstitial because prerenal factors (vasculitis and myocardial depression) combine with a perivascular interstitial nephritis to produce acute renal failure. Glomerular involvement has been described but is overshadowed by the interstitial lesions. Glomerulonephritis has been reported in which a nephritic illness, associated with typical postinfectious changes on biopsy samples, occurred 2 weeks after an acute episode of Rocky Mountain spotted fever. Spontaneous resolution occurred.⁴⁰

Q Fever

Immune complex mesangioproliferative glomerulonephritis has been reported in cases of both endocarditis and sepsis due to *Coxiella burnetii*. Antiphospholipid and anti-DNA autoantibodies have been detected in the sera of these patients, suggesting that the development of antibodies to *Coxiella* antigens cross-reactive to host antigens may have a role in the pathogenesis of Q fever. The diagnosis is based on clinical features and confirmed by serology. Treatment is with doxycycline 100 mg/day PO for 1 week for sepsis, or longer for endocarditis, in which surgical removal of the vegetation, with or without valve replacement, is often required. Renal manifestations have been reported to resolve with cure of the infection.⁴¹

Scrub Typhus

Rickettsia tsutsugamushi, like other rickettsias, has a predilection for the endothelium. Glomerulonephritis has been reported as a rare sequela of scrub typhus. The clinical illness produced is similar to that seen in infections with leptospirosis and Hantaan virus and should be distinguished on epidemiologic and serologic grounds. Treatment with doxycycline 100 mg/day PO for 1 week is beneficial at any stage of the illness.

FUNGAL INFECTIONS

Mucocutaneous candidiasis has been reported as a cause of immune complex-mediated membranoproliferative glomerulonephritis. Proteinuria and renal function improved on clearance of the infection.⁴²

Clinical renal involvement may occur in disseminated histoplasmosis. Proliferative glomerulonephritis, associated with the presence of circulating immune complexes, has been reported in a case of acute primary disseminated histoplasmosis. Renal manifestations resolved following spontaneous recovery from the infection.⁴³ However, disseminated infection in immunocompromised or nonresolving patients does require therapy with antifungal agents.

PARASITIC INFECTIONS

Malaria

Falciparum Malaria

Transient glomerulonephritis may be a common sequela of infection with *Plasmodium falciparum*, but it is generally mild and undetected. Glomerulonephritis has been demonstrated in 18% of patients with fatal falciparum malaria.⁴⁴

Renal failure is a significant contributor to the mortality of severe falciparum infection; however, acute renal failure in this setting is usually due to acute tubular necrosis, which results from shock, renal vasoconstriction, intravascular coagulation, direct tubular toxicity, and hyperbilirubinemia.⁸ Treatment with intravenous quinine and supportive care including hemodialysis is beneficial. Exchange transfusion, designed to reduce parasite load and hyperbilirubinemia, has been reported to be beneficial in selected situations. Elimination of the parasite is accompanied by the resolution of renal abnormalities in surviving patients.⁴⁴

Quartan Malaria

The incidence of childhood nephrotic syndrome is 20 to 60 times more frequent in areas where infection with *Plasmodium malariae* is endemic in comparison with nonendemic areas. A small percentage of patients, mainly children, with quartan malaria develop an immune complex glomerulonephritis. Histologically, this is characterized initially by glomerular capillary wall thickening due to subendothelial immune complex deposition, which evolves to produce capillary collapse and diffuse mesangial sclerosis. The characteristic clinical presentation is with the nephrotic syndrome. Disease progression is the rule, with the development of hypertension and progressive renal failure leading to death in 3 to 5 years. Neither antimalarial treatment nor immunosuppressive therapies have been shown to improve the renal outcome in this condition. Thus, the main therapeutic hope for the future is prevention, either through the development of a vaccine for *P. malariae* or by decreasing the prevalence of the organism.⁵

Schistosomiasis

Chronic schistosomiasis caused by infestation with *Schistosoma haematobium* (endemic in Africa and the Middle East) or *Schistosoma mansoni* (Africa, South America, and the Middle East) has been associated with immune complex glomerulonephritis.⁴⁵

Schistosomiasis due to *S. haematobium* has been associated with membranoproliferative glomerulonephritis and minimal change disease, which responded clinically to antischistosomal treatment. However, the vast majority of cases of renal disease seen in association with *S. haematobium* are due to coinfection with *Salmonella* species, as indicated by the presence of fever and isolation of the organism from blood cultures. In this setting, proteinuria and renal impairment have been shown to respond to treatment of the salmonellosis, with or without antischistosomal treatment.³⁰ Antischistosomal treatment is indicated because persistence of the schistosomiasis renders these patients susceptible to recurrences of renal disease on reexposure to *Salmonella*.

Glomerular involvement in *S. mansoni* infestation is relatively common. Although rarely reported during the earlier hepatointestinal phase, glomerulopathy is seen in 12% to 15% of patients who develop hepatosplenic disease. Glomerulonephritis is due to immune complex disease. A mesangioproliferative or membranoproliferative lesion may be seen on biopsy and may evolve to focal glomerulosclerosis. Patients are frequently nephrotic. Hypertension and progressive renal failure may develop. Treatment with prednisone, with or without cyclophosphamide, has induced occasional remissions, whereas treatment with antischistosomal drugs has been unsuccessful in altering the course

of the renal disease. Amyloidosis may also occur as a complication of chronic schistosomiasis.⁴⁵

Other Parasites

Toxoplasmosis has rarely been associated with glomerulonephritis. Whether nephritis will be increasingly recognized in the setting of toxoplasmosis associated with acquired immunodeficiency syndrome and other immunocompromised states remains to be seen.

Visceral leishmaniasis has been associated with a mild nephritic illness due to mesangioproliferative glomerulonephritis; however, this occurrence is rare and a direct causal link has not been firmly established.

Filariasis due to *Wuchereria bancrofti* has been shown to produce glomerulonephritis with antigen and specific antibody demonstrable within glomeruli. Filariasis caused by *Onchocerca volvulus* and *Loa loa* has also been linked to various types of glomerulonephritis, largely by way of immune complex deposition. Additionally, microfilariae have been demonstrated within glomerular capillaries in association with eosinophilic tubulointerstitial nephritis. The presentation of acute filarial nephropathy is generally nephritic and is responsive to treatment with diethylcarbamazine. Chronic filarial nephropathy more commonly produces a nephrotic presentation and responds poorly to antifilarial drugs.⁵

SUMMARY AND FUTURE DIRECTIONS

Infection with various microbes can cause glomerulonephritis in humans. The percentage of infectious illnesses that result in a clinically apparent episode of infection-associated glomerulonephritis is, however, very small. While the underdiagnosis of infection-associated glomerulonephritis¹⁰ may account for a fraction of this discrepancy, it is clear that a complex interaction of host- and microbe-related factors are involved in determining whether an individual develops glomerulonephritis as a consequence of infection with a particular organism. Such factors remain to be elucidated.

Fortunately, the vast majority of cases of infection-associated glomerulonephritis resolve after either spontaneous or treatment-induced clearance of the underlying infection. A few patients incur progressive renal disease. In some cases, this is caused by a failure of, or a delay in, the clearance of infection. In others, progression may occur despite microbiologic cure. The mechanisms behind progressive disease also remain unclear. As a consequence, therapeutic approaches have been limited to the provision of supportive care and the use of uncontrolled empirical trials of therapy based on regimens that have been successful in the treatment of other forms of glomerulonephritis. Advances in specific therapy for infection-associated glomerulonephritis will require a better understanding of the pathogenetic mechanisms involved. In the interim, if empirical therapies are to be used, then surely it is time for a coordinated effort in mounting a controlled trial of, for example, immunosuppression in infection-associated glomerulonephritis.

Little is known of the long-term consequences of infection-associated glomerulonephritis, with the exception of the follow-up studies of patients after PSGN by Baldwin²² and Rodriguez-Iturbe²⁰ and more recently of patients with infection-associated glomerulonephritis of various etiologies by

Montseny and colleagues.³ The diligent work of these teams has clearly indicated that a significant proportion of patients manifest hypertension, proteinuria, and progressive renal failure as long-term sequelae of infection-associated glomerulonephritis. The risk of developing chronic kidney disease for patients with mild or subclinical infection-associated glomerulonephritis is unknown. What is clear is that patients with infection-associated glomerulonephritis should be followed long term in order to screen for the development of late sequelae amenable to management by conventional renoprotective measures (see Chapter 62). Whether treatment after the acute episode of infection-associated glomerulonephritis with, for example, angiotensin-converting enzyme inhibitors would retard the development of late sequelae is unknown.

In conclusion, several general principles are applicable to the treatment of infection-associated glomerulonephritis, and these are depicted as a treatment algorithm in Figure 13-1. First, prevention should be attempted. This can be accomplished by decreasing the prevalence of infection with nephritogenic organisms in the community, as has been partially achieved in the case of PSGN in developed countries. Prevention remains a difficult issue for many other infections such as neonatal hepatitis B and malaria. Attention to host-dependent risk factors for the development of infection-associated glomerulonephritis, such as alcoholism and intravenous drug abuse, are difficult but potentially modifiable problems of public health. Second, the treatment of cases of infection-associated glomerulonephritis

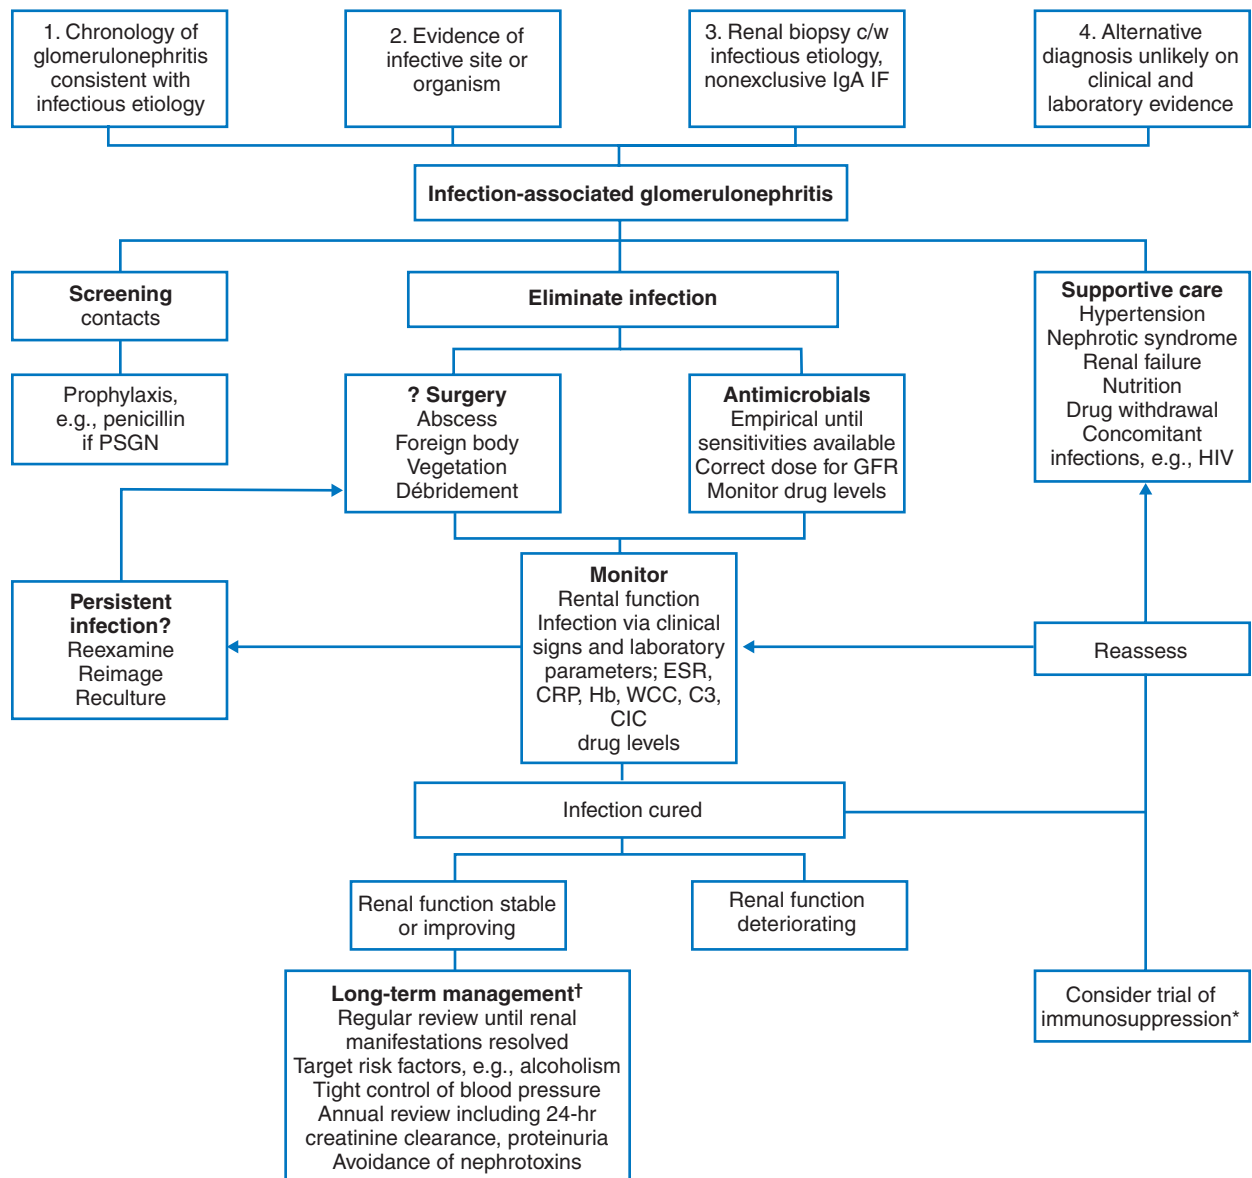

Figure 13-1 Diagnosis and management of infection-associated glomerulonephritis. CIC, circulating immune complex; CRP, C-reactive protein; c/w, combined with; ESR, erythrocyte sedimentation rate; GFR, glomerular filtration rate; Hb, hemoglobin; HIV, human immunodeficiency virus; PSGN, poststreptococcal glomerulonephritis; WCC, white cell count. *Anecdotal evidence only, see text. †See Chapter 62.

should involve the identification and elimination of the infecting organism, combined with supportive care of the patient. Contacts who may be at risk of infection with the same organism should be identified, screened, and given prophylactic treatment if indicated. Long-term follow-up of the patient is indicated. Finally, coordinated investigation into the pathogenesis, natural history, and therapy of this heterogeneous group of disorders is to be supported.

CLINICAL FEATURES, PATHOLOGY, AND PATHOPHYSIOLOGY

Hepatitis C virus (HCV) infection may be associated with the systemic syndrome of mixed cryoglobulinemia or with renal-limited immune complex disease characterized by type I membranoproliferative glomerulonephritis (MPGN).

Cryoglobulinemia is a pathologic condition in which the blood contains immunoglobulins that precipitate reversibly in the cold. Two types of mixed cryoglobulinemia (MC), which are composed of at least two immunoglobulins, have been described. In both types, a polyclonal IgG is bound to another immunoglobulin that is an antiglobulin (i.e., it acts as an anti-IgG rheumatoid factor). The important difference between these two types of MC is that in type II MC, the antiglobulin component, which is usually of the IgM class, is monoclonal, whereas in type III MC, it is polyclonal.

It was demonstrated relatively recently that HCV infection can be associated with the clinical syndrome, first described by Meltzer and colleagues¹ in 1966, characterized by purpura, weakness, arthralgia, and, in some cases, glomerular lesions. This had previously been defined as essential mixed cryoglobulinemia because an underlying or associated disease had not been found. HCV induces dysregulation of B lymphocytes toward the production of polyclonal (type III MC) or monoclonal (type II MC) rheumatoid factors with cryoprecipitable properties. This leads to a form of membranoproliferative glomerulonephritis called cryoglobulinemic glomerulonephritis that occurs only when type II MC with an IgMκ monoclonal rheumatoid factor is induced by HCV infection. This lesion is characterized by intense monocyte infiltration and subendothelial and/or intraluminal deposition of the cryoglobulins.^{2,3}

Consistent data on the pathogenesis of HCV-related MC suggest that lymphotropic HCV bound via CD81 receptor can induce cryoprecipitable IgMκ rheumatoid factor production.^{4,5} In fact, B cells, protected from apoptosis by HCV-dependent gene translocation, develop oligoclonal monotypic lymphoproliferation.⁶ As a consequence, cells expressing oligo- or monoclonal rheumatoid factor infiltrate the portal tracts, spleen, bone marrow,⁷ and renal interstitium (personal observation).

Several studies have pointed out the pivotal role of HCV and IgMκ in the formation, transport, deposition, and removal from circulation of cryoprecipitable immune complexes. Immune complexes are formed by HCV–anti-HCV polyclonal IgG (and/or unbound IgG) and IgMκ rheumatoid factor.⁸ IgMκ is critical for cryoprecipitation and for glomerular deposition. In fact, cryoprecipitable IgMκ has been shown to have high affinity, *in vivo* and *in vitro*, for cellular fibronectin, a normal constituent of the glomerular mesangium.^{9,10} In addition, due to the IgMκ component, these immune complexes also escape the normal immune complex erythrocyte transport system¹¹ and have a direct impact on hepatic and splenic macrophages, which are unable to process them due to abnormalities in the biogenesis of lysosomal enzymes.¹² Although it has been less well studied, it is likely that HCV-associated MPGN arises from similar mechanisms.

Isolated proteinuria with microscopic hematuria is the most frequent presenting renal syndrome in both MC and MPGN and is sometimes associated with signs of moderate chronic renal insufficiency or, less frequently, proteinuria in the nephrotic range. An acute nephritic syndrome, often with macroscopic hematuria, severe proteinuria, hypertension, and a sudden increase in blood urea nitrogen, is present at the onset of the renal disease in approximately 25% of patients, sometimes complicated by acute oliguric renal failure. Arterial hypertension is frequently found at the time of the apparent onset of renal disease, even in patients without nephritic syndrome. Renal and extrarenal vasculitis are frequently present in MC. The corresponding histologic picture is of a membranoproliferative glomerulonephritis with less conspicuous intraluminal deposits and monocyte infiltration, sometimes with a lobular pattern, whereas immunofluorescence shows capillary wall deposits of IgM, IgG, and C3 that are sometimes segmental.^{3,13} Electron microscopy shows subendothelial electron dense deposits. Sometimes intraluminal deposits with an organized substructure can be found. A minority of patients present with isolated urinary abnormalities and may have a rather nonspecific picture of mild segmental mesangial proliferation, without significant monocyte infiltration and capillary wall alterations.

In nearly one third of patients, even in those who present with an acute nephritic syndrome or severe nephrotic syndrome, spontaneous remission of renal symptoms may occur. In one third of patients, the renal disease has a rather indolent course and, despite the persistence of urinary abnormalities, does not progress to renal failure for several years. In as many as 20% of patients, recurrent reversible clinical exacerbations such as nephritic syndrome and nephrotic syndrome occur during the course of the disease and are sometimes associated with flare-ups of systemic signs of the disease.

If a moderate degree of renal insufficiency is not already present at clinical onset, it is frequently found during later stages of the disease. However, progression to end-stage renal failure is less common than was believed in the past, even after multiple relapses. Chronic uremia developed in only 10% of patients reported in the literature, usually several years after the onset of renal symptoms. The most frequent causes of death in patients with essential MC are cardiovascular and cerebrovascular accidents, hepatic failure, infection, and systemic vasculitis.^{13,14}

TREATMENT

Antiviral Therapy of Hepatitis C Virus Infection in Patients with Mixed Cryoglobulinemia and Moderate Renal Involvement

The currently recommended therapy of HCV infection in patients without MC or renal involvement is a combination of formulations of interferon (IFN)- α and ribavirin.^{15–18} IFN- α is a cytokine that has an important function in the innate antiviral immune response. It should be administered three times per week subcutaneously, usually at the dose of 3 million units (mU). Ribavirin is an oral nucleoside analogue with broad activity against viral pathogens. It is administered orally twice daily at the total dose of 800 to 1200 mg. The overall rate of sustained virologic response, defined as the absence of HCV RNA in serum at least 6 months after the discontinuation of therapy, is low (<20%) with the separate use of the two drugs, but their combination has led to a marked improvement in this rate (as much as 40%–45%).

A further improvement in the rate of sustained virologic response was obtained recently with the development of a long-acting IFN, pegylated IFN, produced by the covalent attachment of polyethylene glycol to the IFN molecule. With its increased half-life, this drug can be given as a weekly dose. Two pegylated IFN formulations are currently approved for the treatment of hepatitis C: α -2a, whose recommended weekly dose is 180 μ g SC, and α -2b, whose recommended dose is 1.5 μ g/kg body weight/week SC.

The currently recommended regimen for the treatment of chronic HCV is the combination of weekly subcutaneous injections of pegylated IFN or three times per week subcutaneous injections of IFN- α , and twice-daily oral doses of ribavirin. The optimal duration of therapy and dose of ribavirin vary according to the HCV genotype. Although patients with genotype 2 or 3 infection can receive 24 weeks of combination therapy with a dose of 800 mg/day ribavirin, patients with other genotypes, especially genotype 1, should receive ribavirin for 48 weeks at a daily dose of 1000 mg (if their body

weight is ≤ 75 kg) or 1200 mg (if their weight is > 75 kg). The weekly dose of IFN- α or pegylated IFN does not change according to the genotype.

With the use of these regimens, overall sustained virologic response rates are 75% to 80% among patients with HCV genotype 2 or 3 infection and 40% to 50% among those with genotype 1. The response rate is lower in black patients.

Both IFN- α and ribavirin have adverse effects. The most common side effects of IFN- α and pegylated IFN are muscle aches and fatigue, but there are sometimes also psychological side effects such as depression, anxiety, irritability, sleep disturbances, and difficulty concentrating. The most common serious side effect of ribavirin is hemolytic anemia, especially if renal insufficiency is present, and is the major reason for dose reduction. Ribavirin is also teratogenic, and strict adherence to an effective means of birth control is mandatory for both women and men who receive this drug.

The available literature suggests that the antiviral therapy may be effective even when cryoglobulinemia and moderate renal involvement complicate the viral infection. As early as 1993 to 1994, three controlled trials^{19–21} were published on the effect of IFN- α , administered alone, in HCV infection complicated by MC, sometimes associated with moderate signs of renal involvement. The trial of Ferri and colleagues²⁰ was a crossover, controlled trial in 26 patients with documented HCV infection and clinically active MC (purpura, liver, and/or neurological involvement) but without evident signs of renal involvement. The trial alternated 6 months with IFN- α therapy (2 mU daily for a month, then every other day for 5 months) and 6 months without IFN- α therapy. The majority of patients were on low-dose steroid treatment before the trial, and this medication was continued during the trial. A significant improvement of purpura, together with a reduction of cryoglobulins and transaminases, was reported during treatment compared with periods without treatment; however, rebound was commonly observed during these drug-free intervals. In three patients, signs of renal involvement appeared during the treatment period. In the randomized, controlled trial of Misiani and colleagues,²¹ 53 patients with HCV-associated type II MC, three fourths of whom had some mild renal involvement, were assigned to receive either symptomatic therapy or IFN- α for 6 months (1.5 mU/day for 1 week, then 3 mU three times weekly for the next 23 weeks). Many patients in both subgroups were also receiving low-dose steroid treatment before the start of the trial and continued to take it. IFN- α eradicated the viremia in 60% of patients, improved the systemic signs of the disease, and reduced the cryocrit, although no beneficial effects on liver damage were documented. With regard to the renal disease, only a small but constant decrease in serum creatinine was reported, without significant change in proteinuria. Despite these beneficial effects in 60% of treated patients, none became completely free of the abnormalities that characterize MC, and all patients relapsed after IFN- α was discontinued. In the randomized, controlled trial by Dammaco and colleagues,¹⁹ 65 patients with type II MC due to HCV infection were assigned to four groups: group A, 3 mU of natural IFN- α three times per week for 1 year; group B, IFN- α as in group A plus 16 mg oral 6-methylprednisolone (MP) on non-IFN- α days; group C, 16 mg/day of MP only; group D, no treatment. A good response, arbitrarily defined as decrease in the cryocrit to less than 50% associated with improvement of systemic signs, was obtained in approximately half the

patients given IFN- α alone or IFN- α plus MP, but in only 17% of those given the steroid alone. As in the previous trials, the favorable effect was limited to patients in whom HCV RNA became negative (42% and 50%, respectively, in group A and group B). In patients treated with MP only, despite the demonstration of clinical and biochemical remission in a minority of patients, a significant increase of HCV RNA levels was demonstrated at the end of the treatment in 5 of 13 patients. Recurrence of signs of MP was a frequent phenomenon after discontinuation of the trials, but clinical relapse was delayed in patients receiving the combined treatment (IFN- α plus MP) compared with those treated with IFN- α alone.

Many subsequent studies^{8,22–26} have confirmed the efficacy of antiviral therapy (IFN- α with or without ribavirin) in controlling the extrarenal clinical manifestations of cryoglobulinemia, suggesting that improvement in cryoglobulinemia-related symptoms can be achieved even without complete biochemical or virologic responses and that the presence of cryoglobulins does not affect the response to antiviral treatment in patients with HCV infection.

More recently, some uncontrolled studies in patients with cryoglobulinemia and moderate renal involvement have been performed in small numbers of patients, confirming the efficacy of antiviral therapy, especially if IFN- α has been combined with ribavirin.

Sabry and colleagues,²⁷ in a prospective, uncontrolled study, treated 20 patients with HCV-related glomerulonephritis (17 MPGN) with IFN- α with or without ribavirin. All patients received IFN 9 mU/week. In the case of persistent HCV RNA at 3 months, ribavirin (15 mg/kg/day) was added to the treatment. Four of 20 patients became HCV RNA negative within 3 months and did not receive ribavirin. Only one of the remaining 16 patients who received ribavirin became HCV RNA negative. A reduction of the ribavirin dose was necessary in seven patients because of an adverse event, especially hemolytic anemia. Proteinuria and HCV RNA levels decreased, while serum complement and albumin levels increased significantly. Renal function remained stable. No data are provided regarding the long-term outcome of the renal disease. Bruchfeld and colleagues²⁸ treated seven patients with glomerulonephritis and vasculitis and chronic renal insufficiency (glomerular filtration rate between 10 and 65 mL/min) with a combination of IFN- α (pegylated IFN in two cases) and ribavirin. Plasma levels of ribavirin were monitored because of the renal insufficiency to avoid overdosing. Six of seven patients became HCV RNA (polymerase chain reaction) negative and four of seven were in virologic and renal remission at the time of publication. One of seven maintained virologic and partial renal remission. One patient who did not tolerate IFN had a renal remission, but relapsed virologically and had a minor vasculitis flare-up after 9 months. Only one patient with vasculitis had low-dose immunosuppression therapy in addition to antiviral therapy. The average daily ribavirin dose was 200 to 800 mg. Alric and colleagues²⁹ treated 18 patients with HCV-related cryoglobulinemic MPGN with combined therapy of standard or pegylated IFN and ribavirin. After treatment of the acute phase with steroids and/or plasma exchange, antiviral therapy was started in 18 of 25 patients; 7 of these patients did not receive anti-HCV therapy, 14 patients received standard IFN- α (3 mU three times per week) plus ribavirin 600 to 1000 mg/day, and 4 received pegylated IFN- α 2 (1.5 μ g/kg/week) plus ribavirin

Table 14-1 Antiviral Therapy in Hepatitis C Virus–Associated Cryoglobulinemic Glomerulonephritis or Membranoproliferative Glomerulonephritis with Moderate Renal Involvement

Drug	Dose	Duration
Interferon- α	3 million units 3 times weekly SC	
or		
Peginterferon-2 α	180 μ g once weekly SC	48 wk*
or		
Peginterferon-2 β	1.5 μ g/kg body weight once weekly SC	
plus		
Ribavirin	800–1200 mg/day in 2 oral doses	

*Treatment can be discontinued after 24 weeks if virus genotype is 2 or 3 or if hepatitis C virus (HCV) RNA is still detectable, and after 12 to 16 weeks if HCV RNA is already undetectable by week 4.

600 to 1000 mg/day. The mean duration of antiviral therapy was 18 months (range, 6–24 months). The patients were followed after antiviral therapy for a mean of 16.7 months (range, 6–30 months). Sustained virologic response was observed in 67% of cases (pegylated IFN had virologic response in three of four patients). After treatment, cryoglobulin levels and proteinuria decreased, while serum albumin level increased in responders compared with nonresponders and to the seven patients who did not receive antiviral treatment. Renal function remained stable in all three groups. Cryoglobulins persisted for a long period after HCV RNA clearance. The authors recommend treating patients for at least 48 weeks and to continue the antiviral therapy even in the absence of a decrease in HCV RNA concentration of 2 log at week 12. To avoid adverse effects, especially hemolysis, ribavirin dose should be adapted to creatinine clearance.

In conclusion, the available experience suggests that in patients with HCV infection and MPGN or glomerulonephritis associated with MC, if there is not an acute flare-up of the disease and even if some impairment of the renal function exists, antiviral treatment with a combination of IFN- α and ribavirin is the most valid treatment. When it induces a sustained virologic response, it probably reduces the infection of B cells by the HCV and consequently the production of cryoglobulins and their glomerular and vascular deposition. We propose the schema shown in Table 14-1.

Therapy of Acute Exacerbations of Cryoglobulinemic Glomerulonephritis and Renal Vasculitis

Acute flare-ups of the renal disease, characterized by an acute nephritic syndrome or a nephritic syndrome with less rapid functional deterioration, usually associated with recurrence of the systemic signs of MC (purpura, arthralgia, visceral vasculitis), may occur despite the widespread use of antiviral drugs. In our opinion, they deserve the same aggressive therapy that was used before the viral etiology of the

disease became evident. Although these acute manifestations of cryoglobulinemic glomerulonephritis and vasculitis are in some cases spontaneously reversible, in past years, nephrologists who did not aggressively treat this clinical condition observed that irreversible complete loss of renal function can occur. Before the viral origin of essential MC was shown, such misfortunes prompted investigators to use the same anti-inflammatory and cytotoxic drugs that successfully treated other types of rapidly progressive glomerulonephritis as well as antineutrophil cytoplasmic antibody-positive renal vasculitis. Although data from uncontrolled trials using oral steroids and/or cyclophosphamide were initially discouraging, subsequent experience with a regimen based on high-dose intravenous methylprednisolone pulses at the beginning of the steroid treatment,³⁰ eventually administered with cyclophosphamide, led nephrologists to consider this regimen probably more efficacious because it frequently induced a rapid improvement in the systemic signs of the disease, a progressive regression of the impaired renal function (often with normalization of glomerular filtration rate or serum creatinine), and a decrease in proteinuria.³

Plasma exchange or cryofiltration apheresis has been added in more severe cases. Indeed, although a precise relationship between the level of circulating cryoglobulins and severity of renal damage induced by their intraglomerular deposition has not been confirmed by many investigators, the rationale for sharply reducing their level in the blood with such methods appears convincing. Significant amounts of cryoproteins can be removed with this technique, which may prevent local cryoprecipitation in small renal vessels, restore reticuloendothelial system functions that have been saturated by the chronic overload of circulating cryoglobulins, and remove from the blood potentially toxic mediators of inflammation. Many uncontrolled studies have reported rapid improvement in serum creatinine, proteinuria, and cryocrit after plasmapheresis or cryofiltration.^{31–34} However, in most trials, this treatment was combined with corticosteroids and cyclophosphamide (to avoid rebound production of cryoglobulins by B cells), so that it is difficult to assess whether the beneficial effects were attributable to the plasmapheresis per se, to the concomitant immunosuppression, to the combination of the two treatments, or to spontaneous recovery.

Over the past 20 years in two renal units in Milan, we have routinely used a therapeutic regimen that includes steroids (short courses of intravenous methylprednisolone pulses, followed by oral prednisone), cyclophosphamide (especially when signs of renal and/or systemic vasculitis were present), and, in the most acute cases, plasmapheresis.³ No evident signs of worsening of liver involvement, as indicated by the level of hepatic enzymes, were found in more than 50 patients treated as described, nor was there an increased incidence of serious infectious complications, although increasing viral load has been demonstrated after the use of cyclophosphamide.

Obviously a controlled trial is now mandatory to investigate the effect of IFN- α or other antiviral drugs given alone compared with the same antiviral drugs combined with anti-inflammatory and cytotoxic drugs plus plasmapheresis. Such a trial must establish, by scientifically rigorous procedures, the superiority of the combination treatment, but at the same time must seek to identify the possible adverse effects on the course of the viral disease and its

organ complications (especially liver and nervous system), monitoring also the serum level of viremia by measurement of HCV RNA.

Very recently, rituximab, a human-mouse chimeric monoclonal antibody that binds to B-cell surface antigen CD20, has been used in noncontrolled studies on small numbers of patients in substitution of cyclophosphamide to eliminate the infected B cells that induce oligoclonal monotypic lymphoproliferation and production of type II cryoglobulins. This drug, which is effective and well tolerated in patients with B-cell non-Hodgkin's lymphoma, is expected to interfere with monoclonal IgM production, cryoglobulin synthesis, and their renal deposition. Single cases of such treatment have been described,^{35,36} and Roccatello and colleagues³⁷ described a case series of six patients with HCV-related cryoglobulinemic glomerulonephritis treated with rituximab. One patient received the standard four weekly doses, whereas the other five received two additional doses after 1 and 2 months. Patients invariably showed a decrease in proteinuria, together with a decrease in rheumatoid factor, IgM levels (with unaffected levels of IgG and IgA), and cryocrit. A significant increase in C4 levels was observed while modifications of renal function were not significant. Normalization of bone marrow was also observed in three cases examined. The clinical symptoms purpura, arthralgia, weakness, and paresthesia improved in all cases. No substantial changes in liver enzymes or viral load were observed. Although controlled, randomized studies are required to define the exact indication and dose of rituximab and the

Table 14-2 Treatment of Hepatitis C Virus–Associated Cryoglobulinemic Glomerulonephritis and Vasculitis in the Presence of Severe Acute Signs of Renal Involvement

Drug	Dose	Duration
Interferon- α plus ribavirin plus Steroids	Schedule as in Table 14-1 0.75–1 g/day methylpred- nisolone IV for 3 consecutive days, followed by oral pred- nisolone (0.5 mg/kg body weight/day, ta- pered over a few weeks until small maintenance doses are achieved)	6–12 mo 6 mo
plus Cyclophosphamide	2 mg/kg body weight	3–6 mo
plus Plasmapheresis	Exchange of 3 L of plasma 3 times weekly	2–3 wk

The anti-inflammatory and immunosuppressive therapy indicated may be substituted in most severe cases of type II cryoglobulinemia and nephritis with rituximab (375 mg/m² IV on days 1, 8, 15, and 22 and eventually two more doses 1 and 2 months later).

long-term effect on liver function, anti-CD20 therapy seems a promising tool in the treatment of acute exacerbation of HCV-related cryoglobulinemic glomerulonephritis and should be preferred to cyclophosphamide. Patients are currently being enrolled in such a study at the National Institute of Allergy and Infectious Diseases.

In conclusion, in the presence of acute signs of renal involvement, intensive anti-inflammatory and cytotoxic treatment must be combined with the antiviral therapy described. The suggested protocol is summarized in Table 14-2.

BACKGROUND

Systemic lupus erythematosus (SLE) is a complex systemic disease that develops from a massive overproduction of polyclonal antibodies and impaired clearance of immune complexes. Many of the antibodies are autoreactive, either from loss of self-tolerance or from antigenic cross-reactivity, and are used as criteria for the diagnosis of SLE.¹ Renal disease results from deposition of pathogenic immune complexes and infiltration of lymphoid cells within glomeruli, interstitium, and extraglomerular vessels. These humoral and cellular components, along with a host of soluble mediators, evoke a cascade of inflammation, cell death or proliferation, vasculopathy, and fibrogenesis.^{2,3} Cumulative evidence indicates that complex interactions between environmental factors and disease susceptibility genes contribute to the pathogenesis of SLE and lupus nephritis.

It is well recognized that renal involvement adversely affects the prognosis of SLE. Indeed, patients often consider kidney disease to be one of the most dreaded complications of SLE. The empathic physician can help the patient realize that the prognosis of lupus nephritis is not uniformly grave and that effective therapies are available for many forms of the disease.⁴⁻⁹ Patients should know that prognosis varies greatly among the many clinical and pathologic forms of lupus renal disease.⁷⁻⁹

Delineation of the specific type of renal involvement is critical to effective clinical management.¹⁰ This process depends on diligent surveillance of patients for hypertension and other clinical and serologic evidence of lupus activity as well as periodic screening by appropriate renal function tests. Urinalysis is clearly one of the most cost-effective methods to detect renal involvement, but special efforts on the part of the clinician are usually needed to verify routine clinical laboratory assessment of urine sediment.¹¹ Proteinuria is conveniently as-

sessed by measures of protein-to-creatinine ratios on random urine specimens. Renal biopsies are indicated to help delineate the exact type and severity of pathologic lesions early in the course of lupus nephritis.^{12,13} A particularly noteworthy study has shown that deferral of renal biopsy is commonly associated with a delay in implementation of cytotoxic drug therapy.¹⁴ Thus, information from early renal biopsy has a substantive impact on the development of a comprehensive treatment plan for patients with lupus nephritis. Management of hypertension and the secondary complications of lupus nephritis are addressed elsewhere in this volume.

The present chapter focuses on immunosuppressive drug treatment of the various pathologically defined forms of lupus nephritis in adults, with an emphasis on class III and IV. The classification system to describe the pathology of lupus nephritis was recently revised.^{15,16} One of the goals for the new International Society of Nephrology/Renal Pathology Society classification was to provide a more standardized approach to renal biopsy interpretation that would facilitate the comparison of data across centers. Some of the changes from the earlier World Health Organization classification schemes¹⁷ include the elimination of the normal biopsy category and the subgroups Va-Vd of class V membranous; use of (A) and (C) for designation of active and chronic lesions; and the addition of subcategories within diffuse lupus nephritis (class IV) for predominantly segmental (IV-S) and predominantly global (IV-G) lesions. It is important to keep these differences in mind and to use caution when trying to compare the results of more recent outcome studies based on the newer International Society of Nephrology/Renal Pathology Society classification with older studies using the older World Health Organization classification schemes. A review of the strengths and weaknesses of the new classification system (as well as some of the controversies that have emerged) has recently been published.¹⁸

REVIEW OF CLINICAL TRIALS

Animal Studies

Important insights into the pathogenesis and treatment of lupus nephritis have emerged from studies of murine models of SLE (e.g., NZB/W, SWR/NZB, MRL/lpr, BXSB). The natural history of SLE is known most precisely from studies of murine models in which death from progressive lupus nephritis occurs predictably unless interdicted by effective immunosuppressive treatments. Comparable knowledge about the natural history of human SLE and lupus nephritis is deficient because of the effects of the host of disease-modifying interventions used in this condition. The different strains of lupus-prone mice appear to have distinct immunologic defects that may have counterparts in the diverse mechanisms underlying human SLE.^{19,20} Several strains of lupus mice succumb within a relatively narrow window of time from complications of lupus nephritis; the strain-specific predictable natural history has made them apt subjects for testing new therapies.²¹

Box 15-1 presents a highly simplified overview of experimental therapies that have been tested in the murine models of lupus nephritis. The therapies have been ranked according to their impact on survival (mostly representing amelioration of lupus nephritis). As noted, many therapeutic interventions have a favorable effect on the course of these models. Cyclophosphamide has one of the highest therapeutic indices. Particularly intriguing is a recent study showing that combination of cyclophosphamide and the costimulation inhibitor CTLA4-Ig had a dramatic effect on the advanced stages of murine lupus nephritis.^{22,23} Gene therapy is a more complex process that perhaps will offer future prospects for definitive treatment and perhaps a cure for SLE and lupus nephritis.

Human Studies

Although there is general consensus that the outlook for patients with lupus nephritis has improved greatly over the past half century, there remains substantial controversy about which factors are principally responsible for this improvement in prognosis.²⁴⁻²⁶ A particularly confounding issue is the tremendous diversity in prognosis among patients in different geographic centers. Descriptions of natural history of lupus nephritis range from dismal odds of renal survival despite aggressive immunosuppressive treatment in some populations²⁷⁻³⁰ to excellent long-term survivals with only modest immunosuppressive therapy in other populations.^{7,8,25,31} Thus, studies must be of sufficient duration in order to understand important differences in the biology of SLE and the impact of various interventions on the natural history of lupus nephritis among different demographic populations.^{32,33} Indeed, studies of therapies for lupus nephritis have been plagued by historical evidence that several immunosuppressive drug regimens, including corticosteroids alone, achieve comparable short- and intermediate-term renal survival outcomes. Thus, reliable attributions of treatment efficacy must be based on the results of prospective, randomized, controlled, long-term clinical trials in lupus nephritis.³⁴

Box 15-2 presents a synopsis of the controlled therapeutic trials since 1975 that constitute the foundation for our current recommendations for treatment of proliferative

lupus nephritis. The reader may be surprised to learn that fewer than 1200 patients have been enrolled in these various clinical trials to date. Results of the common treatment regimens (drug, route of administration, duration) are grouped together in this box. The criteria for renal disease, the specific treatment regimens, and the conclusions suggested by these major therapeutic trials are presented for each study.

Corticosteroids

The merit of high-dose corticosteroids in patients with various forms of lupus nephritis has never been rigorously proven by modern clinical trial methodology. There have been no controlled clinical trials proving the benefit of corticosteroids over supportive therapy in lupus nephritis, nor have there been any studies directly comparing conventional prednisone

Box 15-1 Overview of Experimental Treatments and Survival in Murine Lupus Nephritis

Major Benefit

Cyclophosphamide
T-B cell costimulation inhibitors (anti-CD154 [CD40L], CTLA4-Ig, and other B7 inhibitors)
Total lymphoid irradiation
Bone marrow transplantation
Gene therapy

Moderate Benefit

Sex hormones (in females): Castration, androgens, estrogen antagonists, bromocriptine

Chemical immunosuppression: Glucocorticoids, azathioprine, mycophenolate mofetil, methotrexate, cyclosporin A, tacrolimus, sirolimus, deoxyspergualin, ornithine decarboxylase inhibitors, dimethylthiourea, 5-azacytidine

Inflammation modulators: Prostaglandin E analogues, free radical scavengers, platelet-activating factor receptor antagonists, thromboxane synthase and receptor antagonists, nitric oxide synthase inhibitors, endothelin A receptor antagonists, phosphodiesterase inhibitors, 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors

Cytokine and chemokine antagonists against: Interferon gamma, soluble interferon gamma receptors, interleukin-2 receptors, interleukin-6, interleukin-6 receptors, interleukin-10, tumor necrosis factor, B-cell activating factor, transforming growth factor β , soluble interleukin-4 receptors, macrophage chemoattractant protein, fractalkine

Monoclonal antibodies against: Nephritogenic idiotypes, T and B cells, complement

Cell therapy with transfer of T regulatory cells

Anticoagulants: Heparin, heparinoids

Fibrinolytic agents: Ancrod

DNA-related agents: Recombinant murine DNase, bacterial DNA immunization, synthetic oligonucleotide conjugate (LJ-394 DNA toleragen), anti-DNA antibody-based peptide (to manipulate regulatory and suppressor T-cell populations)

Dietary manipulation: Protein, calorie, and fat restriction; vitamin D₃, fish oil, and flaxseed supplements

Box 15-2 Synopsis of Controlled Immunosuppressive Drug and Plasma Exchange Trials in Lupus Nephritis since 1975**Azathioprine: Extended Oral Therapy****Austin and Colleagues (1986)³⁸ and Steinberg and Steinberg (1991)⁴⁴**

Renal disease: Active urinary sediment with lupus nephritis (mostly proliferative) on biopsy. *Treatment:* Prednisone versus prednisone plus azathioprine until major drug toxicity, renal failure, or sustained remission of nephritis. *Conclusions:* Azathioprine did not decrease risk of ESRD compared with prednisone alone during 10 or more years of observation.

Azathioprine plus Cyclophosphamide Combination: Extended Oral Therapy**Austin and Colleagues (1986)³⁸ and Steinberg and Steinberg (1991)⁴⁴**

Renal disease: Active urinary sediment with lupus nephritis (mostly proliferative) on biopsy. *Treatment:* prednisone versus prednisone plus azathioprine and cyclophosphamide combination until major drug toxicity, renal failure, or sustained remission of nephritis. *Conclusions:* After 5 years of observation, azathioprine plus cyclophosphamide significantly decreased the risk of ESRD compared with prednisone alone.

Cyclophosphamide: 6 Months of Oral Therapy**Donadio and Colleagues (1978)³⁶ and Donadio and Colleagues (1982)³⁷**

Renal disease: Severe proliferative lupus nephritis on biopsy with clinical evidence of progression. *Treatment:* Prednisone versus prednisone plus oral cyclophosphamide for 6 months. *Conclusions:* The short course of cyclophosphamide significantly improved the probability of a stable renal course over the first 4 years of observation, but there was no difference in late risk of renal failure.

Cyclophosphamide: Oral Therapy Extended Until Complete Remission**Austin and Colleagues (1986)³⁸ and Steinberg and Steinberg (1991)⁴⁴**

Renal disease: Active urinary sediment with lupus nephritis (mostly proliferative) on biopsy. *Treatment:* Prednisone versus prednisone plus cyclophosphamide until major drug toxicity, renal failure, or sustained remission of nephritis. *Conclusions:* After 5 years of observation, cyclophosphamide significantly decreased the risk of ESRD compared with prednisone alone.

Cyclophosphamide: Extended Quarterly Intravenous Pulse Therapy**Austin and Colleagues (1986)³⁸ and Steinberg and Steinberg (1991)⁴⁴**

Renal disease: Active urinary sediment with lupus nephritis (mostly proliferative) on biopsy. *Treatment:* Prednisone versus prednisone plus pulse cyclophosphamide until major drug toxicity, renal failure, or sustained remission of nephritis. *Conclusions:* After 5 years of observation, cyclophosphamide significantly decreased the risk of ESRD compared with prednisone alone and was less toxic than regimens containing daily cyclophosphamide.

Cyclophosphamide: Monthly and Quarterly Pulse Therapies**Boumpas and Colleagues (1992)⁴⁵**

Renal disease: Active urinary sediment, reduced renal function, or severely active lupus nephritis on biopsy. *Treatment:* Monthly pulse methylprednisolone for 6 months versus monthly pulse cyclophosphamide for 6 months versus monthly pulse cyclophosphamide for 6 months followed by quarterly pulse cyclophosphamide for 2 years. *Conclusions:* Treatment with the extended course of pulse cyclophosphamide significantly decreased the probability of doubling serum creatinine compared with pulse methylprednisolone; relapse after initial improvement of nephritis was increased after the short course compared with the extended course of pulse cyclophosphamide.

Sesso and Colleagues (1994)⁴⁶

Renal disease: Severe lupus nephritis. *Treatment:* Pulse methylprednisolone versus pulse cyclophosphamide each given monthly for 4 months followed by two quarterly pulse treatments. *Conclusions:* At 18 months, no difference in probability of doubling creatinine or developing ESRD.

Combination Pulse Methylprednisolone and Cyclophosphamide**Gourley and Colleagues (1996)⁴⁷ and Illei and Colleagues (2001)⁴⁸**

Renal disease: Active urinary sediment, proteinuria, proliferative lupus nephritis on biopsy. *Treatment:* Pulse methylprednisolone monthly for at least 1 year versus pulse cyclophosphamide monthly for 6 months and then quarterly versus combination pulse methylprednisolone and cyclophosphamide therapy. *Conclusions:* Renal remission was least likely with pulse methylprednisolone therapy; remissions tended to be established more rapidly with combination pulse methylprednisolone and cyclophosphamide therapy.

Cyclophosphamide: Low- versus High-Dose Pulse Therapy with Azathioprine Maintenance**Houssiau and Colleagues (2002)¹⁰⁷ and Houssiau and Colleagues (2004)¹⁰⁸**

Renal disease: Proliferative lupus nephritis. *Treatment:* High doses (≤ 1.5 g) pulse cyclophosphamide monthly for 6 months followed by two quarterly doses versus low doses (0.5 g fixed dose) of pulse cyclophosphamide every 2 weeks for six doses. *Conclusions:* After median follow-up of 6 years, there were no substantive differences in the proportions of favorable and unfavorable renal outcomes.

Continued

Box 15-2 Synopsis of Controlled Immunosuppressive Drug and Plasma Exchange Trials in Lupus Nephritis since 1975—cont'd**Cyclophosphamide versus Azathioprine Induction****Grootscholten and Colleagues (2006)⁴⁹ and Grootscholten and Colleagues (2007)¹⁰⁹**

Renal disease: Proliferative lupus nephritis (mostly class IV). *Treatment:* Pulse cyclophosphamide (750 mg/m²) monthly for 6 months and then quarterly for seven doses versus azathioprine with pulse methylprednisolone (1 g for 3 days repeated at 2 and 6 weeks); all received oral corticosteroids; after 2 years, all received azathioprine and low-dose prednisone for 3 years. *Conclusions:* After 2 years, there were no differences in cumulative incidence of complete or partial renal remissions; however, after median follow-up of 5.7 years, there were more relapses, a trend toward a higher incidence of doubling of serum creatinine, and more progression of chronic renal histopathologic lesions in the azathioprine arm.

Mycophenolate Mofetil versus Cyclophosphamide Induction**Chan and Colleagues (2000)⁵⁶ and Chan and Colleagues (2005)⁵⁵**

Renal disease: Proliferative lupus nephritis with more than 1 g/day proteinuria. *Treatment:* Mycophenolate with a switch to azathioprine at 12 to 24 months versus daily oral cyclophosphamide with a switch to azathioprine at 6 months. *Conclusions:* At 12 months, there were no differences in favorable or unfavorable renal outcomes between the two treatment arms; after an additional year of follow-up into the azathioprine maintenance phase of treatment, patients who initially received mycophenolate had significantly more relapses than did patients receiving cyclophosphamide induction therapy; however, after an extended median follow-up of 63 months, there were no differences in favorable and unfavorable renal outcomes between treatment arms.

Ginzler and Colleagues (2005)⁵⁸

Renal disease: Focal proliferative, diffuse proliferative, and/or membranous with relatively mild renal insufficiency. *Treatment:* Mycophenolate (target dose 3 g/day) for 6 months versus monthly pulse cyclophosphamide (0.5–1 g/m²) for six doses; all received oral corticosteroids. *Conclusions:* At 24 weeks, there were more complete and overall (complete plus partial) remissions in the mycophenolate treatment arm; at 3-year follow-up, there was a nonsignificant trend toward more renal failure and death in the cyclophosphamide treatment arm.

Ong and Colleagues (2005)⁵⁷

Renal disease: Proliferative lupus nephritis. *Treatment:* Mycophenolate for 6 months versus monthly pulse cyclophosphamide for six doses; all received oral corticosteroids. *Conclusions:* After 6 months, there were no substantive differences in the proportions of favorable and unfavorable renal outcomes or renal histology on repeat biopsy between treatment arms.

Maintenance: Cyclophosphamide Versus Mycophenolate versus Azathioprine**Contreras and Colleagues (2004)⁵⁰**

Renal disease: Focal or diffuse proliferative lupus nephritis. *Treatment:* All received induction with monthly pulse cyclophosphamide (four to seven doses) and corticosteroids and then maintenance with mycophenolate (0.5–2 g/day) versus azathioprine (1–3 mg/kg/day) versus IV cyclophosphamide (quarterly) for 25 to 30 months. *Conclusions:* Maintenance with azathioprine or mycophenolate was superior to cyclophosphamide in preventing renal failure and death; relapse-free survival was highest in the mycophenolate arm.

Maintenance: Azathioprine versus Cyclosporine**Moroni and Colleagues (2006)¹¹⁰**

Renal disease: Proliferative or membranous lupus nephritis. *Treatment:* All received induction with oral cyclophosphamide and corticosteroids for 3 months and then maintenance with cyclosporine versus azathioprine for 2 to 4 years. *Conclusions:* There was no difference in number of lupus flares, decrease in proteinuria, or change in renal function between treatment arms.

Plasma Exchange: With Short-Course Oral Cyclophosphamide**Lewis (1992)¹¹¹**

Renal disease: Proliferative or mixed membranous and proliferative lupus nephritis on biopsy. *Treatment:* Prednisone and daily oral cyclophosphamide (8 weeks) only versus prednisone and cyclophosphamide combined with three times weekly plasmapheresis for 4 weeks. *Conclusions:* Plasmapheresis does not improve the clinical outcome in severe lupus nephritis compared with that achieved with prednisone and cyclophosphamide alone.

Plasma Exchange: With Synchronized Intravenous Pulse Cyclophosphamide**Wallace and Colleagues (1998)¹¹²**

Renal disease: Active proliferative lupus nephritis. *Treatment:* Prednisone and six cycles of monthly high-dose pulse cyclophosphamide versus prednisone and six monthly cycles of synchronized plasma exchanges (3 consecutive days) followed by high-dose pulse cyclophosphamide. *Conclusions:* Changes in SLE activity and renal outcomes were comparable in both treatment groups; addition of plasma exchange to a regimen of corticosteroids and pulse cyclophosphamide is not indicated in severe SLE.

with methylprednisolone pulse therapy. Indeed, it is unlikely that prospective clinical trials comparing placebo and low-dose and high-dose corticosteroids for lupus nephritis will ever be performed, because of the potentially confounding effects of the standard clinical practice of using high-dose corticosteroids as first-line treatment for the myriad of extra-renal manifestations and complications of SLE. The best advice for the practitioner is not to withhold corticosteroids for fear of complications, but rather to test regularly the feasibility of reducing doses (preferably to alternate day) and to be willing to substitute alternative immunosuppressive drug strategies if clinical response is delayed. Physicians treating patients with SLE and lupus nephritis should always be inclined to reduce doses of corticosteroids to the lowest necessary for disease control in order to minimize risk of their insidious complications.

The issue whether to use corticosteroids as sole immunosuppressive therapy for the first bout of lupus nephritis has never been resolved. Practices differ considerably, with some arguing that due to the low probability of satisfactory complete remission occurring with corticosteroids alone, one should proceed straight to combination therapy including corticosteroids and a cytotoxic drug as initial therapy, particularly in proliferative lupus nephritis. Others would argue that because corticosteroids occasionally (~10% of cases) may lead to complete remission, one may consider a limited course of high-dose corticosteroids to be rational for previously untreated patients (and those lacking more ominous features such as crescents or fibrinoid necrosis on renal biopsy). The common temptation is to prolong the use of corticosteroids when there is improvement but objectively only partial remission. In our opinion, it is prudent to move to alternative therapy and avoid reliance on corticosteroids unless there is clear-cut complete remission within a time frame before substantive corticosteroid toxicities supervene.

Cyclophosphamide

Daily oral cyclophosphamide has been used as part of several regimens for the treatment of lupus nephritis. Conclusions about efficacy and toxicity have differed dramatically, depending mostly on the duration of cyclophosphamide administration and on the measure of renal outcome. Short-term cyclophosphamide therapy (2–6 months) has been shown to be more efficacious than prednisone alone in decreasing activity and stabilizing lupus nephritis.^{35,36} However, the short course of cyclophosphamide did not eliminate the subsequent risk of renal failure.³⁷ On the other hand, continuation of cyclophosphamide until the patients achieved sustained remission was shown to decrease the risk of late renal failure.³⁸

The cumulative toxicity of extended courses of daily cyclophosphamide provides a substantial argument against the use of protracted daily cyclophosphamide therapy for lupus nephritis³⁹—a conclusion that emerges from studies of systemic vasculitis.⁴⁰ Intermittent pulse therapy has become the preferred method for administering cyclophosphamide, including treatment of children with lupus nephritis.^{41,42} This approach is based mostly on experience in oncology where it has long been practice to use high, intermittent dosing as a method of maximizing the therapeutic index of cyclophosphamide as well as other chemotherapeutic drugs. Pulse

cyclophosphamide was tested extensively in murine and human lupus nephritis during the 1970s. The prolongation of survival in lupus mice was dramatic.¹ Demonstration of comparable benefit of cyclophosphamide in a human cohort with moderately severe lupus nephritis required a protracted period of observation and analysis of multiple endpoints, including urinary findings, stabilization of renal pathology,⁴³ and ultimately decreased risk of renal failure as measures of favorable outcome.^{38,44}

After demonstration of the efficacy of prolonged courses of quarterly pulse cyclophosphamide, a subsequent trial was designed to evaluate shorter (6 months), more intense regimens of monthly pulse cyclophosphamide and monthly pulse methylprednisolone for patients with severe proliferative lupus nephritis (presence of renal insufficiency, necrosis, and/or cellular crescents). Neither of these regimens was as effective in preserving renal function or in preventing lupus relapses over a 5-year period as was monthly pulse cyclophosphamide followed by 2 years of quarterly maintenance pulse therapy.⁴⁵ Neither this study nor the study by Sesso⁴⁶ showed any short-term (i.e., 18 months) differences in renal function outcomes among patients treated with 4 to 6 months of pulse methylprednisolone versus pulse cyclophosphamide.

The most recent National Institutes of Health clinical trial comparing extended courses of pulse methylprednisolone alone, pulse cyclophosphamide alone, and the combination of pulse therapies showed that renal remission was achieved somewhat more rapidly with combination pulse therapy and was least likely with pulse methylprednisolone alone.^{47,48} In short, neither pulse methylprednisolone (in either short or extended courses) nor short courses of pulse cyclophosphamide are as efficacious as extended courses of pulse cyclophosphamide in reducing risk of renal progression or in achieving sustained remission of lupus nephritis.

Nonetheless, pulse cyclophosphamide is not universally effective in controlling lupus nephritis. Furthermore, administration of cyclophosphamide is moderately burdensome for the patient, and cumulative doses of cyclophosphamide pose substantial risk of permanent gonadal toxicity. All these concerns have prompted a continued search for more effective, simple, and safe induction and maintenance immunosuppressive drug regimens for lupus nephritis. Two agents that have been tested most extensively in this regard are azathioprine and mycophenolate mofetil.

Azathioprine

The majority of studies indicate that azathioprine adds marginally to the efficacy of prednisone alone. Several studies have shown that azathioprine was not as efficacious as cyclophosphamide, measured by improvement of urine sediment, proteinuria, lupus activity, and serologies. A recently completed controlled trial in the Netherlands also concluded that an induction regimen of azathioprine (with pulse methylprednisolone) is inferior to pulse cyclophosphamide in preserving renal function and preventing renal relapses.⁴⁹ However, azathioprine appears to be efficacious as maintenance therapy and continues to be used in many centers around the world for this purpose, often after patients have had substantial improvement or achieved remission of lupus nephritis with cyclophosphamide (or other) therapy. A controlled clinical trial in the United States

suggests that azathioprine is as effective as quarterly pulse cyclophosphamide for maintenance therapy.⁵⁰

Mycophenolate Mofetil

Mycophenolic acid was initially tested and shortly abandoned for treatment of several autoimmune diseases in the 1960s. Following its reformulation as mycophenolate mofetil, it was brought to the field of solid organ transplantation as a potential advance over traditional azathioprine. Based principally on studies showing greater efficacy of mycophenolate over azathioprine in reducing transplant rejection, several investigators began exploring the use of mycophenolate in lupus nephritis (particularly for patients averse or refractory to cyclophosphamide).^{51–54} Among the most attractive attributes of mycophenolate is its lack of gonadal and urinary bladder toxicity (compared with cyclophosphamide). Several randomized, controlled trials have compared mycophenolate with cyclophosphamide for induction therapy of active lupus nephritis.^{55–58} The combined results of these trials have shown that mycophenolate has at least equal efficacy as and less toxicity than cyclophosphamide (oral and IV pulses) for induction therapy. Based on these encouraging findings, many clinicians have already adapted the routine use of mycophenolate for induction. However, potentially important limitations need to be highlighted and addressed before this therapy can be widely accepted for the treatment of severe lupus nephritis. The efficacy of mycophenolate in patients with rapidly progressive crescentic glomerulonephritis, significantly impaired renal function at presentation (creatinine clearance < 30 mL/min) and poor prognostic indicators on biopsy is still unproven, as these patients were excluded from the studies. Follow-up was relatively short; longer term observational data are needed to determine the relapse rate and long-term renal survival in patients treated with mycophenolate compared with cyclophosphamide for which long-term data have been demonstrated. Optimal doses for induction are also not known; many patients may not be able to tolerate the higher doses used in some trials due to gastrointestinal side effects, which might adversely affect outcomes. Pharmacokinetic studies may help to find the ideal doses. Finally, fewer than 200 patients have been treated with mycophenolate for induction therapy (and directly compared with cyclophosphamide) in randomized, controlled trials. Data from a greater number of patients are eagerly awaited.

Mycophenolate appears to be a reasonable option for maintenance therapy. Recent data support the efficacy and safety of mycophenolate after induction with pulse cyclophosphamide⁵⁰ or higher doses of mycophenolate.⁵⁵ The optimal doses and duration of mycophenolate for maintenance therapy are not known. It is also unclear whether mycophenolate is superior to azathioprine for maintenance. At least based on one study, they perform equally well.⁵⁰ The cost of mycophenolate may be a practical limitation, particularly if long-term maintenance is necessary, and may make the less expensive azathioprine more attractive if similar efficacy is confirmed in subsequent trials.

Many of these issues will perhaps be addressed by two trials that are currently in progress. One multicenter international trial will compare mycophenolate with standard pulse cyclophosphamide for induction therapy in patients with severe lupus nephritis. Patients with a satisfactory response after 6 months of induction will be randomized to mainte-

nance with either mycophenolate or azathioprine. Another trial will be comparing efficacy of mycophenolate mofetil and azathioprine as remission-maintaining treatment for proliferative lupus nephritis.

Plasma Exchange

Plasma exchange and immunosuppressive drug therapy have had theoretical appeal as a method to rapidly eliminate pathogenic immune complexes and to inhibit production of auto-antibodies.^{59,60} Early uncontrolled studies claimed remarkable effectiveness of this dual approach, but this has not been confirmed by controlled therapeutic trials. Neither plasma exchange combined with conventional prednisone and cyclophosphamide⁶¹ nor plasma exchange synchronized with high-dose pulse cyclophosphamide has been found to be superior to immunosuppressive drug therapy alone.

SPECIFIC RECOMMENDATIONS

Assessment of Prognosis and Selection of Patients for Treatment

Lupus nephritis is extremely heterogeneous, both clinically and pathologically. Many variables affect renal prognosis, and a composite of risk factors can be used in justifying treatment strategies. Box 15-3 contains a selected list of factors associated with adverse prognosis and high risk of renal progression in lupus nephritis.^{62–66} Some of these factors may be evident at presentation and remain static; others change substantially during the course of lupus nephritis. Although the impact of each factor is different and not easily compared, in general, the greater the number of factors present at any one time, the more unfavorable is the renal prognosis and the stronger are the indications for aggressive immunosuppressive therapy.

Some comments regarding the impact of race on prognosis seem timely. Black race and Hispanic ethnicity have been shown to be associated with poor prognosis of lupus nephritis.^{28–30,62,65,67,68} Some studies suggest that black patients with proliferative lupus nephritis respond much less favorably than other racial groups to pulse cyclophosphamide³⁰ and other interventions.⁶⁹ Although this issue clearly warrants continued study, the reader should be mindful that diverse racial mixes may contribute to reported differences in course, prognosis, and treatment responses among studies from different centers around the world.

Treatment Options

Treatment of severe lupus nephritis is generally divided into an initial phase of induction, which is critical to minimize the active immune mediated inflammatory processes, followed by a prolonged maintenance phase aimed at reducing the risk of relapse. The various treatment options and practical recommendations for management of lupus nephritis are presented in condensed format in Boxes 15-4 to 15-7. Nearly all the commonly available immunosuppressive drugs have been used in management of lupus nephritis, and, as described previously, only some have been subjected to scientifically rigorous comparisons. Cyclophosphamide still has the most solid evidence of efficacy for induction of severe lupus nephritis, but mycophenolate is certainly an option for those strongly opposed to

Box 15-3 Factors Associated with Adverse Prognosis and High Risk of Renal Progression in Lupus Nephritis

Demographic

Black race, Hispanic ethnicity, male gender,* extremes of age at onset of SLE,* limited access to health care, poverty.

Clinical

Hypertension, severe extrarenal (especially neuropsychiatric) lupus activity, failure to achieve or marked delay to renal remission, multiple relapses of lupus nephritis, pregnancy.

Laboratory

Nephritic urinary sediment, azotemia, anemia, thrombocytopenia, thrombotic microangiopathy (with or without antiphospholipid antibodies), hypocomplementemia (especially falling levels), high anti-DNA (especially increasing titers), persistent severe nephrotic syndrome (atherosclerotic and thrombotic diathesis).

Renal Pathology

Contracted kidney size,[†] proliferative glomerulonephritis (classes III and IV), mixed membranous (class V) and proliferative (classes III and IV) glomerulonephritis, cellular crescents, fibrinoid necrosis, very high activity index, moderate to high chronicity index,[†] combinations of active (e.g., cellular crescents) and chronic histologic features (e.g., interstitial fibrosis), subendothelial deposits.

*There is controversy regarding the level of impact of these prognostic factors.

[†]These prognostic factors per se are not indications for treatment.

cyclophosphamide or with less severe forms of nephritis. At present, it appears that one can justifiably choose among several options of maintenance therapy including quarterly pulse cyclophosphamide, azathioprine, and mycophenolate.

Box 15-4 contains general comments on various choices of immunosuppressive agents, adjunctive therapies for secondary complications of lupus nephritis, and a selective overview of experimental therapies for proliferative and membranous lupus nephropathies.

Box 15-5 provides practical advice for administration of pulse cyclophosphamide therapy. Pulse cyclophosphamide was initially administered during an overnight hospital stay with the intent of ensuring bladder protection through brisk diuresis and control of nausea and vomiting. The newer serotonin receptor antagonists (e.g., ondansetron, granisetron) have revolutionized nausea control and have allowed the safe administration of pulse cyclophosphamide in the outpatient setting. Some risk of complications of pulse cyclophosphamide remains even with careful dose adjustment and meticulous monitoring. Herpes zoster in this patient population is aggravating but rarely life threatening. The risk of gonadal toxicity is dependent on age and total dose.⁷⁰⁻⁷² Encouraging data from several pilot studies suggest that premature ovarian failure may be reduced by suppressing ovarian function by an analogue of gonadotropin-releasing hormone.⁷²⁻⁷⁴ One such regimen involves monthly intramuscular injections of depot leuprolide acetate at least 10 days before pulse cyclophosphamide infusion. Unfortunately, no consensus

has been reached on the optimal approaches to gonadal protection during cytotoxic drug therapy. While fertility status is normally a supercharged issue, the high-risk patient should be thoughtfully counseled not to risk compromise of both future health and fertility (due to renal failure) by rejecting effective therapy for lupus nephritis. Nevertheless, the lowest effective dose and duration of cyclophosphamide should be considered, and alternative agents can be used during maintenance. Malignancy in SLE has been overblown in the past; indeed, cancer diathesis is quite low for both SLE and its treatment with immunosuppressive drugs.⁷⁵⁻⁷⁸

Box 15-6 provides a set of practical guidelines for treatment of proliferative lupus nephritis. The recommendations are organized by severity of disease, induction therapies, and maintenance regimens as well as alternative approaches to treatment. Box 15-7 contains guidelines and recommendations for treatment of lupus membranous nephropathy.^{79,80}

Relapses of Lupus Nephritis

One of the most perplexing and frustrating aspects of the natural history of SLE is its remitting and relapsing course. Although we now have more treatment options from which to choose, modern treatment neither cures lupus nor completely prevents exacerbations. Furthermore, each major exacerbation is expected to leave residual and cumulative irreversible (often subclinical) damage. Approximately one third to one half of patients have a relapse of nephritis after achieving partial or complete remission of proliferative lupus nephritis.^{45,81-89} Nephritic exacerbations clearly have adverse effects on renal prognosis, while proteinuric exacerbations have much less prognostic importance.⁸² These observations argue in support of strategies to minimize probabilities of flares of nephritis. One controlled trial has suggested that increases in anti-DNA activity predict impending flares, which could be averted by pre-emptive boosts in corticosteroid therapy. While many agree with the general value of monitoring anti-DNA (or other serologic) activity, most clinicians would use this information as motivation to intensify clinical screening for supportive signs of lupus activity before boosting therapy. This would include assessment of renal function, quantification of proteinuria, dipstick analysis, and microscopy of urine. Nevertheless, it still may be difficult to distinguish between inactive, chronic “fixed” injury and active renal inflammation that necessitates treatment. Renal biopsy is an important tool in reassessing disease activity. In fact, some advocate protocol biopsies to assess disease immunologic activity that may be subclinical. However, the procedure is not without risk, and repeated biopsies may not be practical in the clinical setting. Several recent preliminary studies have identified candidate urinary biomarkers that are associated with lupus disease activity.^{90,91} Although these observations need confirmation, such findings raise the possibility that noninvasive monitoring using proteomic profiling assays may help to predict impending relapse and allow more timely intervention.^{90,92,93}

Systemic Lupus Erythematosus and End-Stage Renal Failure

None of the current regimens for treatment of lupus nephritis are fully effective in preventing renal failure. However, severe glomerulonephritis with uremia is not synonymous with

Box 15-4 Therapeutic Options for the Management of Lupus Nephritis**Immunosuppressive Drug Therapy**

Prednisone: Initiate at 1.0 mg/kg/day, continue for no more than 8 weeks (except when extreme clinical conditions mandate), taper to alternate-day therapy in doses of 0.25 mg/kg every other day, use alternative immunosuppressive drugs rather than continued daily prednisone therapy whenever possible, maintain assiduous surveillance and protection against steroid-induced osteoporosis (i.e., exercise, calcium, bisphosphonates).

Methylprednisolone pulse therapy: Initiate at 1.0 g/m² for 3 days for severe activity (rapidly progressive renal failure, crescentic glomerulonephritis) with option to repeat pulse doses at monthly intervals; pulse methylprednisolone is usually used in conjunction with pulse cyclophosphamide.

Cyclophosphamide: Intermittent pulse therapy has the highest therapeutic index, conventional daily cyclophosphamide therapy (2 mg/kg/day) mostly avoided or used for less than 3 months (see Box 15-5 for details on administration of pulse cyclophosphamide).

Azathioprine: Alternative agent in SLE; mostly used for extrarenal disease, in mild lupus nephritis, as maintenance after period of improvement induced by cyclophosphamide or mycophenolate, or as a steroid-sparing agent in patients who require sustained high doses of prednisone or in those unwilling to accept/tolerate cyclophosphamide treatment.

Mycophenolate mofetil: Results are encouraging for use of this drug as an alternative to cyclophosphamide, for both induction and maintenance therapy for proliferative lupus nephritis; expense may be rate limiting; few data are available regarding the value of mycophenolate in membranous lupus nephropathy.

Cyclosporine: Alternative immunosuppressive drug with limited, if any, role in proliferative lupus nephritis; more favorable evidence of use in lupus membranous nephropathy; generally used in low doses (e.g., <5 mg/kg/day); tends to aggravate hypertension and dyslipidemia and worsen renal function; cosmetic side effects (gum hypertrophy, hypertrichosis) are other concerns for its use in young patients with SLE.

Tacrolimus: Another calcineurin inhibitor that shares similar immunosuppressive actions with cyclosporine. Associated with fewer cosmetic side effects than cyclosporine; limited data regarding role in proliferative lupus nephritis; may have benefit in lupus membranous nephropathy; membranous dose titration may be problematic in patients with impaired renal function.

Intravenous immunoglobulins: Expensive, short-term therapy; mostly used in lupus for immune-mediated thrombocytopenia or refractory central nervous system disease; immunosuppressive properties (e.g., suppression of pathogenic anti-DNA idiotypes) under study.

Plasma exchange: Controlled trials have not demonstrated benefit of plasmapheresis in lupus nephritis; mostly used for microangiopathic complications of lupus such as vasculopathy of superimposed thrombotic thrombocytopenic purpura.

Methotrexate: Mostly used as adjunct or alternative anti-inflammatory therapy for extrarenal manifestations of SLE; use in lupus nephritis very limited and mostly anecdotal.

Hydroxychloroquine: Mostly used as adjunct for preventing and alleviating extrarenal manifestations of SLE; it also appears to protect against major disease flares in SLE (including flares of nephritis) and has been shown to be effective in reducing the risk of damage accrual in SLE patients. Inexpensive and widely available even in developing countries. Although serious side effects are rare, retinopathy is an important ophthalmologic complication of therapy—a baseline eye examination and periodic screening are necessary to recognize ocular toxicity and to act accordingly to avoid permanent vision loss; a task force of the American Academy of Ophthalmology has recently published recommendations¹¹³ regarding the intervals for screening, which vary depending on age of the individual, daily and cumulative doses, duration of treatment, coexisting renal or liver disease, and concomitant retinal disease.

Rituximab: Favorable results for proliferative lupus nephritis have been reported in small observational studies, case series, and several pilot studies. Improvement in renal function, proteinuria, serologic activity, and histology has been described even in lupus patients refractory to other conventional immunosuppressives. The data are still limited for both proliferative and membranous lupus nephritis; controlled trials (in progress) are needed to confirm these preliminary results. Development of neutralizing human antichimeric antibodies may influence the efficacy of B-cell depletion. In general, rituximab has an attractive safety profile but in December 2006, the U.S. Food and Drug Administration issued an alert based on two spontaneous reports of fatal progressive multifocal leukoencephalopathy in patients with SLE who had received rituximab therapy. Although extremely rare, candidates for rituximab should be counseled on the possible occurrence of progressive multifocal leukoencephalopathy, and there should be enhanced surveillance for the development of neurological symptoms.

Adjunctive Therapies for Secondary Complications of Renal Disease

Angiotensin antagonists (converting-enzyme inhibitors and receptor antagonists): Glomerular proteinuria persisting after control of active nephritis may be decreased by these agents (this must be balanced against their potential adverse effects on glomerular filtration rate and serum potassium).

Antihypertensives: Treatment of hypertension and drug choices follows standard guidelines; use blood pressure goals appropriate for age of patient (see chapter on hypertension).

Lipid-lowering drugs: These are used for control of hyperlipidemia of nephrotic syndrome. In addition, SLE and lupus nephritis confer a higher risk of accelerated atherosclerosis independent of traditional risk factors. Usually start

Box 15-4 Therapeutic Options for the Management of Lupus Nephritis—cont'd

3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors and/or fibric acid derivatives if nephrotic syndrome persists for more than 2 to 3 months; 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors may also have immunomodulatory properties that are independent of their serum lipid-lowering properties and may help decrease proteinuria (see Chapter 25, "Management of Complications of Nephrotic Syndrome").

Bone protection: Patients with SLE often have low bone mineral density compared with healthy patients. In addition to traditional risk factors, other contributors are long duration of glucocorticoid use, cyclophosphamide, possibly use of gonadotropin-releasing-hormone agonists, and systemic inflammation. Usually start calcium and vitamin D if patients are taking steroids or bisphosphonates if osteopenia or osteoporosis is present on dual-energy x-ray absorptiometry scan.

Thrombotic diathesis: Aspirin should be used if high-titer antiphospholipid antibodies are present; warfarin (Coumadin) anticoagulation should be used if there are thrombotic events related to antiphospholipid syndrome or severe nephrotic syndrome.

Box 15-5 Recommendations for Administration and Monitoring of Pulse Cyclophosphamide Therapy

- Estimate glomerular filtration rate (GFR) by standard methods.
- Calculate body surface area (m^2) by standard methods.
- Cyclophosphamide (CY) dosing and administration:
Initial dose CY is $0.75 \text{ g}/m^2$ (*important note:* start with $0.5 \text{ g}/m^2$ of CY if glomerular filtration rate is less than one third of expected normal).
Administer CY in 150 mL normal saline IV over 30 to 60 minutes (*alternative:* equivalent dose of pulse CY may be taken orally in highly motivated and compliant patients).
- Obtain white blood cell count at days 10 and 14 after each CY treatment (*note:* advise patient to delay prednisone until after blood is drawn to avoid transient acute steroid-induced leukocytosis).
- Adjust subsequent doses of CY to keep nadir white blood cell count above $1500/\mu\text{L}$ (increase CY to maximum dose of $1.0 \text{ g}/m^2$ unless white blood cell count nadir falls below $1500/\mu\text{L}$).
- Repeat CY doses monthly (every 3 weeks in patients with extremely aggressive disease) for 6 months and then quarterly for 1 year *after* remission is achieved (defined by inactive urine sediment, proteinuria $< 1 \text{ g}/\text{day}$, normalization of complement [and ideally anti-DNA], and a state of minimal or no activity of extrarenal lupus).
- Protect bladder against CY-induced hemorrhagic cystitis:
Induce diuresis with 5% dextrose and 0.45% saline (e.g., 2 L at 250 mL/hr) and encourage frequent voiding; continue high-dose oral fluids through 24 hours; counsel patients to return to clinic if they cannot sustain ingestion of enteral fluids.
Give mesna (Mesnex) (each dose 20% of total CY dose) intravenously or orally at 0, 2, 4, and 6 hours after CY dosing (*note:* use of mesna strongly urged whenever sustained diuresis may be difficult to achieve or if pulse CY is given in an outpatient setting).
If patients are anticipated to have difficulty with sustaining diuresis (e.g., severe nephrotic syndrome) or with voiding, insert a three-way Foley catheter with continuous bladder flushing with standard antibiotic irrigating solution (e.g., 3 L) for 24 hours to minimize risk of hemorrhagic cystitis.
- Antiemetics (usually administered orally):
Dexamethasone (Decadron), 10-mg single dose, plus:
Serotonin receptor antagonists: e.g., granisetron (Kytril) 1 to 2 mg with CY dose (usually repeat dose in 12 hours); alternatives in this class include ondansetron, dolasetron, palonosetron, and tropisetron
- Monitor fluid balance during diuresis. If patient develops progressive fluid accumulation, use diuretics to re-establish fluid balance.
- Complications of pulse CY
Expected: Nausea and vomiting (central effect of CY), mostly controlled by serotonin receptor antagonists; transient hair thinning (rarely severe at CY doses $< 1 \text{ g}/m^2$).
Common: Significant infection diathesis only if leukopenia not carefully controlled; modest increase in herpes zoster (very low risk dissemination); infertility (male and female); amenorrhea proportional to age of the patient during treatment and to the cumulative dose of CY.
Rare: Syndrome of inappropriate antidiuretic hormone (SIADH) (occasionally produces severe hyponatremia during the 24 hours following CY administration in the context of positive fluid balance); transient hepatocellular injury with severe elevations in bilirubin and transaminases (very rare).

Box 15-6 Treatment of Diffuse (and Severe Focal) Proliferative Lupus Nephritis**I. Recommended Initial Treatments**

A. *Moderate disease*: defined by limited number and severity of risk factors (see Box 15-3)

1. Prednisone (1.0 mg/kg/day): limited trial (up to 8 weeks)
 - a. If *complete* response occurs, including clearing of cellular casts and proteinuria, normalization of complement, and minimal lupus activity, simply taper prednisone to alternate day (~0.25 mg/kg) and monitor for flares of nephritis.
 - b. If there is no or an incomplete response to prednisone or nephritis worsens, start monthly pulse cyclophosphamide or mycophenolate as outlined in section II. (*Do not delay this therapeutic decision beyond 8 weeks because of a partial response to prednisone.*)

or

2. Moderate dose prednisone (0.5 mg/kg/day tapered) plus mycophenolate (target dose 2–3 g/day) for 6 or more months followed by a maintenance regimen (section IV)

B. *Severe disease*: defined by presence of a constellation of high-risk factors (Box 15-3)

1. Prednisone (1.0 mg/kg/day tapered) plus:
 - a. Monthly pulse cyclophosphamide (0.75 g/m²; 0.5 g/m² if GFR is less than one third normal) for 6 months; increase dose of cyclophosphamide by up to 0.25 g/m² increments, to maximum of 1.0 g/m² unless total leukocytes fall below 1,500/μL at the 10–14 day nadir point; synchronize with monthly pulse methylprednisolone (1 g/m²)

or

- b. Although unproven as an effective alternative in the context of high risk severe disease, mycophenolate has been increasingly used as an alternative induction therapy; target dose 2.0–3.0 g/day for 6 or more months followed by a maintenance regimen (section IV).

II. Alternative Induction Treatment Regimens

A. *Induction therapy*: prednisone (1.0 mg/kg/day tapered) plus:

1. Pulse methylprednisolone 1.0 g/m²/day for three doses; may repeat pulses at 4-week intervals and continue without additional adjunctive therapy for 6 to 12 months if there is steady progress toward remission.
2. Daily oral cyclophosphamide, 2 mg/kg/day for 2 to 6 months (risk of gonadal and urinary bladder toxicities greater than pulse cyclophosphamide therapy).
3. Oral pulse cyclophosphamide, ranging from 0.5 g weekly to 1.0 g/m² monthly (used only in highly motivated, fastidiously compliant patients).

III. Recommended Transition to Maintenance Immunosuppressive Drug Therapy or Early Discontinuance of Pulse Cyclophosphamide Therapy (at 6 Months)

A. In selected patients, cyclophosphamide may be stopped and treatment continued with alternate-day prednisone (0.25 mg/kg) alone. Such patients have exquisitely responsive nephritis (defined by complete clearing of cellular casts and proteinuria, normal complement, and minimal lupus activity within the first 6 months). Limited duration of cyclophosphamide therapy is also important for patients giving high priority to maintaining fertility while accepting the risk of low-grade activity of lupus nephritis.

B. The majority of patients with proliferative lupus nephritis will not be in full remission at 6 months. Convert this group to maintenance therapy using one of the regimens outlined in section IV.

Note: Microscopic hematuria often does not clear for several months, even when most other clinical parameters have remitted; by itself, microscopic hematuria is usually not a sufficient reason to abandon a particular therapeutic program.

IV. Options for Maintenance Therapy

A. Alternate day prednisone (~0.25 mg/kg) plus:

1. Azathioprine, 2 mg/kg/day or
2. Mycophenolate mofetil, 1.0–2.0 g/day or
3. Pulse cyclophosphamide every 3 months (doses adjusted by same guidelines used during the induction therapy phase).

V. Duration of Therapy

A. *Cyclophosphamide*: Continue quarterly maintenance cyclophosphamide treatments for 1 year *after* remission of lupus nephritis is achieved (defined by inactive urine sediment, proteinuria < 1 g/day, normalization of complement [and ideally anti-DNA], and a state of minimal or no activity of extrarenal lupus). Patients with isolated fixed proteinuria or persistently elevated anti-DNA (i.e., without other supportive signs of active lupus nephritis) may be considered in remission. If uncertainty persists, findings from a repeat renal biopsy may be extremely useful in defining status of renal disease and indications for ongoing therapy.

B. *Alternate-day prednisone*: Tapered in very small increments to discontinuance if the patient has been in sustained complete remission for more than 3 years.

C. *Azathioprine and mycophenolate*: Maintenance for at least 18 to 24 months with subsequent tapering. Would consider criteria described in section V, A, when evaluating duration of maintenance therapy with azathioprine or mycophenolate.

Box 15-7 Treatment of Lupus Membranous Nephropathy*

- I. *Mixed membranous and proliferative nephropathies:*
Treat as proliferative lupus nephritis (see Box 15-6)
- II. *Membranous nephropathy with nephrotic range proteinuria*
 - A. First-line treatment is usually high-dose, alternate-day prednisone (e.g., 1–2 mg/kg) for 2 months; taper to approximately 0.25 mg/kg alternate days within 3 to 4 months
 - B. Optional adjuncts to prednisone therapy
 1. Cyclosporine, <5 mg/kg/day
 2. Pulse cyclophosphamide, <1 g/m² every 1 to 3 months
 3. Pulse methylprednisolone alternating with cyclophosphamide: pulse methylprednisolone, 1.0 g/day for 3 days followed by 27 days of prednisone (0.5 mg/kg/day) alternating with 30 days of cyclophosphamide 2 mg/kg/day; three cycles of each therapy over a 6-month period
 4. Oral cyclophosphamide, 2 mg/kg/day
- III. *Membranous nephropathy with nonnephrotic proteinuria:* Treat according to extrarenal disease activity; consider angiotensin antagonists to minimize proteinuria and statins for hyperlipidemia; monitor patients carefully for evidence of progression to nephrotic syndrome or to mixed membranous and proliferative nephropathy.

*Also see Chapter 21, “Idiopathic Membranous Nephropathy.”

irreversible end-stage renal failure in lupus nephritis. The rate of evolution of renal failure has very important implications for treatment. Rapidly progressive renal failure, usually due to necrotizing and crescentic glomerulonephritis, is often reversible with effective treatment. Patients with evidence of active nephritis (specifically, nephritic urine sediment), even if oliguric and in advanced renal failure, warrant treatment with pulse methylprednisolone, prednisone, and pulse cyclophosphamide for approximately 3 months into maintenance dialysis therapy.

This disease profile can be contrasted with that of patients who progress slowly and insidiously to irreversible end-stage renal failure. In the latter case, one should avoid the desperate and injudicious use of aggressive immunosuppressive drug therapy in the setting of “burned out” lupus (e.g., renal failure in context of contracted kidneys and urine sediment showing predominantly broad, waxy casts). Conversely, a substantial proportion of patients on maintenance hemodialysis continue to manifest or experience flares of lupus activity, which are clearly indications for continued treatment.^{25,94,95} A cautious, incremental prescription of prednisone and immunosuppressive drug therapy in such patients is warranted in order not to increase susceptibility to major infections in the uremic host.

Kidney transplantation is a viable alternative for patients with end-stage renal disease (ESRD) caused by lupus ne-

phritis. Clinically active lupus is uncommon, but evidence of recurrence of lupus nephritis in the allograft is increasingly recognized, although it is a rare cause of allograft loss.^{96–99} Indeed, a recent analysis of data from a large-scale transplant registry demonstrated that patients with end-stage renal disease due to lupus nephritis have similar graft, patient, and functional graft survival rates compared with the general transplant recipient population.¹⁰⁰ Nevertheless, it is advisable to avoid transplantation during an acute lupus flare.

FUTURE DIRECTIONS

Experimental Therapies

There are tremendous interest and excitement for use of novel therapies in lupus that allow for more selective targeting of the immune cell subsets, cellular signaling, and molecular pathways believed to be important in disease pathogenesis. Based on encouraging results in lupus mice (see Box 15-1), many biologically based therapies have rapidly evolved from the laboratory to clinical practice. Open-label studies have confirmed the efficacy of some of these therapies for human SLE and lupus nephritis and have led to controlled trials of these agents alone or in combination with conventional immunosuppression agents. Box 15-8 lists some of the therapies that are currently being tested for lupus nephritis in randomized, controlled trials.

There are a number of novel therapies that are candidates for further testing in lupus mice (see Box 15-1) and eventual application to human SLE and lupus nephritis. Translational work has begun employing different methods aimed at overhauling the disordered immune system of patients with severe and conventional treatment-refractory SLE. Recent availability of therapeutic granulocyte colony-stimulating factor has allowed immunoablative regimens involving extreme doses of cyclophosphamide (e.g., 200 mg/kg) with or without adjunctive fludarabine, total body irradiation, antithymocyte globulin, and stem-cell rescue therapy to be tested.^{101–106} The original hope of stem-cell transplantation was “going for the cure” in patients with severe lupus. Initial results were encouraging in SLE patients with refractory life-threatening multiorgan disease, but these immunoablative and reconstituting regimens are associated with substantial morbidity, high costs, and not insignificant risk of failure, relapse, and death. Whether this approach represents a definitive advance over more conventional immunosuppressive therapies will need to be answered in ongoing randomized, controlled trials. With the availability of an increasing number of newer immunosuppressive agents and biologic products, stem-cell transplantation is not the first consideration, and judicious selection of appropriate patients is important.

Unanswered Questions

Several issues remain to be addressed in future clinical trials. These include, among others: (1) studies of the comparative benefits of recycling short-term, intense immunosuppressive drug treatment for relapses versus long-term, low-intensity

Box 15-8 Agents (or Approaches) Currently Being Tested Alone or in Combination in Randomized Trials for Lupus Nephritis

Mycophenolate mofetil
 Azathioprine
 Tacrolimus
 Sirolimus
 Abatacept (CTLA4-Ig: blockade of T cell costimulation)
 Rituximab (anti-CD20)
 LJP 394/abetimus (to reduce circulating autoantibodies)
 Infliximab (inhibition of tumor necrosis factor α)
 Autologous and allogeneic stem-cell transplantation

maintenance therapies to avert relapses and minimize cumulative renal damage in lupus nephritis; (2) identification of maintenance therapy with the best therapeutic index; (3) appropriate use of biologically based therapies; (4) treatment of severe relapses while on maintenance immunosuppression; (5) treatment of refractory lupus; (6) assessment of risks and benefits of early treatment of mesangial disease; and (7) studies to define the optimal treatment of lupus membranous nephropathy.

BACKGROUND

IgA Nephropathy

IgA nephropathy (IgAN) is a common pattern of glomerulonephritis defined by mesangial IgA deposition.¹ Recurrent macroscopic hematuria is the most frequent clinical presentation and typically occurs in the second and third decades of life. Other patients present with microscopic hematuria, proteinuria, and slowly progressive renal failure. Clinical features at the time of diagnosis indicating a poor prognosis include proteinuria greater than 1 g/24 hr and arterial hypertension.² Adverse histopathologic features include glomerular sclerosis, tubular atrophy, and interstitial fibrosis.² Rapidly progressive renal failure is unusual; it may result from acute tubular necrosis as a consequence of macroscopic hematuria or superimposed crescentic nephritis. Recurrent IgA deposition after transplantation is common and may be associated with slowly progressive graft failure.³

Henoch-Schönlein Nephritis

Henoch-Schönlein purpura (HSP) is a systemic vasculitis with characteristic rash, abdominal pain, and arthralgia; it is particularly common in childhood but may occur at any age. Tissue IgA deposition is a hallmark of HSP. The nephritis that accompanies HSP (HS nephritis) may be histologically indistinguishable from IgAN,⁴ although a nephritic/nephrotic presentation with relatively rapid progression to renal failure is more common than in IgAN. It is probable that IgAN is a monosymptomatic form of HSP.^{1,4}

Disease Mechanisms in IgA Nephropathy and Henoch-Schönlein Nephritis

IgAN and HSP share many abnormalities of the IgA immune system.⁴ Exaggerated polymeric IgA1 responses are typical, although increases in circulating IgA1 are modest. Most evidence suggests that the increased polymeric IgA1 originates from the bone marrow rather than the mucosa.⁵ The mechanism of

mesangial IgA deposition is not understood, although IgAN and HS nephritis are often regarded as immune complex diseases. Altered O-glycosylation of IgA1 may promote mesangial IgA deposition.^{6,7} Mechanisms of ongoing inflammation and scarring are probably common to other forms of chronic glomerulonephritis without IgA deposition. There is increasing evidence of genetic susceptibility to IgAN and HSP, for example, the high prevalence of urinary abnormalities in first- and second-degree relatives of those with IgAN and the substantial number of multiplex families, in some of which both HSP and IgAN occur.^{8–10}

TREATMENT APPROACHES

Therapeutic Strategies

With this background, the following approaches to treatment of IgAN could be considered:

- Decrease production of nephrogenic IgA.
- Prevent glomerular IgA deposition or promote its removal.
- Alter early immune and inflammatory events that follow IgA deposition.
- Alter later nonspecific events that promote progressive renal failure.
- Prevent recurrent disease after transplantation.

Therapeutic Endpoints

It is also important to consider how the success of any therapeutic intervention might be judged.

Hematuria

Reduction of episodes of macroscopic hematuria is a clear-cut goal but should not be taken to represent the loss of all disease activity. Properly controlled studies are needed since the natural history of IgAN is that macroscopic hematuria becomes less common with time without intervention.

Proteinuria

Reduction in proteinuria is an attractive short- and long-term goal. If patients are nephrotic, the clinical benefits of reducing proteinuria and correcting serum albumin are unequivocal. However, treatment trial strategy often selects patients using nonnephrotic proteinuria as a marker of poor prognosis. The benefit of modest decreases in proteinuria, even if statistically significant, is uncertain unless accompanied by preservation of renal function.

Prevention of Renal Failure

Prevention of end-stage renal disease (ESRD) is the ultimate goal. However, IgAN is usually so slowly progressive that surrogate markers are required to provide data within an acceptable time frame. Doubling of serum creatinine or decrease in glomerular filtration rate (GFR) can be complemented by histologic data from serial renal biopsies.

Problems of Study Design

Study Group Heterogeneity

It cannot be certain that patients with mesangial IgA deposition always share a common disease process, but, at present, it remains the defining criterion for these studies. Renal histology

can be useful in study recruitment to minimize heterogeneity, but this will be less useful if the interval between biopsy and recruitment is prolonged. Furthermore, the choice of histologic criteria remains controversial. An international consensus on a pathologic classification for IgAN would be of great value in selection for therapeutic trials; the International IgA Nephropathy Network with the Renal Pathology Society, under the auspices of the International Society of Nephrology, are currently developing such a consensus, which it is expected will be announced in 2008.¹¹ Another factor to be considered in any trial design is the frequency of subclinical IgA nephropathy in supposedly “healthy” control populations. This may be as high as 16% in certain Asian populations.¹² Patients with HSP have been excluded from most available studies; it is therefore still uncertain whether any strategies developed for IgAN are indeed applicable to HS nephritis.

Risk versus Benefit

In slowly progressive disease, the balance of risk versus benefit if prolonged treatment is considered is often unfavorable. Acute immune interventions are also not easy to plan. If there is crescentic nephritis with renal failure, intensive treatment is justifiable; more often, visible hematuria is clinically striking but transient and produces no functional renal impairment, weakening the justification for therapy. In any case, clinically apparent hematuria is likely to represent the tip of an iceberg of ongoing injury, so that shaping and timing the intensity of therapy, even if rational treatments were available, are difficult.

The good prognosis for many patients, particularly those with isolated hematuria, argues against their involvement in prolonged studies of therapies with potential adverse effects. Conversely, the selection of patients by proteinuria can introduce heterogeneity because proteinuria may reflect both active immune injury and fixed chronic damage. Any study using proteinuria as an entry criterion will provide therapeutic guidance for only a minority of patients with IgAN.

Randomized, Controlled Trials

The need for randomized, controlled trials (RCTs) of adequate power to answer questions about the prevention of chronic renal failure in IgAN is pressing. The use of historic controls is of limited value because earlier cohorts of patients may not be comparable, for example, because of changing attitudes over recent years in accepted blood pressure (BP) targets and in the use of medications that interrupt the renin-angiotensin system. It is disappointing, despite the prevalence of IgAN and consensus about its definition and natural history, that there are so few published RCTs. Available studies are clearly defined in this chapter as RCTs and are shown in the tables. Those available in 2006 have been critically reviewed.^{13,14} There have been no RCTs in HS nephritis.

Age of Subjects

There is no specific evidence that IgAN is a distinctive disease process when onset is in childhood rather than in adulthood; nevertheless, the application to adult practice of trial findings in children remains uncertain.¹⁵

Defining Early and Late Disease

The distinction between early inflammatory processes in IgAN and later nonspecific processes leading to renal failure is not easily made and is somewhat artificial. In a disease as

indolent as IgAN, such processes will inevitably be concurrent. Diagnosis, defined by the time of renal biopsy, may be many years after the onset of the disease. RCTs of corticosteroids and immunosuppressive regimens have mostly recruited patients with proteinuria and preserved renal function, whereas studies of fish oil have in general recruited those with proteinuria and impaired excretory function.

TREATMENT OF IgA NEPHROPATHY

Decreasing IgA Production

Decreasing Mucosal Antigen Challenge

Attempts have been made in uncontrolled studies to modify food antigen intake or alter mucosal permeability pharmacologically. These have been of little benefit.¹⁶ There is no role for prophylactic antibiotics.

Tonsillectomy

Tonsillectomy may help to prevent episodic macroscopic hematuria in the short term, and proponents of tonsillectomy argue that it also gives long-term renal protection. This view is supported by two large retrospective studies from Japan, although benefit was not apparent until 10 years after tonsillectomy.^{17,18} The concomitant use of other treatment modalities and changing therapeutic goals during the follow-up period make these data difficult to interpret; a retrospective study from Germany suggests no benefit of tonsillectomy.¹⁹ Preliminary data from a prospective Japanese RCT of tonsillectomy combined with steroids versus steroids alone has reported improvement in hematuria and proteinuria in the tonsillectomy group, but no difference in doubling of serum creatinine at 24 months.²⁰

Phenytoin

Phenytoin reduces serum IgA levels and was given in an RCT for 2 years, but it produced no benefit for renal function or proteinuria nor in renal histology in repeat biopsies after treatment.²¹

Other Approaches to Decreasing IgA Production

There are no other known strategies for reducing relevant IgA production. There is no evidence that any immunosuppressive treatment used in IgAN alters circulating IgA levels, although the possibility cannot be excluded that a number of immune manipulations may reduce a specific subset of nephritogenic polymeric IgA1 molecules. However, no intervention is known to modify the abnormal IgA1 O-glycosylation found in IgAN.

Prevention and Removal of IgA Deposits

The ideal treatment for IgAN would remove IgA from the glomerulus and prevent further IgA deposition. This remains a remote prospect while IgA deposition is so poorly understood. Such a treatment would also need to be extremely safe because it would require application to large numbers of patients with benign disease unless reliable early markers of progression risk were available. The high prevalence of recurrent IgA deposition after transplantation suggests that conventional immunosuppression does not prevent IgA deposition even if it may alter subsequent inflammatory events.

Alteration of Immune and Inflammatory Events That Follow IgA Deposition

Rapidly Progressive Renal Failure Associated with Crescentic IgA Nephritis

In this uncommon situation, the risk-benefit balance is most strongly in favor of intensive immunosuppressive therapy because if crescentic IgA nephritis is not treated, there will almost inevitably be rapid progression to ESRD. Unfortunately, there are no available RCTs.

A number of case series have been reported, and these have been reviewed by Tumlin and Hennigar.²² The largest single-center experiences in adults are nine cases reported by McIntyre and colleagues,²³ 12 reported by Roccatello and colleagues,²⁴ 12 reported by Tumlin and colleagues,²⁵ and 16 reported by Harper and colleagues.²⁶ Reports in 19 children have been reviewed.¹⁵ Treatment in the majority of cases has included prednisolone and cyclophosphamide, often combined with plasma exchange. It is not possible to make firm conclusions from these data. The decision to treat is usually made based on histologic evidence of aggressive glomerular injury, and most reports include some patients with preserved renal function at the time that treatment is initiated as well as those with rapidly progressive renal failure. Early clinical response is favorable as in other crescentic nephritis, but medium-term results may be disappointing: 60% of treated patients reached ESRD by 12 months in one series²⁷ and 25% reached ESRD over longer follow-up in another.²⁶ However, a subset of patients has been reported with circulating IgG antineutrophil cytoplasm antibody who have a more favorable response to immunosuppressive therapy, similar to that seen in other types of antineutrophil cytoplasm antibody–positive crescentic nephritis.²⁸

An RCT of immunosuppressive treatments in crescentic IgAN would be particularly valuable, but this is an uncommon condition and such a trial may never be achieved. Based on the available evidence, the use of corticosteroids and cyclophosphamide is justified, but there is insufficient information to recommend the addition of plasma exchange.

Early Treatment with Immunosuppressive/Anti-inflammatory Regimens

Interventions have been made in IgAN soon after diagnosis in those with active disease, even when renal function is still preserved. Treatments have included corticosteroids, cyclophosphamide, azathioprine, mycophenolate mofetil, and pooled human immunoglobulin. In some studies, they have been combined with antiplatelet agents and warfarin. The great majority of such studies are restricted to those with proteinuria greater than 1 g/24 hr, an arbitrary threshold known to be associated with significant risk of progression. The minority with nephrotic syndrome have been excluded from most studies.

Corticosteroids

There has been interest in the potential role of corticosteroids for many years, supported mostly by evidence from uncontrolled trials. In adults with heavy proteinuria,²⁹ corticosteroids appeared to preserve renal function if initial creatinine clearance was more than 70 mL/min, and the same group reported 10-year follow-up in moderate proteinuria that suggests decreased risk of ESRD with corticosteroids.³⁰

However, there have been few RCTs of corticosteroids (Table 16-1). Three months of treatment in children with low-grade proteinuria showed no benefit.³¹ Four months of treatment in nephrotic adults showed no overall benefit,³² although there was a minority with very minor histologic changes who responded rapidly to treatment (see “Nephrotic Syndrome and IgA Nephropathy”).

An RCT evaluated 12 months of corticosteroids with antiplatelet agents in nonnephrotic proteinuria with preserved renal function³³; the control group also received antiplatelet agents. There was a decrease in proteinuria and improvement in histology, but the design and power of the study prevented investigation of any possible protection of renal function.

A larger RCT of 6 months of treatment with corticosteroids showed not only a decrease in proteinuria but also a significant decrease in the risk of a twofold increase in serum creatinine or of ESRD.³⁴ Further analysis showed that the benefit was sustained for as long as 10 years of follow-up.³⁵ Angiotensin-converting enzyme (ACE) inhibitors were not used in all patients in this study but were used in equal proportions in both corticosteroid-treated patients and control subjects, although achieved BP was not in line with current recommendations. Remarkably, the authors also report a lack of steroid adverse effects despite the substantial dose over 6 months.

This study remains the only evidence from an RCT that corticosteroids prevent renal failure in IgAN with proteinuria of more than 1 g/24 hr. However, the benefit must be viewed in context; analysis shows that the protection was no greater than that afforded by female gender,³⁶ emphasizing the need to understand better the many factors that contribute to the highly variable natural history of IgAN. A more recent RCT in which BP was well controlled without renin-angiotensin system blockade showed only a modest decrease in proteinuria with low-dose corticosteroids and no protection of the GFR.³⁷ It is unclear whether this lack of renoprotection was due to the lower dose of corticosteroid or a genuine lack of effect in patients managed to current BP targets.

The recent review of immunosuppressive treatments for IgAN by the Cochrane Renal Group suggests that corticosteroid therapy may be effective in decreasing proteinuria and the risk of ESRD, although lack of available data meant that the meta-analysis was unable to evaluate the influence of renin-angiotensin system blockade or achieved BP in the analysis.³⁸

An interim analysis of a study to assess the additional benefit of azathioprine with corticosteroids has recently reported no improvement in renal outcome at 36 months when azathioprine (1.5 mg/kg/day) is added to prednisone.³⁹ Unfortunately, this study did not have a control group not receiving corticosteroids.⁴⁰ A second study is under way to investigate the additional benefits of 6 months of treatment with corticosteroids in patients with IgAN with proteinuria greater than 1 g/24 hr receiving long-term ACE inhibitor therapy.⁴¹

Cyclophosphamide

Cyclophosphamide (Table 16-2) has been used in combination with warfarin and dipyridamole in two RCTs that are not consistent. Two studies of very similar design both showed modest decrease in proteinuria,^{42,43} but the preservation of renal function in one study⁴³ could not be confirmed in the other.⁴² The use of cyclophosphamide in patients at very high risk of progression (ESRD predicted in all cases

within 5 years) is supported by a single study. Patients received cyclophosphamide followed by azathioprine in conjunction with high-dose prednisolone and were followed for at least 2 years.⁴⁴ Notably, BP control and use of renin-angiotensin system blockade in this trial fell well outside current recommendations. Previous RCTs of cyclophosphamide in less severe, slowly progressive IgAN have shown no consistent benefit (reviewed by Feehally⁴⁵), and this is supported by the Cochrane Renal Group meta-analysis that failed to show any significant renal survival benefit from those RCTs incorporating cyclophosphamide, cyclosporine, or other cytotoxic agents, although there was a significant decrease in daily proteinuria.³⁸

Cyclophosphamide has not been used alone in IgAN. In any case, many physicians, including us, regard the risk of cyclophosphamide as unacceptable in young adults with IgAN. Further studies have therefore assessed the combination of warfarin and dipyridamole without cyclophosphamide (“Antiplatelet Agents”).

Azathioprine

In an open study of children with aggressive disease, azathioprine (see Table 16-2) with prednisolone appeared to preserve renal function.⁴⁶ In a long-term, retrospective study, azathioprine with prednisolone preserved renal function, but unfortunately the control group is not comparable.⁴⁷ A nonrandomized trial of azathioprine or chlorambucil in adults showed no benefit with either agent.⁴⁸ An RCT in children with 2 years of treatment with prednisolone and azathioprine (combined with antiplatelet agents) showed a decrease in proteinuria and lessening of active glomerular injury on repeat renal biopsy.⁴⁹ However, all subjects had preserved renal function at recruitment, and the rather short duration of follow-up precluded any investigation of an effect on preservation of renal function.

Cyclosporine

Cyclosporine (see Table 16-2) was used in one RCT.⁵⁰ There was a reversible decrease in proteinuria, but this occurred in parallel with a decrease in creatinine clearance, suggesting that the changes were a hemodynamic effect of cyclosporine rather than an immune-modulating effect.

Leflunomide

Leflunomide (see Table 16-2) was used in one RCT.⁵¹ In this short trial, there was a significant decrease in proteinuria with leflunomide, but the trial lasted only 28 weeks, and the study was not designed to evaluate an effect on preservation of renal function.

Mycophenolate Mofetil

Two RCTs report no benefit from mycophenolate mofetil (Table 16-3) in patients either at risk of progression (hypertensive and/or proteinuria > 1 g/24 hr and/or decreased GFR within 5 years of diagnosis)⁵² or with more advanced disease (mean serum creatinine at entry 2.6 mg/dL).⁵³ Both of these studies achieved rigorous BP control with use of an ACE inhibitor. In two separate RCTs, mycophenolate mofetil did decrease proteinuria over an 18-month follow-up period; however, neither study demonstrated a change in the rate of renal decline.^{54,55} Again both studies achieved tight BP control with ACE inhibition.

Table 16-1 Randomized, Controlled Trials of Corticosteroid Treatment in IgA Nephropathy

Ref.	Entry Criteria	No. on Active Treatment	Treatment Period (mo)	Follow-up (mo)	Proteinuria before Treatment (mean, g/24 hr)	Proteinuria after Treatment (mean, g/24 hr)	Other Outcomes	Comments
Lai et al ³²	Nephrotic syndrome Cr < 3 mg/dL	17 (adults)	4	12–106	6.5	2.3	Remission of nephrotic syndrome in 6/7 with minor histologic change	40% had steroid-related side effects
Welch et al ³¹	Cr < 1.6 mg/dL	20 (children)	3	6	0.7	0.6	None	No major adverse effects reported
Pozzi et al ^{34,35}	UP 1–3.5 g/24 hr Cr < 1.5 mg/dL	43 (adults)	6	60–120	2.0	0.67	Risk of ESRD reduced	All received dipyrindamole, none received ACEI
Shoji et al ³³	UP < 1.5 g/24 hr Cr < 1.5 mg/dL	11 (adults)	12	13	0.8	0.3	Histologic improvement	No effect on rate of decrease in GFR
Katafuchi et al ³⁷	Cr < 1.5 mg/dL	43 (adults)	24	65 ± 25	2.3	1.3	Increase in serum albumin and decrease in total cholesterol	

ACEI, angiotensin-converting enzyme inhibitor; Cr, serum creatinine; ESRD, endstage renal disease; GFR, glomerular filtration rate; UP, urine protein excretion.

Table 16-2 Randomized, Controlled Trials of Immunosuppressive Treatment in IgA Nephropathy*

Ref.	Entry Criteria	Agent	No. on Active Treatment	Treatment Period (mo)	Follow-up (mo)	Proteinuria before Treatment (mean, g/24 hr)	Proteinuria after Treatment (mean, g/24 hr)	Other Outcomes	Comments
Woo et al ⁴³	UP < 5 g/24 hr Cr < 1.5 mg/dL	Cyclophosphamide and dipyridamole/warfarin	27	6	60	2.4	0.8	Glomerulosclerosis prevented	Cyclophosphamide for 6 mo, warfarin/dipyridamole for 24 mo
Walker et al ⁴²	UP > 1 g/24 hr Cr 1.1–1.8 mg/dL	Cyclophosphamide and dipyridamole/warfarin	25	6	24	1.7	1.2	Renal function unchanged	Cyclophosphamide for 6 mo, warfarin/dipyridamole for 36 mo
Ballardie and Roberts ⁴⁴	Cr > 1.4 mg/dL and increasing by > 15% in previous year	Cyclophosphamide, then azathioprine maintenance and prednisone	19	24–60	24–60	3.9	0.7	Decreased rate of decline in GFR at 2 yr; maintained for 5 yr	Cyclophosphamide for 3 mo; target BP < 160/90; limited use of ACEI and ATRA
Yoshikawa et al ⁴⁹	Not nephrotic; active biopsy; CrCl normal	Azathioprine + prednisone + dipyridamole + low-dose warfarin	39 (children)	24	24	1.3	0.2	Glomerulosclerosis prevented; intensity of IgA deposits decreased	Control group received dipyridamole/warfarin; renal function normal and unchanged in both groups
Lai et al ⁵⁰	UP > 1.5 g/24 hr	Cyclosporine	9	3	6	4.2	1.3	Decrease in proteinuria transient only	Parallel decrease in renal function reversed when cyclosporine withdrawn
Lou et al ⁵¹	UP 1–3 g/24 hr Cr < 4 mg/dL	Leflunomide	30	6	6	1.66	0.6	No difference compared with fosinopril in rate of decline of renal function	Short-term study only but does suggest benefit when used with ACEI and ATRA

*There are no randomized, controlled trials of immunosuppressive agents in crescentic/vasculitic IgA nephropathy; available data are discussed in the text. ACEI, angiotensin converting enzyme inhibitor; ATRA, angiotensin receptor antagonist; Cr, serum creatinine; CrCl, creatinine clearance; GFR, glomerular filtration rate; UP, urine protein excretion.

Table 16-3 Randomized, Controlled Trials of Mycophenolate Mofetil Treatment in IgA Nephropathy

Ref.	Entry Criteria	No. on Active Treatment	Treatment Period (mo)	Outcomes	Comments
Maes et al ⁵²	UP > 1 g/24 hr and/or IC 20–70 mL/min and/or BP ≥ 140/90	21	36	No effect on proteinuria, no effect on decrease in GFR	Target BP 125/75; 100% use ACEI
Chen et al ⁵⁴	UP > 2 g/24 hr Lee grade IV/V	62	18	Proteinuria reduced (mean, 3.2–0.6 g/24 hr); no effect on decrease in GFR	Target BP 130/80; 100% use ACEI/ATRA
Tang et al ⁵⁵	UP > 1 g/24 hr	20	6	Proteinuria reduced (mean, 1.8–1.1 g/24 hr); no effect on decrease in GFR	Target BP 125/85; 100% use ACEI/ATRA
Frisch et al ⁵³	UP 1–3 g/24 hr with 2 of: male, BP > 150/90, Cr < 4 mg/dL, GScl/TI fibrosis	17	12	No effect on proteinuria or on decrease in GFR	Target BP 130/80; 100% use ACEI/ATRA

ACEI, angiotensin-converting enzyme inhibitor; ATRA, angiotensin receptor antagonist; Cr, serum creatinine; GFR, glomerular filtration rate; GScl, glomerulosclerosis; IC, inulin clearance; TI, tubulointerstitial; UP, urine protein excretion.

The relatively small size and short duration of the studies so far available justify further evaluation, and other studies are in progress.⁵⁶

Mizoribine

A recent retrospective study in Japan showed that mizoribine, which blocks purine synthesis in a manner similar to that of mycophenolate mofetil, resulted in a significant decrease in proteinuria when given to 20 pediatric patients in combination with prednisone, warfarin, and dipyridamole.⁵⁷ This was significantly better than the decrease in proteinuria seen in 21 historic control patients who were given only prednisolone, warfarin, and dipyridamole or in 20 historic control patients who also received IV pulses of methylprednisolone. Follow-up renal biopsies in the mizoribine-treated patients showed no progression of chronic lesions, whereas the other two sets of patients had a significant increase in the chronicity index.

Pooled Human Immunoglobulin

The immunomodulatory and anti-inflammatory effects of pooled human immunoglobulin are poorly defined but have some benefit in uncontrolled studies in systemic vasculitis and lupus. Open studies of immunoglobulin have been reported in both severe IgAN (heavy proteinuria with decreasing GFR)⁵⁸ and moderate IgAN (persistent proteinuria with GFR > 70 mL/min).⁵⁹ Proteinuria decreased, deterioration in GFR slowed in the severe group, and histologic activity scores decreased when repeat renal biopsies were available. There have been no confirmatory studies or prospective, controlled trials of this treatment since 1995. Pooled human immunoglobulin administration is associated with acute kidney injury; however, those studies reporting its use in IgAN have not reported an excessive occurrence of osmotic nephropathy.⁶⁰

Nephrotic Syndrome in IgA Nephropathy

Nephrotic syndrome occurs in only 10% of IgAN. In many of these patients, the heavy proteinuria is a manifestation of significant structural glomerular damage and progressive renal dysfunction. However, a small minority, both adults and children, have nephrosis with minimal glomerular change on renal biopsy, although there are IgA deposits with hematuria; proteinuria remits promptly in response to corticosteroids.³² In these patients, two common glomerular diseases may coincide: minimal change nephrotic syndrome and IgAN.^{61,62} This observation justifies a trial of high-dose corticosteroids, using a regimen appropriate for minimal change disease, in IgAN with nephrotic syndrome and preserved renal function when light microscopy shows minimal glomerular injury. However, there is no evidence to support prolonged exposure to corticosteroids if there is not a prompt response, or their use in nephrotic syndrome in the presence of significant glomerular inflammation. Unfortunately, all recent RCTs of corticosteroids in IgAN have excluded those with nephrotic-range proteinuria, so there is little evidence to inform treatment choices for nephrotic IgAN with significant histologic glomerular injury.

Treatment of Slowly Progressive IgA Nephropathy

There is little to suggest that the events of progressive glomerular injury are unique to IgAN. The growing experimental evidence on mesangial injury and its resolution under the influence of growth factors and cytokines seem to be applicable to mesangial glomerulonephritis, whether or not there are IgA deposits. The adverse influence of hypertension and the likely role of proteinuria in progression likewise are common to all glomerular diseases.

Treatments available are nonspecific. They are reported as treatments for IgAN, but it is more precise to regard them as treatments for chronic glomerular disease, of which IgAN is the

most common and most easily defined. (The immunosuppressive stratagems reviewed previously may be equally nonspecific in their efficacy.) The main approaches include treatment of hypertension and the use of antiplatelet agents, anticoagulants, fish oil, and 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors.

Predicting Risk of Progression

At diagnosis, conventional clinical and histologic criteria predict cohorts of patients with a poor prognosis.² Further refinement of such analyses to improve prediction of outcome early in follow-up for the individual patients would be valuable to identify those who will do badly even if they show none of the known adverse features at diagnosis. This would help to identify those who require more intensive therapy.⁶³ Genetic markers for risk of progression have been studied, in particular I/D polymorphisms of the ACE gene.¹⁰ However, the association between the ACE DD genotype or any other currently available genetic marker and risk of progression is not reliable enough to influence treatment strategies for the individual patient or to inform stratification in design of treatment trials.

Antiplatelet Agents

The main studies are summarized in Table 16-4. Two studies of dipyridamole/warfarin in combination with cyclophosphamide produced conflicting results (see Table 16-2). In the study in children given azathioprine and corticosteroids, all subjects received dipyridamole/warfarin, so no effect of these agents can be inferred.⁴⁹ Two RCTs of dipyridamole/warfarin alone are inconsistent: There was no benefit in one,⁶⁴ but some decrease in proteinuria and protection from renal impairment in the other.⁶⁵

Hypertension and the Role of Inhibitors of the Renin Angiotensin System

There is compelling evidence of the benefit of lowering BP in the treatment of chronic progressive glomerular disease.⁶⁶ In IgAN, evidence is accumulating that casual clinic BP measurements may underestimate the early impact of hypertension as judged by ambulatory BP monitoring and echocardiographic evidence of increased left ventricular mass.⁶⁷ The impact of the early active management of BP on the long-term cardiovascular morbidity and mortality of these patients will be considerable, independent of any effect on the preservation of renal function. There is also powerful evidence of the primary role of ACE inhibitors in chronic proteinuric renal disease in view of their additional benefits in decreasing proteinuria and preserving renal function.⁶⁸ However, specific evidence of the role of ACE inhibitors in IgAN is scant (Table 16-5). Short-term randomized studies in normotensive proteinuric IgAN confirm that an ACE inhibitor decreases proteinuria to the same degree as an angiotensin receptor antagonist (ATRA), an effect potentiated by indomethacin.^{69,70} A recently completed placebo-controlled RCT of ACE inhibitors in IgAN with proteinuria greater than 1 g/24 hr and creatinine clearance greater than 50 mL/min/1.73 m² reported a significant decrease in proteinuria and preservation of renal function independent of systolic or diastolic BP.⁷¹ Likewise a recent RCT of 109 patients reported benefit with an ATRA (valsartan) both in decreasing proteinuria and slowing the rate

of renal deterioration, although the investigators were unable to demonstrate a significant improvement in their primary endpoints of doubling of serum creatinine or ESRD at 2 years.⁷² The combination of an ACE inhibitor and ATRA produces a significant additional decrease in proteinuria.⁷³ Indirect evidence of the benefit from such a combination in IgAN is provided by the COOPERATE study in which an ATRA was given in combination with an ACE inhibitor for nondiabetic proteinuric renal disease. An additional decrease in proteinuria was achieved with no further lowering of BP; 131 of the patients in this large study had IgAN.⁷⁴

The only two RCTs of ACE inhibitors in hypertensive IgAN showed no benefit, although this may be attributable to the relatively short follow-up in one study⁷⁵ and the inclusion of patients with advanced disease in the other.⁷⁶ However, two retrospective studies in IgAN demonstrated the benefit of using ACE inhibitors for hypertension compared with β -blockers⁷⁷ and a wide range of other agents.⁷⁸

ACE inhibitors in combination with ATRA are recommended as the preferred treatment for hypertensive IgAN and should also be considered for normotensive IgAN with significant proteinuria (>1 g/24 hr).

Fish Oil

The available studies are summarized in Table 16-6. The favorable effects of supplementing the diet with ω -3 fatty acids in the form of fish oil include decreases in eicosanoid and cytokine production, changes in membrane fluidity and rheology, and decreased platelet aggregability. These features should significantly decrease the adverse influence of many mechanisms thought to affect progression of chronic glomerular disease. Fish oil treatment does not have the drawbacks associated with immunosuppressive treatment. It is safe apart from a decrease in blood coagulability, which is not usually a practical problem, and an unpleasant taste with flatulence, which may make compliance difficult.

The study of Donadio and colleagues⁷⁹ provides convincing evidence of protection with 6 months of treatment with fish oil (12 g/day). However, an unexpected finding was that fish oil did not significantly decrease proteinuria, which is a major risk factor for progression and which has been decreased in all other studies of agents that are renoprotective in IgAN. The benefit was sustained in a longer follow-up of the same cohort, although treatment allocations were not always sustained after the original trial period was completed.⁸⁰ A further study showed no difference in outcome between a high (24 g/day) and low (12 g/day) dose of fish oil; once again, proteinuria did not decrease during follow-up.⁸¹ However, these studies conflict with the smaller study of Bennett and colleagues,⁸² which showed no benefit from fish oil. Pettersson and colleagues⁸³ may have failed to show benefit because of the short follow-up period of 6 months. A meta-analysis of these studies suggests that the available evidence does not yet give unequivocal support for the use of fish oil.⁸⁴ A recent RCT shows no benefit after 2 years of treatment with fish oil compared with placebo, although a subsequent post hoc analysis of the data in the study revealed a dose-dependent decrease in proteinuria in the fish oil group.⁸⁵

A further confirmatory study of fish oil would be of great value.

Table 16-4 Randomized, Controlled Trials of Antiplatelet/Anticoagulant Treatment in IgA Nephropathy

Ref.	Entry Criteria	Agent	No. on Active Treatment	Treatment Period (mo)	Follow-up (mo)	Outcomes	Comments
Woo et al ⁴³	UP < 5 g/24 hr Cr < 1.5 mg/dL	Dipyridamole/warfarin (and cyclophosphamide)	27	24	60	Proteinuria decreased (mean, 2.4–0.8 g/24 hr); glomerulosclerosis prevented	Cyclophosphamide for 6 mo
Walker et al ⁴²	UP > 1 g/24 hr Cr 1.1–1.8 mg/dL	Dipyridamole/warfarin (and cyclophosphamide)	25	36	24	Proteinuria decreased (mean, 1.7–1.2 g/24 hr); renal function unchanged	Cyclophosphamide for 6 mo
Chan et al ⁶⁴	UP < 2 g/24 hr Cr < 1.5 mg/dL	Dipyridamole/warfarin	19	33	33	None	
Lee et al ⁶⁵	Cr 1.6–3.0 mg/dL	Dipyridamole/warfarin	11	36	60	Proteinuria decreased (mean, 1.4–0.6 g/24 hr); renal function maintained	

Cr, serum creatinine; UP, urine protein excretion.

Table 16-5 Randomized, Controlled Trials of Angiotensin-Converting Enzyme and Angiotensin Receptor Antagonist Inhibitor Treatment in Immunoglobulin A Nephropathy

Ref.	Type of Study	Entry Criteria	No. on Active Treatment	Follow-up (mo)	Outcome	Comments
Maschio et al ⁶⁹	Placebo-controlled, crossover	UP 1–2.5 g/24 hr, normotensive	8	8	Proteinuria decreased (mean, 1.8–1.4 g/24 hr)	Short-term study: ? functional importance of minor reduction in proteinuria
Perico et al ⁷⁰	RCT: enalapril vs. irbesartan ± indomethacin	UP 0.5–4.0 g/24 hr, Cr < 2.5 mg/dL	10	1	Proteinuria decreased by 55%–61%; effect of enalapril-irbesartan; potentiated by irbesartan	Short-term study
Bannister et al ⁷⁵	RCT: enalapril vs. nifedipine	GFR 30–90 mL/min, hypertensive	12	12	Proteinuria decreased (mean, 2.0–1.2 g/24 hr); renal function not different	
Cheng et al ⁷⁶	RCT: captopril vs. nadolol/ticlopidipine	UP > 1 g/24 hr, Cr 1.3–4.4 mg/dL, hypertensive sclerosis on biopsy	31	>36	No difference in proteinuria, blood pressure, or renal impairment between ACEI and nadolol	Advanced disease at time of study
Coppo et al ⁷¹	RCT: benazepril vs. placebo	UP > 1–3.5 g/24 hr, CrCl > 50 mL/min	32	38	Proteinuria decreased; (55% achieved <0.5 g/24 hr); renal function maintained	Study in children and young adults
Li et al ⁷²	RCT: valsartan vs. placebo	UP > 1 g/24 hr, Cr 1.4–2.8 mg/dL	54	48	Proteinuria decreased (mean, 1.8–1.2 g/24 hr); reduction in rate of decline of GFR	Target BP 140/90 No difference in primary endpoint (doubling Cr or ESRD)

ACEI, angiotensin-converting enzyme inhibitor; Cr, serum creatinine; CrCl, creatinine clearance; ESRD, end-stage renal disease; GFR, glomerular filtration rate; RCT, randomized controlled trial; UP, urine protein excretion.

Table 16-6 Fish Oil Treatment in IgA Nephropathy

Ref.	Entry Criteria	No. on Active Treatment	Treatment Period (mo)	Outcomes	Comments
Hamazaki et al ⁹⁴	No details	10	12	Renal function stabilized	Randomization not described
Bennett et al ⁸²	Proteinuria	17	24	No benefit	
Cheng et al ⁹⁵	Cr 2–6 mg/dL	11	10 (8–12)	No benefit	Advanced renal impairment at recruitment
Peterson et al ⁸³	UP > 0.5 g/24 hr Cr < 2.8 mg/dL	15	6	No benefit	
Donadio et al ^{79,80}	UP > 1 g/24 hr Cr < 3 mg/dL	55	24	Fish oils lessened deterioration in renal function	Proteinuria unchanged; poor prognosis in control group
Donadio et al ⁸¹	UP 1.7–3.6 g/24 hr Cr 1.5–4.9 mg/dL	73 (high vs. low dose)	24	No difference between high-dose and low-dose fish oils	No control group not receiving fish oils; proteinuria unchanged
Hogg et al ⁸⁵	UP/C > 0.5 eGFR > 50 mL/min	32 (fish oil) 33 (steroids)	24	No difference between fish oil, prednisone, or placebo in rate of decrease in GFR	Significantly higher UP/C in fish oil group at start of trial

Cr, serum creatinine; eGFR, estimated glomerular filtration rate; UP, urine protein excretion; UP/C, urine protein-to-creatinine ratio.

3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Inhibitors

One small RCT showed that 6 months of treatment with the 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor fluvastatin resulted in a 41% decrease in proteinuria with no effect on the GFR.⁸⁶ Further prolonged studies are needed to confirm this effect.

Posttransplantation Recurrence

Mesangial IgA deposition after transplantation is common, occurring in as many as 50% of patients whose primary renal disease was IgAN.³ Graft survival is no worse in registry data than for other primary renal diseases; however, recent data indicate that IgA deposition is accompanied by the slow onset of glomerular injury, indistinguishable histologically from disease in native kidneys and often at the same tempo. There is no substantial evidence that any particular immunosuppressive regimen decreases the risk of recurrent IgA deposits or prevents any subsequent glomerular injury.⁸⁷ One study in Chinese patients suggests that the risk of recurrence may be higher in a transplant from a living related donor than in a transplant from a live unrelated donor or a cadaver, but numerous other studies do not support this.⁸⁸ Based on current evidence, there is no need to recommend any restriction in the use of living as opposed to cadaveric donors.

TREATMENT OF HENoch-SCHÖNLEIN NEPHRITIS

There are no prospective RCTs to guide the treatment of HS nephritis. Most available data are for children. Most therapeutic studies of IgAN exclude those with HSP so it is uncertain whether a number of potential treatments have a role in HS nephritis. Available studies usually include children whose renal abnormalities have been severe or persistent enough to warrant referral to a nephrologist.

Many patients have transient nephritis during the early phase of HSP that spontaneously remits and requires no treatment. It has been proposed that early use of corticosteroids in HSP may prevent nephritis,⁸⁹ but this has not been confirmed in other nonrandomized studies.¹⁵

Rapidly Progressive Renal Failure due to Crescentic Nephritis

Crescentic nephritis is more common in HSP than in IgAN, particularly early in the course. There is little information on treatment in adults; five studies report experience in 81 children.¹⁵ Regimens are variable and include corticosteroids and cyclophosphamide, with the addition of pulse methylprednisolone in some cases; two studies used plasma exchange alone. Precise entry criteria varied in the extent of proteinuria,

renal impairment, and histologic injury. Short-term outcomes are encouraging; for example, Oner and colleagues⁹⁰ report that 11 of 12 children had a normal GFR at 3 months despite a GFR less than 40 mL/min and more than 60% crescents at presentation. However, in the middle term, 20% of reported cases had an adverse outcome including ESRD.¹⁵

Active Henoch-Schönlein Nephritis without Renal Failure

In less aggressive HS nephritis, there is little information. Corticosteroids alone have never been shown to be beneficial.¹⁵ Apparently promising findings with combination therapy of corticosteroids, cyclophosphamide, and antiplatelet agents have been reported only in small nonrandomized studies.¹⁵ A recent nonrandomized study reported that the combination of prednisolone and azathioprine preserved renal function and improved histologic appearance, but this relied on comparison with historic controls.⁹¹ There are only five patients with HS nephritis included in the promising studies of pooled immunoglobulin.^{58,59}

Slowly Progressive Renal Failure

Although the renal histology and clinical course of slowly progressive HS nephritis and IgAN may be indistinguishable, patients with HS nephritis have not been included in the RCTs of corticosteroids, fish oil, or antiplatelet agents.

Transplant Recurrence

Graft recurrence of HS nephritis is common. There is some evidence that it is more common and more likely to cause graft loss in children receiving kidneys from living related donors than in those receiving cadaver kidneys,⁹² although this is not confirmed in adults.⁹³ No treatment is known to decrease risk of recurrence.

TREATMENT RECOMMENDATIONS

Based on the evidence reviewed here, specific treatment recommendations are described in Figure 16-1 for the different clinical patterns of IgAN and HS purpura.

The most controversial issue remains the treatment of IgAN with proteinuria greater than 1 g/24 hr. Physicians are increasingly using corticosteroids when there is preserved renal function (serum creatinine < 1.5 mg/dL) and fish oils when there is more renal impairment (serum creatinine > 1.5 mg/dL). However, in our opinion, the case is not yet made for either of these therapies. Tight control of BP and decreased proteinuria with ACE inhibitors in combination with ATRAs should be the first line of treatment. If physicians wish to consider additional therapy with fish oil or corticosteroids, this should be contemplated only if proteinuria persists at more than 1 g/24 hr on maximal renin-angiotensin system blockade with BP less than 125/75 mm Hg.

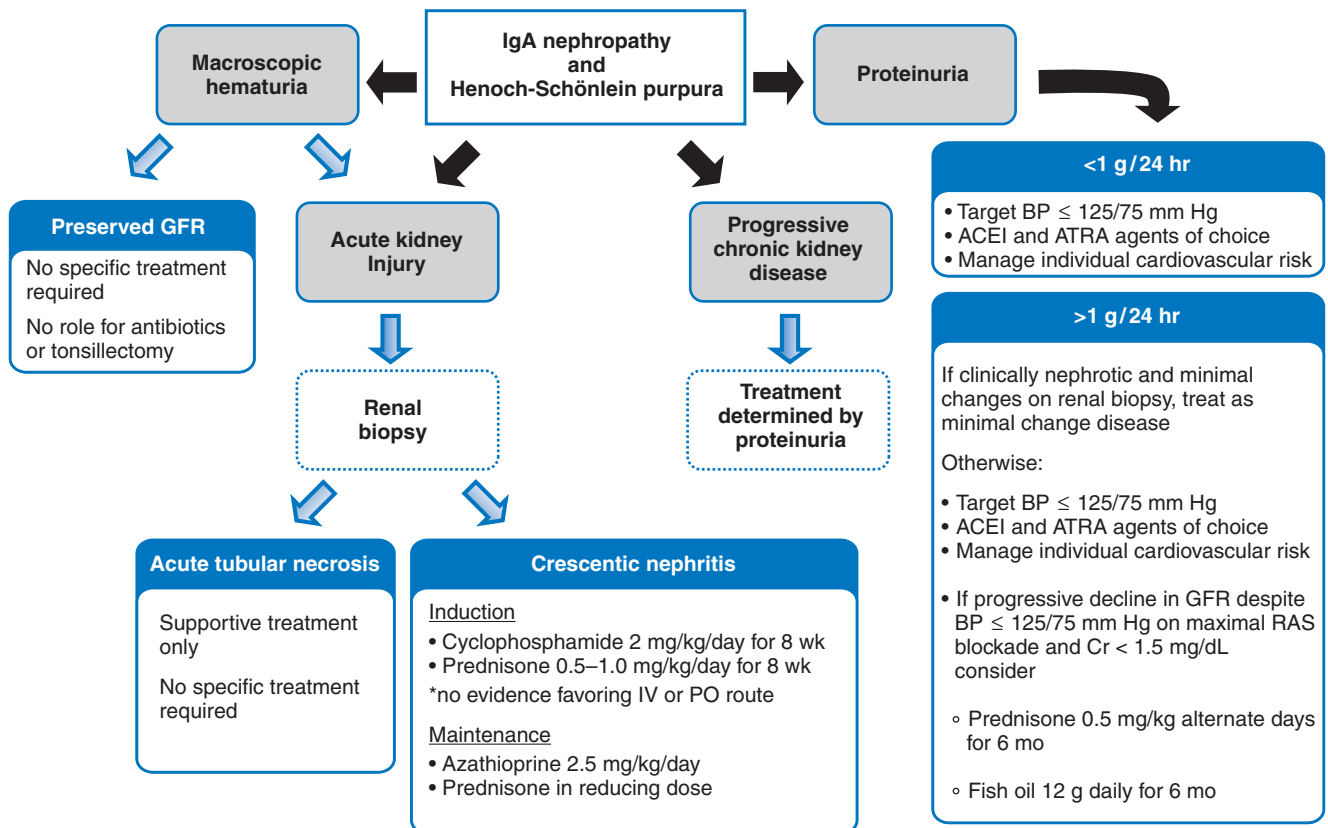

Figure 16-1 Treatment algorithm for the management of IgA nephropathy and Henoch-Schönlein purpura. ACEI, angiotensin-converting enzyme inhibitor; ATRA, angiotensin receptor antagonist; BP, blood pressure; Cr, creatinine; GFR, glomerular filtration rate; RAS, renin-angiotensin system.

FUTURE DIRECTIONS

Specific treatment to prevent mesangial IgA deposition is the ideal goal but remains a remote prospect until the fundamentals of the disease mechanism are understood. It seems unlikely that controlled trials of crescentic IgAN or crescentic HS nephritis will ever be mounted. Prevention of slowly progressive renal failure remains the most promising field, particularly as this may inform the management of chronic glomerular disease other than that associated with IgA deposition. Further studies confirming the value of fish oil and corticosteroids are required. The value of combining ACE inhibitors and ATRAs requires formal confirmation in prospective studies, as does the potential role for 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors. Other low-risk strategies need to be developed from an understanding of the mechanisms of progressive renal scarring.

BACKGROUND

Systemic vasculitis comprises a spectrum of diseases affecting small- and medium-sized blood vessels and can cause severe acute renal failure through glomerular, interstitial, and vascular damage. The diseases can be classified by the size of the blood vessel affected and the organs involved and include microscopic polyangiitis (MP), Wegener's granulomatosis (WG), renal limited vasculitis, and Churg-Strauss syndrome. Pauci-immune glomerulonephritis is the classic histologic diagnosis accompanying all these conditions and allows them to be distinguished clearly from systemic lupus erythematosus, Goodpasture's syndrome, and primary glomerulonephritides with crescentic pathology and rapidly progressive course, because in all these latter conditions, immune deposits are a major feature of the renal histology. Other diseases can also have vasculitic features such as Henoch-Schönlein purpura, essential cryoglobulinemia, rheumatoid arthritis, and Behçet's syndrome, but are not considered further here. It is vital that all patients with rapidly progressive glomerulonephritis (RPGN) have a formal diagnosis confirmed because the potential treatments and outcomes are very different in all these diseases. Most of the vasculitic diseases, especially those affecting the kidneys, are associated with the presence of circulating antineutrophil cytoplasm antibodies (ANCA), and the generic term ANCA-associated vasculitis is often used. This can be helpful because there is a huge overlap between, for example, WG and MP, and the treatments may be similar, particularly in severe disease with renal involvement. This is less true for localized disease, although induction treatments remain very similar. In general, most patients with pauci-immune crescentic glomerulonephritis behave as if they have vasculitis, have serum ANCA, and are thus treated as a renal-limited vasculitis. In all vasculitides, renal damage is irreversible without treatment and historically has led to significant mortality and the need for renal replacement therapy. Immunosuppression has had a major impact and

allows most patients to survive and recover renal function. Until recently, however, treatment recommendations were based on case series with all their inherent problems because of a paucity of controlled clinical trials. Fortunately, over the past 5 years, a series of high-quality randomized, controlled trials have been completed on which treatment decisions can now be based.

DIAGNOSIS

An accurate diagnosis in patients with RPGN is critically important because both the nature of the therapy and the response to treatment will be very different depending on the precise diagnosis. All patients presenting clinically with RPGN or evidence of vasculitis should have a renal biopsy and appropriate serologic investigations performed as a matter of urgency.¹ Assays for anti-glomerular basement membrane (GBM) antibodies, ANCAs, lupus serology, and complement are particularly important, as well as measures of an acute-phase response. ANCAs should be assessed by indirect immunofluorescence on ethanol-fixed neutrophils with confirmation of the antigen specificity by enzyme-linked immunosorbent assay against purified proteinase 3 and myeloperoxidase. The renal biopsy sample should be carefully analyzed for the presence of segmental necrosis and for any immune deposits. Patients with pauci-immune glomerulonephritis usually do have some deposition of complement C3 and immunoglobulin within the mesangium and along the capillary loops, and it is important to try to localize and quantitate the immune deposits to distinguish those patients with truly pauci-immune disease from those who may have underlying primary glomerulonephritis.² There is now good evidence that in patients with vasculitis, the presence and proportion of normal glomeruli are an important predictor of renal outcome, in addition to both acute and chronic tubulointerstitial damage.³ Increasing numbers of patients with crescentic nephritis are being recognized as having both

ANCAs and anti-GBM antibodies, so-called double-positive patients.⁴ The outcome in these patients is unclear, but in our experience may be poor and more like that seen with anti-GBM disease. Thus, all anti-GBM antibody-positive patients or those with linear immunoglobulin deposited along the GBM on renal biopsy should have ANCA assays performed because this might influence subsequent management.

CLINICAL TRIALS

The heterogeneity of crescentic glomerulonephritis confounded many early trials of therapy because studies included patients with diseases as diverse as postinfectious nephritis, SLE, WG, and renal-limited vasculitis, and very few studies clearly separated patients into appropriate diagnostic groups. More recently, trials in vasculitis have been very specific about recruiting patients with clearly defined disease, usually based on ANCA serology. Trials in renal disease have generally included patients with ANCA-associated vasculitis regardless of the precise clinical diagnosis, whereas extrarenal studies have been careful to select patients usually with WG. Patients in such studies have been separated according to the extent of disease (localized or generalized) and severity (organ threatening, life threatening) and based on therapy as initial (induction) or maintenance treatment. This has been extremely useful in allowing a better definition of the precise place for various therapies.

Historically, the outcome of patients with vasculitis was dramatically improved with the introduction of oral immunosuppression as induction therapy, particularly the addition of cyclophosphamide to corticosteroids, as described by Fauci and colleagues^{5,6} and others,^{7,8} at the National Institutes of Health for patients with WG. A similar regimen was subsequently applied to patients with MP^{7,9} and has become standard induction therapy for patients presenting with RPGN from renal vasculitis. Introduction of cytotoxic therapy allowed 75% of patients to achieve remission, and more than 85% to survive the acute illness, however at the cost of significant longer term morbidity including infections, bone marrow suppression, and cancer. Treatments used for therapy in vasculitis have evolved from oral and intravenous steroids, oral and intravenous cyclophosphamide, plasma exchange (PE), azathioprine, and methotrexate to mycophenolate mofetil (MMF), infliximab, etanercept, rituximab, and deoxyspergualin, among others.¹⁰

We concentrate here on treatments supported by good evidence and briefly discuss newer treatments as yet lacking controlled trials. A key feature of all recent trials has been to recognize the difference between induction of remission in patients presenting acutely, maintenance of remission after initial control of disease, and management of relapses, and between disease threatening vital organs and more localized disease, because the relative balance of risks and benefits and the need for intensive acute intervention are clearly different in the two circumstances. Most nephrologists see patients with more severe vasculitis with acute renal failure and RPGN, whereas rheumatologists often see patients with more localized and non-organ-threatening disease.

Induction Treatments

Plasma Exchange

The rationale for the use of PE in MP, WG, and pauci-immune glomerulonephritis was initially based on the similarity of the renal pathology to Goodpasture's syndrome, namely severe focal necrotizing crescentic nephritis and the presumed immune complex etiology. The identification of ANCAs in these conditions strengthens the rationale for the use of PE, although the precise role of the autoantibodies in the pathogenesis of these diseases is not yet clearly defined. Six controlled trials of the value of PE in non-anti-GBM RPGN have been performed.^{11–16} Glockner and colleagues¹¹ could not demonstrate any additional benefit of twice-weekly PE in 14 patients with crescentic RPGN compared with 12 controls treated with oral prednisolone, cyclophosphamide, and azathioprine. However, the patients included in this study were a heterogeneous group, including those with WG, polyarteritis nodosa, systemic lupus erythematosus, scleroderma, and idiopathic RPGN. Furthermore, patients with oliguria were excluded, and three patients in the control group were subsequently successfully treated with PE.

The Hammersmith Hospital controlled trial of PE only treated patients with WG, MP, or idiopathic RPGN, and randomized 48 patients to conventional treatment with oral steroids, cyclophosphamide, and azathioprine, either with or without intensive PE (at least five exchanges in the first 7 days).¹² In this study, PE was of no additional benefit in patients with moderate or severe renal disease who were not dialysis dependent at presentation. However, 10 of 11 dialysis-dependent patients receiving PE discontinued dialysis compared with only three of eight receiving oral immunosuppression alone. Although ANCAs were not routinely measured at that time, these patients fell into diagnostic categories now associated with ANCAs. Rifle and Dechelette¹³ also showed a benefit of PE in dialysis-dependent patients: 6 of 8 patients receiving PE recovered renal function but none of six treated with drugs alone.

The Canadian Apheresis Study Group¹⁴ added PE to induction therapy of intravenous methylprednisolone followed by oral prednisolone and azathioprine. This study excluded patients with systemic disease and included one patient with postinfectious RPGN in the PE group. There was no demonstrable benefit of PE in the non-dialysis-dependent patients. However, in dialysis-dependent patients, a nonsignificant trend in benefit was evident: three of four patients receiving PE discontinued dialysis compared with two of seven in the control group. Zauner and colleagues¹⁵ prospectively randomized 39 patients with non-anti-GBM crescentic nephritis to receive PE in addition to standard immunosuppression (pulsed methylprednisolone, oral steroids, and oral cyclophosphamide): 6 of 11 dialysis-dependent patients recovered renal function overall but with no difference in outcome between the two groups. Combining the results from these early controlled trials clearly demonstrates a significant benefit of PE only in dialysis-dependent patients. In total, 25 of 31 dialysis-dependent patients (81%) treated with PE had independent renal function at follow-up compared with 8 of 25 (32%) treated with immunosuppressive drugs alone. A number of single-center cohort studies have shown very similar results for renal recovery with PE.

The small size of these early trials and the combined outcomes suggesting a benefit from PE in patients with severe disease¹⁶ led the European vasculitis study group (EUVAS) to embark on the prospective, randomized, controlled MEPEX trial comparing the use of intravenous methylprednisolone (3 g over 3 days) with PE (seven exchanges in 2 weeks) in 137 patients with serum creatinine greater than 5.8 mg/dL and a new diagnosis of ANCA-associated systemic vasculitis.¹⁷ All patients received oral prednisolone and oral cyclophosphamide. At 3 months, 49% of patients treated with methylprednisolone compared with 69% of those treated with PE were alive and independent of dialysis. PE was also associated with a significantly decreased risk of progression to end-stage renal disease at 12 months (19% versus 43%). Complications and overall survival were identical.

The evidence now seems very strong that patients with ANCA-associated vasculitis and RPGN and a serum creatinine greater than 5.8 mg/dL have a significantly better outcome if treated with PE in addition to cyclophosphamide and oral steroids rather than the widely used alternative of intravenous steroids. This is not necessarily true of all the vasculitides, for example, Churg-Strauss syndrome,¹⁸ or for patients with less severe ANCA-associated renal vasculitis (creatinine < 5.8 mg/dL). Patients with vasculitis and pulmonary hemorrhage have very high mortality rate and also seem to benefit from PE regardless of the serum creatinine level, although there are no randomized trials in this setting.

Alternatives to PE have been investigated in some centers. Stegmayr and colleagues¹⁹ conducted a randomized, controlled trial of PE versus protein A immunoadsorption in 44 patients with RPGN and more than 50% crescents: 7 of 10 dialysis-dependent patients discontinued dialysis, with no difference between the two antibody removal strategies.

Intravenous Methylprednisolone

Intravenous methylprednisolone has also been advocated for the initial therapy of crescentic glomerulonephritis. There has now been one controlled study in patients with severe renal failure (the MEPEX study) comparing intravenous methylprednisolone with PE as induction therapy.¹⁷ As noted above, steroids were significantly less effective than PE, although half the patients treated with intravenous methylprednisolone were able to discontinue dialysis by 3 months. There have been no controlled trials of oral versus intravenous steroids. Bolton and Sturgill²⁰ reported good results in dialysis-dependent patients with pauci-immune RPGN or vasculitis (excluding WG), with 14 of 19 dialysis-dependent patients treated with intravenous methylprednisolone coming off dialysis. However, this study used very large doses of methylprednisolone (30 mg/kg/day for 3 days, maximum 3 g/day). Andrassy and colleagues²¹ also used intravenous methylprednisolone successfully at much lower doses (250 mg/day for 3 days), enabling 11 of 12 dialysis-dependent patients with WG to recover renal function. In contrast, Garrett and colleagues²² reported improved renal function in only 7 of 17 (41%) patients with ANCA-associated RPGN treated with high-dose intravenous steroids.

Other Treatments for Induction of Remission

Patients with generalized disease but with serum creatinine less than 5.8 mg/dL are often labeled as having generalized organ-threatening disease. These patients historically were treated

with oral cyclophosphamide and oral or intravenous steroids, with remission rates between 7% and 100%. However, it became clear that treatment-related morbidity was a significant issue, and over the past decade, trials have focused on identifying less toxic regimens.

Intravenous cyclophosphamide has been tested in several trials in place of oral cyclophosphamide, in view of the successful use of this treatment modality in patients with severe systemic lupus erythematosus.^{23–25} There are now 10 non-randomized cohort studies and three randomized trials suggesting equal efficacy of the intravenous route but a lower cumulative dose and thus less likelihood of toxicity, especially infections.¹⁰ A meta-analysis in 2001²⁶ confirmed a lower infection rate but also suggested an increased risk of relapse in patients treated intravenously, probably also because of the lower cumulative dose. The EUVAS group therefore conducted a prospective, randomized, controlled trial in 160 patients with ANCA-associated vasculitis and serum creatinine less than 5.8 mg/dL comparing oral cyclophosphamide 2 mg/kg/day with intravenous pulses 15 mg/kg every 2 weeks for 6 weeks, and then every 3 weeks for a further seven pulses (CYCLOPS study). Preliminary results suggest both treatments were equally efficacious, and as yet no differences in outcomes have emerged.

Intravenous cyclophosphamide may be less efficacious in successfully limiting severe renal inflammation.^{25,27} Guillevin and colleagues²⁵ and Haubitz and colleagues²⁷ both reported an inferior rate of recovery from dialysis dependence in patients treated with intravenous cyclophosphamide compared with the response to oral therapy, and Aaserod and colleagues²⁸ demonstrated an increased relapse rate in more than 108 patients treated with intravenous compared with oral cyclophosphamide.

Cotrimoxazole alone may be able to induce remission in patients with WG localized to the upper airways. Two small nonrandomized studies have shown significant benefits,^{29,30} with the majority of patients attaining remission. Cotrimoxazole is well tolerated with few adverse effects. Nephrologists will see very few patients with such limited disease.

Methotrexate has been used in place of cyclophosphamide in a number of patients with WG but without severe crescentic nephritis because methotrexate should be avoided in renal failure.^{31,32} Three small uncontrolled studies achieved remission rates of as high as 75%, but with high relapse rates (as high as 57%) and significant toxicity.¹⁰ Most recently, a EUVAS randomized, prospective, controlled trial included 95 patients with generalized non-organ-threatening disease and minimal renal involvement treated with weekly oral methotrexate (≥ 25 mg/wk) compared with cyclophosphamide, in addition to oral steroids.³³ Complete remissions were achieved in 90% and 94% of patients with methotrexate and cyclophosphamide, respectively (not significant), although patients were slower to achieve remission when treated with methotrexate. Toxicity was no different between the two groups. Relapses were very common, probably because all treatments were stopped at 12 months, and occurred in 69% of those treated with methotrexate and 42% of those receiving cyclophosphamide. Methotrexate, therefore, is certainly an alternative to cyclophosphamide in this setting, especially if patients do not have rapidly progressing disease. It is likely to have less long-term toxicity, but needs to be continued for more than 1 year.

Most recently, patients have been treated with tumor necrosis factor–blocking agents. A pilot study of infliximab in patients with acute disease (including those with renal involvement, but serum creatinine < 5.8 mg/dL) showed significant benefit in inducing remission (88% of patients), although there was concern over the risk of infections.³⁴ These results were not replicated in a larger trial of the alternative tumor necrosis factor blocker etanercept, which was studied in a prospective, randomized, controlled trial of 181 patients with WG without major renal involvement.³⁵ Patients were randomized to receive etanercept in addition to either cyclophosphamide or methotrexate and steroids. Seventy percent of patients achieved remission, with no benefit from etanercept, and relapse rates were very high (>50%) regardless of the use of etanercept. Patients in this study had their baseline immunosuppression (steroids) decreased rapidly, and most came off immunosuppressive drugs completely over the first year, despite being at high risk of relapse. There was also a concern over the possibility of an increased risk of cancer in patients receiving etanercept in this study.

A handful of cases of severe crescentic nephritis responding to cyclosporine have also been reported.^{36,37} The use of intravenous immunoglobulin (IVIG) appears to be more successful. Jayne and Lockwood³⁸ treated 26 patients with WG, MP, and rheumatoid vasculitis in whom disease was refractory to conventional steroid and cytotoxic therapy. IVIG was given as Sandoglobulin at a total dose of 2 g/kg over 5 days. By 2 months, 50% of the patients had achieved a full remission, and the remainder had a partial remission of their disease. After 1 year of follow-up, 19 of 26 patients were still in remission and one patient had died of overwhelming sepsis. However, most of these patients were still on oral cyclophosphamide or azathioprine and oral prednisolone. A subsequent randomized, controlled trial of IVIG (2 g/kg total dose) in 34 patients with ANCA-associated vasculitis demonstrated modest treatment responses (14 of 17 patients improved compared with 6 of 17 placebo treated).³⁹ Benefit was not maintained in the long term, and a reversible increase in serum creatinine was a common complication. Richter and colleagues⁴⁰ reported much less promising results in nine patients with ANCA-associated vasculitis who had responded incompletely to conventional therapy. No patient achieved a complete remission with IVIG. The major concern regarding the use of IVIG has been the frequent (usually reversible) deterioration in renal function in patients with an initial creatinine greater than 200 $\mu\text{mol/L}$.⁴¹ Such nephrotoxicity and questionable efficacy make it difficult to justify the use of IVIG as preferred treatment in patients with severe crescentic nephritis. This contrasts with the successful use of IVIG in another vasculitis, Kawasaki disease.

Mycophenolate has been used to treat patients with a variety of immune-mediated nephritides, usually for chronic disease. Stassen and colleagues⁴² used MMF for induction of remission in 32 patients with active WG who could not be treated with cyclophosphamide for various reasons. Mycophenolate was used at 1000 mg twice daily together with oral steroids at 1 mg/kg/day. Seventy-eight percent of patients achieved complete remission, 19% a partial remission, and only one patient did not respond; however, more than 60% had a subsequent relapse. Relapses occurred in patients with complete and partial remissions 6 to 14 months after starting treatment. Adverse effects included

leukopenia, anemia, abdominal pain, and diarrhea and were usually dose related.

Rituximab (an anti-CD20 antibody that eliminates B lymphocytes) has been investigated in a very small number of patients with vasculitis and appears promising.⁴³ Retreatment may be needed as B cells reconstitute after 6 to 9 months, and a randomized trial comparing rituximab with cyclophosphamide for induction (RAVE) is in progress. Deoxyspergualin has also been reported to be beneficial in small numbers of patients, but has to be given as a daily subcutaneous injection and causes predictable transient leukopenia.⁴⁴

Maintenance Therapy

Long-term maintenance therapy is usually required for crescentic nephritis associated with ANCA. As many as 50% of patients will have a relapse with systemic or local disease.⁹ In the Hammersmith series, use of long-term maintenance therapy and tailoring treatment according to ANCA status have decreased the relapse rate at 5 years from 53% to 22%.⁹ The majority of patients in this series were still taking a cytotoxic agent in the third year, usually azathioprine. Some recent trials have stopped all immunosuppression by 12 months, for example, the Wegener's Granulomatosis Etanercept Trial of etanercept in WG³⁵ and the EUVAS trial of methotrexate and cyclophosphamide in nonrenal WG,³³ and relapses occurred in more than 50% of patients within the next year, mostly in the first 6 months after cessation of immunosuppression. Relapses are not trivial, can be life and organ threatening, and expose patients to significantly more immunosuppression with increased treatment-related toxicity. Long-term immunosuppression is therefore crucial, but the precise duration of treatment remains uncertain, and although we have some evidence now about best drugs for maintenance therapy, the place for newer immunosuppressive agents is unclear (Table 17-1).

Cyclophosphamide and Azathioprine

The long-term use of cyclophosphamide has been associated with significant adverse effects,⁴⁵ whereas azathioprine is usually well tolerated with a reduced risk of hematologic or urothelial malignancy. The CYCAZAREM randomized, controlled trial in 144 patients with ANCA-associated vasculitis and renal disease (serum creatinine < 5.8 mg/dL) clearly demonstrated that 3 months of cyclophosphamide followed by a switch to oral azathioprine was as effective as cyclophosphamide continued for 9 months after induction of remission.⁴⁶ Relapse rates (15.5% and 13.7%, respectively), mortality rates, and end-stage renal disease were identical in both arms of the study, and there was a trend toward less severe complications in patients receiving azathioprine as long-term maintenance therapy. There should therefore no longer be a place for the routine use of long-term cyclophosphamide as maintenance therapy in ANCA-associated RPGN, with the exception of rare patients who are truly cyclophosphamide dependent and have a relapse after switching to all other agents.

Other Agents

In patients taking azathioprine who have a relapse or who are intolerant of it, the use of methotrexate or MMF as maintenance therapy may be considered. Mycophenolate is a more potent immunosuppressive agent than azathioprine and may therefore be more effective than azathioprine in the mainte-

Table 17-1 Drugs Commonly Used in Systemic Vasculitis

Drug	Doses Used	Duration of Use	Adverse Effects
Methylprednisolone and oral prednisolone	15 mg/kg IV, maximum dose 1 g/day 1 mg/kg/day PO, maximum 60 mg	Intravenous given for 3 days; oral continued for at least 1 yr, usually longer, but with decrease in dose; 20 mg by 6 wk, and 10 mg by 6 mo	Infections, hyperglycemia, edema, osteonecrosis, peptic ulcer, psychosis, depression, hypertension, osteoporosis, myopathy, weight gain, bruising
Cyclophosphamide (Cytoxan) (IV)	15 mg/kg every 2 wk \times 3, then every 3 wk. Alternatively, 0.5 g/m ² , maximum 1 g/m ² ; decrease dose in elderly and if GFR < 50 mL/min	12–25 wk	Infections, leukopenia, thrombocytopenia, bone marrow suppression, hemorrhagic cystitis, carcinoma of the bladder lymphoma, sterility, amenorrhea
Cyclophosphamide (PO)	2 mg/kg/day, reduced to 1.5 mg/kg/day in elderly and decreased GFR	3–6 mo	Infections, leukopenia, thrombocytopenia, bone marrow suppression, carcinoma of the bladder, lymphoma, sterility, amenorrhea
Azathioprine (Imuran)	2 mg/kg/day	At least 9 mo after induction, but often up to 5 yr	Hypersensitivity, leukopenia, bone marrow suppression, myelodysplasia, malignancies, hepatic dysfunction, pancreatitis; levels of thiopurine methyltransferase should ideally be checked before use
Methotrexate	10–25 mg once weekly	At least 12 mo, possibly longer	Leukopenia, bone marrow suppression, hepatic dysfunction, rashes, lung toxicity
Mycophenolate mofetil	500 mg bid–1.5 g bid	At least 12 mo	Leukopenia, anemia, gastrointestinal disturbance especially diarrhea, infections, malignancies (in combination with other immunosuppressants)

GFR, glomerular filtration rate.

nance of remission in systemic vasculitis. Data are, however, currently conflicting. In a pilot study of 11 patients with WG or MP,⁴⁷ MMF after standard induction therapy was effective in maintenance of remission in almost all patients. In contrast, in a second study of 14 patients with WG who had been treated with daily cyclophosphamide and steroids to induce remission,⁴⁸ MMF was well tolerated but relapses occurred in 43% of cases. An ongoing EUVAS trial is randomizing patients to either azathioprine or MMF after remission induction. Methotrexate may also be used effectively to maintain remission in patients with nonrenal disease initially treated by corticosteroids and cyclophosphamide. This immunosuppressive protocol is attractive because it combines the efficacy of cyclophosphamide in inducing remission together with methotrexate as a drug with a more favorable long-term toxicity profile. Langford and colleagues⁴⁹ reported on 31 patients treated in this way who achieved a relapse rate of only 16% at 2 years.

Cyclosporine and deoxyspergualin are also agents that could, in theory, provide useful maintenance immunosuppression; however, data are limited to small uncontrolled case series.

Refractory disease has also been treated with anti-T-lymphocyte antibodies. Lockwood and colleagues⁵⁰ used a combination of two humanized monoclonal antibodies, Campath 1H directed against CDw52 and an anti-CD4 antibody, in four patients and achieved a sustained remission in three. Antithymocyte globulin has also achieved a favorable response in a few patients with refractory WG, but, again, relapses were common. In view of the probable importance of ANCAs in the pathogenesis of vasculitis, semi-specific removal of these antibodies has been attempted using L-tryptophan immunoabsorption⁵¹ and, more specifically, with myeloperoxidase-bound immunosorbent columns to remove antimyeloperoxidase ANCAs.⁵² Therapy against tumor necrosis factor using infliximab showed promise in the treatment of chronic disease in a small prospective pilot study of 16 patients, with most patients achieving remission despite chronic active disease.³⁴ Leflunomide has been studied in both pilot studies and a randomized trial compared with methotrexate. Unfortunately, this trial was stopped early as a result of high relapse rates in the methotrexate arm. Leflunomide seemed effective at controlling vasculitis, but toxicity was a significant

problem (neuropathy, leukopenia, hypertension). Finally, at least two patients with severe disease have received immunoablation with autologous bone marrow stem-cell transplantation, both of whom were apparently well 6 months after the procedure. Cotrimoxazole has also been used in maintenance therapy and shown to reduce the risk of relapse significantly, especially in WG and especially in patients with extrarenal disease.

In view of the potential toxicity of immunosuppressive therapy and uncertainty over duration of treatment needed, there would clearly be benefit in identifying patients at higher risk of relapse because this might allow targeting of long-term therapy. There is some evidence that patients with persistent ANCA titers and those with anti-proteinase 3 as opposed to myeloperoxidase antibodies have an increased risk of relapse, and patients with a substantial increase in ANCA titers may also be more likely to have a relapse over the coming weeks.⁵³ Interrogation of immunologic tests can therefore provide some help in guiding maintenance therapy.

Outcome

Crescentic ANCA-positive vasculitis causing RPGN should be controlled with conventional prednisone and cyclophosphamide therapy in more than 70% of patients.⁹ Levy and Winearls⁵⁴ reported patient survival rates at 1 and 3 years of 86.3% in 31 patients with crescentic glomerulonephritis (of various etiologies) and an overall renal survival rate of 78%. Of these 31 patients, 20 were dialysis dependent at presentation. In the Hammersmith series of 73 patients with WG or MP and an initial creatinine value greater than 500 $\mu\text{mol/L}$ (>5.8 mg/dL) who were treated with oral steroids, cyclophosphamide, and PE, 73% were alive with improved renal function 2 months after presentation.⁹ Stegmayr and colleagues¹⁹ treated patients with severe renal failure and RPGN in a similar fashion (with PE or immunoabsorption) and were able to show that 70% came off dialysis. Gordon and colleagues⁵⁵ reported 82% survival at 3 months in 150 patients with small-vessel vasculitis treated with steroids and oral or intravenous cyclophosphamide, whereas Aaserod and colleagues²⁸ showed 74% and 75% patient and renal survival at 5 years, respectively, with 55% patients coming off dialysis. In the MEPEX trial of severe ANCA-associated renal disease,¹⁷ 70% of patients treated with PE were alive and off dialysis at 3 months. Renal recovery usually occurs within 1 month but can be delayed substantially after the initiation of therapy (as long as 6 months). In the CYCAZAREM trial, most patients were in remission by 3 months,⁴⁶ but a further 16% achieved remission between 3 and 6 months after starting treatment with cyclophosphamide. In this study, the relapse rate was approximately 15% at 18 months; 85% of patients therefore were free of disease activity at this point. In contrast, the randomized trial of methotrexate and cyclophosphamide in nonrenal vasculitis withdrew all therapy by 12 months, and relapses occurred in more than 50% of patients.

Patients with extensive interstitial damage found on their initial renal biopsy sample, marked glomerulosclerosis, or a long history of untreated disease may respond to initial induction therapy but subsequently have declining renal function and ultimately require renal replacement therapy.^{3,15,56,57} Increasing age and lack of normal glomeruli on renal biopsy have also been associated with a worse outcome.³ Patients who

achieve a serum creatinine of less than 200 $\mu\text{mol/L}$ (2.3 mg/dL) are subsequently much less likely to require renal support. Patients who suffer relapses of disease with further renal damage are at risk of long-term renal failure, hence, the need to prevent relapses and maintain prolonged remission.

SPECIFIC RECOMMENDATIONS FOR TREATMENT

It is critically important that a specific diagnosis is made in all patients with clinical presentation with RPGN and a renal biopsy sample showing light microscopic changes of crescentic glomerulonephritis. It is also helpful to establish ANCA specificity and the spectrum of organ and vascular bed involvement. For example, the recommended treatment regimen will vary considerably between a patient with anti-GBM disease presenting on dialysis (see Chapter 18) and a patient with MP presenting similarly, and long-term therapy may differ between a patient with WG and anti-proteinase 3 ANCA and one with MP and a myeloperoxidase ANCA that has become undetectable. However, it is also important to recognize that as many as 10% of patients with pauci-immune crescentic glomerulonephritis will have a negative test for ANCA and should be treated in the same way as those with ANCA-positive systemic vasculitis because they have the same renal prognosis.

We recommend that ANCA-positive patients presenting with a creatinine value less than 5.8 mg/dL should be treated with oral prednisolone (1 mg/kg/day, 60 mg maximum dose) and intravenous cyclophosphamide (15 mg/kg, 1.2 g maximum dose) every 2 weeks for the first three infusions and subsequently every 3 weeks for seven further pulses, with a dose decrease in those older than 60 years old and those with a GFR less than 50 mL/min. White blood cell counts should be measured 10 to 14 days after each cyclophosphamide dose, and the dose should be decreased if the white blood cell count has decreased to less than $3 \times 10^9/\text{L}$. Oral cyclophosphamide is a reasonable alternative and is given at 2 mg/kg/day (150 mg maximum) for 3 months, unless disease is not controlled (6 months maximum), but may be associated with a higher risk of infections. We do not routinely use intravenous methylprednisolone but many centers do, and no trials have addressed this. Oral steroids should be decreased slowly so that patients are on 20 mg/day by approximately 3 months. All patients should receive prophylactic cotrimoxazole 960 mg three times per week, oral antifungals while on cyclophosphamide or high-dose steroids, omeprazole (or alternative) and alendronate, calcium supplements, and vitamin D as bone prophylaxis during steroid therapy.

Patients who present with a creatinine value greater than 5.8 mg/dL or who are dialysis dependent should receive urgent PE using human albumin solution (see Chapter 12) in addition to prednisone and cyclophosphamide. Fresh frozen plasma should be added to the replacement fluids within 3 days of renal biopsy or in the presence of bleeding. PE should be repeated frequently and regularly to provide at least seven 4-L exchanges within the first 2 weeks. If PE is unavailable or delayed in such cases, treatment should begin with intravenous methylprednisolone (15 mg/kg/day, 1 g/day maximum), which should be given for three consecutive days; however, this is not an optimal substitute for PE. All patients with pulmonary hemorrhage should receive PE as well as prednisolone and cyclophosphamide as

described previously. Some physicians prefer oral cyclophosphamide in this context based on the MEPEX trial.

Patients with minimal renal involvement can be treated with methotrexate either from induction of therapy or after initial treatment with cyclophosphamide, but response is slower, and treatment certainly needs to be continued for more than 18 months.

Beginning 1 week after initiation of therapy, oral prednisolone should be slowly decreased so that patients are receiving 20 mg by 6 weeks and 10 mg by 5 to 6 months after the initial diagnosis. Cyclophosphamide should only be used for 3 months in most patients and subsequently changed to oral azathioprine (2 mg/kg/day) (as shown by the Cyczarex trial⁴⁷). Renal function, urine sediment, and white blood cell count should be closely monitored, as should inflammatory markers and ANCA. In our view, treatment should be continued for at least 2 years, and longer if there has been any evidence of disease relapse, high titer serum ANCA, or persistent proteinase 3 ANCA. Early cessation of treatment leads to higher relapse rates. In patients with myeloperoxidase ANCA and well-controlled disease, some physicians would attempt earlier withdrawal of therapy.

Patients with resistant disease can be treated with MMF, IVIG, rituximab, infliximab, leflunomide, or deoxyspergualin in centers with experience with these agents. Relapses can be treated in the same way as induction therapy; however, many centers try to avoid large cumulative cyclophosphamide doses and may use alternative agents. However, severe renal relapses usually do require aggressive induction therapy to prevent irreversible damage. Harder to treat is low-grade chronic grumbling disease, and in this setting, MMF, infliximab, rituximab, and methotrexate may all be useful.

RECURRENCE AFTER TRANSPLANTATION

Despite optimal therapy, approximately 20% of patients with renal vasculitis will develop end-stage kidney failure.⁵⁸

In such cases, kidney transplantation has been shown to be an effective treatment option using standard antirejection protocols (reviewed in Schmitt and van der Woude⁵⁸); however, approximately 17% of patients will experience a relapse of renal or extrarenal vasculitis.⁵⁹ Such relapses are generally responsive to treatment with cyclophosphamide, and recent studies have reported excellent 5-year patient and graft survival.⁶⁰ Importantly, ANCA titers at the time of transplantation do not appear to predict the likelihood of relapse.^{58–60} Thus, in patients with advanced renal failure and extensive scarring found on the renal biopsy sample with little or no clinical or histologic activity, reduction or withdrawal of cytotoxic therapy should be considered in preparation for transplantation. Immunosuppression should not be stopped if there is any evidence of extrarenal disease activity (Boxes 17-1 and 17-2).

FUTURE DIRECTIONS

Over the past 5 years the treatment of vasculitis has been dramatically improved by the completion of multicenter, prospective, randomized, controlled trials that have been adequately powered to answer important questions. Such trials will continue and will test the use of rituximab, MMF, monoclonal antibodies directed against T-cell and endothelial antigens, proinflammatory cytokines, etc., many of which have been shown to be effective in animal models. As the molecular mechanisms involved in crescentic glomerulonephritis are dissected, it will be possible to design more specific forms of immunotherapy, such as analogue peptides involved in the major histocompatibility complex–T-cell receptor trimolecular complex. Minimizing toxicity while retaining treatment potency is a major aim of new therapies as well as reducing relapse rates. Whether this will be achievable remains to be seen.

Box 17-1 Treatment Algorithm for Acute Vasculitis with Renal Involvement (Creatinine < 5.8 mg/dL)

Induction

Cyclophosphamide, 15 mg/kg IV (every 2 wk for 3 doses, then every 3 wk). Alternatively, 2 mg/kg/day PO.

Prednisolone 1 mg/kg/day PO (maximum 60 mg); decrease to 45 mg after 1 wk, then 30 mg, then more slowly (at 2-wk intervals)

Methylprednisolone 500 mg–1 g IV for 3 days is used in some units

Prophylactic cotrimoxazole 960 mg PO 3 times per week; omeprazole, oral nystatin, weekly alendronate, calcium, and vitamin D

Maintenance

Azathioprine 2 mg/kg/day PO; after 3 mo, oral cyclophosphamide if in full remission. If disease activity not fully controlled or PR3 ANCA remains positive, may need 6 mo of oral cyclophosphamide before switching. Continue for at least 18 mo and usually much longer. If using IV cyclophosphamide, switch to oral azathioprine after 10 pulses.

Patients intolerant of azathioprine can use mycophenolate mofetil 1–3 g/day or methotrexate (titrated up to 25 mg once weekly) if renal function good (creatinine, 1.7 g/dL).

Oral prednisolone continued; 20 mg by 3 mo and 10 mg by 6 mo; continue 5–10 mg for at least 1 yr.

Prophylactic oral cotrimoxazole continued in Wegener's granulomatosis only; omeprazole, calcium, and vitamin D

Box 17-2 Treatment Algorithm for Severe Acute Vasculitis (Creatinine > 5.8 mg/dl) or Patients with Pulmonary Hemorrhage and Vasculitis

Induction

Plasma exchange 4 L for human albumin solution 5%, at least 7 exchanges in 2 weeks. Use fresh plasma if ongoing pulmonary hemorrhage, recent surgery, or within 3 days of renal biopsy

If plasma exchange not available, methylprednisolone 500 mg–1 g for 3 days

Cyclophosphamide 2 mg/kg/day PO or 15 mg/kg IV (every 2 weeks for 3 doses, then every 3 weeks)

Prednisolone 1 mg/kg/day; decrease to 45 mg after 1 week, then 30 mg, then more slowly (at 2-week intervals)

Prophylactic cotrimoxazole 960 mg PO 3 times weekly, omeprazole, oral nystatin, weekly alendronate, calcium, and vitamin D

Maintenance

Azathioprine 2 mg/kg/day PO; after 3 months, oral cyclophosphamide if in full remission. If disease activity not fully controlled or PR3 ANCA remains positive, may need 6 months of oral cyclophosphamide before switching. Continue for at least 18 months and usually much longer. If using IV cyclophosphamide, switch to oral azathioprine after 10 pulses.

Patients intolerant of azathioprine can use mycophenolate mofetil 1–3 g/day

Oral prednisolone continued; 20 mg by 3 mo and 10 mg by 6 mo; continue 5–10 mg for at least 1 yr.

Oral prednisolone continued; should be on 20 mg by 3 months and 10 mg by 6 months; continue 5–10 mg for at least 1 year

Prophylactic oral cotrimoxazole continued in Wegener's granulomatosis only; omeprazole, calcium, and vitamin D

PR3 ANCA, anti–proteinase 3 antineutrophil cytoplasm antibody.

BACKGROUND

Goodpasture's syndrome, or anti-glomerular basement membrane (anti-GBM) disease, is an uncommon but usually severe disease caused by autoimmunity to a component of certain basement membranes, now identified as NC1 domain of the $\alpha 3$ chain of type IV collagen ($\alpha 3$ [IV]NC1). Autoantibodies with specificity for $\alpha 3$ (IV)NC1 (usually simply referred to as *anti-GBM antibodies*) have generally been used to define the disorder, although conventional assays for them are negative in rare patients.¹ Anti-GBM antibodies had been used for nearly 100 years to induce experimental nephritis before the human disease was identified, and Goodpasture's syndrome remains one of the few types of human nephritis in which there is considerable understanding of the mechanisms leading to renal injury. It was also the first type of inflammatory glomerulonephritis for which rational rather than empirically based treatment was developed and shown to be effective. This was a landmark because similar therapy was then applied to other types of rapidly progressive glomerulonephritis (RPGN) in which it was often even more effective. Goodpasture's syndrome and its pathogenesis have been reviewed in detail by Turner and Rees.²

Clinical and Pathologic Features

Ernest Goodpasture reported a single patient with lung hemorrhage and RPGN in 1919. In retrospect, his patient, like most with this syndrome, probably had systemic vasculitis. Surveys carried out since the introduction of assays for anti-neutrophil cytoplasm antibodies (ANCA) have shown that the various types of systemic vasculitis account for about two thirds of cases of lung hemorrhage with RPGN, whereas Goodpasture's syndrome with anti-GBM antibodies accounts for most of the remaining third.

Typical patients present with fulminant disease of short duration, although minor symptoms, particularly of lung disease, may have been present for weeks or occasionally much longer. The phenomenon of a sudden crescendo in disease intensity is common, and it is often only when this occurs that the disease is diagnosed. In such patients, the time window in which treatment can salvage renal function, or even life, is short, and rapid diagnosis and treatment are essential if this is to be achieved.

As well as the classic presentation of Goodpasture's syndrome, patients may present with renal disease alone or with pulmonary disease alone. As the symptoms of minor renal disease are nonspecific, it is common for presentation with isolated renal disease to be late. Lung hemorrhage, conversely, may cause hemoptysis at a relatively early stage, and patients will often seek medical attention at a time when signs of renal involvement may be minimal, although at least microscopic hematuria is usually present. This is important because anti-GBM assays are more likely to be negative in patients with isolated pulmonary disease.³ Hemoptysis is a poor guide to the severity of pulmonary hemorrhage, and patients may become hypoxic and anemic (typically an iron deficiency anemia if hemorrhage has been occurring for some time) in the absence of gross hemoptysis. Occasionally patients present with subacute renal disease, leading to nephrotic syndrome with hematuria and variable renal impairment. Very mild or rapidly progressive renal disease is much more common. This clinical description was originally based on studies of patients of European Caucoid descent, but recent large series from China confirm that patients from there have similar clinical features.⁴

Pathologically, the renal disease is of varying severity, but characteristically the glomerular crescents appear to be of a similar age. Even when the diagnosis appears to be obvious, renal biopsy is important for prognostic reasons and thus for guiding therapy. In the lung, the appearance is one of alveolar hemorrhage without specific features.

Diagnosis

Diagnosis rests on the demonstration of anti-GBM antibodies, either fixed to basement membranes of affected organs or in the circulation. Because systemic vasculitis may have a similar clinical picture and even overlap with Goodpasture's syndrome, measurement of ANCA is essential whenever the diagnosis is contemplated. The most sensitive technique for detection of antibodies is direct immunohistologic examination of a renal biopsy sample. Although linear fixation of immunoglobulin is described in a number of other circumstances, the concurrence of linear antibody fixation and crescentic nephritis occurs only in Goodpasture's syndrome or in systemic vasculitis associated with Goodpasture autoantibodies.² However, there are two circumstances in which renal biopsy samples from patients with Goodpasture's syndrome may fail to show linear deposition of immunoglobulin: first, on rare occasions when the intensity of glomerular injury is so severe that the GBM is completely destroyed, and second, in reports of exceptional patients whose initial renal biopsy specimen shows crescentic glomerulonephritis without linear staining who subsequently develop typical Goodpasture's syndrome with circulating anti-GBM antibody linear deposition of IgG.^{1,3} Direct immunohistology of lung biopsy samples is less reliable because antibody binding may be patchy.

Immunoassays for circulating anti-GBM antibodies are valuable, but their reliability varies.⁵ High titers of antibodies are usually found in patients with fulminant or rapidly progressive disease, and false-negative results should, in these circumstances, be very uncommon. False positives are occasionally found, according to the quality of the antigen used as the ligand. False-negative results are most likely in patients with relatively low antibody titers. These are typically those with isolated lung disease or minor or slowly progressive renal disease. False-negative results may also be encountered in the post-transplantation anti-GBM disease that occurs in some patients with Alport's syndrome, even in the presence of florid disease. This is because anti-GBM antibodies in this setting are alloantibodies directed against the NC1 domain of the $\alpha 5$ collagen chain that is mutated in Alport's syndrome rather than because the $\alpha 3(\text{IV})\text{NC1}$ that is targeted by the autoantibodies is Goodpasture's syndrome^{6,7} (described later).

As many as one third of patients who present with anti-GBM antibodies also have positive assays for ANCA, usually but not always perinuclear ANCA with specificity for myeloperoxidase.^{4,8} Some of these have clear evidence of small-vessel vasculitis or pulmonary hemorrhage, whereas many do not. The implications for clinical management of double positivity are discussed later.

Basis of Lung Hemorrhage

Lung hemorrhage occurs in approximately 50% of patients at some stage, but, unlike renal injury, its severity and incidence correlate poorly with antibody titers. There is clear evidence from epidemiologic and anecdotal observations and from animal models that local injury to the lung has a powerful influence on whether pulmonary hemorrhage occurs, and this is likely to account for these observations. Several surveys have confirmed a close association of lung hemorrhage with cigarette smoking. Anecdotally, other inhaled substances, notably gasoline and other volatile organic compounds, also appear to precipitate

pulmonary hemorrhage. Pulmonary or other infection and volume overload have also been associated with lung hemorrhage.

Circulating anti-GBM antibodies have direct access to the GBM through the fenestrae in the endothelium of glomerular capillaries. Alveolar capillaries are not fenestrated, and in experimental animals, anti-GBM antibodies that are normally excluded from the alveolar basement membrane gain access to it after lung injury induced by gasoline, oxygen toxicity, or the cytokines interferon alfa and interleukin-2.²

Measurement of the transfer factor corrected for the patient's lung volume and hemoglobin (kCO) can be useful for detecting the occurrence of subclinical pulmonary hemorrhage and is most useful if related to an initial value.

Alport Post-transplantation Antiglomerular Basement Membrane Disease

Renal transplantation in Alport's syndrome is generally successful, and the overall graft survival rate is at least as good as for other patients. However, as many as 5% may develop crescentic nephritis in the allograft with linear binding of immunoglobulin to the GBM.⁹ In the majority of cases, the graft is lost, and retransplantation has been unsuccessful. Typically, the disease develops some months after a first or second allograft and is recognized late, at a stage when the glomeruli have already been destroyed. In subsequent allografts, the disease develops within weeks or even days, and progresses much more rapidly. A few patients have shown less aggressive disease and retained their allografts in these circumstances.¹⁰ Disease is limited to the donor organ.

Most patients with Alport's syndrome lack the network of tissue-specific type IV collagen chains ($\alpha 3/\alpha 4/\alpha 5$) that make up the collagen framework of normal GBM. They are replaced by $\alpha 1/\alpha 2$ chain type IV collagen, the isoforms that form the collagen component of most basement membranes in the body. This seems to be inadequate for long-term structural stability in the GBM, or the cochlea, although Alport lungs do not seem to suffer from the absence of $\alpha 3/\alpha 4/\alpha 5$ from the alveolar basement membrane. Antibodies in Alport anti-GBM disease are therefore directed toward components of the donor GBM that are missing from their own basement membranes, and are therefore allo- rather than autoantibodies. Most cases of Alport's syndrome can be attributed to mutations of the gene encoding the $\alpha 5$ chain of type IV collagen, located on the X chromosome, and our work shows that the usual target of alloantibodies in Alport anti-GBM disease is the NC1 domain of $\alpha 5$ chain type IV collagen.⁶ This is distinct from the Goodpasture antigen, which is carried on the 70% homologous NC1 domain of the $\alpha 3$ chain of type IV collagen, and explains why immunoassays optimized to detect the autoantibodies of spontaneous Goodpasture's syndrome may fail to detect the alloantibodies of Alport anti-GBM disease.⁷

RATIONALE AND RESULTS OF THERAPY

Development of Current Regimens

Before the 1970s, a variety of treatments had been suggested for Goodpasture's syndrome, ranging from the use of corticosteroids and azathioprine to bilateral nephrectomy, the latter as a

last resort for intractable pulmonary hemorrhage.² None had been consistently successful. The observation of Wilson and Dixon¹¹ that 12.5% of patients survived 1 year or more with functioning kidneys after an episode of Goodpasture's syndrome affecting lungs and kidneys was in keeping with other series of the era.² At that time, based on the demonstration that circulating autoantibodies in the disease were directly pathogenic, a potentially highly toxic combination treatment was devised and tested in several patients.^{12,13} The combination had three elements: Intensive plasma exchange was undertaken to remove autoantibodies. Cytotoxic therapy, based on cyclophosphamide, was administered to prevent their resynthesis. Corticosteroids were given as an adjunctive anti-inflammatory agent. The initial results were spectacularly good in a group of patients who had previously had an extremely poor prognosis. Lung hemorrhage was arrested, usually within days, and recovery or preservation of renal function was reported. The initial studies were extended, and similar regimens applied elsewhere met with equally impressive results,¹⁴⁻¹⁷ and this has become the standard treatment for Goodpasture's syndrome. None of these studies was controlled, but the improvement in renal function was dramatically different from previous experience and temporally related to the start of treatment.

Effectiveness and Outcome

In subsequent years, the limits of the effectiveness of this therapy and its potential hazards have been delineated. The major cause of morbidity has been infection, often related to

neutropenia. The cytotoxic therapy employed in the first series comprised both cyclophosphamide and azathioprine. This usually led to leukopenia, and in recent years most have used cyclophosphamide alone without any obvious loss of effectiveness. Some have used significantly less intensive regimens, with less cyclophosphamide and/or less plasma exchange. It has been our impression, supported to some extent by published results, that this has been less effective, although fair comparison of series from different centers and countries is extremely difficult (Table 18-1).^{13,14,16-19}

The mortality of Goodpasture's syndrome is now much improved, but renal survival remains poor. The reason for this is the late stage at which treatment is instituted in most patients. Early treatment is of course difficult in a disease that evolves rapidly and is normally only diagnosed when that evolution occurs, but there is a very clear relationship between the severity of renal disease at presentation and the outcome (see Table 18-1 and Fig. 18-1).

The renal prognosis was originally reported to be better in patients presenting simultaneously with ANCA as well as anti-GBM antibodies,²⁰⁻²² but more extensive experience has shown that this is not always the case. Some double-positive patients have low titers of anti-GBM antibodies that are relatively transient, whereas others have anti-GBM titers similar to those typically found in single-positive patients, and it is this that seems to be the critical determinant of prognosis.^{8,23,24} Some double-positive patients have clear evidence of vasculitis outside the kidneys and lungs, and most have anti-myeloperoxidase autoantibodies, and in the latter group, the anti-GBM response is a

Table 18-1 Results of Treatment in Series Using Immunosuppression and Plasma Exchange

Authors	No. of Patients in Study	% WITH INDEPENDENT RENAL FUNCTION AT ONE YEAR ACCORDING TO INITIAL CREATININE LEVEL		Notes on Treatment Given
		<600 $\mu\text{mol/L}$	≥ 600 $\mu\text{mol/L}$	
Briggs et al, 1979	15	36 (4/11)	0 (0/4)	Only 4 of 15 received plasma exchange
Simpson et al, 1982	12	70 (7/10)	0 (0/2)	8 of 12 received plasma exchange
Johnson et al, 1985	17	69 (7/13)	0 (0/4)	Less cyclophosphamide than in Table 18-2; half received plasma exchange, but only every third day and using frozen plasma
Walker et al, 1985	22	82 (9/11)	18 (2/11)	Slightly less cyclophosphamide and plasma exchange than in Table 18-2
Herody et al, 1993	22	93 (13/14)	0 (0/15)	Variable amounts of plasma exchange and different immunosuppressive regimens were used
Hammersmith, 1975-1999	71	95 (18/19)	15 (8/52)	As in Table 18-2, except early patients also received azathioprine 1 mg/kg/day
Cui et al, 1997-2002	69	61 (14/23)	2 (1/46)	Beijing; follow-up at least 6 mo; treatment included pulsed methylprednisolone; only 31 received plasma exchange

Untreated patients have been excluded. Treated patients are divided into two groups according to their creatinine level at the time treatment started or at presentation if this is not available (number in each group in parentheses); 600 $\mu\text{mol/L}$ –6.8 mg/dL. The percentage of patients who were alive and not requiring dialysis at 1 year is shown.

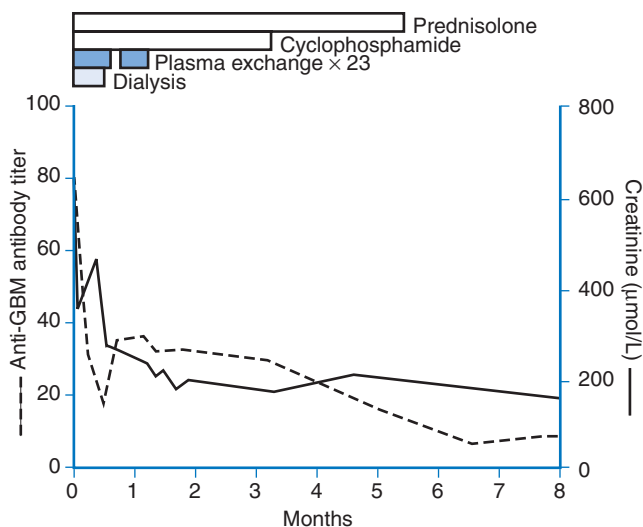

Figure 18-1 Response to treatment of a dialysis-requiring patient with Goodpasture's syndrome (renal disease only, no lung hemorrhage). This patient had 85% crescents but very acute disease. Such a response is unusually good, but many instances have been reported (see text). GBM, glomerular basement membrane.

secondary phenomenon in most, occurring in response to GBM damage caused by small-vessel vasculitis. Other patients, however, clearly develop ANCA-associated disease after presenting with anti-GBM disease and even after its successful treatment.²⁵ This emphasizes the need for prolonged immunologic monitoring in patients with anti-GBM disease.

Autoantibody levels are usually rapidly suppressed by these treatments and usually remain so after only a short period of therapy. Recurrences are then uncommon. Interestingly, they seem to be particularly likely to occur in patients with lung disease but only minor renal disease.¹³ In untreated patients (those with end-stage renal disease but no lung disease), antibodies may persist for 1 or 2 years or even longer. The immune response is therefore usually ultimately self-limiting, but treatment speeds the turn-off of autoantibody synthesis.²⁶

Role of Individual Treatment Components

Historical evidence suggests that corticosteroids alone, or azathioprine alone or in combination with corticosteroids, are not effective.² Anecdotal accounts of plasma exchange given alone describe rapid resynthesis of autoantibodies.²⁶ The only randomized, controlled trial in Goodpasture's syndrome addressed the role of plasma exchange.¹⁸ Although the results showed a better outcome in those receiving plasma exchange, the plasma exchange group had less severe renal disease than the drugs-only group, and the authors were justifiably cautious about making firm conclusions. Both the plasma exchange and cyclophosphamide regimens used in that report were less intensive than recommended here, and this may be reflected in the slightly disappointing results (only 69% of patients with creatinine < 6.8 mg/dL recovered renal function; see Table 18-1). Nevertheless, the study did usefully show that patients with mild renal disease could do well with oral cyclophosphamide and prednisolone alone.

Pulses of intravenous methylprednisolone have been widely used in RPGN of other types, and in Goodpasture's syndrome they have sometimes been used in place of plasma exchange after an initial encouraging report.²⁷ The nonrandomized study of Bolton and Sturgill²⁸ of the use of pulses of methylprednisolone in crescentic nephritis of various types included 17 patients with Goodpasture's syndrome, but most of these had advanced disease requiring dialysis. The report only discusses effects on renal function. Of the four nonoliguric patients who were treated, only two retained renal function, although methylprednisolone was given without other immunosuppression. Williams and colleagues²⁹ reported failures of pulse corticosteroid therapy in arresting pulmonary hemorrhage; Johnson and colleagues thought that it may stop pulmonary hemorrhage but that it had no impact on renal disease.¹⁸ Of major concern in the use of very high doses of corticosteroids is the increased risk of secondary infections, sometimes opportunistic, but usually common bacterial infections. There is clear evidence in Goodpasture's syndrome and in animal models that infections may precipitate or exacerbate lung hemorrhage and aggravate renal injury. We do not believe that the safety and efficiency of high-dose steroids have been established as an alternative to plasma exchange in this disease, in which there is a clear basis for removing autoantibodies.

Other Effects of Current Regimens

Although the original rationale for current treatment regimens was to control autoantibody levels, it is clear that therapy does substantially more than this. Plasma exchange depletes clotting factors, complement components, and other known and unknown mediators of renal damage, as well as circulating antibodies. Although immunoadsorption against protein A removes immunoglobulins much more specifically and appears to be equally effective clinically, it has been undertaken in only a few patients, and no real comparison has been made. Similarly, cyclophosphamide suppresses antibody resynthesis but also has profound effects on cell-mediated immunity. It is effective in other autoimmune diseases where there is no evidence of a role for autoantibodies. It is not possible to disentangle these effects of the treatments from the originally intended ones.

Other Agents for Goodpasture's Syndrome

Although cyclosporine, deoxyspergualin, and anti-T-lymphocyte antibodies have been effective in animal models of Goodpasture's syndrome, there is little to suggest that they will be more effective than conventional therapy in the clinic. Cyclosporine has not been uniformly successful in the few patients reported and cannot be recommended. Anti-B-cell therapy with rituximab has obvious rational appeal, and there is at least one report of its use in Goodpasture's syndrome with apparent success,³⁰ but clearly more data are needed.

Post-transplantation Antiglomerular Basement Membrane Disease

Renal transplantation undertaken in the presence of anti-GBM antibodies has been associated with recurrence of the disease in the allograft, although this has not occurred in all instances.

With the wide availability of immunoassays for anti-GBM antibodies, recurrence now seems to be rare. More frequent is the development of post-transplantation anti-GBM disease in patients in whom the original renal diagnosis was Alport's syndrome.⁹ In a proportion of patients, this diagnosis may not have been made beforehand because of a lack of knowledge of family background, new mutations, or autosomal recessive disease. Typical patients are deaf and have developed end-stage renal failure at a relatively young age. They are more likely to have a large gene deletion as the causative mutation. Once the disease has developed, the graft is usually lost despite treatment, although often the disease is recognized late and initial treatments have often been those used for immunosuppression. Thus, many failures of high-dose corticosteroids are recorded, as are some for antilymphocyte antibodies. In those very few reported instances in which the graft has been retained, the treatments used were not particularly unusual.

Children, Pregnancy, and the Elderly

Goodpasture's syndrome is very rare in childhood, but has been reported in those as young as 2 years of age. Lung hemorrhage is rare. The reported numbers are very small, but there is evidence that response to treatment can be at least as good as that of adults.

Three case reports suggest that the fetus may not be directly harmed by maternal anti-GBM disease, although placental transfer of the autoantibodies is to be expected. The fetus will clearly be harmed by maternal pulmonary hemorrhage and renal failure, however, and the prevention of these will usually be the main concern. Anti-GBM disease in the elderly is less likely to be accompanied by lung hemorrhage, but anti-GBM antibodies are more likely to be associated with ANCA in this age group. The prognosis for renal survival in these circumstances is better, although elderly patients are more susceptible to leukopenia and infection, as well as to other complications of therapy. Doses of cyclophosphamide should be decreased in older patients. The risks of starting or continuing aggressive treatment need to be balanced with these risks.

SPECIFIC RECOMMENDATIONS

Drug Treatment and Antibody Removal

None of the components of currently accepted therapy for Goodpasture's syndrome has been subjected to analysis by rigorous controlled trials, nor are they now likely to be. The recommendations made here are therefore based on theoretical considerations, including the observation that the autoantibodies are directly pathogenic and that this is therefore at least in part an antibody-mediated disease, and on observations of the effects of this and similar treatments. Our regimen for acute severe disease is shown in Table 18-2. The protocol is more intensive than that used by some, but an intensive regimen is required to suppress autoantibody levels as rapidly as possible. Some patients may not require such aggressive therapy, perhaps those with slight lung hemorrhage and no or minimal, nonprogressive renal disease. It is our practice to use full treatment for all patients with severe lung hemorrhage or with significant but potentially recoverable renal disease. The risk of very rapid acceleration of disease is real and can be devastating.

A separate question is whether some patients with severe renal damage but no lung hemorrhage should not be given immunosuppressive treatment or plasma exchange. Given that most dialysis-dependent patients or even those with creatinine greater than 600 $\mu\text{mol/L}$ (6.8 mg/dL) do not recover renal function, there is a strong case for nontreatment in these circumstances.³¹ There are several important caveats to following this policy. First, lung hemorrhage may occur as a late development in response to infection, toxic exposure, or other stimuli and should be guarded against and looked for. Second, some patients with ANCA as well as anti-GBM antibodies have a better renal prognosis with treatment, unless the renal biopsy sample shows advanced scarring, and may be at risk of extrarenal vasculitis. Third, there is strong evidence that treatment shortens the duration of anti-GBM antibody synthesis and consequently not treating lengthens the interval before renal transplantation is possible, sometimes to

Table 18-2 Treatment Recommendations for Acute Goodpasture's Syndrome

Prednisolone	1 mg/kg/24 hr PO. Decrease at weekly intervals to achieve one sixth of this dose by 8 wk (for a starting daily dose of 60 mg, weekly decreases to 45, 30, 25, 20, 15, 12.5, 10 mg). Maintain this dose to 3 months, stop by 4 months.
Cyclophosphamide	2 mg/kg/24 hr PO, rounded down to the nearest 50 mg. Administer by daily IV injection if unable to take orally.
Plasma exchange	Daily exchange of 4 L of plasma for 5% human albumin for 14 days or until the circulating antibody is suppressed. In the presence of pulmonary hemorrhage or within 48 hours of an invasive procedure, 300–400 mL of fresh frozen plasma is given at the end of each treatment. If white blood cell count less than 3.5, stop cyclophosphamide until it recovers. Resume at lower dose if cessation has been necessary.
Monitoring	Daily blood count during plasma exchange and while antibody titer still elevated. At least twice weekly during first month and weekly thereafter. Baseline kCO, with further measurements as indicated. Daily coagulation tests during plasma exchange to monitor for significant depletion of clotting factors. Initially, daily checks of renal and hepatic function and glucose.
Prophylaxis against complications of treatment	Oral nystatin or similar for 1 month. H ₂ antagonist during corticosteroid therapy. Prophylaxis against pneumocystis infection during cyclophosphamide therapy. Avoid other antibiotics unless indicated. Close monitoring for signs of infection with full investigation of any fever.

kCO, transfer factor corrected for the patient's lung volume and hemoglobin.

years, because antibody levels subside slowly. Whether treatment with cyclophosphamide and prednisolone (but not plasma exchange) accelerates the disappearance of anti-GBM antibodies in comparison with no treatment has not been clearly shown. Fourth, some patients in these circumstances have recoverable disease, as shown by patients in several series and case reports and as illustrated in Figure 18-1. Some have been shown on renal biopsy to have acute tubular necrosis, so that the nephritis was not as severe as perceived clinically. Others had a very acute and recent onset of severe disease, and the biopsy sample appearance was notable for the very cellular (and uniform) crescents affecting most or all glomeruli. Renal biopsy is therefore an essential part of the assessment of such patients, and if there is any doubt, it is safer to commence treatment until further information is available. There is little hazard from a few days of treatment, but much to lose by delaying.

The specific contribution of plasma exchange to disease that is not immediately life threatening or rapidly progressive is uncertain, as discussed previously. However, it allows more rapid control of anti-GBM antibody levels and thus decreases the risk of an acceleration of disease activity. Immunoabsorption against protein A may permit even more rapid control of autoantibody levels,³² but it is even more labor intensive and there are no data to suggest it may be more effective.

As discussed earlier, the risks consequent to the use of pulses of methylprednisolone may outweigh potential benefits, and there are no data to suggest they are an adequate substitute for intensive plasma exchange in severe disease. The use of other therapeutic agents must be regarded as experimental in the absence of adequate reported data.

Supportive Treatment

As in other severe illnesses, it is likely that attention to details other than the primary therapy may be critical in determining outcome. These include details of respiratory, renal, and other supportive care.

Lung hemorrhage is precipitated or exacerbated by fluid overload, pulmonary or remote infections, and pulmonary irritants and toxins. Experimentally, this includes oxygen toxicity, so in the intensive care setting, inspired oxygen tension should be kept as low as possible compatible with adequate tissue oxygenation. Patients should be persuaded to stop cigarette smoking.

Infections are the major cause of morbidity and mortality after the first few days. These can be minimized by avoidance of nonessential intravascular lines and obsessive adherence to protocols for the care of those that are in place. Neutrophil counts should be monitored carefully and cyclophosphamide dose adjusted accordingly. Prophylactic agents should be given as indicated (see Table 18-2). Granulocyte-macrophage colony-stimulating factor can be useful for severe neutropenia.

Post-transplantation Antiglomerular Basement Membrane Disease

Recurrences of spontaneous Goodpasture's syndrome are exceptionally uncommon and should respond to treatments similar to those used for the disorder in native kidneys.

As described earlier, anti-GBM disease that occurs after transplantation in patients with Alport's disease is different in that the response is to an alloantigen, not an autoantigen, and there are very few examples of effective therapy on which to base recommendations.^{9,10} It is important to appreciate the low sensitivity of standard assays for anti-GBM antibodies in these circumstances as it seems very likely that here, as in spontaneous Goodpasture's syndrome, early recognition and aggressive treatment aimed at suppressing the antibody response must be critical to success. Renal biopsy, including immunofluorescence examination to identify GBM-fixed immunoglobulin, is usually the quickest way to make the diagnosis, and antibody titers can be followed subsequently by using an assay based on crude antigen or by sending samples to a center with access to recombinant or highly purified antigens. Intensive plasma exchange appears to be a critical part of management, and anti-T-cell therapies do not appear to be powerfully effective when used alone. There are obvious problems in using antilymphocyte antibodies in combination with plasma exchange. By analogy with spontaneous anti-GBM disease, cyclophosphamide is likely to be substantially better at suppressing disease than azathioprine. We are aware of one notable success using mycophenolate mofetil after cyclophosphamide had to be stopped because of bone marrow toxicity. Rituximab would be an obvious therapeutic option, but its use in this setting has not yet been reported.

FUTURE DIRECTIONS

Familiarity with treatment regimens and improvements in intensive care have improved death rates in anti-GBM disease, but there has been little further improvement in renal outcome since combination therapy was first described. Indeed, physicians' familiarity with immunosuppressive regimens and the much wider availability of plasma exchange has reduced the rate of referral of patients with this and similar diseases to centers where there is more accumulated experience. This may not be in patients' best interests.

At present, improved outcomes are heavily dependent on rapid recognition and diagnosis and early institution of currently available therapies. It is interesting to speculate why treatment at apparently similar stages of disease is less effective in Goodpasture's syndrome than in other types of RPGN. It may be that although they appear histologically similar, the underlying structural damage is more severe in Goodpasture's syndrome, or there may be other factors to be understood, which could be controlled by additional therapies. Specific immunoabsorption may become a way to remove anti-GBM antibodies without rendering the patient hypogammaglobulinemic,³³ although there is no reason to think that it should be any more effective or technically simpler than immunoabsorption against protein A, which removes most IgG. Therapies directed against B cells, such as rituximab, could be more effective, though.

Work in models of anti-GBM disease has suggested ways in which the inflammatory response may be down-regulated by agents that interfere with the localization of leukocytes to the inflamed glomerulus or by decreasing their activation state once there. Examples in models of anti-GBM disease

include interference with leukocyte adhesion, infusions of interleukin-1 receptor antagonist, and infusions of cytokines such as interleukin-4 and interleukin-6, which alter the balance of endogenous synthesis of proinflammatory cytokines and their inhibitors.³⁴ Several of these approaches could be applicable to human disease. Because of the rarity of Goodpasture's syndrome it is unlikely that randomized clinical trials in that disease alone can be viable, even between multiple centers. However, it remains a disease where information about the immune and inflammatory responses is so much greater than in other types of nephritis, from work in human and in model systems, that further therapies are likely to spring from it.

BACKGROUND

Minimal change disease (MCD) is an idiopathic glomerular disease that accounts for 70% to 90% of cases of idiopathic nephrotic syndrome in children and 10% to 15% of cases in adults.¹ The name MCD has largely superseded the older terms lipoid nephrosis, nil disease, and idiopathic nephrotic syndrome. The disorder is characterized by the rapid onset of severe, symptomatic nephrotic syndrome with well-preserved renal function, almost normal glomerular histology except for generalized podocyte effacement, and a remarkable sensitivity to treatment with glucocorticoids. Because relapse is common and repeated courses of glucocorticoids are associated with significant toxicities, MCD remains one of the major therapeutic challenges in clinical nephrology.

Clinical Features

The clinical presentation of MCD is that of a pure nephrotic syndrome with heavy proteinuria, hypoalbuminemia, hyperlipidemia, and edema formation. Albumin is the predominant urine protein, although moderately selective or nonselective proteinuria has been observed in a significant proportion of adults with MCD.² Urinalysis reveals lipiduria, and mild microscopic hematuria may occur, especially in adults. Macroscopic hematuria is rare, and red blood cell casts are not present. Renal tubular cells and granular casts may be seen in the acute renal failure that occurs occasionally in association with MCD. Moderate hypertension is present in 13% to 30% of cases and is more frequent in adults.^{1,2} Serum creatinine may be slightly increased at the time of presentation.^{2,3} The increase in blood pressure and creatinine typically resolves with remission of the nephrotic syndrome. Adults are more likely to develop acute renal failure than are children.³⁻⁵ The renal failure is usually reversible and often preceded by severe edema formation. Histologic evidence of ischemic tubular injury has been observed in

many cases, but the mechanism of the acute renal failure is not known.¹

The course of MCD is characterized by multiple remissions and relapses of the nephrotic syndrome and a marked sensitivity to glucocorticoid therapy. In children, the frequency of relapses tends to decrease with age, and in most cases, the episodes cease after several years. The long-term renal outcome of MCD is good, and less than 5% of patients develop end-stage renal disease.⁶ In general, the course of the disease is similar in children and adults. Age-related differences in the response to treatment and the frequency of relapses are discussed in detail in subsequent sections of this chapter.

Pathology

Because the diagnosis of MCD is in many respects a diagnosis of exclusion, a challenge lies in avoiding misclassifying lesions of focal and segmental glomerular sclerosis (FSGS) as MCD. Such misclassification has obvious implications for interpreting clinical studies. Those histologic features that should raise suspicion for FSGS are noted in the discussion that follows.

By light microscopy, the glomeruli in MCD usually appear normal. There may be a slight increase in mesangial cellularity, and the visceral epithelial cells may be swollen. The capillaries are patent, and the walls are not thickened. Dilatation of the glomerular capillaries is common and may be due to loss of compliance of the capillary wall resulting from epithelial cell alterations. Glomerular size is usually normal. Enlarged but otherwise normal-appearing glomeruli may be predictive of steroid-unresponsiveness or subsequent development of FSGS.⁷ Doubly refractile lipid droplets and periodic acid-Schiff-positive protein droplets may be seen in the cells of the proximal tubule. Focal tubular atrophy and mild segmental interstitial fibrosis are accepted by some authorities as features of MCD; however, if tubulointerstitial changes are diffuse or severe, it is likely that FSGS is present. In adults, particularly

elderly patients, vascular changes may be present but are thought to be due to associated conditions such as hypertension rather than MCD.

The results of immunofluorescence studies are negative for immunoglobulin or complement deposition in most cases of MCD. Mesangial IgM, IgG, or C3 deposits have been reported in as many as 20% of cases of MCD in some series and are thought by most investigators to be the result of nonspecific trapping of circulating immunoglobulins.¹ It has been suggested that heavy mesangial IgM deposition, especially in conjunction with some degree of mesangial hypercellularity, may be a marker of glucocorticoid unresponsiveness and/or subsequent development of FSGS. However, this idea remains controversial.

Electron microscopy reveals the major morphologic features of MCD: effacement of the glomerular visceral epithelial cell (podocyte) foot processes and obliteration of the slit-pore complex. These abnormalities are not specific for MCD and occur in other conditions associated with heavy proteinuria. The extent of the foot process effacement and obliteration of the slit-pore complex does not correlate with the amount of proteinuria, but has been shown to correlate with the decrease in glomerular filtration rate.⁸ Other electron microscopic features of the podocytes include hypertrophy, increased numbers of pinocytotic vesicles and intracytoplasmic lipid and protein droplets, and microvillous transformation of their free surfaces.¹ The endothelial cells lining the capillary loop show normal fenestration, and the glomerular basement membrane is usually of normal thickness.

Pathogenesis

The cause of MCD is unknown. Experimental animal models developed to analyze the mechanisms underlying proteinuria and clearance studies in humans suggest that there is a loss of both charge selectivity and size selectivity of the glomerular filter.⁹ Changes in the anionic composition of the glomerular capillary wall are thought to underlie the impairment in charge selectivity and may, in fact, produce defects in size selectivity as well.¹⁰ Whether the primary abnormality occurs in the glomerular basement membrane or in the visceral epithelial cells is not clear. Epithelial cell injury, which is the predominant histologic feature of MCD, may be either the cause or the result of loss of the anionic constituents of the glomerular capillary wall. An immunologic basis of MCD and, more specifically, a disorder of T-lymphocyte function, is suggested by the response to immunosuppressive agents, by the association of minimal change lesions with Hodgkin's disease, and by multiple alterations in the *in vitro* function of T cells of MCD patients.¹ The observation that supernatants of cultured lymphocytes from patients with MCD can increase capillary wall permeability and induce loss of glomerular polyanions has led to a search for vascular permeability factors secreted by the T cells of these patients.^{11,12}

An unresolved question is whether MCD and FSGS represent two distinct clinicopathologic entities or whether they are variants of a single disease process. The differences in responsiveness to glucocorticoids and in long-term renal outcome support the former view. The demonstration of FSGS lesions in subsequent biopsy specimens from patients with an initial histologic diagnosis of MCD has been offered as evidence that MCD can progress to FSGS. However, the possibility of

histologic misclassification due to sampling error limits the conclusions that can be drawn from such observations.

TREATMENT

The impetus for treating MCD arises mainly from the consequences of the nephrotic state, which include malaise from anasarca as well as a predisposition to infection, thrombosis, malnutrition, and possibly atherogenesis. Prior to the availability of antibiotics and glucocorticoids, the mortality of nephrotic syndrome was greater than 50%, with the majority of the deaths during this period resulting from infection.¹³ It has been argued that proteinuria itself may be nephrotoxic and contribute to progressive renal injury. Indeed, in MCD, as in other glomerulopathies, the attainment of remission of nephrotic syndrome is associated with good long-term renal outcome.^{6,14} Although it is not known whether remission of nephrotic syndrome serves as a favorable prognostic indicator or whether it actually affects the outcome, the latter possibility has been offered as an additional reason to treat MCD.¹⁵

Because persistent nephrotic syndrome is considered especially harmful in children, most pediatric nephrologists promptly treat the first episode and relapses.¹⁶ The decision to begin treatment in adults is somewhat more complicated because the consequences of the nephrotic syndrome may be less significant, and the therapy is generally less well tolerated.

Terminology

The course of MCD is often described in terms of the response to glucocorticoid treatment. The classification scheme outlined in Box 19-1 evolved from experience with children with idiopathic nephrotic syndrome but is used in the adult literature as well. However, as will become clear later in this

Box 19-1 Classification of Minimal Change Disease Based on Response to Glucocorticoid Treatment

Steroid Responsive

Complete remission of proteinuria within 8 weeks of initiating glucocorticoid treatment

Frequently Relapsing

Initially steroid responsive but relapses at rate of two per 6 months or six per 18 months

Steroid Dependent

Initially steroid responsive but relapse during tapering of glucocorticoids or within 2 weeks of discontinuing glucocorticoids

Steroid Resistant

No remission within 8 weeks of initiating glucocorticoid treatment

Complete Remission

Reduction in urinary protein excretion to < 4 mg/hr/m² or 0 trace by urine dipstick for 3 consecutive days

Relapse

Reappearance of proteinuria \geq 4 mg/hr/m² for 3 consecutive days

chapter, the definition of steroid-resistant disease should probably differ for children and adults. The criteria for complete remission and relapse shown in Box 19-1 were established by the International Study of Kidney Disease in Children (ISKDC).¹⁷ Although the definitions of these outcomes are relatively uniform in subsequent studies, some variation does exist. Consequently, the ability to generalize from the findings is somewhat limited. Interpretation of the literature is also complicated by the inclusion of patients with primary glomerulopathies other than MCD.

Natural History of Untreated Minimal Change Disease

A clear understanding of the natural history of a disease facilitates both the interpretation of uncontrolled treatment trials and clinical decisions regarding the use of therapies with potential toxicities. Unfortunately, the natural history of untreated MCD has been difficult to establish because the use of glucocorticoids is extremely widespread and data from the preglucocorticoid era is limited by infrequent histologic classification. Spontaneous remissions do occur in MCD and have been reported in 10% to 75% of patients who received only supportive therapy.^{18–22} The accuracy of these estimates is limited by the small numbers of untreated patients and, in many cases, the lack of randomization. Although the occurrence of spontaneous remissions has led some investigators to recommend a period of observation before starting treatment, this is impractical because such a remission may not happen until months or years after the onset of disease.

Treatment with Glucocorticoids

Results in Children

Table 19-1 summarizes selected studies that evaluate glucocorticoid therapy for childhood MCD.^{17,23–27} Although there are no controlled trials directly comparing glucocorticoid therapy with supportive therapy as initial treatment of childhood MCD, the overwhelming consensus is that both the likelihood and the rapidity of remission are increased with glucocorticoids. In the ISKDC, a multicenter, prospective, uncontrolled trial, 93% of children achieved complete remission with an 8-week course of prednisone.¹⁷ The dose of prednisone used in this study was arbitrarily set at 60 mg/m²/day (up to 80 mg/day) for 4 weeks followed by 4 weeks of intermittent prednisone at 40 mg/m² for three consecutive days out of seven. Subsequently, the Arbeitsgemeinschaft für Pädiatrische Nephrologie (APN), a large multicenter study from Germany, and a single-center study in Japan both showed that a prolonged course of alternate-day prednis(ol)one, given after an initial course of daily prednis(ol)one, resulted in fewer relapses than a short alternate-day course²⁵ or the intermittent regimen used in the ISKDC trial.²⁶ The prolonged regimens were not associated with an increase in the cumulative dose or toxicity of glucocorticoids. Bagga and colleagues²⁷ found a trend toward a longer duration of first remission with an initial 16-week course of prednisolone daily for 8 weeks and alternate days for 8 weeks compared with an initial 8-week course. However, the total number of relapses during a 2-year follow-up period did not differ between the two groups, and

the cumulative glucocorticoid dose was greater in the prolonged therapy group than in the standard therapy group.

Even with more intensive initial treatment protocols, as many as 60% of children will have a relapse within 12 months,²⁷ and approximately 40% will have a frequently relapsing course²⁸ (see Box 19-1). Thus, the major challenge in MCD is managing frequently relapsing disease. Using individual frequently relapsing children as their own controls, the APN compared alternate-day prednisolone with intermittent prednisolone (in both cases after 4 weeks of daily therapy) in frequent relapsers and found a lower relapse rate with alternate-day therapy.²³ However, neither treatment was completely satisfactory. Forty-three percent of the alternate-day group suffered at least one relapse during the 6-month treatment period (compared with 72% in the intermittent group), and almost all patients had a relapse during the subsequent 6 months. The use of intravenous methylprednisolone pulse therapy followed by low-dose oral prednisone produced a similar remission rate and relapse rate as the 60 mg/m²/day standard therapy but was associated with fewer glucocorticoid-associated adverse effects.²⁴ This study included both children and adults. Although the efficacy data were analyzed separately for adults and children, the adverse events were analyzed together. Given age-related differences in glucocorticoid toxicities, the conclusions that can be drawn from such an analysis are somewhat limited. Induction therapy with alternate-day glucocorticoids has not been studied in children.

Results in Adults

Table 19-2 summarizes results of studies evaluating glucocorticoid treatment of MCD in adults.^{2,5,21,29–31} All except one of these studies are retrospective analyses. It should be noted that there was marked variation in the treatment regimens used, particularly with regard to duration and tapering schemes. Remission of nephrotic syndrome was achieved in 70% to 97% of adults treated with glucocorticoids in these studies, a remission rate similar to that of children. However, the time to remission after starting treatment was longer in the adults. In the study by Nolasco and colleagues,² 60% of adults were in remission within 8 weeks of starting treatment, and 73% were in remission within 16 weeks. Similar results were reported by Korbet and colleagues.³ The experience of Fujimoto and colleagues⁴ differed somewhat in that a higher percentage (76%) were in remission within 8 weeks, and by 16 weeks, 90% of adults achieved remission. The more rapid response to glucocorticoid treatment in the study by Fujimoto and colleagues may have been due to the younger age of the patients (mean age, 27.7 years in the study by Fujimoto and colleagues versus 40.7 and 42 years in the research by Korbet and colleagues and by Nolasco and colleagues, respectively). The analysis by Korbet and colleagues does, in fact, suggest that the time to remission after initiation of glucocorticoids is shorter in younger adults than in older adults. It is also possible that genetic and environmental factors may influence the outcome. Meyrier and Simon¹⁸ pooled all the published cases of adults treated with glucocorticoids between 1961 and 1987 and found that of 302 patients, 74.8% had complete remission, 7% had partial remission, and 18.2% had no response. The lower rate of complete remission in the pooled data may be due to shorter duration of treatment and the inclusion of patients treated for relapses as well as initial disease.

 NA, not available.

The results of these studies suggest that similar proportions (70%–80%) of adults and children have at least one relapse. However, adults appear to be less likely than children to have frequently relapsing or steroid-dependent disease (21% in Nolasco and colleagues² compared with 40% in the ISKDC³²).

Initial treatment of MCD with alternate-day glucocorticoids has been evaluated in adults.^{5,22,29,31} Nair and colleagues²⁹ retrospectively analyzed the outcomes of 58 adults treated with prednisolone 2 mg/kg (with maximum of 120 mg) as a single dose every 48 hours. Tapering began once remission was achieved. In contrast to the experience described previously with daily prednisone, 82% of patients in this study were in remission within 6 weeks, 93% were in remission within 12 weeks, and only 31% of patients had a relapse during the follow-up period. The low relapse rate has been attributed to the more gradual tapering regimen used for many of the patients in this study. The experience of Wang and colleagues⁵ using alternate-day prednisolone in Malaysian adults with MCD was less impressive. Remission occurred in 78% of 109 patients, but in many cases, it was not achieved until 6 or more months of treatment. Waldman and colleagues³¹ found no difference in remission rate, relapse rate, or time to relapse in a retrospective comparison of adults treated with daily versus alternate-day glucocorticoids. The rationale for alternate-day treatment is to decrease the adverse effects of the glucocorticoids. Although Nair and colleagues²⁹ and Wang and colleagues⁴ commented in the reports of their studies that the adverse effects were low using an alternate-day regimen, this claim has not been substantiated by a prospective comparison with daily dosing.

Treatment with Alkylating Agents

Results in Children

The use of therapies other than glucocorticoids has generally been reserved for those patients with frequently relapsing, steroid-dependent, or steroid-resistant MCD. Table 19-3 summarizes selected studies evaluating the efficacy of cyclophosphamide and chlorambucil in such patients.^{2,28,33–40} In a prospective, controlled study, the ISKDC compared cyclophosphamide with intermittent prednisone in children with frequently relapsing nephrotic syndrome and found a lower relapse rate in the cyclophosphamide group than in the prednisone group (48% versus 88%).²⁸ Although this result is consistent with the findings of earlier studies^{41,42} and supports the use of alkylating agents in frequently relapsing disease, separate analyses were not performed for the patients with MCD and FSGS, thus preventing firm conclusions regarding MCD per se. Furthermore, the intermittent prednisone regimen used in this study has been shown to be less effective than alternate-day therapy in preventing a relapse.²³

Alkylating agents appear to be less effective in steroid-dependent disease than in frequently relapsing disease. In one of the APN studies, children with frequently relapsing and steroid-dependent disease were treated with either cyclophosphamide and prednisone or chlorambucil and prednisone.³⁷ Such treatment produced a remission rate of 72% in those with frequently relapsing disease, but only 28% in the patients with steroid-dependent disease. There is controversy as to whether an increase in the duration of the alkylating agent treatment improves the response in steroid-dependent disease. In a

separate study of steroid-dependent children with MCD, the APN found that a 12-week course of cyclophosphamide was associated with a higher 2-year relapse-free rate (67%) than was an 8-week course (22%).³⁸ However, Ueda and colleagues³⁹ found no difference in the 5-year relapse-free rates in patients with steroid-dependent MCD treated for 8 or 12 weeks (24% and 25%, respectively).

There are fewer studies of alkylating agents for steroid-resistant MCD. This probably reflects the relative rarity of steroid resistance in true MCD. Uncontrolled studies suggest that steroid-resistant patients with MCD may respond to cyclophosphamide^{43,44}; however, in the ISKDC, the early nonresponsive patients (i.e., those whose disease had not remitted after 8 weeks of prednisone) treated with cyclophosphamide plus prednisone did not show a greater remission rate than those treated with prednisone alone.²⁸ It should be noted, however, that among those who did respond, the remission occurred earlier in the cyclophosphamide group than in the prednisone group (mean interval between beginning of treatment and remission was 38.4 and 95.5 days, respectively). In the one study in which they were directly compared, chlorambucil and cyclophosphamide appeared to be equally effective in frequently relapsing MCD and equally ineffective in steroid-dependent disease.³⁷

Results in Adults

In comparison with children, fewer data are available for adults with regard to the response of MCD to alkylating agents. The retrospective analysis by Nolasco and colleagues² showed that 69% of adults treated with cyclophosphamide achieved remission. Moreover, 58% of those who had a remission did so within 8 weeks of the initiation of therapy. The duration of remission was longer after treatment with cyclophosphamide than with prednisone in this series. Two thirds of those who responded to cyclophosphamide were still in remission 4 years after treatment. In a small prospective, controlled study, Al-Khader and colleagues³⁵ treated eight adult patients with MCD with cyclophosphamide and compared the outcome with that in eight patients treated with supportive therapy (diuretics). Seven of those treated with cyclophosphamide attained remission, whereas two of the control patients had a spontaneous remission. None of the patients in either group who achieved remission had a relapse during a mean follow-up period of 6 years. Although this appears to be an impressive outcome, six patients required treatment for longer than 1 month to achieve remission, and it is possible that an equally good result would have been obtained with glucocorticoids.

Toxicity of Alkylating Agents

The bulk of the data in children and adults suggests that cyclophosphamide or chlorambucil therapy, in conjunction with glucocorticoids, will induce remissions of longer duration than those resulting from glucocorticoids alone in patients with frequent relapses, and that these drugs may thus decrease glucocorticoid requirements in steroid-dependent patients. The major toxicities of these agents include reversible alopecia, susceptibility to viral and fungal infections, gonadal failure, and late development of malignancy. Cyclophosphamide can cause hemorrhagic cystitis, and chlorambucil has been associated with the development of seizures. The risk of irreversible gonadal failure increases with patient age (particularly for

women) and cumulative dose. Gonadal failure is usually reversible if the total cumulative dose of cyclophosphamide or chlorambucil is less than 200 mg/kg or 10 mg/kg, respectively. Most cases of late malignancies after treatment with these agents have occurred in patients treated for at least 1 year. The risk of malignancy with short-term therapy with chlorambucil or cyclophosphamide is not known. The steroid-sparing effect of alkylating agents has been considered a justification for their use in cases of frequently relapsing and steroid-dependent disease. Although patients who enter prolonged remission after such therapy will be spared further steroid toxicity, there is a risk of additive toxicity in those who have a relapse or fail to respond. Therefore, alkylating agents should be limited to those patients with severe steroid toxicity or uncontrolled disease.

Treatment with Calcineurin Inhibitors

Multiple small uncontrolled studies suggesting beneficial effects of cyclosporin A (CyA) in patients with frequently relapsing or steroid-dependent MCD provided the rationale for the larger trials summarized in Table 19-4.⁴⁵⁻⁵¹ All but one of these studies included patients with FSGS as well as MCD, and in most cases, separate analyses of the patients with MCD were not performed. Two multicenter, randomized, controlled studies by Ponticelli and colleagues^{45,46} showed that CyA at doses of 5 mg/kg/day in adults and 6 mg/kg/day in children is highly effective in maintaining remission in steroid-dependent or frequently relapsing nephrotic syndrome (88% with CyA compared with 68% with cyclophosphamide) and is capable of producing at least a partial remission in 60% of steroid-resistant cases. In the steroid-responsive patients, the relapse rate and glucocorticoid requirement were decreased during treatment with CyA. However, in both of these studies, as well as in a more recent study by El-Husseini and colleagues,⁵⁰ relapse occurred in approximately 70% of patients after CyA was discontinued. A limited experience with tacrolimus for MCD does not suggest an advantage of this agent over CyA.^{52,53}

The need for prolonged courses of treatment with CyA, owing to the high relapse rate after its discontinuation, has raised concern about chronic cyclosporine nephrotoxicity. Somewhat to the surprise of those involved in the early trials of CyA treatment of MCD, the drug appeared to be well tolerated in the short term, with no discernible alteration in serum creatinine or glomerular filtration rate measurements.⁵⁴ It must be recognized, however, that histologic changes have been documented in the absence of changes in the serum creatinine level. Habib and Niaudet⁵⁵ reviewed serial renal biopsy specimens from 42 children with nephrotic syndrome (35 with MCD and 7 with FSGS) treated with CyA for 4 to 63 months. Tubulointerstitial lesions developed in 24 patients, and none of the 9 patients with extensive lesions had a decrease in the glomerular filtration rate.

Although the high relapse rate and potential nephrotoxicity of CyA have relegated it to third-line therapy after glucocorticoids and alkylating agents for steroid-dependent or steroid-resistant disease, the results of a long-term study by Meyrier and colleagues⁴⁸ in adults with MCD and FSGS give cause to reconsider this position. The essential findings in this study are that adults with MCD (confirmed on repeat biopsy) can be treated with CyA for an extended period (as long as

78 months) without loss of renal function and with scant histologic evidence of CyA nephrotoxicity as long as the dose does not exceed 5.5 mg/kg/day. Not only did this treatment produce complete remission during CyA therapy in 19 of 22 (86%) of these steroid-dependent or steroid-resistant patients, remission was sustained (for 5 months to 6 years) in 10 patients in whom CyA was discontinued after 1 to 5 years. In this study, the factors that were most predictive of histologic CyA nephrotoxicity included dose greater than 5.5 mg/kg/day, the presence of renal insufficiency before treatment, and the percentage of glomeruli with lesions of FSGS on pretreatment biopsy specimen. A similar paucity of CyA nephrotoxicity in adult MCD was reported by Ittel and colleagues.⁴⁹ Although these authors did not observe permanent remission in their patients, they were able to maintain partial or complete remission in 15 patients with steroid-dependent or steroid-resistant MCD for 7 to 91 months. Only one patient showed mild interstitial fibrosis suggestive of CyA toxicity. CyA trough whole blood levels were kept at 50 to 150 ng/mL at a mean dose of approximately 4.5 mg/kg/day.

Evaluations of the nephrotoxicity of long-term CyA treatment in children with MCD have included small numbers of patients and have had varied results. Inoue and colleagues⁵⁶ found histologic evidence of CyA toxicity in 7 of 13 children after a 2-year course of treatment for steroid-dependent MCD. The changes were considered moderate or severe in five of the patients. Much lower rates of CyA toxicity have been reported by others. Gregory and colleagues⁵⁷ performed biopsies on 12 of 22 children with steroid-dependent or steroid-resistant nephrotic syndrome after 12 to 41 months of CyA treatment. Two patients, both with IgM nephropathy, had progression of interstitial fibrosis and tubular atrophy present on pre-CyA biopsy specimens. None of the other patients had histologic evidence of nephrotoxicity. Hino and colleagues⁵⁸ found mild tubular atrophy with striped interstitial fibrosis in 2 of 13 children on whom a biopsy was performed after 12 to 43 months of CyA treatment, and Kano and colleagues⁵⁹ found such changes in only 1 of 14 children treated with low-dose CyA (1.6–3.1 mg/kg/day) for 2 years. In both of these studies, there was no apparent correlation between either the CyA dose or mean trough level and the development of histologic changes, and the serum creatinine did not increase after CyA treatment in those patients with biopsy evidence of nephrotoxicity. The stability of the serum creatinine was particularly noteworthy in the study by Hino and colleagues⁵⁸ because creatinine values were available at 2 to 10.5 years after completion of the CyA treatment.

Thus, although it has yet to be determined whether prolonged treatment with CyA is curative or simply sustains remission until the disease “burns out,” it is reasonable to consider maintenance CyA as an alternative to cyclophosphamide in adults with severe steroid-dependent, steroid-resistant, or even frequently relapsing disease, especially those in their reproductive years. Indeed, some authorities argue that short-term, low-dose CyA might even be preferable to glucocorticoids as first-line therapy.

Treatment with Mycophenolate Mofetil

Although there are as yet no controlled studies to support the use of mycophenolate mofetil (MMF) in MCD, several small case series in children and adults⁶⁰⁻⁶⁴ and personal experience

Table 19-4 Studies of Cyclosporine A in Minimal Change Disease

Ref.	Design	Clinical Setting*	Mean Follow-up (yr)	Treatment	Control	RESULTS†				
						Rx	Cntrl	RELAPSE (%)	Comments	
Ponticelli et al ⁴⁵ (N = 41)	Prospective, controlled, randomized	Children, adults, SR, MCD, FSGS	1.5 (median)	CyA 6 mo, then taper	Supportive therapy	32 P < .05	0	69 [‡]	NA	Complete or partial remission in 60% of CyA group vs. 16% of Cntrl

in adults have shown that remission can be maintained in a high proportion of patients with steroid-dependent or frequently relapsing MCD, including patients who have had a relapse after discontinuation of CyA treatment. In the series of MMF-treated adults with proteinuric glomerular diseases reported by Choi and colleagues,⁶⁰ five of six patients with steroid-dependent MCD were able to discontinue steroid use. Likewise, durable remission, decrease in relapse rate, and steroid sparing have been reported in children with steroid- and CyA-dependent or frequently relapsing MCD.^{61,64} Unfortunately, MMF does not appear to be any better than CyA in effecting a cure, as a high proportion of patients had a relapse after MMF treatment was discontinued.^{61,64} Given that MMF is generally better tolerated and is less toxic than CyA and cyclophosphamide, it would be the preferred choice in patients who require long-term maintenance therapy to prevent relapse if future studies confirm the current experience. Unfortunately, MMF has not proved to be effective in inducing remission in steroid-resistant MCD in more than a few anecdotal cases.^{61,64}

Treatment with Azathioprine, Levamisole, and Rituximab

Most of the data on the use of azathioprine in MCD comes from anecdotal reports, and the general view is that this drug has limited value in the treatment of this disease. In the only controlled study examining its use in MCD, Abramowicz and colleagues⁶⁵ found that azathioprine was ineffective in 31 children with steroid-resistant nephrotic syndrome (only 5 of the patients had MCD). More promising results were reported by Cade and colleagues⁶⁶ who treated 13 adults (8 with MCD) with prolonged courses (4 years) of azathioprine and found that all the patients had a progressive decrease in proteinuria and ultimately achieved complete remission. The results of this study and the decreased toxicity profile of azathioprine compared with the alkylating agents led some investigators to argue for further evaluation of its efficacy in MCD.¹⁸ However, interest in azathioprine has lessened in recent years as experience with MMF has accrued for a variety of glomerular diseases.

Levamisole, an immunopotentiating drug, has been used as a steroid-sparing agent in children with frequently relapsing MCD. The British Society of Pediatric Nephrology performed a controlled study of 61 children treated with levamisole or placebo after a steroid-induced remission.⁶⁷ Fourteen of 31 patients treated with levamisole were in remission at the end of a 3- to 4-month treatment period compared with three of 30 patients treated with a placebo. However, discontinuation of the drug was associated with a rapid relapse, and only four of the responders were still in remission at the end of the study. A second controlled trial of levamisole found that treatment with this drug resulted in a statistically nonsignificant increase in the proportion of patients with a sustained glucocorticoid-induced remission.⁶⁸ Multiple uncontrolled studies suggest a potential role for this drug as a steroid-sparing agent, but adequately powered randomized trials are needed to evaluate its long-term efficacy and safety.⁶⁹

Rituximab is a monoclonal antibody directed against CD20, a cell-surface molecule on B lymphocytes. A case report of attainment of a long-lasting remission with rituximab of frequently relapsing MCD in a 23-year-old woman who had

previously been treated with glucocorticoids, CyA, cyclophosphamide, MMF, and basiliximab (an anti-CD25 antibody directed against T lymphocytes) suggests a possible role for B cells in MCD, a disease that has generally been viewed as resulting from disordered T-lymphocyte function.⁷⁰

SPECIFIC RECOMMENDATIONS

Although maintaining MCD patients free of urine protein could probably be accomplished in more than 90% of cases using prednisone, cyclophosphamide, or CyA, such regimens are associated with significant toxicity. Thus, the therapeutic challenge of this disease is to identify the treatment with the highest probability of producing a sustained remission with the lowest risk of toxicity. The literature reviewed earlier is helpful in this regard but is not conclusive. Individual patient variation remains a major factor in choosing among treatment options. Therefore, the recommendations that follow (summarized in Figs. 19-1 and 19-2) should be viewed as flexible guidelines rather than definitive treatment protocols.

Regardless of the specific therapy used, symptomatic management of nephrotic patients should include dietary sodium and fluid restriction to prevent further edema formation. Diuretics may be necessary before specific therapy takes effect, and high doses are often required because of the marked sodium avidity that accompanies nephrotic syndrome. Angiotensin-converting enzyme inhibitors may decrease proteinuria in nephrotic patients and thus may have a role during initial management or in steroid-resistant patients; however, one should be alert to the possibility of an acute reduction in the glomerular filtration rate from alterations in intrarenal hemodynamics. To prevent glucocorticoid-induced osteoporosis, we recommend a daily intake (either through diet or supplements) of 1500 mg of calcium and 400 to 800 IU of vitamin D (with age-appropriate decreases in children) for all patients during glucocorticoid therapy. Additionally, for adult patients receiving long-term glucocorticoid treatment, it is appropriate to obtain a baseline bone mineral density measurement and to consider further prophylactic treatment with bisphosphonates.⁷¹ Although the risk of accelerated atherogenesis in patients with MCD is debated, the use of lipid-lowering agents, preferably 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, should be considered in hyperlipidemic patients with sustained proteinuria. Nephrotic patients are also at risk for thromboembolic disease; however, routine anticoagulation is not recommended for patients with MCD.

Almost all children with idiopathic nephrotic syndrome should be treated empirically with glucocorticoids because of the high probability that they have MCD. A typical regimen for a first attack is as follows: prednisone 60 mg/m²/day with a maximum of 80 mg/day, given as a single daily dose for 4 weeks. The dose is reduced to 35 to 40 mg/m² every other day for the subsequent 4 weeks and then tapered off over an additional 4 weeks. A more gradual tapering scheme consisting of alternate-day dosing at 60 mg/m² for 8 weeks after the initial 4 weeks of daily therapy, with tapering over an additional 4 to 6 weeks, such that the total duration of therapy is approximately 4 to 5 months, is preferred by some. A decrease in proteinuria will occur in most children after 2 weeks of treatment. If proteinuria persists in a child after 4 weeks of treatment, a renal biopsy should be performed.

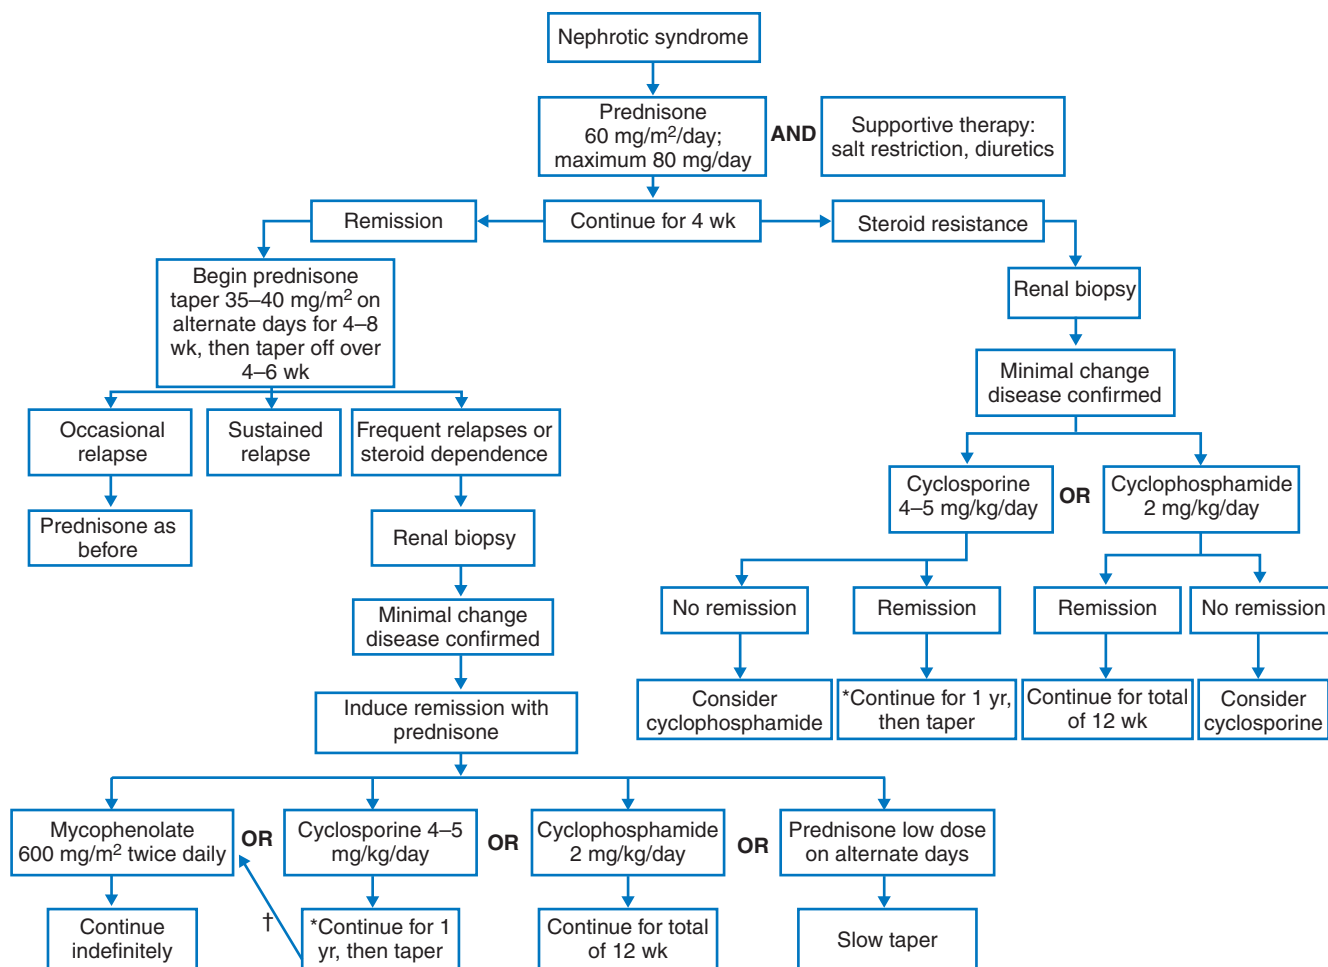

Figure 19-1 Treatment algorithm for children with minimal change disease. *Renal biopsy should be performed to evaluate for cyclosporine toxicity before continuing cyclosporine treatment beyond 1 year. †Patients who relapse after withdrawal of cyclosporine may be maintained on mycophenolate mofetil.

Since MCD accounts for only 10% to 15% of cases of nephrotic syndrome in adults, a renal biopsy should be performed before initiating therapy. If secondary causes of MCD have been eliminated, we recommend treatment with prednisone at 1 mg/kg as a single daily dose. Because the response to glucocorticoids occurs less rapidly in adults than in children, the prednisone therapy should be continued for 12 weeks before the disease is considered to be steroid resistant. A progressive shift to alternate-day dosing beginning at 1 mg/kg should be started 1 week after proteinuria remits and tapered off over 2 to 3 months. Initial treatment with alternate-day prednisone at 2 mg/kg, with a maximum dose of 120 mg every other day, may also be effective and have fewer side effects, but there is less published experience with such a regimen.

Treatment of MCD relapses must take into account their frequency and the severity of glucocorticoid-related toxicities. A first relapse in either a child or adult can usually be treated with a second course of prednisone with tapering beginning as soon as remission occurs. We recommend gradual, rather than rapid, tapering of the second course of prednisone therapy because available data suggest that this results in a lower probability of a subsequent relapse. How-

ever, this approach may not necessarily result in a lower cumulative glucocorticoid dose.

If a relapse occurs during prednisone tapering, the prednisone dose should be increased immediately to the level at which remission occurred. In most cases, remission will result, and a relatively rapid taper can begin. As the dose at which the relapse occurred is approached, the rate of tapering should be made more gradual in order to decrease the likelihood of a second relapse. We recommend that the patient or parent monitor the urine for protein by using a dipstick during the taper to facilitate early detection of relapse.

In some cases of frequently relapsing or steroid-dependent MCD, remission can be sustained with long-term, low-dose, alternate-day prednisone therapy. However, the doses required to maintain remission may be intolerably high, in which case alkylating agents should be considered. Indeed, elderly patients may tolerate cyclophosphamide better than glucocorticoids. Although cyclophosphamide and chlorambucil appear to have similar efficacy, we prefer cyclophosphamide 2 mg/kg/day for 8 to 12 weeks for frequently relapsing disease and 12 weeks for steroid-dependent disease. Prednisone is usually administered with cyclophosphamide, although this may not necessarily improve efficacy. Patients are often already taking glucocorticoids

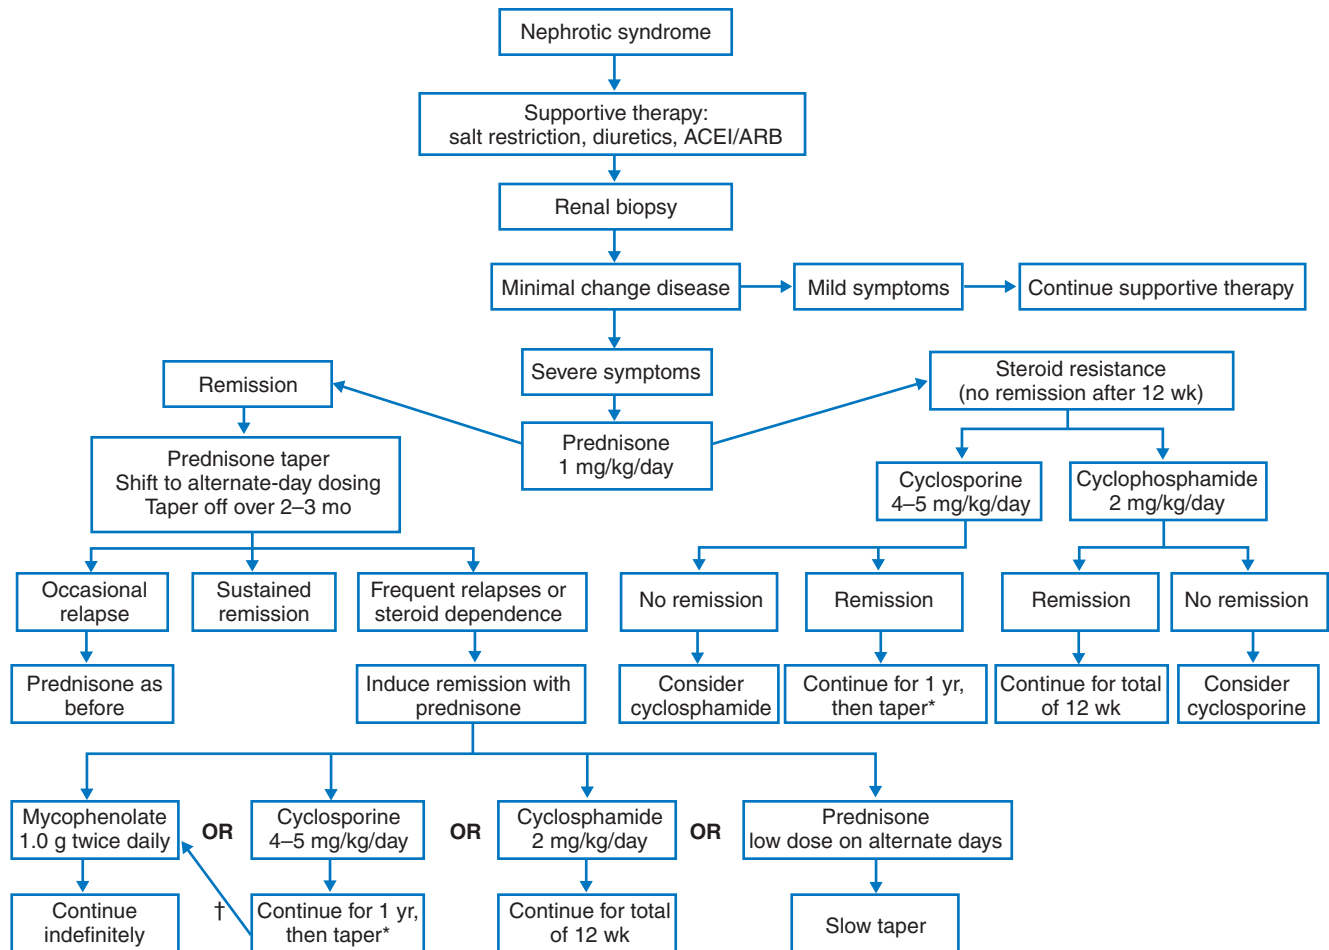

Figure 19-2 Treatment algorithm for adults with minimal change disease. *Renal biopsy should be performed to evaluate for cyclosporine toxicity before continuing cyclosporine treatment beyond 1 year. †Patients who relapse after withdrawal of cyclosporine may be maintained on mycophenolate mofetil. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.

when the decision is made to start therapy with an alkylating agent. A potential benefit of inducing a remission with glucocorticoids before starting cyclophosphamide therapy is that it may allow the high fluid intake required for protection against cystitis. The usual dose of chlorambucil is 0.1 to 0.2 mg/kg/day. The cumulative doses of cyclophosphamide and chlorambucil should be kept to less than 200 mg/kg and 10 mg/kg, respectively, to avoid gonadal toxicity. The leukocyte count should be monitored during treatment with alkylating agents with dose adjustments as needed to maintain the count between 2000 and 5000 cells/mm³.

CyA is a reasonable option for patients who have a relapse after one or two courses of cyclophosphamide therapy, and we believe that it is a good alternative to an alkylating agent in young adults. The dose of CyA should be initiated at 4 to 5 mg/kg/day in adults and 4 to 6 mg/kg/day in children and adjusted to maintain a whole blood trough level by monoclonal antibody assay of 100 to 150 ng/mL. Treatment should be continued for 1 year and then tapered. If a relapse occurs, CyA should be restarted at the dose that maintained remission but in adults should not exceed 5.5 mg/kg/day. If a response to CyA has not occurred within 3 to 4 months, the drug should be discontinued. It is important to note that the optimal dose

for long-term CyA therapy in children has not been established. In the studies describing outcomes with CyA treatment for longer than 1 year, many of the children had mean trough levels that were less than 100 ng/mL. Steroid-dependent patients may require low doses of prednisone together with CyA to maintain remission and are more likely than those with frequent relapses to have a relapse after discontinuation of CyA therapy. Serum creatinine and creatinine clearance should be monitored periodically during administration of CyA; however, early CyA nephrotoxicity may not be accompanied by changes in these measurements. Therefore, repeat renal biopsy to look for nephrotoxicity is advisable in patients requiring treatment with CyA for more than 1 year.

At present, MMF has a role as maintenance therapy in patients who experience a relapse whenever CyA or cyclophosphamide are discontinued, but if results of several case series are confirmed, it may become the treatment of choice in patients with frequent relapses or steroid-dependent patients.

Steroid-resistant MCD is rare. Children who have nephrotic syndrome that does not remit with prednisone should undergo renal biopsy, as it is likely that they actually have FSGS. Adults who have presumed MCD based on a biopsy performed before treatment may actually have had FSGS that

was not apparent on the initial biopsy specimen. Steroid-resistant MCD can be treated with alkylating agents or with CyA using the regimens described for frequently relapsing or steroid-dependent disease, but such patients are less likely to respond.

In conclusion, despite many years of accumulated experience with immunosuppressive agents, the treatment of frequently relapsing MCD remains a challenge. The approach that we have outlined favors a shift from repeated courses of high-dose glucocorticoids or alkylating agents to a maintenance type of treatment with longer courses of low-dose, alternate-day glucocorticoids, CyA, or MMF. In the final analysis, however, treatment must be customized for each patient based on clinical characteristics, disease course, and treatment-associated toxicities.

Focal segmental glomerulosclerosis (FSGS) is a clinicopathologic entity defined by proteinuria and segmental glomerular scars involving some but not all glomeruli. It is a leading cause of nephrotic syndrome in adults and is the predominant cause of end-stage renal disease (ESRD) among children.¹ The incidence of FSGS has been increasing over the past two decades, with idiopathic FSGS responsible for 3.3% of incident ESRD cases in the United States. FSGS accounts for 7% to 35% of glomerular lesions in children and adults undergoing renal biopsy for nephrotic syndrome.²⁻⁷ Additionally, the prevalence of FSGS in nephrotic black patients is two to four times that in white patients (50%–60% vs. 20%–25%).^{6,7}

Few clinical features distinguish patients with new-onset idiopathic nephrotic syndrome due to minimal change nephropathy (MCN) versus FSGS. FSGS is distinguished from MCN by a higher frequency of hematuria and a poorer response to immunosuppressive drug therapies. Although patients with FSGS are more likely to have subnephrotic proteinuria than those with MCN, FSGS patients have a higher frequency of persistent nephrotic syndrome and a greater risk of progression to ESRD. It often progresses over several years to renal insufficiency and hypertension. Approximately 50% of patients with idiopathic FSGS progress to ESRD within 10 years of diagnosis. The progressive nature of this lesion and the high recurrence rate in transplanted kidneys have made the treatment of primary FSGS a serious concern to nephrologists.

FSGS, defined by the characteristic pathologic findings, is a complex syndrome associated with multiple etiologies and variable clinical severity (Table 20-1).⁸ FSGS can be classified into idiopathic, genetic, and reactive forms (the last including postadaptive and medication-associated FSGS). Idiopathic FSGS accounts for 10% of all children presenting with nephrotic syndrome.⁹ Although FSGS generally carries a poor prognosis, considerable heterogeneity exists in clinical features, renal histology, and outcome. The existing data guiding the treatment of FSGS are mostly drawn from patients with the idiopathic form, and significant uncertainty exists regarding the optimal therapy approach for postadaptive and genetic forms of FSGS.

ETIOLOGY

FSGS is a disease of podocytes with diverse causes. Until recently, the understanding of glomerular injury in FSGS has been limited to more broad concepts and little has been known about biochemical components essential for the glomerular filtration barrier. At the core of pathogenesis of MCN and FSGS, podocyte dysfunction has now been demonstrated as having a particular importance in mediating glomerular permselectivity. The recent series of discoveries has identified specific proteins that are critical to podocyte function, including cellular signaling and maintenance of cytoskeletal structure.

Table 20-1 Taxonomy of the Podocytopathies

	Idiopathic Forms	Genetic Forms	Reactive Forms
Minimal change nephropathy	Idiopathic Steroid sensitive Steroid resistant	Nonsyndromic <i>NPHS2</i> Syndromic <i>DYSF</i> (limb-girdle muscular dystrophy 2B)	Reactive Hodgkin's disease Immunogenic stimuli Medication associated Nonsteroidal anti-inflammatory agents, gold, penicillamine, lithium, interferon alfa and beta, pamidronate
Focal segmental glomerulosclerosis	Idiopathic	Nonsyndromic <i>NPHS1</i> + <i>NPHS2</i> <i>NPHS2</i> <i>ACTN4</i> <i>CD2AP</i> <i>TRPC6</i> <i>WT1</i> mtDNA tRNA ^{Leu} <i>PLCE1</i> Syndromic <i>WT1</i> (Frasier) mtDNA tRNA ^{Leu} (MELAS) <i>PAX2</i> (renal-coloboma syndrome with oligomeganephronia) <i>LMX1B</i> (nail-patella) <i>COQ2</i> <i>ITGB4</i> <i>COL4A3, A4, A5</i> (Alport's) <i>GLA</i> (Fabry's)	Postadaptive Reduced nephron mass Renal dysplasia, surgical renal mass reduction, reflux nephropathy, chronic interstitial nephritis Initially normal nephron mass Obesity, increased muscle mass, sickle cell anemia, cyanotic congenital heart disease, hypertension* Medication associated Cyclosporine, tacrolimus, interferon alfa, lithium, pamidronate
Diffuse mesangial sclerosis	Idiopathic	Nonsyndromic <i>NPHS1</i> (Congenital nephrotic syndrome, Finnish type) <i>WT1</i> <i>NPHS2</i> <i>PLCE1</i> Syndromic <i>LAMB2</i> (Pierson) <i>WT1</i> (Denys-Drash)	
Collapsing glomerulopathy	Idiopathic	Nonsyndromic <i>COQ2</i> Syndromic <i>ZMPSTEZ4</i> Action myoclonus renal failure	Infection Viruses (HIV-1, parvovirus B19,* CMV*) Others (Loa loa filariasis,* visceral leishmaniasis,* <i>Mycobacterium tuberculosis</i> *) Disease associations Adult Still's disease,* thrombotic microangiopathy, multiple myeloma* Medication Interferon alfa, pamidronate

*Disease associations for which causation has not been clearly established. The primary podocytopathies are organized into four morphologic patterns and three etiologic categories. Named syndromes are shown. The genes, encoded proteins, and syndrome abbreviations are as follows: *ACTN4*, α -actinin-4; *CD2AP*, CD2-associated protein; *CMV*, cytomegalovirus; *COL4*, type IV collagen; *COQ2*, coenzyme Q synthetase 2; *DYSF*, dysferlin; *GLA*, α -galactosidase A; HIV-1, human immunodeficiency virus type 1; *ITGB4*, B₄-integrin; *LAMB2*, laminin B₂ chain; *LMX1B*, Lim homeobox transcription factor 1B; MELAS, mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes; mtDNA, mitochondrial DNA; *NPHS1*, nephrin; *NPHS2*, podocin; *PAX2*, paired homeobox protein 2; *PLCE1*, phospholipase C ϵ ; *TRPC6*, transient receptor potential cation channel, member 6; *WT1*, Wilms' tumor-1.

This exciting and rapidly expanding field of podocyte biology should provide new avenues to gain better understanding of molecular mechanisms underlying foot process effacement, proteinuria, and progressive glomerulosclerosis.

Experimental and clinical studies have shown that podocyte injury can occur from the mutations in podocyte proteins, toxins, viral infections, immunologic factors, and injury from preexisting or ongoing insults (such as obesity and possibly hypertension). Thus, although some forms of FSGS reflect innate abnormalities, others result from the adaptive process of various injuries, including previous glomerular injury.

Idiopathic Focal Segmental Glomerulosclerosis

Like MCN, some cases of idiopathic FSGS may have an immunogenic component in the setting of genetic susceptibility. In some cases of idiopathic FSGS, circulating permeability factor may lead to proteinuria, as suggested by a case of a nephrotic mother who transmitted the factor to her child in utero.¹⁰ In addition, rapid recurrence of proteinuria after transplantation in some cases supports the hypothesis that circulating factor increases the permeability of the glomerular filtration barrier. Permeability factor studies over the past decade, however, have produced conflicting data with limited clinical applicability.

Postadaptive Focal Segmental Glomerulosclerosis

Postadaptive FSGS, or secondary FSGS, arises as a consequence of structural adaptation (glomerular hypertrophy) and/or functional adaptation (glomerular hyperperfusion and hyperfiltration) to either reduced nephron mass or particular disease states (obesity, sickle cell anemia, cyanotic congenital heart disease, and others). The term *postadaptive FSGS* was selected to emphasize that there is believed to be a phase of adaptation that includes glomerular hyperfiltration and glomerulomegaly and that the adaptive phase is followed by the focal and segmental scarring and absolute decrease in podocyte numbers that characterize FSGS. The diagnosis of postadaptive FSGS remains a challenge, given that there are no pathologic hallmarks unique to this form. As the postadaptive form may have different responses to therapy, however, the distinction from the other forms of FSGS becomes important.

Currently available methods to identify postadaptive FSGS include measuring glomerular size, evaluating the degree of foot process effacement on electron microscopy, and determining the fraction of glomeruli with perihilar sclerosis (Table 20-2). Glomerulomegaly may be one of the few distinguishing features of postadaptive FSGS, particularly in obese patients. Obesity is associated with increased renal blood flow, glomerular filtration rate (GFR), and microalbuminuria, features that

Table 20-2 Clinical and Pathological Recognition of Postadaptive Focal Segmental Glomerulosclerosis

Feature	Utility	Limitations
High risk clinical setting		
1. Reduced nephron mass: renal dysplasia, ureteral reflux	++	The life-time incidence of postadaptive FSGS in these uncommon or rare conditions is probably relatively high, although precise incidence figures are not available
2. Initially normal renal mass: sickle cell anemia, cyanotic congenital heart disease		
Moderate- or low-risk clinical setting: obesity, hypertension	+	These are common clinical conditions, for which the lifetime incidence of postadaptive FSGS is probably low; idiopathic FSGS may also occur in these individuals.
Nephrotic proteinuria without edema or hypoalbuminemia	+	This pattern is more common in postadaptive FSGS but also occurs in idiopathic FSGS ¹³⁰
Perihilar FSGS variant: at least one glomerular showing perihilar hyalinosis and perihilar hyalinosis and/or sclerosis involving > 50% glomeruli	++	Sensitivity and specificity remain to be determined
Glomerulomegaly (average glomerular diameter > 185 μ m)	+++	Requires a sufficient number of glomeruli (probably 5–10), multiple levels (possibly 4), and measurement of glomeruli cut at or near hilus. ¹³¹
Podocyte foot process effacement	+	There are significant group differences between idiopathic FSGS and postadaptive FSGS, but there is considerable overlap between the groups, so this has limited utility in a particular cases

When confronted with a renal biopsy specimen that shows FSGS, no history suggesting a genetic cause of FSGS (onset in childhood, family history of FSGS, extrarenal manifestations), and no use of FSGS-associated medication, the pathologist and clinician must weigh the likelihood of idiopathic FSGS versus postadaptive FSGS. Multiple features must be considered in making this distinction. FSGS, focal segmental glomerulosclerosis.

it shares with diabetes mellitus. The mechanisms for these renal abnormalities are not well understood, but the relationship between metabolic syndrome and the risk of renal disease has been well established in recent years. Contributing factors likely include increased renal venous pressure, hyperlipidemia, and increased production of vasoactive and fibrogenic substances by adipocytes, including angiotensin II, insulin, leptin, and transforming growth factor β_1 .

It remains unclear whether glomerulomegaly is a necessary precursor lesion to postadaptive FSGS and whether there is a specific genetic susceptibility to developing postadaptive FSGS, as most obese people do not develop glomerulopathy. Whether an individual threshold body mass index for the appearance of glomerulomegaly and FSGS exists is unknown. More research is required to understand the molecular pathways by which increased fat/muscle mass or body mass index lead to glomerular hyperfiltration.

Another differentiating pathologic feature of postadaptive FSGS from idiopathic FSGS is the extent of foot process effacement. Kambham and colleagues¹¹ found that obesity associated–glomerulopathy in the setting of a body mass index greater than 30 kg/m² has a mean foot process effacement of 40% (range, 10%–100%), whereas idiopathic FSGS patients have a mean foot process effacement of 75% (range, 30%–100%). Although there were significant differences in the group means for the extent of podocyte foot process effacement in idiopathic FSGS versus postadaptive FSGS, there was much overlap, so the utility of particular diagnostic criteria (such as podocyte foot process effacement > 50% in the former and < 50% in the latter) is limited.¹²

Another difference in renal histology is that the initial lesion in postadaptive FSGS is preferentially localized to the hilum. Rat models of FSGS that are characterized by increased transcapillary hydraulic pressure, for example, possibly emphasizing the susceptibility of podocytes to injury under increased vascular wall tension.^{13,14} Although intriguing, the application of such knowledge is limited in clinical practice, given the difficulty of correctly identifying the location of the sclerosis in limited number of glomeruli. It remains to be determined whether the perihilar variant of idiopathic FSGS also arises as a consequence of glomerular overload from an unrecognized risk factor or biologic process.

Postadaptive FSGS may have a milder clinical course; in comparing obesity-related FSGS and idiopathic FSGS, Khambam and colleagues¹¹ reported that the patients with obesity-associated glomerulopathy had lower levels of proteinuria and a more indolent course (progression to ESRD 4% vs. 42%). By contrast, Praga and colleagues¹⁵ found that the outcome in obesity-related disease was almost as poor as that of idiopathic FSGS. In this study, 80% of patients had nephrotic range proteinuria at presentation or on follow-up. The level of proteinuria correlated with the body mass index. Despite high proteinuria, hypoalbuminemia and edema were absent, unlike in patients with idiopathic FSGS. The final diagnosis of postadaptive FSGS will depend on carefully integrated data that reflect on medical history, comorbidities, family history, medication history, and the renal pathology.

Genetic Focal Segmental Glomerulosclerosis

One of the areas of intense research has focused on the podocytopathy that underlies FSGS. Investigations illustrating the gene mutations altering protein structure or function crucial

to podocytes represented major progress (Table 20-3). The first of the recent discoveries began with the cloning of *NPHS1*, the gene that encodes nephrin and is mutated in congenital nephrotic syndrome.¹⁶ Nephrin localizes to the slit diaphragm and plays a critical role in glomerular permselectivity. Mutations in *ACTN4*, the gene encoding α -actinin 4, an actin filament cross-linking protein important for cytoskeletal function and highly expressed in the glomerular podocyte, cause an autosomal dominant form of FSGS.¹⁷ Mutations in *NPHS2*, the gene encoding podocin that is an integral podocyte protein, causes autosomal recessive FSGS with early onset (age typically younger than 20 years) and rapid progression to ESRD.¹⁸ Another example leading to defective slit diaphragm is deletion of CD2-associated protein; it leads to nephrotic proteinuria in mice and possibly humans.¹⁹ Some mutations may lead to altered trafficking or intracellular retention of the abnormal proteins, suggesting that potential targets for future therapy include chaperones to ameliorate processing defects.²⁰ Recent studies suggest that approximately 20% of children with idiopathic FSGS have inherited defects in podocyte proteins that underlie their diseases.²¹

PATHOLOGY

The characteristic renal pathology of FSGS includes segmental areas of podocyte damage and detachment and solidification of glomerular capillaries associated with a marked local increase in collagen accumulation. In many cases, the scar contains areas of hyalinosis. Adhesions or synechiae to Bowman's capsule are common. The uninvolved portions of the glomeruli with segmental sclerosis and the remaining glomeruli in the biopsy are essentially normal.

Immunofluorescence typically shows deposits of IgM and C3 within the segmental scars and concentrated in the hyalinosis lesions. The major ultrastructural finding in nonsclerotic glomerular capillaries is foot process effacement, which varies from mild to severe. In general, the degree of fusion correlates with the severity of proteinuria.

D'Agati and colleagues²² have proposed a working classification (the Columbia classification) for idiopathic FSGS that comprises five categories: collapsing variant, tip lesion, cellular lesion, perihilar variant, plus a final category for those cases that do not have the diagnostic criteria for the other categories, not otherwise specified, corresponding to classic FSGS. These distinctive pathologic subtypes of FSGS may represent differences in pathogenesis. Collapsing FSGS is a form of FSGS that has been associated with viral infections, notably human immunodeficiency virus, and follows a particularly aggressive course. Patients with the collapsing variant of idiopathic FSGS have a strikingly poor renal survival, with 70% probability of ESRD at 2 years.²³ Because the collapsing variant significantly differs histologically and clinically from other variants, some investigators argue that collapsing glomerulopathy (CG) should be a separate entity from FSGS altogether.⁸

CLINICAL PRESENTATION AND COURSE

The presenting feature in all patients with FSGS is proteinuria, frequently resulting in the nephrotic syndrome, although many patients, particularly adults, may present with nonnephrotic

Table 20-3 Genetic Causes of Human Podocyte Diseases

Gene	Gene Product	Function	Inheritance Chromosome	Renal Syndrome	Prevalence	Extrarenal Findings
<i>NPHS1</i>	Nephrin	Slit-diaphragm complex	AR 19q13.1	Congenital nephrotic syndrome, infantile onset FSGS	Insufficient data	None
<i>NPHS2</i>	Podocin	Slit-diaphragm complex	AR 1q25-31	FSGS onset < 20 yr	Up to 20% of familial or sporadic pediatric FSGS	None

range proteinuria (<3.5 g/day). In addition, microscopic hematuria, hypertension, and renal insufficiency are common presenting features.

The clinical course and prognosis of FSGS patients are influenced by their presenting features, the histologic characteristics, and response to the therapy. The presence of nephrotic range proteinuria (>3.5 g/day) has been consistently associated with poor outcome, with 50% of patients reaching ESRD within 6 to 8 years (Table 20-4).²⁴ Massive proteinuria (>10 g/day) is predictive of even worse outcome, with the possibility of reaching ESRD within 3 years of the diagnosis.^{25,26} In contrast, nonnephrotic patients tend to have more favorable prognosis, with renal survival of greater than 80% after 10 years. Additional clinical features of prognostic significance include serum creatinine at presentation and race. Patients presenting with serum creatinine greater than 1.3 mg/dL have significantly higher risk of renal demise, irrespective of the degree of proteinuria.^{24,27} Some investigators have also noted that black race portends a poorer prognosis with more rapid decline toward ESRD.⁶ Others argue that there is no racial difference in renal survival when the analysis is restricted only to nephrotic patients.²⁸

Another important predictor of renal outcome is the response to therapy. A retrospective study evaluating a long-term outcome in both children and adults suggested that the achievement of complete remission is the most significant factor determining the clinical course; in both age groups, those

with complete remission had a renal survival rate of 100% at 10 years.²⁹ Those without a complete remission generally progressed with a 10-year renal survival rate of 62% in adults and 58% in children. Achievement of partial remission and its maintenance are also important, with implications for both slowing the progression rate and improving renal survival.³⁰

The prognostic importance of histology in FSGS has also been extensively studied.^{23,31-33} The degree of interstitial fibrosis ($\geq 20\%$) has been demonstrated consistently to predict poor renal outcome. In addition, the presence of diffuse mesangial hypercellularity has been associated with more rapid decline of renal function, but this relationship has not been uniformly confirmed in larger studies. The distinct pathologic variants of FSGS, as described by D'Agati,¹² have also been studied to explain the variable clinical course. Among the five pathologic variants of idiopathic FSGS (collapsing, cellular, glomerular tip lesion, perihilar, and not otherwise specified), collapsing FSGS has the highest rate of renal insufficiency at presentation with chronic tubulointerstitial disease, fewest remissions, and highest rate of ESRD.^{23,33} In contrast, patients with tip lesion FSGS tend to be older and have the highest remission rate and lowest rate of ESRD. Retrospective analysis has revealed that cellular FSGS also portends poorer prognosis.³¹ Patients with the cellular lesion are more often black and severely proteinuric and appear to have higher risk of progressing to ESRD, with poor response to treatment.

Table 20-4 Long-Term Outcome in Focal Segmental Glomerulosclerosis

Location, Year	Population	Average Observation (yr)	Complete Remission (%)	Persistent				Lost to Follow-up (%)	Ref.
				Renal Abnormalities (%)	CKD (%)	ESRD (%)	Nonrenal Death (%)		
London, 1978	12 children, 28 adults	9.5	10	18	20	50	2	0	132
Quebec, 1981	32 children	8	24	40	4	20	12	0	133
Southwest United States, 1985	75 children	4.8	11	37	23	21	0	8	134
Hong Kong, 1991	2 children, 30 adults	6.8	9			16			135
Ontario, Canada, 1998	38 children, 55 adults	11	42 22	13 24	11 13	34 42	0 (4)	0	136
Christchurch, New Zealand, 2000	165 adults	6.9	29	8	16	44			46

All reports that included at least 30 patients provided group outcomes after an average duration of more than 4 years. Most patients appear to have had idiopathic focal segmental glomerulosclerosis (FSGS), but some reports included a limited number of postadaptive FSGS or focal global glomerulosclerosis. Children are defined as individuals younger than 15 to 18 years at the time of initial presentation, depending on reference. When data are presented for children and adults separately, the data for children are presented first. Chronic kidney disease (CKD) is defined as an impaired glomerular filtration rate. The proportion of patients experiencing nonrenal deaths is shown in parentheses when these patients are also included in another category. Empty cells indicate that no data were provided from the report.

The ability to accurately delineate the prognostic significance of these pathologic variants of idiopathic FSGS will require careful analysis of long-term data of large numbers of patients. The multivariate analyses of all the clinical and histologic features of FSGS suggest that only the achievement of a remission in proteinuria is the independently significant predictor of ESRD. Improving our understanding of the pathophysiology and developing more effective therapy, therefore, is critical to reduce the profound morbidity associated with FSGS.

TREATMENT OF FOCAL SEGMENTAL GLOMERULOSCLEROSIS: BACKGROUND

The goal of treatment of all podocyte diseases is to reduce proteinuria to normal or to the lowest level possible. Regardless of the choice of immunosuppressive therapy, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers, given their antiproteinuric and antifibrotic effects, are important components of the treatment of FSGS. Hyperlipidemia and hypertension should also be aggressively treated in nephrotic patients. The following section focuses on the efficacy of immunosuppressive agents.

Initial Therapy of Idiopathic Focal Segmental Glomerulosclerosis

Glucocorticoids

Glucocorticoids remain the main therapeutic agent in nephrotic FSGS, as for MCN. Because children undergo renal biopsy only if they have not responded to glucocorticoids, they may be considered steroid resistant by the time they are diagnosed as having FSGS. Compared with the response rates in MCN, the initial response to conventional doses of glucocorticoid therapy for idiopathic FSGS is poor. The initial treatment for primary FSGS in children has followed the regimen outlined for the treatment of primary nephrotic syndrome by the International Study of Kidney Disease in Children. This consists of prednisone 60 mg/m²/day (up to 80 mg/day) for 4 to 6 weeks, followed by 40 mg/m²/day (up to 60 mg/day) every other day for an additional 4 to 6 weeks, and then discontinued.² Although this regimen has been found to be satisfactory for the treatment of children with the highly steroid-sensitive lesion of minimal change glomerulopathy, the data suggest that it may be inadequate for those with primary FSGS.

Although pediatric studies of MCN have suggested that longer durations and higher doses of glucocorticoids result in significant decrease in the relapse rate,^{34–40} the optimal duration of steroid therapy is not known. Retrospective studies of FSGS have suggested that treatment beyond 6 months does not appear to be beneficial.^{29,41} The best predictor of long-term prognosis remains complete remission because the 15-year renal survival rate in both children and adults with complete remission was 100% compared with 51% in those who remain unresponsive.²⁹ Half of the unresponsive patients had doubled their serum creatinine by 4 years. Based on these data, experts recommend that nephrotic children with idiopathic FSGS be treated with glucocorticoids for up to 6 months. The overall duration of the initial prednisone dose and rapidity of the steroid taper depend on whether and how quickly a complete or partial remission is attained.

Korbet and colleagues,^{41–44} who have analyzed the efficacy of steroid therapy in adults with FSGS, have noted that the highest complete remission rates (>30%) were observed in cases treated for longer than 5 months and the lowest rates (≤20%) in patients treated for 2 months or less. Table 20-5 summarizes the results of uncontrolled clinical trials evaluating the efficacy of glucocorticoid therapy in FSGS.^{28,29,45–51} These trials include different durations of glucocorticoid therapy, and the overall response rate is typically less than 50%. Importantly, relapse rates are high, from 38% to 67%, although some of these patients may be brought to a second remission by additional glucocorticoid therapy or other therapies.

Because of the possibility of a delayed response, corticosteroid treatment must be sufficiently long. Among nephrotic adult patients with FSGS, approximately 30% may enter complete remission after a course of daily prednisone given at a dose of 1 mg/kg/day for at least 4 months.⁴⁴ Given the comorbidities associated with long-term high-dose prednisone therapy, many providers start a slow taper of prednisone after 8 to 12 weeks. Patients who are refractory to steroid therapy tend to have a significant risk of progression to ESRD. Many FSGS patients thus require cytotoxic agents or calcineurin inhibitors to either decrease steroid use or achieve remission.

Mechanisms of Glucocorticoid Efficacy

Glucocorticoids exert potent anti-inflammatory effects on leukocytes and inhibit expression of cytokines and adhesion molecules. Their effectiveness in a noninflammatory disease such as MCN or FSGS is thus difficult to understand. Given the recently discovered significance of the podocyte biology in the pathogenesis of nephrotic syndrome, multiple studies have investigated whether the therapeutic mechanism of glucocorticoids may be through a direct protective effect on podocytes. Using immortalized human podocytes, Xing and colleagues⁵² demonstrated that dexamethasone enhanced and accelerated podocyte maturation, with an especially striking effect on up-regulating expression of nephrin. Nephrin, a podocyte protein that plays a key role in regulating signaling pathways, is a critical component of the slit diaphragm regulating glomerular permselectivity. Dexamethasone also down-regulates cyclin kinase inhibitors, augmenting podocyte survival. In addition, dexamethasone treatment led to the down-regulation of vascular endothelial growth factor, which is normally produced by podocytes but is up-regulated in patients with MCN. Other studies have also suggested similar protective effects of glucocorticoids on podocytes to enhance recovery. Dexamethasone has been shown to increase intracellular levels of adenosine 5' triphosphate through up-regulation of mitochondrial genes, thereby allowing proper glycosylation of nephrin.⁵³ Other possible therapeutic mechanisms of glucocorticoids include enhancing recovery of podocytes via actin filament stabilization and preventing podocyte apoptosis.^{54,55} Therefore, the therapeutic effects of corticosteroids may stem from their direct action on podocytes to promote repair and survival rather than on their immunosuppressive effect. It is possible that the benefit seen with other immunosuppressive agents may also be explained by their direct action on podocyte physiology.

Treatment of Steroid-Refractory or Steroid-Resistant Patients

Cytotoxic Agents

The rationale for using alkylating agents, as with the use of other immunosuppressive agents, is based on the hypothesis that FSGS is a T cell–driven immunologic disease and on empirical data on response. The most common indication for cytotoxic agents such as cyclophosphamide or chlorambucil is steroid dependence. Steroid resistance, in contrast, is highly predictive of resistance to alkylating agents, particularly in adults. Although alkylating agents may yield complete remission in 51% of steroid-sensitive children, they may be effective in only approximately 17% of children who are steroid resistant.⁴⁴

In a randomized, controlled trial involving 60 steroid-resistant FSGS children, the efficacy of prednisone, dosed at 40 mg/m² on alternate days for a period of 12 months, and the same prednisone regimen plus a 90-day course of daily cyclophosphamide dosed at 2.5 mg/kg were compared.⁵⁶ In both groups, 25% of the children had complete resolution of proteinuria, but those who were treated with cyclophosphamide were 1.6 times more likely to experience a decrease in renal function, suggesting that cyclophosphamide therapy for children with steroid-resistant FSGS may be potentially harmful.

In contrast, there are multiple uncontrolled studies reporting variably beneficial effects of cyclophosphamide in steroid-resistant pediatric patients, with the rate of complete remission ranging from 22% to 66%.^{57–59} A recent retrospective study with a follow-up period of more than 10 years suggested that cyclophosphamide leads to complete remission in 43% of steroid-resistant children.⁶⁰ The mean duration to enter complete remission was 46 days (range, 8–78 days). More than 60% of the patients who achieved complete remission, however, suffered relapses requiring further immunosuppressive therapy with chlorambucil, vincristine, cyclosporine, or a second course of cyclophosphamide.

Considering the paucity of data from controlled trials and the long-term toxicity, cytotoxic agents are considered mostly inefficient and possibly hazardous in FSGS patients with steroid resistance. The efficacy of alkylating agents, however, may partly depend on certain host factors. In a recent South African retrospective analysis of 223 children, the authors noted that a majority of steroid-resistant Indian children treated with prednisone and cyclophosphamide achieved complete remission, whereas only a minority of steroid-resistant black children responded to the same combination.⁶¹ It is unclear whether the difference in the response truly reflects inherent host differences such as race or uncontrolled biases in a retrospective study design. The data regarding efficacy of alkylating agents stem mostly from uncontrolled studies or retrospective analysis, making it difficult to draw firm conclusions. Nonetheless, cytotoxic agents may be an option for some steroid-resistant nephrotic patients who have otherwise exhausted other options or have contraindications to other medications.

Calcineurin Inhibitors

The generally accepted therapy for patients with steroid-resistant FSGS at the present time is cyclosporine in both children and adults. In a randomized, double-blind, placebo-controlled trial in steroid-resistant children, cyclosporine

therapy for 6 months led to 76% decrease in proteinuria compared with no change in the placebo group.⁶² Another pediatric prospective, randomized study also suggested that cyclosporine is more effective in decreasing proteinuria compared with chlorambucil, with nearly all patients achieving a decrease in proteinuria with complete remission in 23% of the cohort.⁶³ In one retrospective study, cyclosporine led to remissions in 40% of steroid-resistant patients.⁶⁰

A randomized, controlled trial demonstrated that cyclosporine is also efficacious in inducing remission in steroid-resistant adult FSGS patients. Cattran and colleagues⁶⁴ compared cyclosporine treatment plus low-dose prednisone with placebo plus prednisone and monitored the patients for a mean of 4.2 years. By 26 weeks, 69% (12% complete and 57% partial) of the treatment group versus 4% of the placebo group achieved remission of their proteinuria. Relapses were common, however, occurring in 40% of those who had achieved remission by 1 year and 60% by 18 months. Despite this high relapse rate, renal function was better preserved in the cyclosporine group; the patients treated with cyclosporine were half as likely to experience 50% decrease in their creatinine clearance from baseline. These results suggest that cyclosporine is an effective therapeutic agent in the treatment of steroid-resistant cases of FSGS. In the pediatric literature, limited data also suggest that a combination of steroids and cyclosporine improves the chance of complete remission from 14% with cyclosporine monotherapy to 24% with the combination.⁶⁵

There is more limited experience with tacrolimus in steroid-resistant FSGS patients. In an uncontrolled, prospective trial involving steroid-dependent and steroid-resistant FSGS patients, tacrolimus therapy led to an overall response rate of 90%, with 50% of the patients achieving complete remission and 40% of the patients achieving partial remission.⁶⁶ Tacrolimus therapy was, however, associated with small increases in blood glucose, systolic blood pressure, and serum creatinine. Furthermore, as seen with cyclosporine, there was a relapse of nephrotic syndrome in 80% of patients.

Despite recent reports of encouraging short-term success in induction of remission in steroid-resistant FSGS, long-term use of calcineurin inhibitors is associated with nephrotoxicity, progressive interstitial fibrosis, and glomerulosclerosis even in patients who remain in partial remission.⁶⁷ Given their additional adverse effects on metabolic profile and blood pressure, it is difficult to assess whether calcineurin inhibitors improve long-term renal survival. Attempts have been made to introduce newer therapies to treat steroid-resistant FSGS, including mycophenolate mofetil (MMF) and sirolimus.

Mycophenolate Mofetil

After the successful use of MMF in the treatment of lupus nephritis, there has been a growing interest in using this agent to treat other proteinuric glomerular disorders. Several small and uncontrolled trials suggest that MMF may be beneficial in patients with FSGS. Choi and colleagues⁶⁸ reported that MMF can facilitate steroid withdrawal in otherwise steroid-dependent MCN patients and significantly decrease proteinuria in FSGS patients. A recent prospective study evaluated the efficacy of MMF to induce remission in nephrotic patients who are both steroid and cyclosporine dependent or resistant.⁶⁹ After 6 months of MMF therapy, steroid sparing was achieved in 71% of steroid-dependent patients and 42% remained in remission. In steroid-resistant patients, 20% achieved complete

Table 20-5 Clinical Trials of Glucocorticoid Therapy for Adults with Focal Segmental Glomerulosclerosis: Regimen, Remission, Relapse, and Long-Term Outcome

First Author, Location, Year	Design	No. of Patients	Black Subjects (%)	Duration of Therapy
Agarwal, India, 1993	Prospective	65 children, adults (23 lost)	0	High-dose 8-12 wk, taper to 6 mo
Rydel, Illinois, 1995	Retrospective	30 adults	63	High-dose 4-8 wk, total therapy mean, 5 mo
Cattran, Ontario, 1998	Retrospective	18 adults	0	Median, 5 mo; range, 2-50
Ponticelli, Italy, 1999	Retrospective	53 adults	0	A) mean, 24 wk; B) mean, 19 wk
Chitalia, New Zealand, 1999	Retrospective	28	28	High-dose 6-8 wk to 12 wk
Stiles, Washington, DC, 2001	Retrospective	12	83	Mean, 4 mo
Pokhariyal, Lucknow, India, 2003	Retrospective	83 (12 lost)	0	Mean, 3 mo
Franceschini, North Carolina, 2003	Retrospective	36 adults	31	Daily or alternate days for mean of 9 mo
Smith, Bethesda, MD, 2003	Prospective	14 adults	50	Pulse oral dexamethasone for 8 mo

The results of nine uncontrolled studies are summarized. The number of patients treated with glucocorticoids in each study is shown (No). The study of Agarwal et al.⁴⁵ included children and adults; the other studies only included adults or, alternatively, only the data from adults are included here. All studies except the study of Cattran et al.²⁹ stated that one or more forms of postadaptive focal segmental glomerulosclerosis and human immunodeficiency virus-type 1-associated nephropathy were excluded. The duration of high-dose glucocorticoid therapy (generally prednisolone or prednisone 1 mg/kg/day) is shown. In the study of Ponticelli et al,⁴⁹ patients received either regimen A, prednisone 1 mg/kg/day for 8 weeks, followed by a taper to a mean of 24 weeks, or regimen B, three doses of intravenous methylprednisolone, followed by prednisolone 0.5 mg/kg/day for 8 weeks, and then a taper to a mean of 19 weeks. The definitions of complete remission and

remission. Withdrawal of MMF, however, resulted in immediate relapse in 47%.

MMF may also be used as an adjunctive therapy in those who are resistant to steroids or cyclosporine or to maintain longer remission in those who relapse frequently.⁷⁰ In another prospective pediatric study including steroid-dependent MCN and FSGS, MMF therapy led to 70% reduction in relapse rate (from 6.6 to two episodes per year) after 1 year.⁷¹ After discontinuation of MMF treatment, however, 68% of patients had an increased frequency of relapses and recurrence of steroid dependence, requiring treatment with other medications. Long-term therapy with MMF, therefore, may result in significant steroid sparing and a decrease in relapse rates in patients with steroid dependence or in those who are unresponsive to other immunosuppressive therapies, with a response similar to that to cyclosporine. The data, however, are based on small, uncontrolled trials, and further systematic studies are necessary to better understand the indications and efficacy of MMF in the treatment of FSGS. Furthermore, the available current data do not allow direct comparisons of short- and long-term efficacy and safety between MMF and other treatment options.

Sirolimus

Sirolimus, approved for use in organ transplantation by the U.S. Food and Drug Administration in 1999, has antiproliferative and immunosuppressive effects that may be beneficial in FSGS. Sirolimus blocks mesangial, endothelial, and vascular smooth muscle cell proliferation.⁷²⁻⁷⁴ Sirolimus also reduces expression of fibrosis-associated genes in the renal ischemia reperfusion injury model⁷⁵ and exerts antifibrotic effects in an experimental model of hepatic fibrosis.⁷⁶ Furthermore, preclinical studies and early transplantation literature suggested that sirolimus may lack nephrotoxicity, unlike calcineurin inhibitors.

To determine the efficacy of sirolimus in decreasing proteinuria, Tumlin and colleagues⁷⁷ conducted a prospective, open-label trial of 21 patients with idiopathic, steroid-resistant FSGS. After 6 months of therapy, sirolimus induced complete remission in 19% and partial remission in 38%. The GFR was maintained only among the responders, whereas the nonresponders had a mean decrease in the GFR of 3 mL/min/1.73 m² during the 6 months.

This favorable effect of sirolimus, however, was not confirmed in two other clinical studies, neither of which was controlled. Fervenza and colleagues⁷⁸ evaluated the safety

COMPLETE REMISSION		PARTIAL REMISSION		Complete + Partial Remission (%)	Relapse	Follow-up Status	Ref.
Definition	%	Definition	%				
<0.3 g/day	18	2 g/day	15	33	ND	ESRD: 5% (34 mo)	45
<0.25 g/day	33	<2.5 g/day	17	50	From CR or PR: 67%	CR: 30%, PR: 16%, ESRD: 20% (79 mo)	28
<0.2 g/day	44	ND	ND	ND	From CR: 38%	CR: 44%, CKD/ES RD: 50% (155 mo)	29
<0.2 g/day	40	<2 g/day	19	59	From CR or PR: 55%	ND	49
<0.3 g/day	21	ND	ND	ND	ND	ND	46
<0.2 g/day	0	<3 g/day	42	42	ND	ND	51
<0.3 g/day	25	<2 g/day or 50% decrease if subnephrotic	25	50	ND	ND	48
<0.6 g/day	ND	ND	ND	ND	ND	CR: 11% ESRD: 18% (18 mo)	47
<0.3 g/day	7	<2 g/day	29	36	From CR or PR: 60%	CR: 7%, PR: 14% (20 mo)	50

partial remission are shown. The percentage of subjects in CR is derived from each study; for the study of Agarwal et al.,⁴⁵ 23 patients were lost, without endpoint determination, and the calculation of outcome was made here on an intent-to-treat basis (rather than as follow-up). The mean duration of follow-up is shown and the percentage of patients in remission are shown. CKD, chronic kidney disease; ESRD, end-stage renal disease; ND, no data provided.

and efficacy of sirolimus in treating patients with primary glomerular diseases, including FSGS. Of the 11 patients, 6 developed acute renal failure within 6 weeks of starting sirolimus, with improvement after stopping sirolimus. One patient recovered renal function after discontinuation of the drug but again deteriorated with rechallenge, further strengthening the causal relationship between sirolimus and acute renal failure. In a prospective, open-label study by Cho and colleagues,⁷⁹ sirolimus therapy was associated with precipitous fall in GFR in five of six steroid-resistant FSGS patients. In three patients, a decrease in the GFR was also associated with more than a twofold increase in proteinuria, raising concerns that sirolimus may be harmful in some patients with long-standing FSGS.

The discrepancies among the studies may partly reflect differences in study populations. The mechanism underlying sirolimus nephrotoxicity is not clear but appears to involve direct tubular injury. In pathologic conditions characterized by ischemic or chronic tubular injury such as delayed graft function or long-term calcineurin-inhibitor therapy, hindrance of tubular regeneration by sirolimus may severely impair renal recovery. Future studies may help

define the role of sirolimus in glomerular disease and provide better understanding of the risk factors for sirolimus nephrotoxicity.

Other Treatment Considerations

Aggressive control of blood pressure (mean arterial pressure of ≤ 92 mm Hg or $\leq 130/80$ mm Hg) and the use of ACE inhibitors have been shown to decrease proteinuria and the rate of decrease in the GFR by as much as 50% in patients with primary glomerulopathies, including FSGS.^{80–82} In addition, combining ACE inhibitors with angiotensin receptor blockers may safely slow the progression of nondiabetic renal disease compared with monotherapy.⁸³

While blood pressure control and angiotensin antagonists are beneficial in decreasing proteinuria and progression of renal disease, they rarely lead to remission of nephrotic syndrome.⁸¹ Therefore, there is an urgent need for development of more effective therapy options for treating patients with FSGS. The potential future options for treatment of fibrotic renal diseases are listed in Table 20-6. Agents that block fibrotic pathways or mitigate profibrotic

Table 20-6 Potential Novel Therapies for Progressive Glomerulosclerosis

Class	Agent	Molecular Target or Pathway	Animal Model	Ref.	Proteinuria	Matrix	Human Use
Small molecules	Bosentan	ET _A , ET _B receptor antagonist	Ren-2 transgenic rats	137	Reduced	Reduced	Approved

effects of various cytokines may serve an important role. Pirfenidone, for example, is a potent inhibitor of transforming growth factor β , and a small pilot study has suggested that it may slow the decrease in the GFR in FSGS patients.⁸⁴ The safety and efficacy of various antifibrotic agents will need to be defined through controlled clinical trials in the future. Currently, a prospective, randomized, open-label trial sponsored by the National Institutes of Health is ongoing to compare two treatment regimens in children and adults with steroid-resistant FSGS: cyclosporine versus the combination of MMF and dexamethasone over 52 weeks. The treatment regimens in both arms also include ACE inhibitor therapy and alternate-day low-dose prednisone. The results are expected within the next year.

Treatment of Postadaptive Focal Segmental Glomerulosclerosis

ACE inhibitors and angiotensin receptor blockers are important in treating postadaptive FSGS. Praga and colleagues⁸¹ showed that captopril therapy over 12 months decreased proteinuria to a greater extent in postadaptive FSGS (associated with decreased nephron mass and reflux nephropathy) compared with idiopathic FSGS. In addition, Praga and colleagues⁸⁵ studied 17 patients with obesity-associated proteinuria with more than 1 g/day. Captopril therapy in eight patients decreased proteinuria by 79% (mean, 3.4 g/day decreasing to 0.7 g/day); interestingly, weight loss in nine patients (mean body mass index decreasing from 37 kg/m² to 33 kg/m²) was associated with a similar decrease in proteinuria by 86%. It is, however, unclear whether the decrease in proteinuria with angiotensin antagonist therapy can be maintained.¹⁵ Early treatment with ACE inhibitors appears to preserve renal function in obesity-associated FSGS, although appropriate controls are lacking. When the diagnosis of postadaptive FSGS is not clear and/or patients are significantly symptomatic from nephrotic proteinuria, the therapeutic approach for idiopathic FSGS is generally applied.

CURRENT THERAPEUTIC RECOMMENDATIONS

Idiopathic Focal Segmental Glomerulosclerosis

The available data suggest that the initial therapy for idiopathic FSGS, unless there are significant contraindications, should be glucocorticoids at 1 mg/kg/day (maximum 80 mg/day) or 2 mg/kg every other day (maximum 120 mg/kg every other day) (Fig. 20-1). Glucocorticoids should be administered long enough to avoid a premature diagnosis of steroid resistance. Many experts recommend a decrease in dose after 2 to 4 months, particularly for those who have not shown a significant decrease in urine protein. Those who do not respond to 16 weeks of glucocorticoid therapy are then diagnosed with steroid resistance and progress to other therapies. Ultimately, the duration of the initial prednisone dose and rapidity of the steroid taper will depend on whether and how rapidly a complete or partial remission is attained.

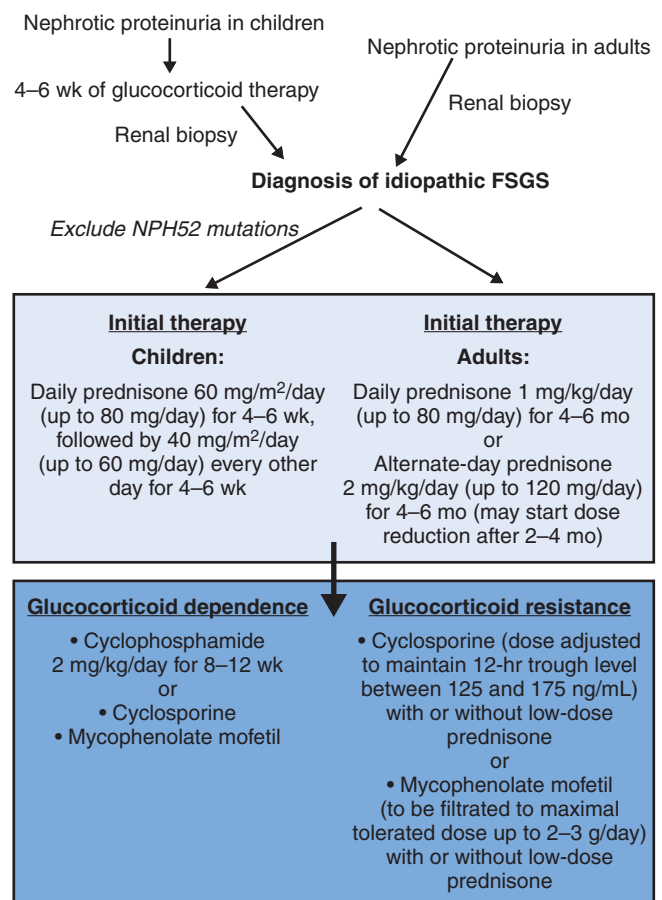

Figure 20-1 Therapy of idiopathic focal segmental glomerulosclerosis (FSGS) in children and adults. The selection of initial therapy and subsequent therapies is shown. The diagnosis of genetic FSGS, postadaptive FSGS, and adaptive FSGS should be considered, in which case therapeutic recommendations will differ (see text). Patients with persistent proteinuria are typically started on angiotensin-converting enzyme inhibitors or angiotensin receptor blockers before, during, or after the first course of glucocorticoids. The dose and duration of glucocorticoid therapy must be modified based on patient factors including age, obesity, diabetes, osteoporosis, and other conditions.

For those who are steroid responsive but become steroid dependent or steroid resistant, cyclosporine should be tried, either as a monotherapy or in addition to a low-dose prednisone (0.15 mg/kg, maximum 15 mg/day). The typical starting dose of cyclosporine is 3 to 4 mg/kg/day given in two divided doses and is generally continued for at least 6 months after attaining complete remission. Some patients require long-term therapy with a low dose (2–3 mg/kg) of cyclosporine to maintain the remission. The utility of calcineurin inhibitors in patients with a GFR less than 40 mL/min/1.73 m², significant renal vasculopathy, or significant tubulointerstitial fibrosis is unclear, given the concern for the nephrotoxicity of these agents. While there are fewer data to suggest efficacy of other immunosuppressive agents, these may be considered, particularly in patients who have contraindications to prednisone or cyclosporine. Patients with frequently relapsing or

steroid-dependent FSGS may also receive some benefit from cyclophosphamide. Until more data are available, it is difficult to recommend the use of sirolimus for the treatment of FSGS at this time.

Postadaptive Focal Segmental Glomerulosclerosis

Immunosuppressive therapy is generally contraindicated. The therapeutic approach is focused on treating the underlying cause whenever possible. In addition, aggressive control of hypertension and hyperlipidemia, and ACE inhibitors and angiotensin receptor blockers, should be used.

Genetic Focal Segmental Glomerulosclerosis

Pediatric patients with homozygous or compound heterozygous *NPHS2* mutations are refractory to glucocorticoids (defined as 6 weeks of therapy) and have only limited responsiveness to cyclosporine.⁸⁶ By contrast, *NPHS2* homozygous and compound heterozygous mutations were absent in 124 children with steroid-sensitive nephrotic syndrome. Immunosuppressive treatment is thus of limited benefit in children with *NPHS2* homozygous and compound heterozygous mutations. It would also likely be prudent to withhold aggressive immunosuppression, particularly glucocorticoids, in patients with *ACTN4*, *CD2AP*, *TRPC6*, and mitochondrial DNA mutations.

Reactive Focal Segmental Glomerulosclerosis

FSGS associated with medication is probably best managed by withdrawing the implicated medication and instituting conservative therapy.

Limitations

Currently, there are no clinical characteristics that can reliably predict the response to a given therapy. Furthermore, there are no published data to determine the balance between the risks and benefits of immunosuppressive therapy in many patient subgroups. Examples include patients with subnephrotic proteinuria at presentation, especially those with proteinuria less than 2 g/day, patients with postadaptive FSGS, and those with idiopathic FSGS who are at significantly increased risk of toxicity associated with glucocorticoid therapy, including those with obesity, diabetes mellitus, severe osteoporosis, or advanced age.

RECURRENT FOCAL SEGMENTAL GLOMERULOSCLEROSIS

In 1972, Hoyer and colleagues⁸⁷ published the first report of a rapid recurrence of idiopathic nephrotic syndrome in three patients after renal transplantation. It is now well established that 15% to 50% of patients with FSGS undergoing renal transplantation have a recurrence of the disease, with the average rate of 25% to 30%. The clinical course and outcome have been well documented in both pediatric and adult patients.^{88,89}

In a retrospective study analyzing recipients of 78 allografts over a 10-year period, FSGS recurred in approximately 30% of allografts within a mean of 7.5 months (range, 0.5–44 months) after transplantation.⁸⁸ Once the diagnosis was made, ESRD eventually developed in 56% of the allografts within an average of 23.7 months (range, 1–65 months). For those who lost their first allograft to recurrent FSGS, the study suggested an even higher risk of a second recurrence of 80%. Risk factors associated with the recurrence of FSGS include young age at initial diagnosis (younger than 15 years), rapid progression of the initial disease (<3 years from diagnosis to ESRD), white race, mesangial hyperplasia, and recurrence in previous allograft within 1 year of transplantation. Patients younger than 5 years of age have a 50% likelihood of a recurrence versus only 10% to 15% in patients older than 30 years.⁹⁰ None of these factors, however, is highly predictive in an individual patient.

Although those with genetic causes of FSGS would not be expected to have a recurrence of FSGS after transplantation, multiple reports have described a recurrence in approximately 10% of patients with homozygous or compound heterozygous *NPHS2* mutations.^{86,91–93} The mechanism underlying this recurrence is unclear. Recurrence has not been reported in patients with FSGS associated with mutations in *ACTN4* or *TRPC6*, although it is premature to draw any conclusions at the present time.^{94,95}

Pathogenesis

The pathogenesis of recurrent FSGS remains unknown. Because prompt institution of plasma exchange after early diagnosis of recurrence can be associated with reversal of epithelial foot process effacement and remission of proteinuria, a circulating permeability factor has long been suspected to initiate injury in recurrent FSGS. Consistent with this hypothesis, rats infused with the serum of a patient with recurrent FSGS develop proteinuria, suggesting that the permeability factor is present in the circulation of FSGS patients and that it can reproduce the glomerular injury when transferred into a normal host.⁹⁶ After more than 20 years of research, however, the identity of the permeability factor remains obscure.

Further complicating the attempt to identify the permeability factor is the possibility that the glomerular injury in FSGS patients may stem from the loss of an inhibitor that normally blocks the permeability effect in normal individuals. To determine whether normal serum improves the glomerular albumin permeability in FSGS, Sharma and colleagues⁹⁷ incubated isolated rat glomeruli in a mixture of medium containing FSGS serum and normal human serum. Normal human serum prevented the increase in glomerular albumin permeability, and this protective effect diminished as the concentration of normal serum was decreased, suggesting the presence of an inhibitor in the normal serum. Further support for the role of inhibitor loss leading to increased glomerular permeability was provided by Coward and colleagues.⁹⁸ The investigators found that the addition of nephrotic FSGS plasma to isolated human podocytes led to an altered distribution of the slit-diaphragm proteins, including selective down-regulation of nephrin and synaptopodin and disruption of intracellular calcium signaling. The altered distribution of nephrin induced by nephrotic plasma could be reversed by co-incubation with nonnephrotic

plasma. This work demonstrates that nephrotic plasma seems to be deficient in factors critical for maintaining the physiologic function of the podocyte slit-diaphragm complex.

Given the recurrence of proteinuria after transplantation in genetic forms of FSGS, it is also intriguing to question whether there is an interaction between the molecular defects of the slit diaphragm and permeability factor or whether certain genetic defects actually reflect the loss of certain plasma factors that regulate permselectivity. Due to the surge of interest in podocyte biology stemming from the discovery of disease-associated podocyte genes, the subject of recurrent FSGS provides opportunities to further understand the pathogenesis and thus develop better alternative therapy options.

Treatment

There are no systematic controlled trials to guide the treatment of recurrent FSGS. Clinical practice is based on relatively small series. Immunoabsorption and plasma exchange with or without cyclophosphamide, cyclosporine, glucocorticoids, and intravenous immunoglobulin have been used with limited success.

Plasma Exchange

Although several reports have suggested that plasma exchange can markedly decrease proteinuria in some cases of recurrent FSGS, long-term remission has been difficult to achieve.^{88,99–101} A single course of plasma exchange or immunoabsorption may be associated with variable degrees of decrease in proteinuria in approximately half of the cases.^{102–104} Although there are no systematic studies to suggest the optimal dosing and frequency of plasma exchange, analysis of 44 cases suggests

that the median number of treatments to response is nine.¹⁰⁵ Based on this review, the standard clinical practice is to start early treatment after diagnosis with a regimen of three daily plasmapheresis treatments followed by six treatments on an every-other-day basis. Unfortunately, most patients experience a relapse, and their renal disease progresses. Children, in particular, often require a maintenance schedule of plasma exchange to sustain remission.

The limited efficacy of plasma exchange has led investigators to a trial of cyclophosphamide in children, either with or without plasma exchange. The available data suggest that addition of cyclophosphamide to plasma exchange may lead to sustained remission in 50% to 80% of cases (Table 20-7).^{106–111} These studies do not allow firm conclusions, however, given their small size, lack of controls, and often retrospective design.

High-dose cyclosporine has also been used in pediatric patients with recurrent FSGS. Salomon and colleagues¹¹² adjusted intravenous cyclosporine dose to achieve trough levels of 250 to 350 ng/mL in 17 cases of recurrence. In 14 cases (82%), proteinuria completely disappeared after a mean of 3 weeks. The long-term graft survival at 1 and 5 years was 92% and 70%, respectively. Similar results have been published using oral cyclosporine in children.¹¹³ The safety data in the long term, however, have not been systematically studied, and it is unknown whether any benefit that may be drawn from the prolonged survival of renal graft outweighs the potential complications from the more intensified immunosuppression. Furthermore, there are no published data regarding the efficacy of cyclophosphamide or cyclosporine in adults. Prophylaxis against recurrent FSGS remains a major challenge, and currently there are no methods to reliably decrease the risk of recurrence.

Table 20-7 Use of Increased Immunosuppression for Recurrent Focal Segmental Glomerulosclerosis

Authors	Design	Population	Treatment	No.	Complete Response	Partial Response	No Response	Long-Term Response, Mean No. of Years (Range)
Cochat et al ¹⁰⁷	Prospective	Children	PE + CTX 3 mo	3	3	0	0	3 CR (1 retreatment)
Kershaw et al ¹⁰⁹	Prospective?	Children	CTX 2–3 mo	3	3	0	0	2 CR (1 relapse)
Dall' Amico et al ¹⁰⁸	Retrospective	Children	PE + CTX 2 mo	11	9	0	2	7 CR
Cheong et al ¹⁰⁶	Retrospective	Children	PE + CTX 3 mo	6	3	3	0	2 CR
Saleem et al ¹¹¹	Prospective case series	Children	PE + CTX 2 mo (IVIG in 2 of 3 children)	3	0	2	1 (death after 4 mo)	2 PR, 3.25 (3.0–3.5)
Nathanson et al ¹¹⁰	Retrospective	Children	Variable (PE, IV, CyA, CTX)	14	6	5	3	7 CR, 8.1 (1–14)

CR, complete remission (generally defined as proteinuria < 500 mg/day); CTX, cyclophosphamide; CyA, cyclosporin A; IVIG, intravenous immunoglobulin; PE, plasma exchange; PR, partial remission (generally defined as proteinuria < 2 g/day).

COLLAPSING GLOMERULOPATHY

In 1984, human immunodeficiency virus–associated nephropathy was first recognized as a clinical syndrome and its characteristic histologic features, including podocyte swelling and proliferation, were first characterized.¹¹⁴ The term CG, however, was not introduced until 1986. The discovery of idiopathic CG soon followed in 1986 by Weiss and colleagues,¹¹⁵ with subsequent reports from elsewhere within the United States and Europe.^{116–120} Since its first recognition, CG has quickly become increasingly common.¹¹⁷ Although such an epidemiologic pattern strongly suggests a new environmental agent, possibly a virus or toxin, the cause remains unknown.

Idiopathic CG typically presents with a sudden onset of heavy proteinuria, although some patients have subnephrotic proteinuria. Patients have a strikingly poor renal survival, with a 70% probability of ESRD at 2 years, although this is not invariably the case.²³ Some patients report a virus-like prodrome occurring before presentation, with symptoms that may include fever, cough, and diarrhea. Parvovirus B19 infection has been linked with CG, although controversy remains about the strength and specificity of the association.^{121–123} CG has also been associated with certain medications, including pamidronate¹²⁴ and interferon alfa.¹²⁵ The mechanism is unknown.

The pathophysiology of CG remains unclear, although the underlying pathogenic event appears to be injury to podocytes. Podocytes are postmitotic cells in the normal human kidney, and it has been proposed that depletion of podocytes may be critical in the development of FSGS. Unlike the depletion of podocytes as seen in FSGS, however, both human immunodeficiency virus–associated and idiopathic CG are characterized by podocyte dysregulation and proliferation.¹²⁶ In contrast to MCN and other glomerulopathies, podocytes undergo characteristic, irreversible ultrastructural changes in CG, including the loss of maturity markers such as synaptopodin. This phenotypic dysregulation of podocytes is associated with cell proliferation, a feature not seen in other glomerular diseases, including idiopathic FSGS. Because CG significantly differs histologically and clinically from other variants, some investigators argue that CG should be a separate entity from FSGS altogether.⁸

There are no published prospective, controlled studies that have examined efficacy of therapy in CG. Unfortunately, the response rate in CG is even lower than that for FSGS, with only 9.6% of patients achieving long-term remission and 15.2% of patients achieving partial remission.¹²⁷ As there is no evidence-based treatment of CG, the current therapeutic strategies derive from the empirical approach used for FSGS. According to the available data, response to steroids, cyclosporine, and cyclophosphamide is very poor.^{116,117,119} Limited data suggest that early, aggressive treatment may achieve higher remission rates, particularly in patients with better preserved renal function (serum creatinine concentrations < 2.0 mg/dL and < 20% interstitial fibrosis on renal biopsy).^{119,128,129}

CONCLUSIONS

MCN, FSGS, and CG represent a complex syndrome with multifactorial causes that culminate in podocyte injury. Although both disorders are considered to have immunologic basis, recent discoveries of the genetic defects associated with

podocytopathy have increased the complexity underlying the pathogenesis. Although the diagnosis of MCN and FSGS require careful pathologic examination, considerable variability exists in renal histology, and this heterogeneity may reflect the diverse causes and clinical outcomes of the diseases. The therapeutic responses and prognosis of MCN and FSGS are equally as heterogeneous, reflecting the fact that these disorders do not represent a single clinical or pathologic entity. Most of the patients with MCN and some of those with FSGS are steroid sensitive. The remaining patients with MCN and a larger proportion of those with FSGS and CG are steroid resistant. Steroid resistance is generally associated with poor long-term response with other available therapies, denoting more refractory cases. Much work is needed to better understand the pathophysiology, which may allow identification and development of more specific therapy options in the future. Some of the possible future therapy options are summarized in Table 20-6. Particular areas of interest include molecular pathways involved in initiating podocyte injury and recurrence of nephrotic syndrome after renal transplantation, the molecular determinants of steroid sensitivity, and the relationship between the various histologic variants and clinical outcome.

SUMMARY 245

Membranous nephropathy is a common cause of adult-onset nephrotic syndrome, accounting for as many as 33% of cases in which a biopsy was performed to determine the cause of the nephrotic syndrome.^{1,2} Characteristic changes in a renal biopsy specimen include diffuse glomerular capillary wall thickening and subepithelial and/or intramembranous electron-dense deposits (described further by Falk and colleagues³). Various medications and toxins as well as certain rheumatologic, neoplastic, and infectious diseases account for approximately 20% of membranous nephropathy from developed countries.⁴ The underlying cause (e.g., neoplasia or systemic lupus erythematosus) may not be evident at presentation in some patients, requiring an ongoing evaluation to ferret out a specific and, it is hoped, treatable disorder.⁴ Treatment of secondary membranous nephropathy is beyond the scope of this chapter.

NATURAL HISTORY

Despite evidence that immunologic mechanisms induce glomerular injury in membranous nephropathy, immunosuppressive drug treatments are not justified for all patients with this disorder. The clinical course of idiopathic membranous nephropathy is highly variable. Although patients with non-nephrotic proteinuria have a favorable prognosis, du Buf-Vereijken and colleagues⁵ analyzed 10 studies published during the past 25 years and estimated that nearly 50% of patients with the nephrotic syndrome experienced a decline in renal function. Cattran and colleagues⁶ observed that on average approximately 20% of patients in 12 studies progressed to end-stage renal disease within 10 years. Conversely, spontaneous remissions of nephrotic proteinuria occur in approximately one third of cases within 5 years.^{7,8}

Patients with persistent proteinuria and hyperlipidemia are at increased risk of cardiovascular and thromboembolic complications of the nephrotic syndrome. Ordonez and colleagues⁹ found that patients with the nephrotic syndrome had a fivefold increased risk of myocardial infarction (after statistical adjustment for hypertension and cigarette smoking) compared with

age- and sex-matched control subjects who participated in the same health plan. Thus, the nephrotic syndrome is an independent risk factor for accelerated coronary artery disease. The nephrotic syndrome due to membranous nephropathy is also associated with an increased risk of thromboembolic complications.^{10,11}

Survival data compiled by Hogan and colleagues¹² illustrate the potential morbidity and mortality attributed to idiopathic membranous nephropathy. A pooled analysis was conducted to estimate renal survival, defined as the probability of not progressing to end-stage renal failure and not succumbing to death due to kidney disease or cardiovascular events associated with persistent nephrotic syndrome. Employing this approach, the probability of renal survival was 86% at 5 years, 65% at 10 years, and 59% at 15 years.

PROGNOSTIC INDICATORS

Generalizations about the prognosis of patients with idiopathic membranous nephropathy are of limited value because the natural history of this disorder is highly variable. To refine estimates of prognosis and to derive relatively objective criteria for instituting therapeutic interventions, investigators have sought to identify high-risk subgroups of patients. Several potentially important prognostic factors have been examined including age, gender, renal function, kidney pathology, and the quantity and types of urinary proteins.¹³ Neugarten and colleagues¹⁴ reported a meta-analysis of 21 studies that showed that men with membranous nephropathy experience significantly more rapid deterioration of renal function than women. Zent and colleagues¹⁵ compared renal outcomes in 74 elderly patients (60 years of age and older) with membranous nephropathy with outcomes observed in 249 younger patients. Although the elderly patients were significantly more likely to develop chronic renal insufficiency than the younger patients, there was no difference in the rate of change in renal function or the probability of complete remission in the two groups. Thus, elderly patients with membranous nephropathy are more likely to develop chronic renal insufficiency because of

an age-related decrease in renal function reserve at baseline rather than more severe membranous nephropathy. These observations were extended by Troyanov and colleagues¹⁶ who reported that patients with interstitial fibrosis, tubular atrophy, vascular sclerosis, and focal segmental glomerulosclerosis lesions had a lower creatinine clearance at presentation and were more likely to progress to renal failure. Conversely, these chronic histologic features were not correlated with the rate of decline in renal function, nor did they predict the probability of remission in patients treated with immunosuppressive agents. Furthermore, they observed that the stage and pattern (i.e., synchronicity) of electron-dense deposits did not predict the rate of renal function deterioration or renal function survival. The extent of C3 deposition did correlate with the rate of renal function decline but not with renal survival, remissions of proteinuria, or response to immunosuppressive drug therapy.

Clinical observations acquired during a period of time are likely to be stronger predictors of long-term renal function outcome than those obtained at a single time point. Thus, increased serum creatinine at presentation is associated with an increased risk of renal failure, but may reflect age-related changes in renal reserve or readily reversible functional alterations rather than indicate the severity of the membranous nephropathy. Patients observed to have declining renal function due to membranous nephropathy are at particularly high risk of progressive deterioration in renal function.¹⁷ Furthermore, persistent high-grade proteinuria is more predictive than a comparable degree of proteinuria at a single point in time. Pei and colleagues¹⁸ observed that persistent severe proteinuria (≥ 8 g/day for ≥ 6 months) was associated with a 66% probability of progression to chronic renal insufficiency. Less severe proteinuria for longer periods was also associated with an increased risk of developing chronic renal insufficiency. In patients with a moderate level of persistent proteinuria (≥ 4 g/day for ≥ 18 months), the predictive value of persistent proteinuria was enhanced substantially by considering additional prognostic factors, namely, creatinine clearance at the start of persistent proteinuria and the rate of change in creatinine clearance during the period of persistent proteinuria.

Concern that prolonged observation might delay therapy excessively in some patients has prompted Cattran and colleagues¹⁹ to reassess the predictive models by employing a 6-month period of observation for all levels of persistent proteinuria. A mathematical model was derived and validated by employing data from two additional distinct populations of patients. The algorithm uses the highest level of proteinuria that persisted for a 6-month interval as well as the initial value and the rate of change in creatinine clearance during the period of persistent proteinuria. The equation and examples of how to calculate the probability of progression to chronic renal insufficiency are described by Cattran and colleagues.¹⁹ Based on this equation, Cattran⁸ identified low-, medium-, and high-risk groups of patients. Patients with normal renal function and proteinuria 4 g/day or less for 6 months are at low risk (<5%) of renal function decline during the next 5 years. Patients with normal renal function and persistent proteinuria between 4 and 8 g/day for 6 months (despite optimal doses of angiotensin-converting enzyme [ACE] inhibitors and/or angiotensin receptor blockers [ARBs]) are included in the medium-risk group. High-risk patients are identified by declining renal function and/or by persistent

severe proteinuria (8 g/day) or more despite optimal conservative management.

Observation of patients for the evolution of time-dependent prognostic factors is recommended for some, but not all, cases of idiopathic membranous nephropathy. Patients who present with combinations of ominous time-independent features (including impaired renal function and/or very severe proteinuria [>10 g/day]) should be considered for treatment without prolonged observation in an effort to reduce the risks of irreversible renal parenchymal injury as well as cardiovascular and thromboembolic complications of the nephrotic syndrome. Quantification of specific urinary proteins at presentation may enhance predictions of clinical outcomes and obviate the need for extended observation before recommending immunosuppressive therapy. Bazzi and colleagues²⁰ showed that levels of urinary IgG and α_1 -microglobulin were significantly associated with the probabilities of remission and progression and could identify those most likely to benefit from immunosuppressive therapy. Branten and colleagues²¹ have confirmed and extended these observations. They have also shown that previously established cutoff values for urinary β_2 -microglobulin and IgG excretion are useful predictors of renal insufficiency in patients with membranous nephropathy. It will be important to continue to study the predictive value of these and other urinary markers in diverse populations of patients with membranous nephropathy.

CLINICAL TRIALS AND SPECIFIC RECOMMENDATIONS

General Strategy

Patients with membranous nephropathy should be treated with doses of ACE inhibitors and/or ARBs that have been titrated to reduce proteinuria as much as possible and to achieve optimal blood pressure control without excessive increases in serum creatinine and/or potassium.²² Whereas the response to ACE inhibitors is not consistent in this population, modulation of intrarenal hemodynamic parameters may decrease proteinuria by as much as 50%.^{23–25} and may decrease the risk of progressive glomerulosclerosis as well. A meta-analysis of 11 randomized, controlled trials showed that ACE inhibitors reduced the risk of progressive renal function deterioration in patients with nondiabetic kidney disease after statistical adjustment for levels of systolic blood pressure and proteinuria.²⁶ The analysis also showed that the risk of kidney disease progression was lowest in patients whose systolic blood pressure was controlled in the range of 110 to 129 mm Hg and whose protein excretion rate was less than 2 g/day at follow-up visits. If these goals cannot be achieved with an ACE inhibitor, the combination of an ACE inhibitor and an ARB may be beneficial.²⁷ In a randomized, controlled trial that included 336 patients with nondiabetic renal disease, Nakao and colleagues²⁸ showed that the combination of an ACE inhibitor and an ARB decreased proteinuria and protected renal function more effectively than either drug alone. The risk of hyperkalemia was not increased by combination therapy compared with ACE inhibitor monotherapy. The ACE inhibitor and ARB monotherapy arms appeared to be equally effective. The incidence of hyperkalemia and nonproductive cough was lowest in the ARB monotherapy group, so ARBs appear to be a

reasonable alternative for patients with membranous nephropathy who cannot tolerate ACE inhibitors. Studies in other populations of nephrotic patients suggest that a low-protein diet may augment the hemodynamic effect of blocking the renin-angiotensin system.²⁹

It is important to address coronary risk factors in patients with the nephrotic syndrome.³⁰ Whereas ACE inhibitors may decrease proteinuria and partially correct hyperlipidemia,³¹ specific lipid-lowering agents are often indicated as well. 3-Hydroxy-3-methylglutaryl coenzyme A reductase inhibitors are widely used for this purpose and typically lead to 30% to 45% decreases in low-density lipoprotein cholesterol.^{32–34}

Concern for the morbidity and mortality associated with pulmonary embolism has led to interest in the possible role of prophylactic anticoagulation for patients with severe nephrotic syndrome due to membranous nephropathy (serum albumin < 2.0–2.5 g/dL).¹¹ By decision analysis, the risks of life-threatening complications of pulmonary embolism appear to outweigh those associated with prophylactic anticoagulation.¹⁰ However, data from prospective, randomized clinical trials are not available to support this approach.

Patients with membranous nephropathy should be carefully evaluated and started on an individualized regimen of conservative therapies directed at the symptoms and risks of the nephrotic syndrome. Unless there are pressing indications to start immunosuppression sooner, patients should be followed for at least a month on a stable regimen of ACE inhibitors and/or ARBs to assess the response to this intervention. Cattran⁸ recommends observation for 6 months on conservative therapies to clarify whether the patient needs immunosuppressive treatment; immunosuppression should start sooner in high-risk patients who manifest declining renal function or other serious complications. It is generally agreed that patients who have low-grade proteinuria (<3.5 or 4 g/day) and normal renal function after the initial assessment and conservative interventions have a low risk of renal function deterioration and should be followed without immunosuppression. At the opposite end of the clinical spectrum, there is consensus that patients with the nephrotic syndrome and declining renal function due to membranous nephropathy should receive immunosuppressive agents.^{5,8,13}

Treatment for patients with normal renal function and nephrotic proteinuria has prompted an interesting debate. Some investigators have recommended that immunosuppressive treatments should only be used in patients who develop renal insufficiency or severe intolerable nephrotic syndrome (persistent proteinuria \geq 8 g/day).^{5,35,36} Others have recommended that patients with nephrotic proteinuria (>3.5 or 4 g/day) despite conservative measures should receive immunosuppressive agents.^{8,13} Torres and colleagues³⁵ identified 19 patients with nephrotic proteinuria plus the recent onset of renal insufficiency (serum creatinine \geq 1.5 mg/dL) and treated them with oral prednisone for 6 months accompanied by chlorambucil (0.15 mg/kg/day) for the first 14 weeks. At the end of follow-up (average 52 months), only 36% were in a complete or partial remission. The probability of renal survival was 90% at 7 years compared with 20% for a group of historical controls who had been managed conservatively. du Buf-Vereijken and colleagues³⁷ treated 65 patients with renal insufficiency (serum creatinine > 1.5 mg/dL or > 50% increase in serum creatinine) with cyclophosphamide (1.5–2.0 mg/kg/day) for 1 year and concurrent corticosteroids (1 g/day IV methylprednisolone for

3 days at the beginning of the first, third, and fifth months plus prednisone 0.5 mg/kg every other day for the first 6 months). At the end of follow-up (average 51 months), 72% were in a complete or partial remission. Renal survival was 74% at 7 years. Treatment-related complications were reported in 66% of patients, mainly due to bone marrow depression and infection. These studies illustrate the concern that delaying immunosuppressive therapy until renal dysfunction has evolved may decrease the probability of remission and increase the risk of treatment-related complications. In a recent review, du Buf-Vereijken and colleagues⁵ indicate that the threshold serum creatinine value of 1.5 mg/dL typically indicates significant renal function impairment, especially in elderly patients. They now seek to start immunosuppression earlier (at lower serum creatinine values) in high-risk patients by estimating the glomerular filtration rate based on the Modification of Diet in Renal Disease study equations and by assessing other prognostic factors such as urinary β_2 -microglobulin and IgG. Considering that an increased serum creatinine and chronic histologic changes indicate a poor prognosis, moderate- to high-risk patients should be identified as efficiently as possible before the patient experiences an irreversible loss of renal function reserve or serious complications of the nephrotic syndrome.

Nephrotic Syndrome without Renal Insufficiency

The value of alternate-day oral glucocorticoid monotherapy has been studied in three randomized controlled trials.^{38–40} Corticosteroids alone failed to increase the rate of long-term remissions of proteinuria in each of these controlled trials. Furthermore, corticosteroids appeared to prevent deterioration in renal function only in the U.S. collaborative trial; the apparent efficacy of corticosteroid therapy in this study may reflect the unusually high incidence of adverse outcomes in the control group. The aggregate impression is that corticosteroid monotherapy offers only marginal benefits, if any. Consequently, investigators have sought to identify alternative immunosuppressive drug regimens that might be more beneficial. Several studies support the value of cytotoxic drug regimens that combine corticosteroids with either chlorambucil or cyclophosphamide for the treatment of patients with idiopathic membranous nephropathy, nephrotic syndrome, and well-preserved renal function (Table 21-1).

Chlorambucil

The most convincing evidence has emerged from the multicenter, prospective, randomized clinical trials of Ponticelli and colleagues.^{41–44} They have shown that a 6-month regimen of alternate-month corticosteroids and chlorambucil decreases the risk of deterioration in renal function as well as the duration of the nephrotic syndrome. Ten-year renal survival was 92% in the treatment group compared with 60% among the controls.⁴⁴ The recommendation to employ chlorambucil and methylprednisolone for this subset of patients is supported by well-controlled clinical observations. However, a substantial number of patients are unable to tolerate the regimen. Ponticelli and colleagues⁴⁴ reported that 4 of 42 patients in one study had to discontinue this therapy because of adverse effects (two because of peptic ulcers that developed while on methylprednisolone, one because of pneumonia, and one

Table 21-1 Selected Randomized, Controlled Trials of Cytotoxic Drug Therapies and Calcineurin Inhibitors

Ref.	Baseline	Treatment	Outcome
Alternate-Month Corticosteroid and Cytotoxic Drug Therapy			
Ponticelli et al ^{41,42,44}	Plasma creatinine < 150 $\mu\text{mol/L}$; proteinuria > 3.5 g/day	Methylprednisolone alternating monthly with chlorambucil ($N = 42$) vs. control ($N = 39$) for 6 mo	Treatment favored remission of nephrotic syndrome and preservation of renal function
Ponticelli et al ⁴³	Plasma creatinine < 150 $\mu\text{mol/L}$; proteinuria > 3.5 g/day	Methylprednisolone alternating monthly with chlorambucil ($N = 45$) vs. methylprednisolone alone ($N = 47$) for 6 mo	Combination drug regimen associated with earlier remission of the nephrotic syndrome
Ponticelli et al ⁴⁵	Plasma creatinine < 150 $\mu\text{mol/L}$; proteinuria > 3.5 g/day	Methylprednisolone alternating monthly with either chlorambucil ($N = 50$) or cyclophosphamide ($N = 45$) for 6 mo	Regimens were equally effective in inducing remission of the nephrotic syndrome and preserving renal function
Reichert et al ⁶²	Nephrotic syndrome and deteriorating renal function	Methylprednisolone alternating monthly with chlorambucil ($N = 9$) vs. monthly pulse cyclophosphamide and pulse methylprednisolone every 2 mo ($N = 9$) for 6 mo	Renal function improved on chlorambucil regimen but not on pulse cyclophosphamide
Jha et al ⁴⁶	Nephrotic syndrome ≥ 6 mo; average MDRD GFR > 80 mL/min	Methylprednisolone alternating monthly with cyclophosphamide ($N = 47$) vs. control ($N = 46$) for 6 mo	Treatment favored remission of nephrotic syndrome and preservation of renal function
Calcineurin Inhibitors			
Cattran et al ⁷⁵	Declining renal function; persistent proteinuria ≥ 3.5 g/day	Cyclosporine ($N = 9$) vs. placebo ($N = 8$)	Average proteinuria and rate of renal function deterioration were decreased in the cyclosporine group, but not the placebo group
Cattran et al ⁴⁸	Creatinine clearance ≥ 42 mL/min/ 1.73 m ² ; nephrotic-range proteinuria despite at least 8 wk of prednisone ≥ 1 mg/kg/day	Cyclosporine + low-dose prednisone ($N = 28$) vs. placebo ($N = 23$) + low-dose prednisone	Complete or partial remissions of proteinuria in 75% of the cyclosporine group and 22% of the placebo group; relapse occurred after 50% of remissions
Praga et al ⁵²	Nephrotic syndrome ≥ 9 mo; Cockcroft-Gault eGFR ≥ 50 mL/min/ 1.73 m ²	Tacrolimus monotherapy ($N = 25$) vs. control ($N = 23$) for 18 mo	Treatment favored remission of nephrotic syndrome and preservation of renal function

Cockcroft-Gault eGFR, estimated glomerular filtration rate by the Cockcroft-Gault formula; MDRD GFR, glomerular filtration rate calculated by the Modification of Diet in Renal Disease study formula.

because of gastric intolerance to chlorambucil). The potential advantage of this approach must be balanced against the risks of malignancy, gonadal toxicity, reversible myelosuppression, infection, gastrointestinal intolerance, and hepatotoxicity associated with chlorambucil. Furthermore, patients should be informed that the long-term toxicities of this and other cytotoxic drug regimens for membranous nephropathy have not been fully defined.

Cyclophosphamide

Because most nephrologists are more familiar with cyclophosphamide than chlorambucil, Ponticelli and colleagues⁴⁵ conducted a multicenter controlled clinical trial to compare the efficacy and toxicity of these two alkylating agents when alternated with corticosteroids for the treatment of idiopathic membranous nephropathy. The two regimens appeared to be equally effective, and both are recommended for the treatment

of this subset of patients (Box 21-1). The authors observed a complete or partial remission of nephrotic syndrome in 82% of patients in the chlorambucil group and 93% of patients in the cyclophosphamide group. Approximately 30% of patients in each group experienced a relapse between 6 and 30 months after stopping treatment. Renal function tended to improve and then stabilize in both treatment groups. Notably, fewer patients stopped therapy prematurely because of adverse events in the cyclophosphamide group (4.5%) than in the chlorambucil group (12%).

More recently, Jha and colleagues⁴⁶ reported a randomized, controlled trial comparing a 6-month regimen of alternate-month prednisolone and cyclophosphamide to supportive treatment in adults with the nephrotic syndrome for at least 6 months. Remissions occurred significantly more frequently in the treatment group (72%) compared with the controls (35%). The 10-year dialysis-free survival rate was 89% in treated patients compared with 65% in controls ($P = .016$). Thus, cytotoxic drug therapy in this study appears to be associated with a renal survival advantage that is comparable with that observed by Ponticelli and colleagues.⁴⁴ Although these prospective, controlled trials provide evidence that cytotoxic drug therapy is more effective than supportive treatments or corticosteroids alone, Ponticelli and colleagues⁴⁷ report that patients randomized to a potentially less toxic regimen of synthetic corticotropin therapy experienced outcomes comparable with those seen in the patients randomized to cytotoxic drugs. This observation underscores the need for additional randomized, controlled trials to compare the efficacy and toxicity of cytotoxic drugs with those of other regimens described in this chapter.

Calcineurin Inhibitors

A randomized clinical trial reported by Cattran and colleagues⁴⁸ compared a 6-month course of cyclosporine with placebo in 51 patients with steroid-resistant idiopathic membranous nephropathy, nephrotic-range proteinuria, and a creatinine clearance of at least 42 mL/min/1.73 m². Adverse effects of cyclosporine included reversible decline in renal function,

an increased occurrence and severity of hypertension, and nausea. Two patients in each group progressed to renal insufficiency, defined as a doubling of serum creatinine. A complete or partial remission of proteinuria evolved by week 26 in 75% of the cyclosporine group and 22% of the control group ($P < .001$). By week 72, relapse occurred in approximately 40% of patients in each group. The authors questioned whether the high relapse rate observed in this study was related to the dose (3.5 mg/kg/day) or the duration of treatment (6 months rather than 1 year).

Fritsche and colleagues⁴⁹ analyzed data from the German Cyclosporine in Nephrotic Syndrome Study Group in an effort to estimate the optimal duration of cyclosporine therapy for idiopathic membranous nephropathy. They observed that complete remissions occurred up to 20 months after starting cyclosporine; the median treatment period before a complete remission was 225 days in this study. At present, there is insufficient information to determine the optimal duration of cyclosporine therapy for idiopathic membranous nephropathy. The high-risk characteristics of these patients justify a 6- to 12-month course of cyclosporine if the patient can be followed very closely (initially weekly, then biweekly). The risk of chronic cyclosporine nephrotoxicity can be decreased by initiating treatment at 3 mg/kg/day or less⁵⁰ and by frequent dose adjustments to avoid clinical and laboratory signs of toxicity. Once a complete or partial remission of proteinuria has been achieved, it is reasonable to taper the dose to approximately 1 to 1.5 mg/kg/day in an effort to maintain remission with a lower risk of nephrotoxicity. Alexopoulos and colleagues⁵¹ observed that relapses occurred significantly more often among patients on low-dose cyclosporine monotherapy compared with those on combination low-dose cyclosporine and prednisolone. Cyclosporine trough levels less than 100 ng/mL appeared to increase the risk of relapse. Most relapses responded to a temporary increase in cyclosporine and/or prednisolone dose.

Recently, Praga and colleagues⁵² reported a randomized, controlled trial evaluating tacrolimus monotherapy in patients with Cockcroft-Gault estimated glomerular filtration rate of 50 mL/min/1.73 m² or more and the nephrotic syndrome for

Box 21-1 Proposed Immunosuppressive Treatments for Idiopathic Membranous Nephropathy: Nephrotic Syndrome without Renal Insufficiency

Recommended Approaches

Alternate-month corticosteroids and cyclophosphamide for 6 months
 Months 1, 3, and 5: methylprednisolone 1 g/day IV for 3 days followed by 0.4 to 0.5 mg/kg/day orally for 27 days
 Months 2, 4, and 6: cyclophosphamide 2.0 to 2.5 mg/kg/day (initial dose) orally for 30 days
 Alternate-month corticosteroids and chlorambucil for 6 months
 Months 1, 3, and 5: methylprednisolone (as above)
 Months 2, 4, and 6: chlorambucil 0.2 mg/kg/day (initial dose) orally for 30 days

Alternative Approaches

Cyclosporine 3.5 mg/kg/day in two divided doses (initial dose) and low-dose prednisone for 6 to 12 months
 Tacrolimus monotherapy 0.05 mg/kg/day in two divided doses (initial dose), initial target trough 3 to 5 ng/mL, increase target trough to 5 to 8 ng/mL if remission not achieved within 2 months
 Mycophenolate mofetil 1 to 2 g/day in two to three divided doses for 6 to 24 months; attempt to taper off corticosteroids
 Synthetic corticotropin 1 mg IM every other week (initial dose), gradually increase to 1 mg IM twice weekly for 1 year (see Ponticelli and colleagues⁴⁷ and Berg and colleagues⁷⁹)
 Rituximab four weekly intravenous infusions of 375 mg/m²

at least 9 months despite treatment with maximally tolerated doses of ACE inhibitors or ARBs. The tacrolimus target trough was initially 3 to 5 ng/mL and was increased to 5 to 8 ng/mL after 2 months if the patient was persistently nephrotic. After treatment for 12 months, tacrolimus was tapered off over 6 months. The patients treated with tacrolimus were significantly more likely than controls to achieve a remission by 18 months (94% vs. 35%) and to have stable renal function. No patient in the tacrolimus group had a nephrotic relapse during drug tapering, but 47% had a relapse on average 4 months after tacrolimus was withdrawn.

Mycophenolate Mofetil

Several case series have described mycophenolate mofetil (MMF) treatment for patients who had previously failed to achieve a satisfactory response on corticosteroids, cytotoxic drugs, and/or cyclosporine. Miller and colleagues⁵³ treated 16 nephrotic patients and observed a 50% decrease in proteinuria in six patients and a sustained partial remission in two patients. MMF was discontinued due to adverse events in two patients (one had persistent diarrhea and the other had varicella-zoster infection). Choi and colleagues⁵⁴ treated 17 patients and reported that 2 achieved a complete remission and 8 had a partial remission. Corticosteroids and cyclosporine were successfully withdrawn in 14 of 15 patients who had been steroid or cyclosporine dependent. MMF was discontinued in three patients because of adverse events (severe erosive gastritis, pneumonia, and squamous cell cancer). Additional study is needed to determine the role of MMF in this condition.

Rituximab

Remuzzi and colleagues⁵⁵ and Ruggenti and colleagues^{56,57} have described an innovative approach using rituximab (375 mg/m² infusions weekly for 4 weeks) to treat patients with the nephrotic syndrome for at least 6 months despite ACE inhibitor therapy. The average protein excretion rate decreased significantly from 9.1 g/day to 4.6 g/day in eight patients with mild or no chronic tubulointerstitial lesions but did not improve significantly in six patients with more severe chronic histologic changes. The authors recommend a prospective trial to compare the efficacy and toxicity of rituximab with other

less specific immunosuppressive treatments in patients with mild or no chronic tubulointerstitial changes.

Nephrotic Syndrome with Renal Insufficiency

Several immunosuppressive drug regimens have been proposed for the treatment of nephrotic patients with impaired and declining renal function (Box 21-2); none is clearly superior. Pulse methylprednisolone regimens have yielded favorable short-term outcomes in some patients, but long-term outcomes have been less satisfactory.⁵⁸ Combining corticosteroids and azathioprine has led to inconsistent results in this population of patients.⁵⁹⁻⁶¹

Chlorambucil

Although there is considerable experience using alternate-month corticosteroids and chlorambucil for patients with well-preserved renal function, efforts to apply this regimen to patients with a decreased glomerular filtration rate have met with discordant results and a relatively high incidence of adverse events. To address this issue, modified dose schedules have been studied for azotemic patients⁶²⁻⁶⁵ and for elderly patients who are likely to have impaired renal functional reserve.^{66,67} A decreased dose of chlorambucil (~0.12 mg/kg/day) appears to ameliorate toxicity in patients with impaired renal function.⁶⁸ Concerns regarding the toxicity of corticosteroids in these patients has led several investigators to omit pulse methylprednisolone or to use alternate-day rather than daily oral prednisolone. Because the aggregate experience suggests that intravenous pulse methylprednisolone may contribute to favorable short-term outcomes in patients with declining renal function,^{58,64,65} 0.5- to 1-g doses of pulse methylprednisolone are recommended rather than omitting this component of the therapy (see Box 21-2).

Cyclophosphamide

Several regimens that combine corticosteroids and cyclophosphamide may be considered for the treatment of nephrotic patients with impaired renal function (see Box 21-2). There is evidence that cyclophosphamide can be substituted

Box 21-2 Proposed Immunosuppressive Treatments for Idiopathic Membranous Nephropathy: Nephrotic Syndrome with Renal Insufficiency

Recommended Approaches

Cyclosporine 3.5 mg/kg/day in two divided doses (initial dose) for 12 months

Alternate-month corticosteroids and cyclophosphamide for 6 months

Months 1, 3, and 5: methylprednisolone 0.5 to 1.0 g/day IV for 3 days followed by 0.4 mg/kg/day (or 1 mg/kg every other day) orally for 27 days

Months 2, 4, and 6: cyclophosphamide 1.5 to 2.0 mg/kg/day (initial dose) orally for 30 days

Alternate-month corticosteroids and chlorambucil for 6 months

Months 1, 3, and 5: methylprednisolone (as above)

Months 2, 4, and 6: chlorambucil 0.12 mg/kg/day (initial dose) orally for 30 days

Alternative Approaches

Cyclophosphamide 1.5 to 2 mg/kg/day (initial dose) for 1 year plus prednisone 0.5 mg/kg every other day for 2 to 6 months, then taper to 0.25 mg/kg every other day for the duration of therapy; consider methylprednisolone 1 g/day IV for 3 days at the beginning of months 1, 3, and 5

Mycophenolate mofetil 0.5 to 2 g/day in two to three divided doses plus low-dose prednisone for 6 to 12 months

for chlorambucil in the regimen of Ponticelli and colleagues for patients with well-preserved renal function, but this approach has not been rigorously evaluated in patients with impaired and declining renal function. Intuitively, this appears to be a reasonable (but unproven) approach given the extensive experience employing cyclophosphamide for the treatment of severe glomerular diseases and the relatively brief (3 months) exposure to a cytotoxic drug in the regimen of Ponticelli and colleagues.

Alternatively, several groups^{37,69–72} have studied daily oral cyclophosphamide and corticosteroids for a year or more in patients with declining renal function. Renal function stabilized or improved and at least partial remissions of nephrotic proteinuria were observed in most patients treated by investigators in the Netherlands,³⁷ Toronto,^{69,70} and Pittsburgh.⁷¹ These results were superior to those observed among concurrent (non-randomized) control subjects,^{69,70} but serious complications of treatment were observed including leukopenia, infections, amenorrhea, and cancer. Extended oral cyclophosphamide regimens for the treatment of Wegener's granulomatosis have been associated with an 11-fold increase in the incidence of lymphomas and a 33-fold increase in bladder cancers.⁷³

In an effort to reduce the toxicity of cytotoxic drug regimens, several investigators have evaluated intermittent pulse regimens of cyclophosphamide and methylprednisolone for high-risk patients with progressive disease. Falk and colleagues⁷⁴ observed that an intensive regimen of monthly pulse cyclophosphamide (for 6 months), pulse methylprednisolone (for 3 days), and alternate-day prednisone (starting at 1 mg/kg) was not superior to alternate-day prednisone alone (starting at 2 mg/kg) for patients with deteriorating renal function or persistent proteinuria associated with morbid complications.

A few prospective studies have compared cytotoxic drug regimens for the treatment of patients with nephrotic syndrome and declining renal function. Reichert and colleagues⁶² showed that a 6-month regimen of alternate-month methylprednisolone and chlorambucil was more effective than a 6-month regimen of monthly pulse cyclophosphamide and alternate-month pulse methylprednisolone. Branten and colleagues⁷² reported that daily oral cyclophosphamide and corticosteroids for 1 year was more effective than alternate-month methylprednisolone and chlorambucil for 6 months. Stable renal function and remissions of proteinuria were observed more frequently after cyclophosphamide treatment for 1 year. Treatment was modified, interrupted, or terminated prematurely because of adverse effects significantly more frequently in the chlorambucil group than in the cyclophosphamide group. Although 60% of the patients were randomly assigned to their treatment groups, this was a complex study in which some patients were not randomized concurrently and others were not randomized at all. Additional studies are needed to compare the risks and benefits of various cytotoxic drug regimens for nephrotic patients with declining renal function.

Cyclosporine

Future studies should include comparisons of the long-term efficacy and toxicity of cyclosporine and cytotoxic drug regimens. There has been interest in cyclosporine for patients with idiopathic membranous nephropathy, persistent nephrotic-range proteinuria, and declining renal function since Cattran and colleagues⁷⁵ reported the results of a controlled clinical

trial in which 17 patients with these characteristics were randomized to receive either cyclosporine (initially 3.5 mg/kg/day in two divided doses) or placebo for 12 months. Proteinuria and the rate of decline in creatinine clearance decreased significantly in the cyclosporine group (but not in the placebo group). Improvement in renal function and proteinuria was sustained in 75% of patients for a mean follow-up period of 21 months after cyclosporine was discontinued. Six of the nine cyclosporine-treated patients experienced elevations in serum creatinine ($\geq 30\%$) that reversed in five after a decrease in dose. Cyclosporine-treated patients also tended to require additional antihypertensive medication to maintain adequate blood pressure control. Geddes and Cattran⁷⁶ have recommended cyclosporine as preferred immunosuppressive therapy for patients with high-grade proteinuria and renal insufficiency. Conversely, Ponticelli and Villa⁷⁷ have underscored the nephrotoxic potential of cyclosporine and have suggested that patients with impaired renal function (creatinine clearance < 60 mL/min), severe hypertension, or severe interstitial fibrosis and tubular atrophy should not receive cyclosporine.

SUMMARY

Clearly, the optimal immunosuppressive therapy for patients with persistent high-grade proteinuria and renal insufficiency has not been determined. Meta-analyses published to date do not resolve this issue.^{12,78} New studies^{46,52} have been reported since those meta-analyses were performed, so this discussion focuses on data from individual studies, especially randomized, controlled trials. Box 21-2 depicts several recommended treatments. Although the recommendation to offer cyclosporine to patients with impaired renal function has been debated,^{76,77} evidence supporting this approach includes a small, randomized, controlled clinical trial.⁷⁵ Toxicities are largely reversible if the cyclosporine dose is adjusted in response to early signs of toxicity detected by very close follow-up of these patients. Studies supporting the use of alternate-month corticosteroid and cytotoxic drug therapy in patients with renal dysfunction include a small, randomized, controlled clinical trial⁶² and several uncontrolled case series.^{63–65,68} Renal function has tended to improve or stabilize at least transiently, and toxicity has been modulated by dose reduction. Alternative cytotoxic drug regimens have been studied as well. Intermittent pulse cyclophosphamide has not proven to be effective.^{62,74} Daily oral cyclophosphamide and corticosteroids for 1 year or more have been employed as salvage therapy for patients with progressive renal failure. Evidence supporting this approach includes a nonrandomized trial with concurrent controls,^{69,70} a clinical study that included randomized and nonrandomized patients,⁷² and uncontrolled case series.^{37,71} Although Branten and colleagues⁷² noted fewer short-term adverse effects among patients receiving daily oral cyclophosphamide and corticosteroids for 1 year than among those treated with alternate-month chlorambucil and corticosteroids for 6 months, it is the long-term toxicities of extended courses of daily oral cytotoxic drug therapy that prompt the greatest concern. Thus, an extended course of daily oral cyclophosphamide and corticosteroids should be reserved for patients manifesting progressive renal insufficiency who understand and accept the potential long-term toxicities of this approach.

At present, the choice of cyclosporine, cytotoxic drug therapy, or no immunosuppression should reflect the priorities of the individual patient as well as comorbid conditions that might affect the risk profile of each approach. Furthermore, attention should be focused on the comprehensive management of cardiovascular risk factors that are frequently observed in this population of patients. Modulation of non-immunologic factors that influence the rate of progression of chronic renal disease are likely to contribute to quality of life and to extend survival by delaying the need for dialysis. Thus, dietary modifications, diuretics, ACE inhibitors, angiotensin II receptor antagonists, and lipid-lowering agents are important therapeutic interventions that should be considered in all patients with membranous nephropathy to decrease the morbidity and mortality associated with the nephrotic syndrome.

NEW INSIGHTS INTO PATHOGENESIS AND RATIONAL BASIS FOR TREATMENT

Membranoproliferative glomerulonephritis (MPGN) is an uncommon disease, although its prevalence varies and is reportedly much higher in less prosperous countries.^{1–5} It most often affects older children or young adults who present with acute nephritis, nephrosis, or abnormal urine analysis. Based on differences resolved by electron microscopy, three types of MPGN are recognized, a simple classification belying considerable etiologic heterogeneity. MPGN type 1 and some cases of MPGN type 3 are immune complex diseases and may be associated with infection, systemic lupus erythematosus, or malignancy, although in other instances, MPGN type 3 appears to be unrelated to immune complex deposition.^{6–9} Serum complement profiles reflect classic pathway activation in at least some cases of MPGN types 1 and 3.^{10,11} Interestingly, the incidence of MPGN type 1, the most common variant of the three, is decreasing in a number of countries for reasons that are unclear but may reflect changing patterns of infectious disease.^{1,3,12} MPGN type 1 can be triggered by hepatitis C virus infection, an observation made primarily in Japan and the United States; this association is less frequent in some parts of Europe.^{13,14} (See Chapter 14 for detailed discussion and treatment of hepatitis C virus–associated renal disease). Unrecognized pathogens may be causally linked to many cases of idiopathic MPGN types 1 and 3. MPGN type 2 (more appropriately known as dense deposit disease [DDD]) is characterized by intramembranous glomerular basement membrane (GBM) deposits of unknown composition, but C3 deposition without immunoglobulin is another consistent glomerular abnormality.¹⁵

A series of observations in animals deficient in the complement regulator factor H (CFH) and a few families segregating mutations in the same gene have definitively established dysregulation of the alternative pathway (AP) of

complement as a pathogenetic mechanism for DDD.^{15–18} These studies validate earlier hypotheses based on the frequency of C3 hypocomplementemia and C3 nephritic factors ([CeNeFs] autoantibodies that stabilize the C3 convertase) in a significant proportion of MPGN patients together with rare examples of DDD in individuals with acquired AP dysfunction (Fig. 22-1).^{19,20} Patient data, however, indicate that familial AP dysregulation may be associated with all types of MPGN.^{21–24} The complexity of CFH-associated renal disease is revealed by its association with atypical hemolytic uremic syndrome (aHUS)²⁵ (see Chapter 26 for detailed discussion and treatment of aHUS): homozygous CFH mutations associated with decreased CFH serum levels are observed in some patients with DDD, whereas heterozygous mutations, especially of the C-terminus of CFH, are found in patients with aHUS.²⁶ Interestingly, some aHUS patients have decreased CFH serum levels, and there are reports of not only sequential development of MPGN type 1 and aHUS in a single individual but also of MPGN patients with mutations or polymorphisms in regions of the CFH gene usually associated with aHUS.^{27–29}

The functional importance of the polymorphisms in CFH (and CFH-related protein 5) that have been linked to DDD can be inferred from their overrepresentation in individuals with age-related macular degeneration, another condition strongly associated with the complement cascade and indeed identical retinal abnormalities arise prematurely in some patients with DDD.^{27,30} Mutations in other *CFHR* genes, such as *CFRH1* and *CFRH3*, have been described in aHUS but remain to be examined in MPGN.³¹ The potential influence of AP dysregulation on the classic complement pathway may also be relevant because experimental models of immune complex glomerulonephritis emphasize the impact of AP amplification on complement activation triggered through the classic pathway.^{32–34} It is feasible that mutations or polymorphisms in genes encoding AP-regulatory proteins

Figure 22-1 Membranoproliferative glomerulonephritis (MPGN) is caused by dysregulation of the alternative pathway (AP) of complement activation in some individuals, particularly those with dense-deposit disease (DDD). Normally, the AP is constitutively active at low levels through the hydrolysis of the thioester in C3 to C3(H₂O). Hydrolyzed C3 combines with factor B, and in the presence of factor D, C3(H₂O)Bb is formed. This intermediate convertase leads to the production of C3a and C3b from C3, and C3b enters the C3bBb amplification loop, which is indicated by the curved arrow. Amplification by fluid phase C3bBb occurs with low efficiency because free C3b is rapidly inactivated by factors H and I. However, C3b can also bind covalently to surfaces or to IgG as a covalent dimer. C3bC3bIgG is partially protected from inactivation by factors H and I by steric hindrance and is 7 to 10 times more efficient in generating a C3 convertase than surface-bound monomeric C3b. On surfaces or on IgG in the fluid phase, C3 convertase can become a C5 convertase by acquiring an additional C3b in its vicinity, which increases affinity for C5. Since factor H is required to control levels of C3b in the fluid phase, the *Cfh*^{-/-} mouse mutant develops DDD. Factor B is also critical to the formation of C3bBb, and consequently the *Cfb*^{-/-} mouse mutant does not develop DDD. In the *Cfh*^{-/-}.*C5*^{-/-} mouse mutant and the *Cfh*^{-/-} mouse mutant treated with anti-C5 antibodies, the degree of kidney disease is decreased compared with the degree of kidney disease seen in the *Cfh*^{-/-} mutant. This decrease is due to the prevention of C5a formation. The complement-regulating properties of factor H are as a decay-accelerating factor (destabilizing C3bBb) and as a cofactor for factor I. In addition to regulating the AP in the fluid phase, factor H binds polyanionic surfaces and regulates attached C3bBb. The glomerular basement membrane (GBM) lacks constitutive membrane-bound complement regulators and is particularly dependent on factor H for protection from the AP. GAGs, glycosaminoglycans.

contribute to the development of MPGN types 1 and 3 in individuals exposed to stimuli that incite IC deposition.

Genetic predisposition to MPGN may arise through mutations in other components of the complement system including membrane cofactor protein (MCP, CD46), and various factors in the classic and terminal pathways.^{29,35} The mechanisms underlying these associations remain to be determined but may include susceptibility to infection and impaired IC processing and clearance, which are likely to be important in MPGN types 1 and 3. Finally, MPGN has been linked to genes seemingly unrelated to complement regulation (X-linked MPGN and *LMNA* associated with partial lipodystrophy and DDD in the absence of C3NeF or hypocomplementemia).^{36,37}

The prognosis for patients with MPGN is guarded, with 40% to 50% requiring permanent renal replacement therapy in many series with extended follow-up (≥ 10 years). The impact of treatment has been at best limited (no significant effect on renal survival in most trials), and recurrence with graft loss is frequent in transplant recipients.^{14,38-41} A review of published data in 1999 advocated corticosteroid and antiplatelet therapy for selected children and adults with MPGN,

respectively, but the evidence for these recommendations is not compelling.⁴² There have been no subsequent sizable or prospective, randomized trials of treatment of MPGN, and, given the decreasing incidence of at least MPGN type 1, there are obstacles to future studies. Nevertheless, the remarkable developments in understanding the molecular basis for MPGN hold the promise of novel, targeted therapies that can be rapidly translated into patient care. As we learn more about the pathophysiology of MPGN, there may also be rationale for replacing current histologic classifications with pathogenetic descriptions to recognize homogeneous conditions with logical targets for treatment.⁴³ On that basis, we believe that there is good reason to collect DNA from all individuals with “idiopathic” MPGN and to perform CFH genotyping in at least all individuals with DDD, irrespective of serum complement levels because these are not invariably depressed in the context of abnormal complement regulation. Every opportunity should be taken to understand the basis of these increasingly uncommon conditions if we are to avoid relying solely on the results of historical trials in patient treatment. Herein we briefly review evidence relating

to classical treatments of MPGN and highlight experimental data that point toward future directions in therapy.

WHEN IS TREATMENT OF MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS NECESSARY?

The aggressive natural history and low (<5%) spontaneous remission rate of MPGN suggest that treatment is desirable. Indeed, data from Japan, where early detection of MPGN has been possible through school urinary screening programs, suggest that treatment can be highly effective.⁴⁴ In most countries, however, there is a delay in diagnosis, and, coupled with the uncertain efficacy, long duration, and potential toxicity of immunosuppressant protocols, treatment decisions can be difficult. Identifying patients with perceived adverse prognostic features is desirable, but the evidence base on which these decisions can be made remains limited. For example, heavy proteinuria and/or the presence of the nephrotic syndrome have been highlighted as markers of poor outcome in many but not all studies.^{14,38,39,41,45,46} Similarly, the impact of impaired renal function, hypertension, hypocomplementemia, C3NeF, and histologic features of DDD have also been contested.^{38,40,41,47-49} A recent retrospective series of 70 children and adults from Ireland used a multivariate analysis to show that nephrosis-range proteinuria, interstitial fibrosis, cellular crescents, and mesangial proliferation are independently associated with end-stage renal disease, which ranged from 12% for those with the most favorable composite histologic features to 92% for those with nephrosis-range proteinuria and cellular crescents at 10-year follow-up. DDD was associated with a comparatively worse outcome, but this was not independent of histologic parameters, an observation that is consistent with early reports.⁴⁵ In a retrospective series of 53 U.K. children, nephrotic syndrome and 20% chronic damage or more on biopsy at presentation predicted a worse outcome as did renal function at 1 year but not initial renal function.⁴⁶ MPGN type also did not predict outcome in this series.

Given our current understanding of the role of angiotensin II and proteinuria in progressive kidney disease, meticulous blood pressure control and generic strategies to decrease albuminuria based on angiotensin-converting enzyme (ACE) inhibitors or angiotensin II antagonists seem prudent in all patients with MPGN.⁵⁰ Smoking cessation, dietary salt restriction, and statin therapy where appropriate should not be overlooked. In practice, a high proportion of patients with MPGN, particularly children, continue to receive immunosuppressive therapy, which is most often corticosteroid based.^{46,51}

CORTICOSTEROID THERAPY

During the past 35 years, there have been a number of trials of prolonged steroid therapy for MPGN, primarily conducted in children. Methylprednisolone and alternate-day prednisolone have been the most often used treatments, but the results are not persuasive. In the largest randomized trial of extended alternate-day prednisolone in proteinuric children with MPGN ($N = 80$), improved renal survival in the treatment group at 130 months was marginal (62% vs. 12%, $P = .07$) and even less clear at

earlier time points.⁵² Among 71 children treated predominantly with extended alternate-day prednisolone in uncontrolled studies by West and colleagues,⁵³ 10- and 20-year renal survival rates were 82% and 56%, respectively, from disease onset. Notably subcapsular cataracts and growth failure occurred in 11 and 17% respectively. The same authors have suggested that MPGN type 3 is less responsive to alternate-day prednisolone than MPGN type 1, but the mean GFR of the two groups at entry was significantly different, which may have influenced outcome.⁵⁴ Patients with DDD in general do not respond to corticosteroid therapy,⁹ although children with juvenile acute nonproliferative glomerulonephritis, which may be a distinct entity or a rare crescentic variant of DDD, have been suggested to benefit.^{55,56} Data on the treatment of adult MPGN with steroids are extremely limited.

ANTIPLATELET AGENTS AND ANTICOAGULANTS

Antiplatelet and anticoagulant therapies have been advocated in MPGN based on platelet activation and reduced half-life. In a crossover trial ($N = 18$), unpaired analysis of warfarin plus dipyridamole versus placebo showed stabilization of serum creatinine and decreased proteinuria in the treatment group compared with the placebo group. However, analysis of patients completing crossover did not support an overall benefit of treatment, and there were significant risks, with a 37% hemorrhagic complication rate and one death from intracranial hemorrhage.⁵⁷ Encouraging results at 1 and 4 years from a randomized trial ($N = 40$) of aspirin plus dipyridamole versus placebo were not maintained in longer term follow-up (10-year renal survival rate was $49 \pm 11.5\%$ with treatment versus $41 \pm 11\%$ with placebo, not significant).^{58,59} A subsequent study comparing aspirin plus dipyridamole to placebo for nephrotic adults with MPGN ($N = 18$) reported a significant decrease in proteinuria with treatment and no excess bleeding.⁶⁰ Sizable but comparable decreases in blood pressure were achieved in the two groups, and more patients in the placebo arm received ACE inhibitors. Serum creatinine was unchanged at 36 months in both arms of the study.

CYTOTOXIC THERAPIES

A number of largely uncontrolled trials have combined cyclophosphamide with anticoagulant or antiplatelet treatments since the 1970s.^{61,62} Although none of these studies demonstrates a convincing advantage and serious adverse effects were not uncommon, cytotoxic agents are probably still in use because in two cohort studies that commenced in the 1980s, 11% and 17% of children received cyclophosphamide.^{46,51} Published data on the use of newer agents such as mycophenolate mofetil are extremely limited and are insufficiently well controlled to permit any definitive conclusions to be reached.⁶³

PLASMA EXCHANGE

Interest in the use of plasma exchange and infusion has been renewed by increased understanding of the role of dysregulated complement activation in MPGN. There are no sizable or controlled trials of these therapies, but case reports in both

MPGN and aHUS signal its potential efficacy where deficiencies or mutations in circulating complement regulators such as CFH are implicated.^{64–66} The half-life of factor H is approximately 6 days, and thus plasma infusions of 10 to 20 mL/kg every 14 days have been described.

KIDNEY TRANSPLANTATION

Concern persists over comparatively high rates of recurrence and consequent graft loss in patients undergoing transplantation for MPGN. MPGN type 1 and DDD recur in at least approximately 30% and approximately 50% of allograft recipients, respectively.^{67–69} United States Renal Data System data on graft loss with MPGN type 1 ($N = 1574$) demonstrate that the 5-year incidence of graft failure due to recurrent disease has increased from 3.5% in 1988 to 1994 to 7.2% in 1995 to 2003 ($P = .02$), whereas graft loss from other causes has decreased.⁷⁰ Five-year graft survival in North American children with DDD has been reported to be less favorable than that of pediatric allograft recipients as a whole ($50.0 \pm 7.5\%$ vs. $74.3 \pm 0.6\%$, $P < .001$) with 14.7% of grafts lost to recurrent disease.⁵¹ Glomerular crescents on transplant biopsy samples were associated with graft loss in that study. Little and colleagues¹⁴ reported that crescents on native renal biopsy were negatively correlated with allograft survival in a multivariate analysis and that this adverse histologic parameter accounted for a trend toward worse outcome of patients with DDD.

POTENTIAL THERAPEUTIC TARGETS IN THE COMPLEMENT CASCADE

Animal models of DDD and available human data provide clear rationale for attempting to correct uncontrolled activation of the alternative complement pathway in patients. The replacement of deficient or defective CFH by plasma infusion or exchange has been discussed and is likely to be most appropriate when CFH levels are decreased or genotyping identifies mutations known to impair CFH protein function. In the future, administration of purified or recombinant CFH may become feasible. Plasma exchange will also deplete circulating nephritic factors, although at present, there is limited evidence to suggest that removal of C3NeF is beneficial. Nephritic factors capable of stabilizing the AP convertase were first recognized more than 30 years ago, but their importance has remained in doubt because neither hypocomplementemia nor the presence/persistence of C3NeF appear to have prognostic value in most series, and there is no evidence to suggest that nephritic factors form part of the immune deposits in patients with MPGN.^{47,49} Nevertheless, because it is now clear that abnormal stabilization of the AP convertase (through CFH deficiency or defect) is sufficient to incite disease, interest in nephritic factors has been revived.

Considerable heterogeneity exists in the function of C3NeFs, which may well be relevant to the selection of patients most likely to benefit from therapeutic intervention targeting these autoantibodies.^{71–73} Meyers, West, and colleagues^{74,75} have argued that an autoantibody (terminal pathway NeF), which stabilizes the C3/5 convertase is largely

restricted to patients with MPGN type 3 and is likely to have pathogenetic significance, although others have disputed that it is invariably present. The serum complement profile and composition of glomerular immune deposits in patients with terminal pathway NeF and MPGN type 3 typically resemble those seen with factor H deficiency (in both humans and animals) with marked activation of the terminal pathway.^{7,11,16,17,22,76} In contrast, the C3NeF found in more than 80% of patients with DDD (C3 amplifying NeF) stabilizes the C3 convertase but not the C3/C5 convertase. West and colleagues⁷⁷ have demonstrated that glomerular immune deposits in at least some patients with DDD are derived from circulating C3 convertase that is not accompanied by C5 deposition and consequently their pathologic significance is unknown. Mice deficient in both CFH and C5 still develop proteinuria implying that C3 deposition alone is sufficient to damage the GBM, although the severity of renal disease is greater in mice with intact C5 expression.⁷⁸ Nephritic factors are least frequently observed in patients with MPGN type 1 but may still occur and can stabilize both AP and classic pathway convertases.^{8,79–81} Once the pathogenetic significance of these various nephritic factors is better comprehended, there will be a clearer rationale for plasma exchange and B cell–targeted therapies (e.g., rituximab) in selected patients.⁸²

As we have indicated (see Fig. 22-1), AP dysregulation of various origins impinges on the terminal complement pathway, which leads to assembly of the membrane attack complex and production of the anaphylatoxin C5a, and this identifies another potential therapeutic target. Preventing C5 activation has a protective effect in CFH-deficient mice and a humanized monoclonal anti-C5 antibody, eculizumab, has been shown to be clinically efficacious in another disease defined by defective complement regulation, paroxysmal nocturnal hemoglobinuria.^{78,83} There is a clear rationale for considering eculizumab in patients with MPGN and documented abnormal AP activation (in particular, those with DDD, CFH dysfunction associated with any clinicopathologic variant of MPGN, or MPGN type 3 with terminal pathway C3NeF). There is also reason to consider eculizumab in patients with MPGN types 1 and 3 associated with IC deposition and/or classic pathway activation because again recruitment of the terminal pathway may well incite glomerular injury. Notably, there has been interest in the use of eculizumab to treat both lupus nephritis and membranous nephropathy in which similar mechanisms are operational, although experience in membranous nephropathy suggests that adequate dosing may be critical to achieve benefit.^{84,85} Careful exclusion of occult infection is essential before considering modulation of this arm of the innate immune system.

Correction of complement dysregulation is theoretically possible through liver transplantation, and combined kidney/liver transplantation have been reported in patients with recurrent aHUS.⁸⁶ Perioperative plasma exchange is probably advisable given the apparent increased potential for graft thrombosis in the setting of CFH deficiency.⁸⁷ It seems likely that such strategies will be attempted in MPGN.

Finally, the GBM may be another potential therapeutic target in MPGN even when the precipitants of complement activation cannot be readily identified. Complement activation is

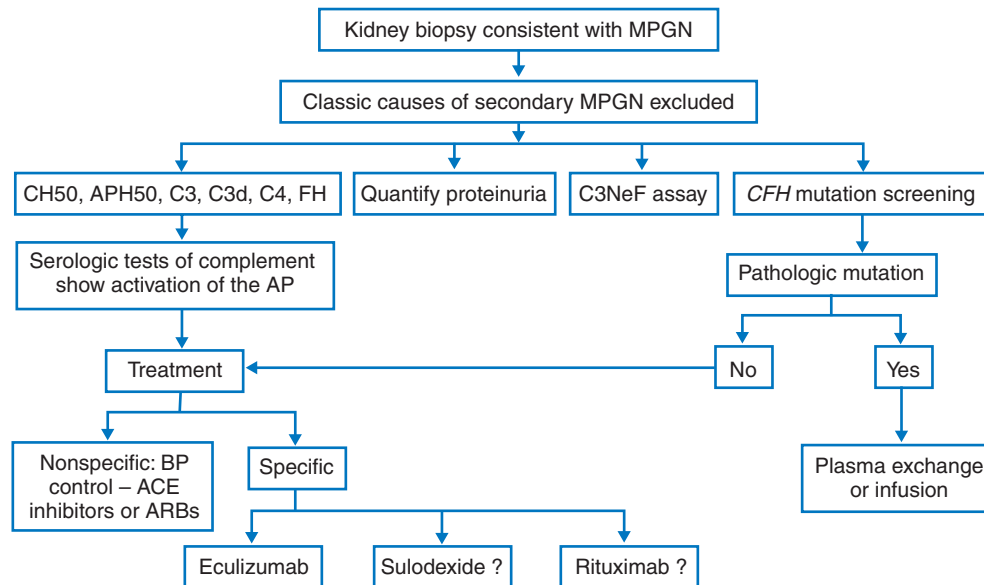

Figure 22-2 Flow diagram for the diagnostic evaluation and possible treatment of idiopathic membranoproliferative glomerulonephritis (MPGN) in which there is evidence of dysregulation of alternate pathway (AP) activity (e.g., dense-deposit disease). Diagnosis requires a renal biopsy, which must show pathognomonic electron-dense deposits. Serologic tests should include C3 (expected to be low), C3d (a breakdown product of C3, expected to be increased), C4 (may be low), and CH50 and APH50, two general tests of activity of the classic and APs, respectively. Screening should also include assaying C3NeF and determining levels and the nucleotide sequence of factor H. The rationale for the treatment options presented is discussed in the text. Serologic markers of AP activity and serologic and urinary markers of kidney function should be monitored regularly. Suggested drug regimens are eculizumab 600 mg IV once weekly for 4 weeks followed by maintenance dosing with 900 mg IV every 2 weeks (based on its use in paroxysmal nocturnal hemoglobinuria⁵⁷); sulodexide 200 mg/day PO; rituximab 375 mg/m² IV weekly for 4 weeks (based on its use in hepatitis C virus–associated cryoglobulinemia and idiopathic membranous nephropathy; monthly maintenance doses may also be considered). ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; BP, blood pressure.

known to cause loss of heparin sulfate from cells and extracellular matrices and could mediate GBM injury during ischemia reperfusion.⁸⁸ Furthermore, polymorphisms in the CFH gene that may affect its interaction with heparin and other glycosaminoglycans have been described in patients with DDD, and up-regulation of GBM-associated heparanase occurs in the context of DDD.^{27,89} Therefore, the efficacy of sulodexide, a highly purified glycosaminoglycan now being tested in diabetic nephropathy where the glycosaminoglycan composition of GBM is also altered may be relevant to MPGN.⁹⁰ Potential indications for these new therapeutic options are shown in Figure 22-2.

SUMMARY

The treatment of MPGN remains a clinical challenge because the available evidence base is limited in scope and offers only qualified endorsement for conventional treatments. At least some forms of MPGN are becoming less common and the current classification system may benefit from restructuring. The importance of the alternative complement pathway in DDD is clear and is potentially amenable to novel therapeutic manipulations. Furthermore, these same observations may well be pertinent to many cases of MPGN types 1 and 3: patients with terminal pathway C3NeF exhibit overt

AP dysregulation, activation of the terminal complement pathway through either classic pathways or APs probably mediates glomerular damage, and polymorphisms in AP-regulator genes could influence amplification of classic pathway activation. At present, the comparative benefits of treatments such as plasma infusion/exchange, eculizumab, and rituximab have not been examined, and although plasma infusion/exchange seems most logical for patients with identified CFH deficiency or functional mutation, definitive protocols cannot be offered. However, we believe that these options are therapeutically attractive and should be considered in the context of the limited efficacy of conventional therapies. A key question that remains to be addressed is the appropriate timing for the use of newer complement-modulating therapies. Reserving treatment for patients who have not responded to generic treatments may decrease cost and risk of treatment-related adverse events in patients with disease that has a favorable natural history, but at the same time irreversible glomerular scarring and recruitment of nonimmunologic mechanisms of injury may occur, thus limiting the effectiveness of new treatments in those with more aggressive disease. Clearly there is a need for further investigation of pathogenetic mechanisms, and this may well be the most successful strategy for improving outcomes in uncommon diseases for which the organization of large, controlled therapeutic trials is problematic.

Diagnosis, Clinical Features, and Kidney Histology 265	

Several disorders fall into the broad category of fibrillary and monoclonal immunoglobulin-associated kidney diseases (Table 23-1). Fibrillary kidney diseases include all types of amyloidosis that affect the kidney, fibrillary glomerulonephritis (GN), and immunotactoid glomerulopathy. Monoclonal immunoglobulin-associated kidney disorders include AL amyloidosis, light-chain or heavy-chain deposition disease (LCDD and HCDD, respectively), and myeloma cast nephropathy. There is probably a monoclonal immunoglobulin component in at least some cases of immunotactoid glomerulopathy, and thus, like AL amyloidosis, this disorder should be considered both fibrillary and monoclonal immunoglobulin-associated. Type I and II cryoglobulinemias are monoclonal immunoglobulin-associated diseases that are covered in Chapter 14.

AMYLOIDOSIS

Classification, Clinical Features, and Kidney Histology

Amyloidosis is a group of diseases in which proteins that are normally soluble form insoluble fibrils in tissues. The fibrils have a specific structure that renders them morphologically

indistinguishable regardless of the protein from which they form. Amyloid fibrils are composed of four to six protofilaments with a high β -pleated sheet content that interact in a highly ordered manner. The ultrastructure of amyloid fibrils is responsible for the binding by Congo red dye and the amyloid-defining birefringence when Congo red-stained fibrils are viewed under polarized light.¹

The amyloidoses are classified based on the precursor protein that forms the fibrils and by the distribution of amyloid deposition as either systemic or localized. Localized amyloidosis refers to disease in which the amyloid is deposited only at the site of synthesis of the amyloidogenic protein. Localized disease does not affect the kidney and is not covered in this chapter. The major types of systemic amyloidosis are immunoglobulin light chain (AL), amyloid A (AA), the familial or hereditary amyloidoses, senile systemic amyloidosis, and β_2 -microglobulin amyloidosis (Table 23-2). Immunoglobulin heavy chain (AH) amyloidosis is extremely rare and is not discussed separately from the much more common AL amyloidosis. Senile systemic and β_2 -microglobulin amyloidosis do not affect the kidney and also are not discussed further in this chapter.

The clinical manifestations of amyloidosis depend on the organs involved.² Organ involvement can be widespread, as is frequent in AL amyloidosis, or restricted to one or two

Table 23-1 Fibrillary and Monoclonal Immunoglobulin Diseases of the Kidney

Disease	Fibril Diameter and Orientation	Congo Red Staining	Detectable Monoclonal Immunoglobulin Protein*	Urinary Findings	Kidney Pathology	Extrarenal Manifestations
Amyloidosis	8–10 nm, randomly arrayed	Yes	AL or AH: yes [†] ; light-chain isotype more often λ than κ ; other amyloidoses: no	Albumin, usually nephrotic range	Mesangial expansion and/or nodules, weakly PAS positive; reactivity by IF to single light-chain isotype; fibrils by EM	Yes
Fibrillary glomerulonephritis	15–20 nm, randomly arrayed	No	Usually not	Albumin, nephrotic or subnephrotic range; microscopic hematuria	Mesangial expansion by PAS-positive material, capillary wall thickening, double contours; reactivity by IF to Ig, light chains, complement, usually without restriction to single heavy-chain subclass or light-chain isotype; fibrils by EM	Rare
Immunotactoid glomerulopathy	30–60 nm microtubules, organized parallel distribution	No	Sometimes [‡]	Albumin, nephrotic, or subnephrotic range; microscopic hematuria	Mesangial expansion with PAS-positive material, mild mesangial hypercellularity, thickening of glomerular capillary walls; reactivity by IF to complement and Ig; can be restricted to single heavy-chain subclass and light-chain isotype; electron-dense deposits with substructure and fibrils by EM	Rare
Light or heavy chain deposition disease	No fibrils	No	Usually [§] ; light-chain isotype more often κ than λ	Albumin, often nephrotic range, unless isolated tubular involvement; microscopic hematuria in some patients	Strongly PAS-positive nodular glomerulosclerosis; reactivity by IF along glomerular and tubular basement membranes to single light-chain isotype (LCDD) or immunoglobulin class (HCDD); large, granular electron-dense deposits along basement membranes and in mesangium	Yes
Myeloma cast nephropathy	No fibrils	No	Yes; high plasma cell burden; light-chain isotype more often κ than λ	Light-chain proteinuria	Intratubular highly refractile and often fractured casts, interstitial inflammatory cells and fibrosis	Yes

*Methods for detection of monoclonal immunoglobulin protein include serum immunofixation electrophoresis and urine immunofixation electrophoresis, quantitative serum-free light-chain assay, and bone marrow biopsy.

[†]Plasma cell burden is usually low, unless occurring in conjunction with multiple myeloma.

[‡]Lymphoproliferative disorder is evident in some patients.

[§]Plasma cell burden is usually low, unless occurring in conjunction with multiple myeloma. Serum immunofixation electrophoresis or urine immunofixation electrophoresis usually reveals monoclonal protein but in some cases the only evidence of monoclonality is single light chain isotype or heavy chain class in tissue biopsy.

EM, electron microscopy; HCDD, heavy-chain deposition disease; IF, immunofluorescence; LCDD, light-chain deposition disease; PAS, periodic acid-Schiff.

Table 23-2 Types of Systemic Amyloidosis

Disease	Amyloidogenic Protein	Organ Involvement
AL amyloidosis	Monoclonal immunoglobulin light chain or fragment	Kidney, heart, liver, gastrointestinal tract, spleen, nervous system, soft tissue, thyroid, adrenal gland
AH amyloidosis	Monoclonal immunoglobulin heavy chain or fragment	Rare; kidney involvement predominates in the small number of reported cases
AA amyloidosis	Serum amyloid A fragment	Kidney, liver, gastrointestinal tract, spleen, autonomic nervous system, thyroid
Hereditary amyloidoses		
Transthyretin amyloidosis	Transthyretin	Peripheral nervous system, heart, vitreous opacities; kidney involvement is not typical
Fibrinogen A α amyloidosis	Fibrinogen A α chain	Kidney, liver, spleen; hypertension is common; kidney involvement is predominantly glomerular
Apolipoprotein A1 amyloidosis	Apolipoprotein A1	Kidney, liver, heart, skin, larynx; kidney involvement is predominantly medullary
Apolipoprotein A2 amyloidosis	Apolipoprotein A2	Kidney
Lysozyme amyloidosis	Lysozyme	Kidney, liver, gastrointestinal tract, spleen, lymph nodes, lung, thyroid, salivary glands
Gelsolin amyloidosis	Gelsolin	Cranial nerves, cornea
Senile systemic amyloidosis	Transthyretin (wild type)	Heart, soft tissue
Dialysis-related amyloidosis	β_2 -microglobulin	Osteoarticular tissue; less commonly involves gastrointestinal tract, blood vessels, heart

organs or tissue types (see Table 23-2). The kidney is the most common site of amyloid deposition for AL, AA, apoA1, and apoA2 amyloidosis and also is often involved in fibrinogen A α disease. Nephrotic syndrome with progressive loss of glomerular filtration rate and eventual development of end-stage renal disease (ESRD) is the typical clinical course for amyloid nephropathy, although nonproteinuric disease does occur when amyloid deposition is confined to the tubulointerstitium or vasculature. Nephrotic syndrome from amyloidosis can be severe with urinary protein excretion in the range of 10 to 20 g/day, marked hypoalbuminemia, and diuretic-resistant anasarca. Amyloid deposition in the heart produces a restrictive cardiomyopathy with thickening of the ventricular walls. Because the wall thickening is caused by an infiltrative rather than a hypertrophic process, the electrocardiographic signal typically is of low voltage. The finding of low voltage on the electrocardiogram can help distinguish amyloid heart disease from hypertensive heart disease. Autonomic nervous system involvement typically causes orthostatic hypotension, impaired motility of the gastrointestinal tract manifested as early satiety, diarrhea or constipation, and erectile dysfunction. Hepatic involvement is characterized by an enlarged liver and elevated alkaline phosphatase blood concentration, but preserved liver function in most cases. Sensory neuropathy, soft-tissue amyloid deposition, and ecchymoses from capillary fragility are other common disease manifestations in some, but not all, types of amyloidosis.

Amyloid can deposit anywhere in the kidney. Glomerular involvement tends to predominate but is not always present, particularly in certain types of hereditary amyloidosis. By light microscopy, glomerular amyloid appears as amorphous material in the mesangium and capillary loops. Mesangial deposits can produce nodules that resemble lesions of diabetic nephrop-

athy or LCDD. However, in contrast to diabetic nephropathy or LCDD, nodules in amyloid-associated nephropathy stain weakly with periodic acid–Schiff because they are composed of amyloid protein rather than extracellular matrix. Amyloid deposition in the tubulointerstitium produces tubular atrophy and interstitial fibrosis. By electron microscopy, amyloid fibrils appear to be randomly arrayed without an ordered orientation; they are nonbranching and have diameters of 8 to 10 nm.

Light or electron microscopic examination of a kidney biopsy specimen does not enable determination of the type of amyloidosis. Immunofluorescence examination can, but does not necessarily, reveal deposition of a single light-chain isotype in AL amyloidosis and should be negative for reactivity against intact immunoglobulins or complement. AA protein can be detected by immunofluorescence or immunohistochemistry with commercially available antibodies.³

Treatment of Amyloidosis

AL Amyloidosis

AL amyloidosis is the most common of the systemic amyloidoses. The disease course varies substantially among patients; however, in general, AL disease tends to progress more rapidly than other types of amyloidosis and, if not effectively treated, is usually fatal. There have been tremendous advances in the treatment of AL amyloidosis during the past decade, and it is now possible to produce remission of the hematologic disease, or at least a reduction in the production of the amyloidogenic light chain, in a significant proportion of patients.

Current treatments for AL amyloidosis are summarized in Table 23-3.⁴⁻¹⁷ The treatments are all directed at the clonal

Table 23-3 Treatments for AL Amyloidosis

Regimen	REPRESENTATIVE STUDIES (REF.)			Utility
	Study	Description	Result	
Cyclic oral melphalan with prednisone	Skinner et al, ⁴ N = 100 (2 treatment groups)	Randomized, controlled trial of melphalan/prednisone/colchicine vs. colchicine	Extended survival from 7 to 12 mo	Reserve for patients unable to tolerate more effective treatments
	Kye et al, ⁵ N = 220 (3 treatment groups)	Randomized, controlled trial of melphalan/prednisone/colchicine vs. melphalan/prednisone vs. colchicine	Extended survival from 8 to 18 mo	
IV high-dose melphalan and autologous stem cell transplantation (HDM/SCT)	Comenzo et al, ⁶ N = 25	Single-center observational study	Established feasibility of the approach	Reasonable to consider as first-line treatment for selected patients. Treatment at centers specializing in amyloidosis is recommended because of treatment-associated toxicity.
	Dispenzieri et al, ⁷ N = 126	Single-center case-control study of HDM/SCT vs. oral melphalan/prednisone	4-yr survival 71% vs. 41% in HDM/SCT and melphalan/prednisone groups, respectively	
	Skinner et al, ⁸ N = 312	Single-center observational study	Complete hematologic response: 40%; median survival: 4.6 yr; TRM: 13%	
	Goodman et al, ⁹ N = 92	Multicenter observational study	Median survival: 5.3 yr; TRM: 23%	
	Sanchorawala et al, ¹⁰ N = 53	Single-center observational study of tandem transplantation	5 of 17 patients (31%) who had 2nd HDM/SCT converted from partial to complete hematologic response	
	Jaccard et al, ¹¹ N = 100	Multicenter randomized, open-label trial of HDM/SCT vs. oral melphalan plus dexamethasone	Median survival: 22.2 and 56.9 mo in HDM/SCT and melphalan/dexamethasone groups, respectively; TRM with HDM/SCT was 24% (higher than that seen in most single-center studies)	
Oral melphalan with high-dose dexamethasone	Palladini et al, ¹² N = 46	Single-center observational study of patients not eligible for HDM/SCT	33% had complete hematologic response; median time to response; 4.5 mo	First-line treatment for patients too ill to tolerate HDM/SCT or for patients receiving treatment at center that does not specialize in amyloidosis
	Jaccard et al, ¹¹ N = 100	Multicenter, randomized, open-label trial of HDM/SCT vs. oral melphalan plus dexamethasone	Median survival: 22.2 and 56.9 mo in HDM/SCT and melphalan/dexamethasone groups, respectively, TRM with HDM/SCT was 24% (higher than that seen in most single-center studies)	Duration of hematological response and tolerability of repeated courses of dexamethasone not established

Thalidomide/ dexamethasone	Seldin et al, ¹³ N = 16	Single-center observational study of thalidomide as single agent	None of the patients had complete hematologic response; 50% of patients discontinued treatment because of drug-related toxicity (e.g., pulmonary edema, peripheral neuropathy, renal impairment, sedation)	Thalidomide is poorly tolerated in AL amyloidosis; lenalidomide, a thalidomide analogue, appears to be as effective and better tolerated (see below)
	Dispenzieri et al, ¹⁴ N = 12	Single-center observational study of thalidomide as single agent	All patients withdrew from the study because of treatment-related toxicity	
	Palladini et al, ¹⁵ N = 31	Single-center observational study of thalidomide with intermediate-dose dexamethasone	31% of patients had complete hematologic response; 65% of patients had treatment-related toxicity	
Lenalidomide/ dexamethasone	Sanchorawala et al, ¹⁶ N = 34	Single-center observational study	29% of assessable patients had complete hematologic response; toxicities included fatigue, myelosuppression, and thromboembolic events	Based on small published experience, appears to be good option for patients unable to tolerate or unresponsive to HDM/SCT or melphalan with high-dose dexamethasone
	Dispenzieri et al, ¹⁷ N = 23	Single-center observational study	40% of patients had hematologic response (partial or complete); toxicities were fatigue, myelosuppression, and rash	

TRM, treatment-associated mortality.

plasma cells producing the amyloidogenic light chain. Treatment efficacy is usually evaluated based on the hematologic response and patient survival. A complete hematologic response is defined as the absence of detectable monoclonal light chain by serum and urine immunofixation electrophoresis, normal serum concentrations or ratios of κ and λ light chains by a quantitative nephelometric assay, and a bone marrow biopsy specimen without increased plasma cells or evidence of plasma cell clonality. Because the toxicities of the treatments differ in both quality and severity, selection of treatment requires careful consideration of the distribution of organ involvement and the level of organ dysfunction in an individual patient.

For many years, the standard treatment of AL amyloidosis consisted of repeated cycles of oral melphalan with prednisone.^{4,5} Although such treatment has been shown in randomized, controlled trials to extend survival, its benefit is modest, increasing median survival by only approximately 5 to 10 months (see Table 23-3). Multiple cycles of treatment are required before there is benefit; during this period, progression of organ dysfunction is likely. Importantly, attainment of a complete hematologic response is exceedingly rare with this approach. Although the use of cyclic oral melphalan and prednisone is appropriate for patients who cannot tolerate more aggressive alternatives, the regimen has been replaced, to a large extent, by more effective treatments.

High-dose melphalan and autologous stem-cell transplantation (HDM/SCT) is currently viewed by many as the treatment most likely to produce a complete hematologic remission.^{7,8,18} This treatment approach consists of mobilization of peripheral stem cells using growth factor, typically granulocyte colony-stimulating factor, collection of stem cells with leukopheresis, intravenous administration of myeloablative doses of melphalan, and infusion of the stem cells to support bone marrow recovery. In single-center series, complete hematologic remission rates with this approach range from 25% to 67%, and median survival, in those studies that reported it, is approximately 5 years.^{8,19-24} The eligibility criteria for treatment with HDM/SCT vary among these series, and it is important to recognize that in most of the studies, the treatment was conducted at referral centers with particular expertise in treating patients with amyloidosis. Treatment-associated mortality appears to be higher in multicenter studies than in single-center studies, probably because in the former, many of the patients received care at centers that do not have extensive experience treating amyloidosis.^{9,25}

The toxicities of HDM/SCT include those associated with the chemotherapy (e.g., mucositis, cytopenia, infection, bleeding), as well as toxicities related to stem-cell mobilization and collection. The administration of growth factor for stem-cell mobilization can cause substantial fluid retention that is poorly tolerated in patients with heart involvement or severe nephrotic syndrome. Collection of stem cells can trigger arrhythmias or hemodynamic alterations, particularly in individuals with heart involvement. Treatment-related mortality is substantially higher when HDM/SCT is used for AL amyloidosis (approximately 14% in amyloidosis referral centers) than when used for multiple myeloma (<5%), undoubtedly because of the underlying organ dysfunction in patients with amyloidosis.²⁶ Advanced

cardiac disease, reduced renal function, hypotension from autonomic nervous system dysfunction, involvement of more than two organs, and poor performance status by oncologic assessment scales are predictors of treatment-associated morbidity and mortality with HDM/SCT.

For patients who have a partial, but not complete, hematologic response to HDM/SCT, tandem cycles of high-dose melphalan can be performed if adequate stem cells for two courses of chemotherapy are collected initially. A single-center study evaluating this approach in 53 patients was recently published.¹⁰ Twenty-seven (55%) of the enrolled patients attained a complete hematologic response after the first cycle of high-dose melphalan and thus did not undergo tandem transplantation. Of the 22 patients who did not achieve a full response after initial treatment, 17 received a second treatment with HDM/SCT. One of these patients died during the peritransplantation period, and five (31%) achieved a complete hematologic response. These findings suggest that for some individuals, a second stem-cell transplantation can convert a partial hematologic response to a full response.

An alternative to myeloablative doses of melphalan with stem-cell transplantation that is gaining increasing attention is cyclic oral melphalan with high-dose dexamethasone (40 mg/day), typically administered for 4 consecutive days every 4 weeks. Experience with this approach was initially reported by Palladini and colleagues¹² in a study of 46 patients who were not eligible for HDM/SCT. Fifteen patients (33%) had a complete hematologic response and 31 (67%) had a partial hematologic response after a median of four cycles. The treatment was well tolerated in this series, although fluid retention, particularly in patients with amyloid cardiomyopathy or nephrotic syndrome, and myopathy are potential problems associated with repeated courses of high-dose dexamethasone. A multicenter, randomized trial comparing HDM/SCT to cyclic oral melphalan with dexamethasone was recently published.¹¹ The trial randomized 50 patients to each treatment arm. Median survival, the primary endpoint of the trial, was 22.2 months in the HDM/SCT group compared with 56.9 months in the cyclic oral melphalan with high-dose dexamethasone group, a statistically significant and clinically important difference. Importantly, 47% of the 38 patients in the melphalan plus dexamethasone group who received at least three cycles of melphalan with high-dose dexamethasone had a complete hematologic response, suggesting that the treatment approach can, at least temporarily, eradicate the clonal plasma cells. This study is the first multicenter, randomized trial comparing two different treatments for AL amyloidosis, and that alone makes it important. Although the findings of the trial suggest that the efficacy of oral melphalan with high-dose dexamethasone is as good as or better than that of HDM/SCT, it is important to note that (1) the treatment-related mortality with HDM/SCT was higher in this trial than that observed in single-center studies carried out at referral centers, (2) the median survival with HDM/SCT was substantially lower in this trial than in several previously reported single-center experiences, and (3) the durability of hematologic response after discontinuation of melphalan/dexamethasone was not reported. Clarification of the respective roles of HDM/SCT and oral melphalan with

dexamethasone should emerge over the next few years with additional experience and additional studies.

Thalidomide is an immunomodulatory agent with activity against plasma cells that has been used either alone or in combination with dexamethasone for patients with AL amyloidosis who either are too ill to undergo HDM/SCT or have not responded to the treatment. Although the drug appears to have some efficacy, it has been found to be poorly tolerated in patients with AL amyloidosis.^{13,14} Lenalidomide is a thalidomide analogue that patients with amyloidosis seem to tolerate better as it is less sedating and less likely than thalidomide to cause peripheral neuropathy. Small studies suggest that lenalidomide has efficacy in AL amyloidosis.^{16,17} Bortezomib, a proteasome inhibitor approved for the treatment of multiple myeloma, is starting to be studied as a treatment for AL amyloidosis, but its efficacy has not been established.

An important finding from the HDM/SCT experience is that improvements in function of affected organs can occur in AL amyloidosis and that the improvements are much more likely for patients who achieve a complete hematologic response than for those with persistent hematologic disease. With regard to kidney disease, substantial reductions in proteinuria and other features of nephrotic syndrome occur in the majority of patients if production of the amyloidogenic light chain is halted.^{27,28} Because of the variability among patients in the rate of decline in GFR, as well as high mortality rates among patients who do not respond to treatment, it has been more difficult to evaluate the impact of hematologic response on progression of renal impairment; such studies are under way.

AA Amyloidosis

AA amyloidosis occurs in the setting of long-standing inflammation when a proteolytic fragment of the acute phase reactant serum amyloid A forms amyloid. The most common inflammatory conditions underlying AA amyloidosis are rheumatoid arthritis, familial Mediterranean fever, inflammatory bowel disease, and chronic infections such as osteomyelitis. The current treatment approach for AA amyloidosis is to treat the underlying inflammatory disease and thereby reduce production of serum amyloid A. In familial Mediterranean fever, a disease associated with a high rate of development of AA amyloidosis, lifelong treatment with colchicine to inhibit familial Mediterranean fever-associated inflammation prevents amyloidosis in many patients.²⁹ Marked reductions in proteinuria have been reported in individuals with AA amyloidosis-associated kidney disease from a variety of underlying inflammatory conditions after treatment with cytotoxic agents or tumor necrosis factor receptor blockers.^{30–32} These functional improvements are presumed to be due to suppression of serum amyloid A production and resultant decrease in AA amyloid formation. However, it is possible that these agents also have additional antiamyloid effects through suppression of cytokine production or by altering the expression of specific mediators of amyloid fibril-induced cellular toxicity.

For many individuals with AA amyloidosis, adequate suppression of serum amyloid A production is not possible. Fibrillogenesis inhibition using small molecules that have structural similarity to glycosaminoglycan moieties is a treatment approach that is currently under investigation. Because of the role of glycosaminoglycans in promoting amyloid fibril formation and tissue deposition, interfering with interactions between

glycosaminoglycans and amyloidogenic proteins or fibrils should decrease new amyloid formation and might promote degradation of existing amyloid deposits. A multicenter, randomized placebo-controlled trial of 183 individuals with AA amyloidosis-associated kidney disease found that eprodisate treatment reduced the risk of a composite endpoint of renal decline or death.³³ The results of this trial are promising; however, the drug is not yet approved for use by either the U.S. Food and Drug Administration or the European Agency for the Evaluation of Medicinal Products.

Hereditary Amyloidoses

Because transthyretin (TTR) is synthesized by the liver, production of amyloidogenic variants of TTR can be eliminated by orthotopic liver transplantation. The abnormal amyloidogenic TTR variant disappears from the circulation after the liver is removed and replaced with a liver expressing only wild-type TTR. Orthotopic liver transplantation has been performed in more than 660 individuals with TTR amyloidosis and is considered the definitive treatment for the disease.³⁴ Unfortunately, amyloid deposition sometimes persists because wild-type TTR can deposit as amyloid at sites of preexisting amyloid deposits. Nonetheless, disease progression usually is slowed, and in many patients, clinical manifestations improve after liver transplantation. There is substantially less experience using liver transplantation for fibrinogen A α amyloidosis, a disease that is more likely than TTR amyloidosis to involve the kidney. Case reports describe individuals with fibrinogen A α disease who have undergone combined liver and kidney transplantation.^{35–37} In all these patients, liver and kidney failure from amyloid disease was present, as fibrinogen amyloidosis, in contrast with TTR disease, often involves the liver. Outcomes were considered satisfactory without evidence of amyloid in the transplanted organs at 2 to 6 years. Liver transplantation is not appropriate for lysozyme amyloidosis because lysozyme is synthesized by polymorphonuclear cells and macrophages. Similarly, for apolipoprotein AI amyloidosis, because apolipoprotein AI is synthesized by the intestine in addition to the liver, amyloid formation would be anticipated to continue after liver transplantation, although perhaps at a slower rate.

The renal response to orthotopic liver transplantation has been evaluated in a small series of patients with TTR amyloidosis and kidney involvement.³⁸ Proteinuria did not change significantly in these patients, but serum creatinine levels remained relatively stable over several years. Although these patients had histologically evident renal amyloid, the clinical manifestations were mild before liver transplantation, limiting extrapolation of the findings to patients with more pronounced kidney manifestations.

Amyloidosis-Associated End-Stage Renal Disease

For any of the types of amyloidosis, dialysis dependence should not preclude aggressive treatment aimed at reducing ongoing amyloid production. Although amyloidosis-associated ESRD is not reversible, treatment can prevent progression of extrarenal disease. Concern has been expressed about the appropriateness of offering HDM/SCT to dialysis-dependent patients with AL amyloidosis because of treatment-associated toxicities. However, experience with treating selected patients with HDM/SCT

suggests that both the hematologic response rate and treatment-associated mortality are similar in dialysis-dependent patients compared with the overall population of patients undergoing this treatment.³⁹ Furthermore, attainment of a complete hematologic response has enabled subsequent kidney transplantation in some of these patients.

Because of the likelihood of recurrence of amyloid nephropathy in renal allografts, under most circumstances, kidney transplantation should be restricted to patients with inactive disease, that is, those in whom ongoing amyloid production has been eliminated with treatment. However, proceeding with kidney transplantation might be reasonable if disease is limited to the kidney and if the progression to ESRD occurred over many years rather than rapidly.

Summary of Treatment Recommendations for Amyloidosis

The treatments that are currently available for amyloidosis all target the source of the amyloidogenic protein. For AL amyloidosis, treatments are directed against the clonal plasma cells, the source of the amyloidogenic immunoglobulin light chains. It is now clear that cyclic oral melphalan and prednisone, the main treatment for this disease for many years, is less effective than newer, more aggressive approaches such as HDM/SCT, oral melphalan with high-dose dexamethasone, and possibly lenalidamide-based regimens. Because of the variability of organ involvement and severity of organ dysfunction, as well as the toxicities associated with different treatment regimens, decisions about which approach to use must be individualized. Because of the unique toxicities associated with HDM/SCT in patients with AL amyloidosis, it is our opinion that, for most patients, HDM/SCT should be performed only at centers with experience caring for patients with amyloidosis. The relative benefits of HDM/SCT and oral melphalan with high-dose dexamethasone are not clear at present but should emerge as additional experience accumulates. For AA amyloidosis, the goal of treatment should be to suppress the underlying inflammatory disease. If regulatory approval for eprodisate is obtained, this drug will provide an additional treatment option for patients with AA amyloidosis. For hereditary TTR amyloidosis, a disease that sometimes involves the kidney, orthotopic liver transplantation is an effective treatment. The much more limited experience with liver transplantation for fibrinogen A α disease suggests that it is reasonable to consider the approach, possibly in conjunction with kidney transplantation.

LIGHT-CHAIN DEPOSITION DISEASE

Nomenclature, Clinical Features, and Histology

LCDD is a plasma cell disorder in which monoclonal light chains deposit in glomerular and tubular basement membranes. The light chains do not form fibrils. Related but much rarer disorders are HCDD and light and heavy chain deposition disease (LHCDD). In HCDD, monoclonal heavy chains form deposits similar to those seen in LCDD, and in LHCDD both monoclonal heavy and monoclonal light chains form deposits. The pathogenesis of these disorders is probably

similar, and as a group, they are often referred to as monoclonal immunoglobulin deposition diseases (MIDD). The discussion that follows is restricted for the most part to LCDD but probably is applicable to all forms of MIDD.

LCDD can occur in association with multiple myeloma or in the absence of an overt plasmacytosis. In some patients, the plasma cell burden is sufficiently low that restricted expression by plasma cells of light chains of one isotype is not evident. Additionally, in some patients, the combination of a low plasma cell burden and a high avidity of the monoclonal light chain for tissue can result in the absence of detectable monoclonal light chain in the serum or urine even with sensitive immunofixation studies or quantitative free light-chain assays. In such cases, the evidence of a plasma cell dyscrasia may be limited to the kidney biopsy findings. However, usually a monoclonal light chain is detected by serum or urine immunofixation electrophoresis. The light chain is more often κ than λ .

Most patients with LCDD have proteinuria, which is often in the nephrotic range. The urinary protein is composed mostly of albumin; thus, patients often have other manifestations of nephrotic syndrome. Light chain deposition can be restricted to the tubular basement membranes, in which case proteinuria will be minimal. Microscopic hematuria is present in some patients. Many patients have renal impairment at the time of diagnosis, and progression to ESRD is frequent. The rate of decline in GFR varies. Most patients progress to ESRD over many months to years; however, rapid progression can occur. Importantly, small series suggest that recurrence in renal allografts is nearly universal.⁴⁰ Extrarenal disease is present in a substantial proportion of patients but is often not appreciated. The liver and heart are probably the most common sites of extrarenal disease, but clinical or histologic evidence of light-chain deposition in many other tissues has been reported.^{41–44}

The kidney biopsy findings in LCDD usually involve both the glomeruli and tubules. Mild mesangial expansion with thickened glomerular capillary walls or full-blown nodular glomerulosclerosis can be seen by light microscopy. In contrast to amyloidosis, the nodules are strongly periodic acid-Schiff positive because they are composed of extracellular matrix rather than the light chains. Thickened tubular basement membranes and interstitial fibrosis are often evident. By immunofluorescence, deposition of light chain of a single isotype is present along the capillary walls, mesangium, and tubular basement membranes. The staining often has a linear, ribbon-like appearance. Electron microscopy reveals granular, and often large, deposits along glomerular and tubular basement membranes and, to a lesser extent, in the mesangium. The glomerular capillary deposits are predominantly subendothelial.^{44,45}

Treatment of Light-Chain Deposition Disease

Until recently, LCDD occurring in the absence of multiple myeloma was viewed by many as a renal-limited disorder rather than a systemic disease. An appreciation for the poor renal prognosis, the frequency of extrarenal involvement, and the disease pathogenesis has altered this perception at least to some extent. Aggressive treatment directed at the clonal plasma cells, although not in widespread use, is beginning to be recognized as a justified approach to the management of this disease.⁴⁶

The published experience with HDM/SCT for LCDD is limited to a few case reports and two small case series. Royer and colleagues⁴⁷ reported the outcomes of 11 patients with LCDD or HCDD treated with HDM/SCT. Ten of the patients had multiple myeloma, seven patients had extrarenal manifestations, and four patients were dialysis dependent. Six patients had a complete hematologic response after HDM/SCT, and a decrease in proteinuria or improvement in renal function occurred in four patients. Extrarenal manifestations improved in the six patients who had heart or liver involvement. A description of the outcomes after HDM/SCT of nine patients with LCDD without multiple myeloma was included in a recent publication.⁴⁶ Seven of the patients had a complete hematologic remission. One of the patients was dialysis dependent at the time of treatment and underwent kidney transplantation after attaining a hematologic remission. All the patients were alive at a median follow-up of 17 months. Several reports have documented regression of histologic lesions in the kidney, heart, and liver after treatment, suggesting that end-organ damage from LCDD is potentially reversible.^{48,49}

Summary of Treatment Recommendations for Light-Chain Deposition Disease

The results from the admittedly limited experience treating LCDD with high-dose chemotherapy, together with the poor prognosis associated with untreated disease, provides a compelling argument for aggressive treatment of this disorder. Additional experience with HDM/SCT as well as the use of alternative treatments that have been found to be effective for AL amyloidosis or multiple myeloma should enable refinement of treatment approaches, a decrease in treatment-related toxicities, and improved outcomes for this disease.

MYELOMA CAST NEPHROPATHY

Multiple Myeloma and the Kidney

Multiple myeloma is a hematologic malignancy that results from clonal expansion of plasma cells in the bone marrow. The clinical manifestations of multiple myeloma result from both the high burden of proliferating plasma cells as well as from the immunoglobulin molecules secreted by the clonal plasma cells. Kidney disease in the setting of multiple myeloma can be caused by the plasma cells themselves (e.g., hypercalcemia-induced acute renal failure) or the secreted monoclonal immunoglobulin molecules. Most myeloma-associated immunoglobulin-mediated kidney disease is caused by light chains or light-chain fragments. However, intact monoclonal immunoglobulin molecules can cause type I cryoglobulinemia or noncryoglobulinemic proliferative GN, and monoclonal heavy chains can cause HCDD or AH amyloidosis. Two of the light-chain-associated disorders, AL amyloidosis and LCDD, are discussed in separate sections of this chapter; this section of the chapter addresses myeloma cast nephropathy, the most common myeloma-associated light-chain disorder. Fanconi syndrome resulting from damage to proximal tubular cells by filtered light chains is an addi-

tional light-chain-mediated kidney process that can occur in multiple myeloma.

Diagnosis, Clinical Features, and Kidney Histology

The diagnosis of multiple myeloma requires the combination of a bone marrow biopsy with a cellular composition of at least 10% plasma cells, demonstration of a monoclonal immunoglobulin protein in the blood or urine, and myeloma-related end-organ damage such as renal insufficiency, hypercalcemia, anemia, and lytic bone lesions. Diagnostic criteria and staging systems have been published by the International Myeloma Working Group.^{50,51} Although a definitive diagnosis of cast nephropathy requires a kidney biopsy, the diagnosis is often made based on clinical suspicion.

Cast nephropathy typically occurs in individuals with a high plasma cell burden and a high concentration of monoclonal light chains in the serum and urine. Thus, unlike AL amyloidosis or LCDD, cast nephropathy usually occurs in the presence of overt multiple myeloma. Patients with cast nephropathy present with an increased serum creatinine concentration that can be either acute or chronic. Proteinuria is present but, because the urinary protein is composed of light chains and not albumin, the urine dipstick will be negative for protein, and nephrotic syndrome will not be present. The presence of nonalbumin urinary protein in a patient with multiple myeloma and renal impairment makes cast nephropathy a more likely diagnosis than myeloma-associated AL amyloidosis or LCDD, both of which usually, but not always, cause high-grade albuminuria (see Table 23-1). Many factors have been implicated as triggers of cast nephropathy; these include volume depletion, hypercalciuria, low urine pH, diuretics, and intravenous administration of radiographic contrast media.

The major histologic findings of cast nephropathy are casts within distal tubules, tubular dilatation, and tubular atrophy. By light microscopy, the casts are eosinophilic and refractile and often appear fractured. Macrophages and, in some cases, giant cells are often present in the interstitium surrounding the occluded tubules. The interstitial inflammation and fibrosis contribute to the renal failure in patients with cast nephropathy and may be more important in terms of long-term renal prognosis than the intratubular obstruction. By immunofluorescence, the casts show reactivity to immunoglobulin light chain of the same isotype as that of the circulating monoclonal protein.

Treatment of Cast Nephropathy

The main objectives in treating cast nephropathy are to minimize the propensity of filtered light chains to form intratubular casts, to decrease production of the light chains by the clonal plasma cells, and to enhance removal of the light chains from the circulation. Aggressive hydration to increase urinary flow will decrease the concentration of the light chains in the tubular fluid. Alkalinization of the urine by administration of sodium bicarbonate in an effort to decrease cast formation is often recommended; however, it should be recognized that the benefit of raising urine pH depends on the characteristics of the specific light chain. Decreasing production of light chains is accomplished with chemotherapy. Although a detailed

discussion of chemotherapeutic regimens for multiple myeloma is beyond the scope of this chapter, issues that have particular relevance to cast nephropathy or to the treatment of patients with renal failure are addressed. Removal of light chains with plasma exchange or hemodialysis has received recent attention and is the major focus of this section of the chapter.

Plasma Exchange for Cast Nephropathy

The objective of plasma exchange is to rapidly remove circulating light chains and prevent ongoing renal injury before chemotherapy effectively eliminates or decreases monoclonal light-chain production. Case reports from as far back as 30 years ago have documented the use of plasma exchange to treat acute renal failure due to cast nephropathy.^{52–58} Over the subsequent years, case series and small controlled trials have suggested a benefit of plasma exchange in this setting. Key features of these studies are summarized in Table 23-4.^{59–65}

With the exception of the study by Movilli and colleagues,⁶⁵ all the small retrospective studies that compared renal outcomes in patients who received plasma exchange in addition to chemotherapy with those for patients who received chemotherapy alone reported a benefit of plasmapheresis. The limitations of all these studies include their retrospective nature, the lack of randomization to treatment approach, and small sample size. In addition, for several of the studies, follow-up was too short to allow assessment of long-term outcomes.

One of the first randomized, controlled trials of plasma exchange evaluated 29 patients with multiple myeloma and acute renal failure. Fifteen patients were randomized to plasma-exchange treatment in addition to cyclophosphamide therapy and glucocorticoids, whereas the control group received only cytotoxic therapy and glucocorticoids. Among dialysis-dependent patients, 11 of 13 in the plasma exchange group compared with 2 of 11 in the group receiving chemotherapy alone were

Table 23-4 Representative Studies of Plasma Exchange for Myeloma Cast Nephropathy

Study (Ref.)	Design	Treatment	Findings
Pozzi et al, ⁵⁹ N = 50	Retrospective review	Chemotherapy/plasma exchange vs. chemotherapy	Recovery of renal function occurred in 61% of patients who received plasma exchange compared with 27% of patients who received chemotherapy alone
Misiani et al, ⁶⁰ N = 23	Retrospective review	Chemotherapy/plasma exchange	8 of 10 patients with acute renal failure had recovery of renal function; 11 of 13 patients with chronic renal failure had improvement in renal function
Zucchelli et al, ⁶¹ N = 29	Randomized trial	Plasma exchange/chemotherapy vs. chemotherapy	11 of 15 patients in the plasma exchange group compared with 2 of 14 patients in the control group had improved renal function; 1-year survival rates were 66% and 28% in the plasma exchange and control groups, respectively
Johnson et al, ⁶² N = 21	Randomized trial	Plasma exchange/hydration/chemotherapy vs. hydration/chemotherapy	10 of 11 patients in plasma exchange group compared with 5 of 10 patients in control group had improved renal function
Moist et al, ⁶³ N = 26	Retrospective review	Hydration/plasma exchange/chemotherapy	15 of the 26 patients had improved renal function by 3 mo
Clark et al, ⁶⁴ N = 97 (104 patients randomized; 97 patients included in analyses)	Randomized, controlled, multicenter trial	Plasma exchange/conventional therapy vs. conventional therapy	No statistically significant difference between groups in the composite outcome of death, estimated glomerular filtration rate < 30 mL/min/1.73m ² or dialysis dependence; 42% of dialysis-dependent patients in the plasma exchange group compared with 37% of dialysis-dependent patients in the control group became dialysis independent (difference not statistically significant)
Movilli et al, ⁶⁵ N = 55	Retrospective review	Plasma exchange vs. no plasma exchange	No difference between groups in renal or patient survival

able to discontinue dialysis. Patient survival at 1 year was also higher in the plasma exchange group. The authors concluded that plasma exchange provides both renal and overall survival benefit. Interestingly, the dialysis-dependent patients in the plasma exchange group were treated with hemodialysis, whereas the patients in the control group received peritoneal dialysis. This source of bias might be expected to favor the plasma exchange group if hemodialysis is more effective than peritoneal dialysis at removing light chains.

A second trial randomized 11 patients to plasmapheresis and 10 patients to control therapy.⁶² A greater number of patients in the plasmapheresis group than in the control group had a favorable renal response. There was no survival difference at 1 year. Drawbacks of this study are its small sample size, heterogeneity of plasma exchange regimens, and exclusion from the trial of patients with melphalan-resistant disease.

The Canadian Apheresis Group performed a multicenter trial that evaluated 104 patients with newly diagnosed multiple myeloma and acute renal failure.⁶⁴ Patients were randomly assigned to conventional therapy plus four to seven plasma exchange treatments or conventional therapy alone. Approximately 30% of patients in both groups were dialysis dependent at study entry. During follow-up, 66% and 50% of dialysis-dependent patients in the plasma exchange group and control group, respectively, were able to discontinue dialysis, and approximately 20% of patients in both groups initiated dialysis. There was no difference between treatment groups in the composite endpoint of death, dialysis dependence, or severe renal impairment at 6 months, and the investigators interpreted the trial as showing no benefit of plasma exchange. This trial had several strengths including its multicenter nature and the sample size that was substantially larger than that of earlier randomized trials. However, the study has been criticized because approximately 20% of patients did not have detectable monoclonal light chain in the urine, and biopsy documentation of cast nephropathy was not required. If cast nephropathy was not the cause of renal failure in many of the patients, the ability to detect a benefit of plasma exchange would be reduced.

In summary, there is not strong evidence supporting a role for plasma exchange in cast nephropathy. Although earlier retrospective case series and small randomized trials suggested a benefit, a more recent, larger multicenter, randomized trial found similar outcomes among patients treated with or without plasma exchange. It is possible that because of a more rapid decrease in production of the pathogenic light chains, current chemotherapeutic approaches have lessened the impact of plasma exchange. It is also possible that plasma exchange, at least as currently performed, is not sufficiently effective at removing light chains.⁶⁶ The recent availability of a quantitative assay for measuring serum light-chain concentrations should enable better assessment of efficacy of interventions aimed at light-chain removal.

Hemodialysis for Cast Nephropathy

The molecular weight of light chains (approximately 25 kD for κ and λ light-chain monomers and 50 kD for λ dimers) precludes their passage through the pores of conventional or high-flux hemodialyzer membranes. However, adsorption of light chains by dialyzer membranes has been demonstrated, so it is possible that some light-chain removal does occur with standard hemodialysis treatments. Indeed, one of the limita-

tions of the studies of plasma exchange is that they did not standardize the dialyzer membranes or dialysis regimens for those patients who were dialysis dependent. A recently proposed approach to the treatment of cast nephropathy is the use of “superflux” or “protein-leaking” dialyzer membranes.⁶⁷ These membranes have pore sizes that are substantially larger than high-flux membranes. In the only published study evaluating large-pore dialyzers for cast nephropathy, the mean in vitro decreases in κ and λ light-chain concentrations by a superflux dialyzer were 96% and 94%, respectively, after 4 hours. Use of the dialyzers in a small number of patients with acute renal failure from cast nephropathy suggested that extended daily dialysis in combination with chemotherapy might be more effective at light-chain removal than is plasma exchange. The findings from this pilot study are intriguing, but as the authors acknowledge, further study is required to establish a role of such dialyzers in the treatment of cast nephropathy.

Chemotherapy for Multiple Myeloma: Kidney-Specific Issues

The general approach to treating patients with newly diagnosed multiple myeloma is to start with an induction regimen such as thalidomide and dexamethasone to decrease the plasma cell burden, followed by high-dose chemotherapy (usually melphalan) with SCT. Although SCT extends survival and results in a hematologic remission in a substantial proportion of patients, most patients eventually experience a relapse and require additional treatment. Tandem SCT, thalidomide, lenalidomide, dexamethasone, and bortezomib, all of which are discussed in the AL amyloidosis section, are currently being used as salvage treatment for patients with resistant or relapsed disease or as initial treatment in individuals who are not eligible for SCT.⁶⁸

A general observation is that multiple myeloma patients with renal impairment have greater treatment-associated toxicity and decreased overall survival than those with preserved renal function.^{69–71} There are several potential contributors to the relatively poor outcomes. Renal impairment may be a marker of high tumor burden or aggressive disease. Additionally, renal failure increases susceptibility to infection, bleeding, and other complications of chemotherapy. Finally, renal failure often excludes patients from aggressive treatments or leads to administration of lower and therefore less effective doses of drugs.

For many of the agents used to treat multiple myeloma, optimal dosing in patients with renal impairment has not been determined. For example, although melphalan elimination is the result of degradation and very little is excreted by the kidney, studies evaluating pharmacokinetics of melphalan in individuals with renal impairment have yielded conflicting results.⁷² Some studies suggest that melphalan clearance is decreased in the setting of renal failure and others have not. Moreover, information about clearance of many of these drugs by hemodialysis or peritoneal dialysis is limited or nonexistent. Most centers decrease the dose of melphalan when it is administered as part of a myeloablative regimen from 200 mg/m² to 140 or 100 mg/m² in individuals with significant renal impairment. Thalidomide clearance is not dependent on renal function. Lenalidomide dosing is adjusted based on renal function, but there is little information to guide dosing in patients undergoing dialysis.⁷³ Clearance of bortezomib is dependent on both the liver and the kidney, and decreased dosing may be required if the creatinine clearance is less than

30 mL/min. Bisphosphonates, which are typically administered long term to patients with multiple myeloma, are contraindicated when the glomerular filtration rate is decreased, and among patients with multiple myeloma and normal renal function, rare complications of bisphosphonate treatment include focal and segmental glomerulosclerosis, collapsing glomerulopathy, and acute tubular necrosis.^{74–76}

Kidney Transplantation in Multiple Myeloma

Malignancy is generally a contraindication for kidney transplantation; however, for multiple myeloma, combined kidney and allogeneic stem-cell transplantation from the same donor has been performed in a small number of individuals. Three case reports describe a total of seven patients with multiple myeloma and ESRD who underwent dual kidney and stem-cell transplantation from HLA-identical siblings.^{77–79} These patients all received nonmyeloablative preparative therapy with intravenous cyclophosphamide, antithymocyte globulin, and thymic irradiation with the goal of attaining donor-specific allotolerance and temporary chimerism. Long-term patient and renal survival in six of these patients has been maintained, even in the presence of donor marrow rejection.⁷⁹

Summary of Treatment for Cast Nephropathy

Multiple myeloma is a common malignancy with frequent kidney involvement. The goal of treatment is to eliminate the malignant clone of plasma cells using cytotoxic agents, immunomodulatory agents, and proteasome inhibitors. A benefit of plasma exchange in conjunction with anti-plasma cell treatment for cast nephropathy has not been demonstrated, although one could argue that it might be helpful to some individuals and that its utility has not been adequately assessed. The use of superflux hemodialysis to remove light chains may have benefit, but experience with this approach is limited to a single pilot study.

FIBRILLARY GLOMERULONEPHRITIS AND IMMUNOTACTOID GLOMERULOPATHY

Classification, Clinical Features, and Kidney Histology

Fibrillary GN and immunotactoid glomerulopathy are relatively rare disorders in which immunoglobulin-containing fibrillary deposits are present in the mesangium and glomerular capillary walls. The fibrils do not stain with Congo red dye, thereby distinguishing them from amyloid. The major discriminating features between fibrillary GN and immunotactoid glomerulopathy are the size and distribution patterns of the fibrils. In fibrillary GN, the fibrils are 15 to 20 nm in diameter and deposit in what appears to be a random array. In immunotactoid glomerulopathy, the fibrils are actually microtubules with hollow centers and diameters of 30 to 60 nm. The microtubules deposit in organized, parallel arrays providing a substructure to the deposits evident by electron microscopy.⁸⁰ Although there is controversy about whether the two disorders differ pathogenetically,⁸¹ it does appear that immunotactoid glomerulopathy is more likely

than fibrillary GN to occur in association with a lymphoproliferative disorder. Additionally, the microtubules of immunotactoid glomerulopathy are often composed of what appears to be monoclonal immunoglobulin molecules, whereas the immunoglobulin components of the fibrils of fibrillary GN more often appear to be polyclonal, albeit with some restriction of the heavy-chain subtype.

The clinical manifestations of fibrillary GN and immunotactoid glomerulopathy are similar. Proteinuria is always present and is often in the nephrotic range, microscopic hematuria is common, and patients are often hypertensive. Creatinine is often elevated at presentation. The rate of decline of renal function is variable; in several series, approximately 50% of patients with fibrillary GN or immunotactoid glomerulopathy had progressed to ESRD within 2 to 4 years.^{80,82–84} Extrarenal manifestations of these disorders are rare, but patients with associated lung, heart, or liver involvement have been reported.^{85,86}

Renal histologic findings vary but are predominantly glomerular. In both fibrillary GN and immunotactoid glomerulopathy, light microscopy usually reveals mesangial expansion with periodic acid–Schiff-positive material and focal or diffuse glomerular capillary wall thickening with double contours or spikes. Proliferative GN, sometimes with cellular or fibrocellular crescents, can occur. Immunofluorescence reveals complement and immunoglobulin heavy and light chains in the mesangium and along capillary walls. In fibrillary GN, the immunoglobulin appears to be polyclonal, although subtyping suggests some restriction to IgG subtypes 1 and 4. In a substantial proportion of biopsy specimens from patients with immunotactoid glomerulopathy, the immunoglobulin deposits appear to be monoclonal intact immunoglobulin (usually IgG κ). By electron microscopy, the deposits are present in the mesangium, within the glomerular capillary walls, and rarely in the tubular basement membranes or interstitium. Ultrastructural examination reveals fibrils or microtubules in the same location as the electron-dense deposits. The glomerular capillary fibrils are usually within the basement membrane but can also have a subepithelial or subendothelial distribution.

Both fibrillary GN and immunotactoid glomerulopathy have been found in association with systemic diseases such as diabetes mellitus, solid tumors, human immunodeficiency virus, and hepatitis C, but pathophysiologic links between the systemic illnesses and the glomerulopathy are not established. Lymphoproliferative disorders with or without a circulating paraprotein are present in some patients with immunotactoid glomerulopathy.^{80,87–91}

Treatment of Fibrillary Glomerulonephritis and Immunotactoid Glomerulopathy

There are no established treatments for fibrillary GN or immunotactoid glomerulopathy. The published experience regarding treatment of these disorders is restricted to case reports and small series. Because of the apparent involvement of immunoglobulin, various immunosuppressive therapies have been tried. Case reports and anecdotal evidence suggest that glucocorticoids alone or in combination with cyclophosphamide, cyclosporine, or plasma exchange may occasionally be effective.^{80,83,84,89,92–97} However, the response rate is probably less than 10%,⁸⁴ and among those who do respond with remission of nephrotic syndrome, many relapse after treatment is discontinued.⁸⁹ Some authors have suggested that

steroid treatment may be particularly helpful for patients with preserved renal function⁹⁴ and that more aggressive treatment with cyclophosphamide therapy should be attempted if there are cellular crescents and/or diffuse proliferation on kidney biopsy.⁹⁵ It is our opinion that evaluation for an underlying lymphoproliferative disorder with bone marrow biopsy and immunofixation electrophoretic studies of the serum and urine should be performed in all individuals with a histologic diagnosis of fibrillary GN or immunotactoid glomerulopathy. If there is evidence of an associated lymphoproliferative disorder, treating the underlying malignancy may have a beneficial effect on the kidney process.⁸⁰

Kidney Transplantation

Individuals with fibrillary GN or immunotactoid glomerulopathy have undergone kidney transplantation. Recurrence of disease in the allograft has been reported in approximately 50% of patients in small case series.^{82,98–100} However, it appears that despite recurrent disease, deterioration of allograft function is slow, perhaps because of the administration of immunosuppressive therapies.^{82,99}

Summary of Treatment Recommendations for Fibrillary Glomerulonephritis and Immunotactoid Glomerulopathy

There is no specific treatment for fibrillary GN or immunotactoid glomerulopathy. All patients with these disorders should undergo evaluation for a lymphoproliferative disorder with bone marrow biopsy, immunofixation electrophoresis of the serum and urine, and quantitative serum-free light-chain assay. If a disorder is identified, appropriate chemotherapy should be administered. In the absence of an underlying hematologic disease, we recommend supportive care but do not believe that evidence justifies the use of immunosuppressive or cytotoxic agents. Kidney transplantation should be considered if there is progression to ESRD because adequate renal function may be sustained even in the setting of recurrent disease.

HEPATITIS B VIRUS AND RENAL DISEASE

Background

Hepatitis B virus (HBV), a partially double-stranded circular DNA hepadnavirus first discovered in 1966,¹ is a major cause of acute and chronic hepatitis, cirrhosis, and hepatocellular carcinoma. An estimated 350 million people are chronically infected with HBV worldwide.² Although HBV remains endemic in Southeast Asia and sub-Saharan Africa with reported prevalence rates of 3% to 26%,³ the United States has significantly lower levels of infection with a prevalence rate of less than 0.5% or approximately 1.25 million chronic carriers.⁴ Since the implementation of a national vaccination strategy in 1991, the incidence of HBV infection in the United States has decreased by an estimated 80%.⁵ Continued universal vaccination of the general populations in the United States and Western Europe should ultimately eliminate incident HBV infection in those areas.

Hepatitis B Virus–Associated Renal Disease

An association between HBV and renal disease was first recognized in 1971 when hepatitis B surface antigen (HBsAg) was demonstrated in immune complexes deposited in the glomeruli of a 53-year-old man with membranous nephropathy.⁶ Since then, HBV has been associated with a variety of renal diseases, including membranous nephropathy (MN),

membranoproliferative glomerulonephritis (MPGN), mesangial proliferative glomerulonephritis, IgA nephropathy, and polyarteritis nodosa (PAN) (Table 24-1). The frequency of HBV-associated renal disease correlates with the prevalence of HBV in the general population and is higher in countries where HBV is endemic. Although there are few data documenting the actual prevalence of HBV-associated renal disease, it is thought to affect only a small percentage of the large number of chronic carriers worldwide.⁷

Pathogenesis

The pathogenesis of HBV-associated renal disease is classically believed to be mediated by the formation of circulating immune complexes composed of viral antigens and host antibodies that are passively trapped within the glomerular basement membrane.⁸ Alternatively, studies demonstrating the presence of HBV DNA and RNA in the glomeruli and renal tubular epithelial cells of patients with HBV-associated glomerulonephritis suggest HBV-associated renal disease could be the result of local expression of viral antigens with subsequent in situ immune complex formation.^{9,10} Although HBsAg, hepatitis B core antigen, and hepatitis B early antigen (HBeAg) have all been identified in the glomerular deposits of patients with HBV-associated renal disease, HBeAg is considered the most highly correlated with HBV-associated nephropathy, particularly HBV-associated MN (HBV MN).^{10–12} The pathogenic role of HBeAg in HBV-associated renal disease is supported by the

remission of proteinuria that typically occurs with clearance of the HBeAg and seroconversion to anti-HBe.^{13,14}

Indications for Renal Biopsy

All patients with suspected HBV-associated renal disease should undergo a kidney biopsy to confirm the diagnosis and rule out other virally mediated renal diseases (e.g., cryoglobulinemic glomerulonephritis secondary to hepatitis C virus) that may be present in co-infected individuals. Magnetic resonance angiography may be preferred over a percutaneous renal biopsy or conventional angiography in diagnosing renal disease in HBV-associated PAN because it avoids both the potential to puncture a renal arterial aneurysm and the risk of radiocontrast-induced nephrotoxicity; however, care should be taken in using gadolinium-containing contrast agents in patients with severe renal insufficiency due to their reported association with nephrogenic systemic fibrosis.¹⁵

Membranous Nephropathy

HBV MN is most often observed in children, predominantly males, living in HBV endemic areas.^{16,17} Patients typically present with proteinuria, commonly in the nephrotic range and often complicated by the nephrotic syndrome. Serologic studies in the majority of patients reveal hepatitis B surface and hepatitis B early antigenemia. The natural course of HBV MN in children has been associated with a 30% to 60% rate of spontaneous remission,¹¹ and the overall prognosis is considered favorable with one retrospective study reporting a cumulative probability of remission in 84% of children after 10 years.¹³ In contrast, adult-onset HBV MN has a poorer prognosis and spontaneous remission is rare. In one study of 21 patients, 29% developed progressive renal failure and 10% required long-term renal replacement therapy after a mean follow-up of 60 months.¹⁸

Membranoproliferative Glomerulonephritis

HBV MPGN is the most common HBV-associated renal disease in adults.¹⁶ Both type I and III MPGN have been described in the setting of HBV but not type II (dense deposit disease).¹⁰ HBV MPGN usually occurs in the absence of cryoglobulins, and most reported cases of HBV associated with cryoglobulinemia involves patients co-infected with the hepatitis C virus or patients who presented before hepatitis C virus testing was available.¹⁹ Spontaneous improvement is rare, and prognosis with this lesion is poorer than with HBV MN.

Polyarteritis Nodosa

Patients with HBV-associated PAN typically present with fever, rash, abdominal pain, new-onset or severe hypertension, mononeuritis multiplex, hematuria, and renal failure. The clinical manifestations of HBV-associated PAN are essentially the same as PAN in HBV-negative patients except that malignant hypertension, renal infarction, and orchiepididymitis may be more common in the setting of HBV.²⁰ The characteristic renal lesions of PAN are aneurysms of the medium-sized arteries of the kidney.^{21,22} Serologic studies typically reveal high levels of HBV DNA and the absence of antineutrophil cytoplasmic antibody. Wild-type HBV, characterized by HBeAg, accounts for most but not all cases.²³ Proteinuria, elevated serum creatinine, and gastrointestinal involvement confer the highest mortality, with death usually following gastrointestinal hemorrhage, infarction, or perforation.²⁴

Treatment

Antiviral Therapy

Antiviral therapy is the cornerstone of treatment for HBV-related kidney disease. Although our experience is limited to earlier antiviral agents, such as interferon alfa (IFN- α) and lamivudine (Table 24-2), newer nucleoside/nucleotide analogues are available and more are in development. Optimal treatment of HBV-related renal disease may require several antiviral agents, either alone or in combination, and we recommend consulting a hepatologist or an infectious disease specialist before initiating therapy.

Nucleoside/Nucleotide Analogues

Nucleoside/nucleotide analogues act on the HBV polymerase to inhibit viral DNA replication.²⁵ There are currently three nucleoside/nucleotide analogues approved for the treatment of chronic hepatitis in patients with HBV: lamivudine (3TC), adefovir, and entecavir²⁵ (Table 24-3). Lamivudine (3TC), a cytosine analogue reverse transcriptase inhibitor developed in 1989, was the first nucleoside analogue approved for the treatment of HBV in 1998 and has been demonstrated to lower HBV DNA levels, induce seroconversion, and yield an hepatic histologic response.²⁶ Several anecdotal case reports have demonstrated the efficacy of lamivudine in HBV-associated renal disease.²⁷⁻³⁰ A recent Chinese cohort study compared 10 patients with biopsy-proven HBV MN treated with oral lamivudine (100 mg/day) versus 12 historic controls from the pre-lamivudine era.³¹ The baseline demographics and clinical characteristics of both groups were similar, and all patients received either an angiotensin-converting enzyme inhibitor or an angiotensin II receptor blocker.³¹ After 12 months of

Table 24-2 Summary of Intervention Trials for Hepatitis B Virus– and Human Immunodeficiency Virus–Related Renal Disease

Design	Treated (N)	Control (N)	Therapy	Outcome	Comment	Ref.: Disease
Retrospective	15	None	IFN- α	Decreased proteinuria and HBeAg clearance in 53%	Better response with MN than MPGN	32: HBV MN and MPGN
Prospective, randomized	20	20	IFN- α	100% proteinuria resolution, 80% HBeAg cleared	All subjects were children with steroid-resistant disease	33: HBV MN
Retrospective	6	None	IFN- α	100% PAN recovery, 66% HBeAg cleared	Concomitant steroids and PE	34: HBV PAN
Retrospective	10	12	Lamivudine 100 mg/day	60% in remission by 1 yr, 100% renal survival at 3 yr	All patients on ACEI or ARB	41: HBV MN
Retrospective	10	None	Lamivudine 100 mg/day	70% HBeAg cleared	Concomitant steroids and PE	23: HBV PAN
Retrospective	8	11	Protease inhibitor	Slower decline in CrCl	Only 6 biopsy-proven cases, ACEI and prednisone in some	84: HIVAN
Retrospective	26	10	HAART	Renal survival improved	Higher baseline Scr in controls	85: HIVAN
Prospective, nonrandomized	12	8	Fosinopril 10 mg/day	SCr and proteinuria improved	Controls refused ACEI	88: HIVAN
Retrospective	9	9	Captopril 6.25–25 mg tid	Renal survival improved	One suicide in ACEI group	89: HIVAN
Retrospective	20	None	Prednisone	SCr improved in 17/20 60 mg/day	Infectious complications common	90: HIVAN
Retrospective	15	87	Prednisone 1 mg/kg/day	Renal survival improved	No significant improvement in proteinuria	91: HIVAN
Retrospective	13	8	Prednisone 60 mg/day	Renal survival improved	No mortality benefit, increased hospital days	92: HIVAN

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; CrCl, creatinine clearance; HAART, highly active anti-retroviral therapy; HBeAg, hepatitis B early antigen; HBV, hepatitis B virus; HIVAN, HIV-associated nephropathy; IFN- α , interferon alfa; MN, membranous nephropathy; MPGN, membranoproliferative glomerulonephritis; PAN, polyarteritis nodosa; PE, plasma exchange; SCr, serum creatinine.

therapy, 60% of lamivudine-treated patients were in complete remission (defined as having <300 mg of proteinuria/day) as compared with 25% of patients in the control group.³¹ Furthermore, the cumulative 3-year renal survival rate was 100% in the lamivudine-treated group compared with 58% in the control group.³¹ There are few data involving the use of nucleoside analogues for the treatment of HBV PAN; however, in one as yet unpublished report, of 10 patients treated with oral lamivudine (100 mg/day) as part of an HBV PAN regimen (which includes initiation corticosteroid therapy for 1–2 weeks), nine recovered and seven achieved HBeAg/Hbe antibody seroconversion.²³ Although there are no data concerning the use of the newer antivirals in the treatment of HBV-associated renal disease, given the direct role of the virus in the pathogenesis of the renal lesions and the increased incidence of resistance with prolonged lamivudine use (15%–20% per year

with an estimated 70% at 5 years), it is reasonable to assume that adefovir and entecavir, in combination with lamivudine or as monotherapy, should play key roles in the treatment of HBV-associated nephropathy.²⁵ Of note, in higher doses (30–120 mg), adefovir is associated with renal tubular toxicity; however, this complication has not been reported in the lower doses (10 mg) proposed for long-term HBV therapy.³²

Interferon

A meta-analysis of 16 randomized, controlled trials in which subcutaneous IFN- α was used to treat patients with chronic HBV (without known renal disease) showed benefit with high-dose (more than 15 million units/m² per week) IFN- α therapy for 3 to 6 months.³³ A retrospective National Institutes of Health study of 15 patients with chronic HBV and

Table 24-3 Dosing Recommendations for Anti-Hepatitis B Virus-Approved Agents in Renal Impairment

Antiviral Agents (HBV)	Creatinine Clearance (mL/min)	Recommended Dose
Lamivudine	≥50	300 mg once daily
	30–49	150 mg once daily
	15–29	150 mg first dose, then 100 mg once daily
	5–14	150 mg first dose, then 50 mg once daily
	<5	50 mg first dose, then 25 mg once daily
Adefovir	≥50	10 mg once daily
	20–49	10 mg q 48 hr
	10–19	10 mg q 72 hr
	Hemodialysis	10 mg once weekly (after hemodialysis)
Entecavir	≥50	Treatment naive: 0.5 mg once daily Lamivudine refractory: 1 mg once daily
	30–49	Treatment naive: 0.25 mg once daily Lamivudine refractory: 0.5 mg once daily
	10–29	Treatment naive: 0.15 mg once daily Lamivudine refractory: 0.3 mg once daily
	<10	Treatment naive: 0.05 mg once daily Lamivudine refractory: 0.1 mg once daily
	Hemodialysis	Dose for creatinine clearance <10 (after hemodialysis)

glomerulonephritis (10 patients with HBV MN, 4 patients with HBV MPGN, 1 with unknown biopsy result) treated with 16 weeks of daily or alternate-day subcutaneous IFN- α 2b (5 million units) demonstrated resolution of HBeAg and reduction in proteinuria in eight patients (53%).³⁴ Of note, all eight responders had HBV MN, whereas four of the seven nonresponders were the patients with known HBV MPGN.³⁴ An open trial of 40 Chinese children with heavy proteinuria and biopsy-proven steroid-resistant HBV MN also showed benefit with IFN- α therapy.³⁵ Patients were randomized to three times weekly subcutaneous IFN- α 2b (5 or 8 million units, based on weight) versus supportive treatment alone.³⁵ After 12 months of therapy, proteinuria resolved in 100% of patients in the IFN- α -treated group compared with only 10% of patients in the control group.³⁵ Furthermore, although 80% of the IFN- α -treated patients became HBeAg negative, none of the patients in the control group achieved seroconversion.³⁵ In a review of 41 patients with HBV PAN, approximately 30% of whom had either renal failure or the nephrotic syndrome, six patients received treatment with IFN- α 2b in addition to a short course of steroids and plasma exchange therapy.³⁶ All the IFN- α -treated patients recovered from PAN and 66% demonstrated HBeAg seroconversion.³⁶

Adjunctive Therapy

Corticosteroids

Use of corticosteroids in vitro and in vivo promotes HBV replication and transcription, and up-regulates viral antigen expression, including HBsAg and HBeAg.^{37–39} Although there

are few published data regarding corticosteroid use in HBV MPGN, HBV MN responds poorly to corticosteroid therapy, and even a short course of corticosteroids may exacerbate hepatocellular injury in an HBV-infected patient.^{11,13,40} Corticosteroid therapy should therefore be avoided in HBV MN and HBV MPGN. However, a short course (2 weeks) of corticosteroids (oral prednisone 1 mg/kg), with or without pulse methylprednisolone (15 mg/kg for 1–3 days), rapidly tapered after 1 week and withdrawn completely by the end of 2 weeks and followed by plasma exchange and antiviral therapy, is recommended to control the life-threatening manifestations of HBV PAN.^{41,42}

Plasma Exchange

Alternate-day plasma exchange is used to clear immune complexes in HBV PAN and is part of the protocol described previously.^{36,41,42} The duration of plasma exchange therapy should be tailored to the severity of the PAN manifestations.

Hepatitis B Virus and Renal Replacement Therapy

Management of Hepatitis B Virus in End-Stage Renal Disease

The incidence and prevalence of HBs antigenemia in U.S. hemodialysis patients has decreased dramatically since the 1970s^{43,44} as a result of improved adherence to infection control practices, strict segregation of HBsAg-positive patients

and their hemodialysis equipment from HBV-susceptible (HBsAb-negative) patients, and routine vaccination of HBV-susceptible patients and staff. Routine serologic testing for HBV (monthly HBsAg) in all HBV-susceptible hemodialysis patients is recommended to rapidly detect and isolate newly infected patients.⁴³ Due to what is likely an impaired cellular immune response, seroconversion after conventional HBV vaccination is suboptimal in dialysis patients compared with the general population (50%–73% versus > 90%), and it is therefore recommended that end-stage renal disease (ESRD) patients receive a four-dose (40 µg/dose) vaccination schedule as opposed to the conventional three-dose (20 µg/dose) schedule.⁴⁵ Diagnosing active liver disease in an HBV-positive ESRD patient is complicated by the fact that dialysis patients tend to have lower transaminase levels as compared with non-uremic patients and a liver biopsy is often the only way to correctly grade the degree of hepatic damage.⁴⁵ Although the impact of HBV infection on ESRD mortality may often be overshadowed by cardiovascular disease and other comorbidities, cirrhosis imparts a 35% increased risk of death in ESRD patients,^{45,46} and antiviral treatment should be considered in all HBV-infected ESRD patients.

Management of Hepatitis B Virus in Renal Transplantation

Although immunosuppressive therapy is known to increase viral replication and worsen underlying liver disease,⁴⁷ there are conflicting data regarding the effect of chronic HBV infection on patient and graft survival after renal transplantation. Earlier studies comparing HBsAg-positive and HBsAg-negative kidney transplant recipients reported no difference in patient survival and demonstrated no difference or an increase in graft survival.^{47–50} More recently, a large French case-control study comparing long-term outcomes in HBV-infected versus noninfected kidney transplant recipients demonstrated that, in addition to age and biopsy-proven cirrhosis, HBsAg positivity was independently associated with decreased 10-year patient and graft survival rates.⁵¹ A recent meta-analysis of six retrospective cohort studies also concluded that HBsAg-positive renal transplant recipients have decreased patient and graft survival rates.⁵² Therefore, although HBsAg is not a contraindication to renal transplantation, most centers perform a liver biopsy before transplantation, and antiviral therapy should be initiated if there is histologic evidence of active disease. Furthermore, a post-transplantation immunosuppressive regimen that avoids the use of antilymphocyte globulin is recommended because it may trigger fulminant hepatic failure in HBV-infected renal transplant recipients.⁵³ Nucleoside/nucleotide analogues are currently the agents of choice in the treatment of both pre- and post-transplantation HBV, as IFN-α is poorly tolerated in patients on dialysis and may precipitate graft rejection in the post-transplantation setting.⁵⁴ Lamivudine therapy before renal transplantation (prophylactic), at the time of renal transplantation (preemptive), and after renal transplantation in response to recurrent hepatic dysfunction (reactive)^{53,55,56} have all proven successful, as measured by the elimination of serum HBV DNA, but data suggest that prophylactic or preemptive lamivudine use may be superior. One nonrandomized study reported a recurrence of viremia in 10% of patients treated with lamivudine before or at the time of renal transplantation compared with 42% of patients in the group not treated with lamivudine.⁵⁵ Another small retrospective study reported that 100% of

patients prophylactically or preemptively treated with lamivudine remained negative for HBV DNA compared with 50% of untreated patients.⁵⁷ However, due to the risk of developing antiviral resistance with prolonged use and the risk of potentially inducing a hepatitis flare with antiviral withdrawal, the optimal timing and duration of pretransplantation lamivudine therapy require further study.

HUMAN IMMUNODEFICIENCY VIRUS AND RENAL DISEASE

Background

The human retrovirus human immunodeficiency virus (HIV) type 1 (HIV) was discovered in 1983,⁵⁸ 2 years after the first published reports of acquired immunodeficiency syndrome (AIDS).⁵⁹ In 2006, an estimated 40 million people were living with HIV infection worldwide, with nearly 25 million affected individuals living in sub-Saharan Africa.⁶⁰

HIV-Associated Renal Disease

The spectrum of kidney disease associated with HIV infection includes acute renal failure, electrolyte abnormalities, medication nephrotoxicity, and glomerular disease. This section focuses on the glomerular diseases associated with HIV infection, primarily HIV-associated nephropathy (HIVAN) and HIV-associated immune complex disease (see Table 24-1).

Pathogenesis

The pathogenesis of HIVAN involves HIV infection of the kidney. HIV mRNA and DNA can be detected in tubular and glomerular epithelial cells in biopsy tissue from patients with HIVAN,^{61,62} and mouse models expressing HIV transgenes develop kidney disease that closely resembles human HIVAN.^{63–65} Two specific retroviral genes, HIV *nef* and *vpr*, contribute to the pathogenesis of HIVAN.^{66,67} The strong association with black race also suggests a role for host genetic factors, and studies in the mouse model have identified a potential genetic susceptibility locus on chromosome 3.⁶⁸

Indications for Renal Biopsy

Kidney biopsy is required for the definitive diagnosis of HIV-infected patients with significant proteinuria or renal failure of unknown etiology because a significant proportion of patients with suspected HIVAN will have an alternative diagnosis.⁶⁹ This is particularly true in the aging antiretroviral-treated HIV population in the United States and Western Europe, in whom comorbid kidney disease due to diabetes, hypertension, or viral hepatitis is increasingly common.

HIV-Associated Nephropathy

Classically, HIVAN presents with heavy proteinuria and progressive renal failure, with the rapid onset of ESRD in the absence of treatment. Hypertension and edema may be less common than in other rapidly progressive glomerular diseases, and ultrasonography often reveals normal or increased kidney size. Although presentation can occur at any time, HIVAN is most often a complication of advanced HIV infection.⁷⁰ The epidemiology of HIVAN is most

remarkable for the striking predominance of black race, with nearly 90% of the ESRD attributed to HIV occurring in blacks.⁶⁰ Classic renal pathology includes focal and segmental glomerulosclerosis with capillary collapse, tubular microcystic dilatation, and interstitial infiltration.⁶⁹ Endothelial tubuloreticular inclusions, a characteristic finding in untreated cases of HIVAN, are uncommon in highly active antiretroviral therapy (HAART)-treated patients. The glomerular lesion of HIVAN is distinguished by podocyte proliferation rather than podocyte loss.⁷¹ When these characteristics are found in aggregate, the diagnosis of HIVAN is highly likely; however, similar pathology has been reported in HIV-negative patients and has been associated with the bisphosphonate pamidronate.⁷² HIV testing should be offered to all patients with suggestive biopsy findings.

HIV-Associated Immune Complex Disease

A variety of glomerular diseases are described in HIV-infected patients, including minimal change disease, IgA nephropathy or other mesangial proliferative glomerulonephritis, MN, MPGN, and crescentic glomerulonephritis. In contrast to HIVAN, patients with HIV-associated immune complex disease are more likely to have hematuria, hypocomplementemia, mild to moderate proteinuria, and a more indolent course. Unlike HIVAN, immune complex glomerular disease is not strongly associated with black race.^{73,74} Although evidence supporting a pathogenic role for HIV has been demonstrated in rare cases,⁷⁵ the relationship between HIV infection and immune complex disease is not well established. Because of the association with hepatitis B and C viruses, immune complex disease should prompt serologic testing for hepatitis virus co-infection.

HIV and Thrombotic Microangiopathy

The classic pentad of microangiopathic hemolytic anemia, thrombocytopenia, renal dysfunction, neurological signs, and noninfectious fever is found in a minority of HIV-infected patients with thrombotic microangiopathy.⁷⁶ Microangiopathic hemolytic anemia, thrombocytopenia, and increased serum lactate dehydrogenase are required to establish the diagnosis.⁷⁶ Before the introduction of HAART, the 1-year mortality rate after the development of HIV-related thrombotic microangiopathy approached 100%.⁷⁶⁻⁷⁸ This complication is increasingly rare in populations with access to HAART.⁷⁹

Treatment

Antiretroviral Therapy

Treatment of the underlying cause is a primary principle in the management of secondary glomerular disease. Improvement in HIVAN has been demonstrated in patients receiving HAART, and the annual incidence of ESRD attributed to HIV decreased substantially after the widespread introduction of HAART.⁶⁰ Pre- and post-HAART kidney biopsies in two severe HIVAN cases demonstrated dramatic improvement in renal pathology, with associated improvement in kidney function.^{61,80} Although HAART-related improvements have also been reported in HIV-related pediatric nephrotic syndrome and MN,^{81,82} the benefit of HAART in

non-HIVAN kidney disease is less clear.⁸³ The role of HAART in the treatment of HIV-related kidney disease is primarily supported by epidemiologic data and cohort studies,^{84,85} with no data from rigorous clinical trials. Randomized, placebo-controlled clinical trials are no longer ethical given the established benefits of HAART for HIV infection, and expert guidelines recommend consideration of HAART in all patients with HIV and chronic kidney disease based on existing data.⁸⁶

Nephrologists involved in the care of HIV patients should be familiar with HAART agents with potential nephrotoxic effects, as well as those agents that require dose adjustment in patients with reduced kidney function. For example, the protease inhibitors indinavir and atazanavir have been associated with nephrolithiasis and obstructive nephropathy, and the nucleotide reverse transcriptase inhibitor tenofovir has been associated with Fanconi syndrome and acute renal failure.⁸⁷ In general, the nucleoside and nucleotide reverse-transcriptase inhibitors require dose adjustment in patients with a decreased glomerular filtration rate, whereas protease inhibitors and most nonnucleoside reverse-transcriptase inhibitors do not require dose adjustment.⁸⁷ Interested readers are encouraged to consult recent review articles and package inserts because of the rapid pace of antiretroviral drug development.

Adjunctive Therapy: Angiotensin System Blockade and Corticosteroids

Nonrandomized studies of adult HIVAN patients have shown improvements in proteinuria and delayed progression using angiotensin-converting enzyme inhibitors (see Table 24-2).^{88,89} Because of the known benefits of angiotensin system blockade in other proteinuric kidney diseases, many nephrologists consider these agents the standard of care for the treatment of HIVAN. As such, randomized clinical trials are unlikely to be performed, and current guidelines recommend these agents for first-line therapy of hypertension or proteinuria in patients with HIV and chronic kidney disease.⁸⁶

Case reports and retrospective series have shown improvement in kidney function and modest improvement in proteinuria with corticosteroids in adults with HIVAN.⁹⁰⁻⁹² The presumed role of corticosteroids is improvement in interstitial inflammation.^{93,94} The potential risks of therapy and unknown long-term effects make these third-line agents in selected cases (see Table 24-2).

HIV and Renal Replacement Therapy

Management of HIV in End-Stage Renal Disease

HIVAN is an important cause of ESRD in young African Americans, who represent 90% of the incident ESRD cases attributed to HIV in the United States.⁶⁰ The prevalence of HIV infection in the dialysis population varies with center location and the demographics of the local ESRD population. Voluntary HIV testing should be offered to all new dialysis patients because HAART may be associated with improved survival and potential improvement in kidney function. Survival of HIV-positive dialysis patients has dramatically improved in the HAART era,⁹⁵ with similar outcomes with peritoneal dialysis and hemodialysis.⁹⁶

Effects of HIV in Renal Transplantation

With improved long-term survival in the HAART era, kidney transplantation is now a reasonable alternative in selected patients with preserved immune function and undetectable viral load on HAART.^{97,98} Ongoing studies are investigating whether the long-term survival advantage conferred by kidney transplantation in the general ESRD population is also realized in patients with HIV. Communication between transplantation nephrologists and HIV providers is essential to avoid significant interactions between antiretroviral and immunosuppressive agents. Potential transplant recipients should be referred to a transplantation center with experience in the evaluation and management of HIV-positive recipients.

BACKGROUND

Nephrotic syndrome (NS) is a clinical complex characterized by proteinuria of more than 3.5 g/1.73 m²/24 hr (in practice > 3.0–3.5 g/24 hr), hypoalbuminemia, edema, hyperlipidemia, and lipiduria.^{1–4} The key component is proteinuria, which results from altered permeability of the glomerular filtration barrier, namely the glomerular basement membrane and podocytes with their slit diaphragms. Proteinuria sets in motion a series of homeostatic and compensatory mechanisms that result in the clinical features of NS.^{1,2} These features can occur with lesser degrees of proteinuria or may be absent even in patients with massive proteinuria. Although the diseases and pathogenic mechanisms underlying NS are diverse, the result is alteration in the charge- and/or size-selective properties of the glomerular capillary wall such that permeability to albumin and other intermediate-sized macromolecules is enhanced.^{3,4}

Management of NS focuses on (1) treatment of the causative disease where possible, generally with a combination of immunosuppressive drugs such as corticosteroids, cytotoxic agents, and calcineurin inhibitors, and (2) treatment of the complications that are responsible for much of the morbidity associated with this condition. In this chapter, we discuss management of the complications of NS. Specifically, we address the treatment of hypoalbuminemia, edema, hyperlipidemia, abnormalities of calcium homeostasis, thromboembolic phenomena, and increased susceptibility to infection. It must be stressed that in many areas, there is a dearth of prospective, controlled clinical trials, so that recommendations on treatment remain somewhat empirical. Where there is controversy or inadequate data regarding the management of a particular problem, the authors' view is presented.

HYPOALBUMINEMIA/PROTEINURIA

It is becoming increasingly clear that proteinuria per se may be deleterious to the kidney and play a role in the progression of renal disease.⁵ The rate of progression is increased in patients with heavy proteinuria, and interventions that reduce urinary protein excretion have been demonstrated to slow the rate of decline of glomerular filtration rate (GFR) in both diabetic and nondiabetic renal disease.^{6,7} The sequelae of hypoalbuminemia include an increased risk of acute renal failure (from renal hypoperfusion and filtration failure), systemic and renal drug toxicity (because of alterations in free and protein-bound drug levels), enhanced platelet aggregability, hyperlipidemia, and edema formation.¹ Protein malnutrition is an important complication, particularly in children in whom normal growth and development may become stunted. Although outside the scope of this chapter, drug dosing needs to be approached with care in patients with NS, especially those with hypoalbuminemia and impaired renal function.⁸ Not only will hepatic and renal clearances be affected, but the range of therapeutic levels will need to be lowered for drugs having a high degree of protein binding because therapeutic ranges are typically based on total drug concentration rather than the bioactive free portion.

In general, the greater the magnitude of the proteinuria, the lower the serum albumin concentration. However, this relationship is not constant, and many patients do not develop hypoalbuminemia even in the presence of persistent heavy proteinuria. Other factors that may contribute to decreased serum albumin levels in patients with nephrotic-range proteinuria include an inappropriately low rate of hepatic albumin synthesis and, although controversial, an increased rate of renal albumin catabolism.¹

Management

Therapeutic strategies employed to decrease proteinuria and increase serum albumin levels include manipulations of dietary protein intake and treatment with a combination of angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), nonsteroidal anti-inflammatory drugs (NSAIDs), and aldosterone antagonists. The antiproteinuric mechanisms are thought to involve both hemodynamic and local factors affecting glomerular permselectivity characteristics. These measures may confer substantial benefit in patients with severe NS, for whom much of the morbidity derives from persistent heavy proteinuria. Furthermore, a decrease in proteinuria may be associated with slowing of the rate of progression of the underlying renal disease (see later).

Manipulation of Dietary Protein Intake

Although early reports advocated the use of high-protein diets to treat hypoalbuminemia, more recent work has called into question the rationale and efficacy of such an approach. In general, it appears that a high-protein diet results in increases in the rates of both hepatic albumin synthesis and urinary protein loss such that the plasma albumin level fails to increase and may actually decrease.^{1,9,10} Furthermore, a high protein intake, by increasing glomerular capillary pressures, has been implicated in the progression of a variety of renal diseases.¹¹

Early studies suggested that ingestion of a low-protein diet may reduce urinary protein loss, although this effect was offset by a concomitant decline in hepatic albumin synthesis, so that serum albumin concentrations were not consistently increased.^{9,12,13} Recent studies have failed to show a consistent effect of dietary protein restriction on proteinuria. In a randomized, crossover trial, Remuzzi and colleagues¹⁴ found that protein restriction (0.6 mg/kg/day) had no effect on renal hemodynamics or proteinuria in nephrotic patients with membranous nephropathy. D'Amico and colleagues¹⁵ reported similarly disappointing results with a protein-restricted diet that was supplemented with essential amino acids and contained a high ratio of polyunsaturated to saturated fats. At variance with these results, Giordano and colleagues¹⁶ reported a significant decrease in proteinuria (38%) and a small but significant increase in serum albumin in seven patients with NS ingesting a low-protein diet for 4 weeks (0.55 g/kg/day plus 1 g of dietary protein per gram of daily protein excretion). Walser and colleagues¹⁷ studied 16 nephrotic patients fed a very low protein diet (0.33 g/kg/day) supplemented with 10 to 20 g/day of essential amino acids for an average of 10 months. All patients had a decrease in proteinuria and an increase in serum albumin. Indeed, for the five patients with an initial GFR higher than 30 mL/min, the response was especially dramatic, with the serum albumin increasing from 2.5 to 3.8 g/dL and proteinuria declining from 9.1 to 1.9 g/day.

Debate also continues about the potential risk of increasing protein malnutrition by restriction of dietary protein intake in patients who are already severely hypoalbuminemic.^{13,18,19} A lack of patient tolerability and the need for close nutritional monitoring are additional factors that may dissuade prescription of such regimens.

Until the benefits and potential risks of dietary protein manipulation are further clarified, it would appear reasonable to advise a moderate dietary protein intake of 0.8 to 1.0 g/kg/day

in adults. In children, a greater intake, of approximately 1.2 g/kg/day, may be preferable to avoid the hazards of growth retardation. Several studies suggest a lack of risk with such moderate restriction. Lim and colleagues²⁰ showed that nephrotic patients ingesting 0.84 g/kg/day protein maintained a positive nitrogen balance of 0.5 g/day. Similarly, Maroni and colleagues²¹ demonstrated positive nitrogen balance in a group of patients consuming 0.8 g/kg/day protein plus 1 g protein per gram of urine protein. Giordano and colleagues²² showed that the rate of synthesis of IgG was unchanged in seven nephrotic patients whose protein intake was decreased from 1.2 to 0.66 g/kg/day. Finally, to achieve optimal nutrition, an adequate energy intake (≥ 35 kcal/kg/day) must also be ensured.

Angiotensin Antagonists

ACEIs can decrease proteinuria by as much as 50% in a variety of proteinuric states without decreasing GFR or effective renal plasma flow.^{23,24} The mechanism of this effect is still debated, but appears to entail both hemodynamic and structural factors. Structural factors may predominate because the maximal antiproteinuric effect takes 4 to 8 weeks to develop. This would also explain why short-term infusion of angiotensin reversed the renal and systemic hemodynamic effects of ACEIs without affecting the decrease in proteinuria.²⁵ Moreover, ACEIs have been shown to decrease selectively the fractional clearance of large molecular weight dextrans, suggesting a direct improvement in the size-selective properties of the filtration barrier.^{26,27} Whether this effect is mediated via inhibition of angiotensin or other angiotensin-independent effects of ACEIs is not yet clear.

The antiproteinuric effect of ACEIs is dose dependent and apparently independent of changes in systemic blood pressure. Other antihypertensive agents that lower blood pressure to a comparable degree do not similarly decrease proteinuria. The degree of decrease in proteinuria varies considerably among patients, and some may not respond at all. Importantly, the antiproteinuric effect of ACEIs appears to depend on sodium restriction. Heeg and colleagues²³ showed that a high sodium intake (200 mmol/day) abrogated the decrease in proteinuria mediated by lisinopril during a period of low salt intake (50 mmol/day). Buter and colleagues²⁸ demonstrated that addition of a thiazide diuretic to patients ingesting a high-sodium diet can reverse the blunting effect of a high sodium intake on the decrease in proteinuria. Finally, the effects of ACEIs tend to be greater in patients with higher baseline proteinuria, probably because of the greater room for a measurable reduction.²⁹

It is now well established that ACEIs slow the progression of both diabetic and nondiabetic renal disease.^{6,7,30-37} In the REIN trial of ACEIs in proteinuric renal disease, the renoprotective effect of ramipril correlated with the observed decrease in proteinuria.⁶ Four recent meta-analyses involving the same pool of 1860 nondiabetic patients from 11 randomized, controlled trials analyzed closely the beneficial effect of ACEIs in slowing the progression of renal disease, an effect that again was more pronounced in patients with higher levels of baseline proteinuria.³⁴⁻³⁷ These meta-analyses suggest that proteinuria may be a specific marker identifying patients with renal disease for whom ACEIs possess an added benefit over other antihypertensive agents that lower blood pressure to a comparable degree.³⁴⁻³⁶ Indeed, the specific benefit of ACEIs appeared to be limited to patients with significant proteinuria

(≥ 500 mg/day).³⁷ Among patients at high risk of progression of renal disease, but lacking significant proteinuria (< 500 mg/day), ACEIs showed no advantage over other antihypertensive regimens.³⁷

Although debate continues as to the superiority of ACEIs versus ARBs,^{38,39} it appears that, at optimal doses, the antiproteinuric and renoprotective effects of these two classes of drugs are fairly equivalent.^{40,41} In the COOPERATE study of 263 patients with nondiabetic renal disease and proteinuria exceeding 300 mg/day, an ACEI (trandolapril 3 mg/day) and an ARB (losartan 300 mg/day) were equally effective in preventing a doubling of creatinine and/or end-stage renal disease.⁴⁰ ACEIs and ARBs not only lowered proteinuria equivalently ($\sim 45\%$ decrease of median maximum), but their effects occurred with similar kinetics and were sustained for the 3 years of the study.⁴⁰ The recent ROAD study compared an ACEI (benazepril) and an ARB (losartan), each dosed according to one of two regimens: conventional (benazepril 10 mg/day vs. losartan 50 mg/day) or optimal (benazepril up to 200 mg/day [median, 100 mg/day] vs. losartan up to 40 mg/day [median, 20 mg/day]).⁴¹ The study population of 339 nondiabetic patients with chronic renal insufficiency and proteinuria (> 1 g/day) were followed for a median of 3.7 years. The ACEI and ARB performed equivalently for all endpoints. Optimal doses of each agent were more effective than conventional doses in decreasing proteinuria (50%–55% vs. 35%–40%).⁴¹ Compared with conventional doses, optimal doses also decreased by approximately 50% the number of patients reaching the combined primary endpoint of death, end-stage renal disease, and/or doubling of creatinine.⁴¹ Importantly, the number of adverse events, such as hyperkalemia and acute decreases in the GFR, did not differ between patients given an ACEI and ARB or between conventional and optimal dosing.⁴¹ The ROAD study suggests that ACEIs and ARBs may currently be used at doses that incompletely inhibit the renin-angiotensin-aldosterone axis.

Given that ACEIs and ARBs antagonize the effects of angiotensin through different mechanisms and have distinct effects beyond the renin-angiotensin-aldosterone axis,³⁹ a clear rationale exists for using these drugs in combination. Most studies examining this issue (including several meta-analyses and systematic reviews) have indicated a superiority of a combination of an ACEI and ARB over either agent alone.^{39,40,42–73} The major endpoint in these studies, most of which were of short duration (< 6 months), was proteinuria reduction, although blood pressure lowering and renoprotection were also examined in several.^{39,40,72,73} Overall, the data are most convincing for patients with nondiabetic proteinuric renal disease, largely based on the COOPERATE study^{39,40,72} because of its superior design (parallel group vs. crossover), longer duration (3 years vs. < 1 year), larger sample size (263 patients), and clearly defined endpoints. Among patients receiving combination therapy with ACEI and ARB (trandolapril plus losartan), 11% reached the combined primary endpoint (end-stage renal disease and/or doubling of creatinine) compared with 23% of patients who received either agent alone. A similar advantage was observed for lowering of proteinuria ($\sim 76\%$ reduction in median maximum change for combination therapy versus $\sim 45\%$ reduction for either agent alone). Although it seems likely that a similar result will apply to diabetic patients with proteinuric renal disease, available studies involving diabetic patients preclude a definitive conclusion because of their short duration (< 12 weeks).⁷³

These studies unfortunately leave unresolved the basis for the superiority of combination therapy. Two major possibilities, not mutually exclusive, exist: an additive benefit may be attributable to nonoverlapping pharmacologic effects of ACEIs and ARBs³⁹ or to suboptimal dosing as individual agents.⁴¹ The latter important possibility has been inadequately addressed. As discussed earlier, titrating the dose of an ACEI or ARB upward led to significant further renoprotection and decreases in proteinuria.⁴¹ On average, this added benefit was obtained by a doubling of the daily dose of either agent. Until the basis for the superiority of combined therapy is determined, we recommend that an ACEI and an ARB be used together at conventional doses, especially in patients with nondiabetic proteinuric renal disease. ACEIs and ARBs have a number of important adverse effects in patients with renal disease, including a decrease in the GFR and hyperkalemia. Although the prevalence of these adverse effects does not appear to be increased by combination therapy, patients should be monitored carefully after the introduction of an ACEI and an ARB, either alone or in combination.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs decrease proteinuria to a comparable degree as ACEIs.^{74,75} The mechanism of action is not clear, although the decrease in proteinuria likely depends on inhibition of renal prostaglandin synthesis. In a small study of seven nephrotic patients, a significant correlation was observed between the decrease in proteinuria and decreased renal prostaglandin E₂ excretion.⁷⁶ Indomethacin improved the profile of fractional dextran clearance and decreased flux through the shunt pathway, a major source of abnormal proteinuria in NS.⁷⁷

The beneficial effect of NSAIDs occurs more rapidly than that of ACEIs (1–3 days). In some studies, decreased proteinuria is associated with decreases in both the GFR and effective renal plasma flow.⁷⁵ Sodium depletion enhanced both the antiproteinuric effect and the decrease in the GFR.⁷⁴ Although lisinopril and indomethacin had an additive effect in decreasing proteinuria, the combination produced a pronounced decrease in the GFR and significant hyperkalemia.⁷⁵ In another study, indomethacin had an additive antiproteinuric effect in combination with either the ACEI enalapril or the ARB irbesartan.⁷⁸ No adverse effect on renal hemodynamics was seen with short-term administration.⁷⁸ NSAIDs have a number of adverse renal effects, including hyperkalemia, acute renal failure, and salt and water retention. In general, we recommend that ACEIs and ARBs be used as preferred antiproteinuric agents and that NSAIDs be reserved for patients who are refractory to other measures.

Aldosterone Antagonists

Addition of the aldosterone antagonist spironolactone at 25 mg/day to the regimen of nondiabetic patients with chronic renal disease and proteinuria (> 1 g per gram of creatinine per day) led to a decrease in both proteinuria ($\sim 50\%$) and the rate of decrease in the estimated GFR ($\sim 30\%$) after 1 year compared with a control group not given spironolactone.⁷⁹ Before the start of the study, patients had been stably treated with conventional doses of an ACEI and an ARB, either alone or in combination. Baseline aldosterone levels correlated with the level of proteinuria and predicted the degree of proteinuria decrease, in support of the authors' contention that ACEIs and/or ARBs incompletely inhibit

aldosterone synthesis.⁷⁹ Similar results were observed in a smaller study of diabetic patients.⁸⁰

Although these results are encouraging, it remains unclear whether circulating aldosterone in the presence of an ACEI and/or an ARB represents true escape or merely incomplete inhibition of the renin-angiotensin-aldosterone axis from suboptimal doses of an ACEI and/or an ARB. Also, the addition of spironolactone is not without risk, especially of hyperkalemia. Although the addition of spironolactone to an ACEI and/or an ARB increased serum potassium from a mean of 4.2 mEq/L at baseline to 5.0 mEq/L after 12 months of treatment, this necessitated discontinuation of the drug in only a few patients.⁷⁹ Conversely, serious hyperkalemia from the combination of spironolactone and an ACEI has been previously reported.⁸¹

Measures to Ablate Renal Function in Refractory Nephrotic Syndrome

Therapeutic ablation of renal function may be considered in occasional patients with refractory complications of NS, particularly when renal function is already depressed. A variety of measures have been used, including medical nephrectomy with high doses of NSAIDs, percutaneous transfemoral embolization using artificial agents or autologous blood clot, balloon occlusion of the renal arteries, and surgical nephrectomy.^{82–85} Bilateral renal arterial embolization with autologous blood clot is probably the safest of the methods but should be considered only as a last resort in intractable cases.⁸⁵

EDEMA

Edema is one of the most common symptoms of NS and often the reason patients come to medical attention. Fluid accumulates predominantly in areas of dependency or low tissue pressure. Hence, periorbital edema is common in the morning and leg edema at the end of the day. Pleural effusions and ascites occur frequently. Pulmonary edema does not occur in the presence of normal cardiac function, although in patients with very low plasma oncotic pressure (<8 mm Hg), minor elevations in left atrial filling pressure may lead to pulmonary congestion, despite the normally protective low-pressure features of the pulmonary circuit.³

The classic theory of edema formation in NS postulates that hypoalbuminemia leads to decreased intravascular oncotic pressure, with leakage of extracellular fluid from the blood into the interstitium and a decrease in blood volume. Hypovolemia then leads to activation of both the renin-angiotensin-aldosterone axis and the sympathetic nervous system, as well as release of antidiuretic hormone and suppression of atrial natriuretic peptide, thereby signaling the kidney to retain salt and water.⁸⁶ However, it is now clear that this classic theory applies to a minority of patients because the majority of patients with established NS have normal or even elevated blood volumes and stimulation of the renin-angiotensin-aldosterone axis is not consistently present.^{87,88} Hence, primary renal sodium retention must also contribute to edema formation, although the factors responsible for this sodium avidity and the role of hypoalbuminemia in its genesis remain unclear.^{88,89} Given the heterogeneity of NS in terms of patient age, the underlying pathophysiologic process, and the level of renal function, it is likely that different mechanisms of sodium retention exist in different patients.^{88,90}

Management

Treatment of edema involves restriction of dietary sodium and the judicious use of diuretics (see Chapter 33). Considerable improvement should be possible for nearly all patients. For many patients, however, complete resolution of edema is not only unattainable but also undesirable because of the risk of volume contraction. In cases of mild edema, dietary sodium restriction to 100 to 150 mEq/day may be sufficient by itself. Restriction to less than 100 mEq/day is indicated in patients with more severe edema. Compliance with sodium restriction can be ascertained by measuring 24-hour urinary excretion of sodium. Institution of diuretic therapy is indicated in patients with symptomatic edema unresponsive to sodium restriction.

Furosemide pharmacokinetics and pharmacodynamics are often abnormal in patients with NS, many of whom show a degree of diuretic resistance. Although the following discussion focuses on the loop diuretic furosemide, similar principles apply to nearly all other diuretics in common clinical use, including the loop diuretic bumetanide, the thiazide diuretics, and the potassium-sparing diuretics amiloride and triamterene. The diuretic effect of furosemide depends on binding to, and inhibition of, a specific transporter located in the luminal membrane of the loop of Henle. Because furosemide is highly protein bound (>90%), it cannot enter the urine by glomerular filtration. Entry into the urine occurs instead via secretion by the proximal tubule. Binding of furosemide to albumin aids secretion in two ways: (1) because of its tight association with albumin, furosemide is restricted to the vascular space and therefore has a higher rate of delivery to the kidney and (2) optimal secretion of furosemide may depend on the presence of albumin.

Thus, several mechanisms probably account for the diuretic resistance observed in patients with NS and hypoalbuminemia.^{91,92}

1. Oral bioavailability may be decreased because of bowel wall edema and impaired absorption.
2. In the presence of hypoalbuminemia, furosemide will be incompletely bound to albumin and therefore diffuse out of the vascular space, thereby decreasing delivery of furosemide to the kidney.⁹³
3. Even that fraction of furosemide that makes it into the urinary space may be limited in efficacy because tubular furosemide may bind to filtered albumin, thereby limiting the availability of free drug to interact with its receptor on the luminal brush border.⁹⁴
4. Short-term hemodynamic and long-term renal structural changes may further diminish the diuretic response to furosemide. Structural changes include hypertrophy of distal tubular cells, leading to enhanced sodium reabsorption at sites distal to the loop, as well as intrinsic changes in the activity of the target of furosemide, the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter.⁹⁵ In some instances, resistance may reflect the coexistence of renal impairment, with resulting impaired secretion of furosemide into the proximal tubular lumen.⁹⁶
5. A continued high dietary sodium intake and the ingestion of NSAIDs may also cause an inadequate diuretic response.

A recent study casts doubt on the contribution of urinary protein binding of loop diuretics to diuretic resistance in NS.⁹⁷ In this study, coadministration of sulfisoxazole with furosemide was used to displace furosemide from binding to urinary

albumin, but failed to enhance the natriuretic effect. Moreover, despite an observed increase in the volume of distribution of furosemide, there was no decrease in the rate of diuretic excretion, thereby questioning the pharmacodynamic role of hypoalbuminemia *per se*. These results suggest that normal renal compensatory mechanisms to diuretic use and/or a primary increase of sodium avidity may play a predominant role in the diuretic resistance of NS.

Dosing recommendations for diuretics in NS are empirically derived and will vary according to the degree of diuretic resistance.^{92,98} Short-term diuretic resistance may be overcome by increasing the diuretic dose and frequency of administration, or by switching to a continuous intravenous infusion. Long-term resistance may require sequential nephron blockade through the combined use of loop and distal diuretics. In many cases, a lack of appreciation of the pharmacokinetic properties of diuretics can lead to improper dosing and seeming resistance in an otherwise responsive patient.⁹⁹ We have reviewed extensively the pharmacology and principles of diuretic use as well as strategies to overcome resistance extensively elsewhere.⁹⁹

Some authors advocate intravenous coadministration of furosemide and albumin for patients with severe refractory edema. The use of such a regimen presumes that pharmacokinetic factors contribute importantly to diuretic resistance. In the most successful study, an equimolar infusion of salt-poor albumin (40 mg furosemide premixed with 6 g of salt-poor albumin) increased recovery of furosemide from the urine and led to an enhanced diuretic response.⁹³ More recent studies have provided less encouraging results.¹⁰⁰ Fliser and colleagues¹⁰¹ infused 60 mg furosemide plus 200 mL of 20% human albumin to a group of nephrotic patients. The rate of urinary furosemide excretion was unchanged, suggesting that the observed modest increase in sodium excretion and urine volume was secondary to alterations in renal hemodynamics. Other workers failed to find any potentiation of furosemide by intravenous albumin.^{102–104} Some of this lack of effect may be due to the fact that the albumin and furosemide were not admixed before infusion or that furosemide was administered at submaximal doses. In addition, in some studies, the natriuretic response to furosemide alone was substantial, suggesting that the patients studied may not have been truly diuretic resistant. Taken together, these studies are consistent with a critical role for primary sodium retention in the pathophysiology of the edema of NS. Based on current evidence, we recommend that the combination of furosemide and albumin should be reserved for patients with refractory edema. When used in combination, the drugs should probably be admixed before intravenous administration.

If the response to furosemide alone is inadequate, a thiazide diuretic can be added. The combination of two drugs acting at different sites may yield a synergistic response with enhanced natriuresis.¹⁰⁵ Thiazide diuretics are generally ineffective in the presence of renal impairment (GFR < 20–30 mL/min). Some patients may show an exaggerated response to the combination of a thiazide and loop diuretic, and severe volume contraction and dangerous hypokalemia can result. Careful monitoring for the first few days is therefore essential. Metolazone may also be useful in the treatment of nephrotic edema, either alone or combined with a loop diuretic.¹⁰⁶

As discussed previously, activity of the renin-angiotensin-aldosterone system is highly variable in patients with NS, so

that the response to aldosterone antagonists is highly inconsistent.⁸⁶ Aldosterone antagonists may be most useful in conjunction with loop diuretics to prevent hypokalemia. Conversely, hyperkalemia is always a risk with this class of diuretics, particularly in patients with diminished renal function.

Intravenous infusion of salt-poor albumin is also sometimes employed for the treatment of intractable nephrotic edema and in some patients appears to restore diuretic responsiveness (300 mL of 15% albumin infused over 45 minutes, followed by a furosemide bolus to establish a diuresis, given on alternate days).¹⁰⁷ This treatment is expensive, and any benefit is short-lived because the injected albumin is rapidly excreted in the urine or redistributes to extravascular tissue spaces. Despite these considerations, some authors recommend that a therapeutic trial of 50 to 75 g of albumin be undertaken over 2 to 3 days in patients in whom diuretics have effected no improvement in their edema or in whom complications of diuretic therapy preclude further increases in drug dose.² As the infusion of hyperoncotic albumin can precipitate pulmonary edema in patients with severe hypoproteinemia and any degree of cardiac impairment, patients should be monitored closely during therapy. The use of ultrafiltration for the treatment of edema resistant to standard therapy has also been described.¹⁰⁸

All patients must be monitored carefully for adverse effects of diuretic therapy. Particular attention should be paid to intravascular volume and renal perfusion because of the risk of precipitating prerenal failure. Changes in orthostatic blood pressure, neck vein distention, and the ratio of blood urea nitrogen to serum creatinine may be helpful in assessing renal perfusion. In patients who have evidence of volume depletion and in whom diuretics exacerbate a prerenal state, bed rest and the use of support stockings may help mobilize edema.

HYPERLIPIDEMIA

A host of abnormalities of lipid metabolism exist in patients with NS.^{109–112} These include elevations in all the following: total plasma cholesterol, very low density lipoprotein, intermediate-density lipoprotein, low-density lipoprotein (LDL), and lipoprotein (a). Triglyceride levels may also be elevated, particularly in patients with very heavy proteinuria. Although levels of high-density lipoprotein (HDL) are variable, the distribution among subclasses is altered such that HDL2 is decreased and HDL3 is increased. Elevated levels of apoproteins B, C, and E have also been shown, whereas the levels of apoproteins AI and AII, the major apoproteins in HDL, have been reported as normal. Qualitative abnormalities in lipoprotein composition are also described.¹⁰⁹

The mechanisms of hyperlipoproteinemia in NS have not been fully elucidated. Increased hepatic synthesis of apoprotein B-containing lipoproteins, stimulated by decreased plasma oncotic pressure, may be an important factor.¹⁰⁹ In general, however, decreased lipid catabolism is thought to play a more important role than hepatic overproduction of lipoproteins.^{113–115} Depletion of endothelium-bound lipoprotein lipase and alterations in the binding capacity of very low density lipoprotein are thought to contribute importantly to decreased catabolism.¹¹⁵ Lowered plasma viscosity, decreased

oncotic pressure, decreased plasma tonicity, urinary loss of liporegulatory substances, and decreased lipoprotein lipase activity may all play a role in the genesis of hyperlipidemia.²

Although the same lipid abnormalities in nonnephrotic populations have been associated with an increased incidence of cardiovascular disease, there is controversy as to whether these findings can be extrapolated to NS. Most reports on cardiovascular disease in NS are small, retrospective, and lacking in appropriate control groups, perhaps accounting for their conflicting results.^{116,117} A more recent retrospective study of 142 patients with NS documented a 5.5-fold increased risk of myocardial infarction after controlling for other risk factors such as hypertension and smoking.¹¹⁸ Hyperlipidemia has also been implicated in accelerating glomerular injury.^{109,119} Indeed, similar pathophysiologic mechanisms are thought to contribute to progression of both glomerulosclerosis and atherosclerosis.¹²⁰ Such considerations provide an additional rationale for the treatment of nephrotic hyperlipidemia. Until the results of prospective, controlled trials dictate otherwise, it seems prudent to treat severe and/or prolonged hyperlipidemia, particularly in patients with other cardiovascular risk factors.^{113,121}

Management

The approach to management of nephrotic hyperlipidemia is similar to that for nonnephrotic patients and consists of dietary measures, oral lipid-lowering agents, and modification of associated risk factors such as smoking and hypertension.^{110,121,122} Available studies are small, mostly uncontrolled, and of short duration. Most studies were designed to test short-term efficacy and safety of specific therapeutic interventions rather than long-term benefits in cardiac or progressive renal disease. Thus, recommendations regarding treatment are based on limited data, much of which awaits confirmation in long-term, prospective, controlled studies.

Dietary Manipulations

Given the magnitude of hyperlipidemia seen in association with NS, dietary measures alone, unless highly restrictive, are usually ineffective as sole therapy.^{15,122–124} Institution of a moderately restricted diet, low in cholesterol (<300 mg) and fat, with a high ratio of polyunsaturated to saturated fats, during the run-in phase of small trials of lipid-lowering agents failed to effect any significant improvement in lipid parameters.^{125–127} More impressive results have been reported with more restricted diets. After 6 months on a diet low in cholesterol (<200 mg), low in fat (<30% total calories), and rich in polyunsaturated fatty acids, total and LDL cholesterol decreased by 24% and 27%, respectively.¹⁵ A vegetarian soy-based diet low in fat and protein and essentially cholesterol free decreased total cholesterol by 28% and LDL by 33% in 20 nephrotic patients over an 8-week period.¹²⁸ It is doubtful that such strict diets would be tolerated by most patients with NS. Moreover, the long-term safety of such diets has not been assessed. Uncontrolled human studies have suggested that a diet high in long-chain ω -3 polyunsaturated fatty acids (e.g., enriched in fish oil) may decrease total plasma triglycerides and cholesterol as well as decrease proteinuria.^{129,130} As other studies have failed to confirm this effect,¹²³ further evaluation

is needed before the routine use of fish oil supplementation can be recommended.

Pharmacologic Therapy

A variety of agents have been used in the treatment of nephrotic hyperlipidemia, including bile acid sequestrants, fibric acid derivatives, probucol, and 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors. The bile acid sequestrants cholestyramine and colestipol lowered LDL cholesterol by 19% to 32% and total cholesterol by 8% to 20%.^{131,132} However, these drugs are not ideal first-line agents because of a high incidence of gastrointestinal adverse effects and a tendency to increase triglyceride levels. The fibric acid derivative gemfibrozil decreased triglycerides by 51%, total cholesterol by 15%, and LDL by 12.5%, while increasing HDL by 18%, in a 6-week randomized, double-blind, placebo-controlled trial in 11 patients.¹³³ Addition of the resin colestipol led to further improvements in lipid parameters, but the combination was poorly tolerated. Gemfibrozil alone was well tolerated, although one patient developed a markedly elevated creatine phosphokinase after vigorous exercise. Clofibrate, an older fibric acid derivative, has been associated with severe adverse effects in patients with renal impairment and should be avoided.¹³⁴ The use of probucol effected a moderate decrease in total and LDL cholesterol in two studies, but decreases also occurred in HDL cholesterol.^{133,135}

3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors decrease hepatic cholesterol production by inhibiting the rate-limiting enzyme involved in cholesterol synthesis. These agents decrease total cholesterol, LDL cholesterol, and very low density lipoprotein triglycerides, and in some studies also increase HDL cholesterol.^{124–127,131,136–148} Lipoprotein (a) levels were decreased in one study in patients with high baseline levels,¹⁴⁵ but they were unchanged in two other studies.^{127,144} In general, HMG-CoA reductase inhibitors are well tolerated and appear to be safe in studies up to 2 years in duration. Occasional patients have developed mild asymptomatic increases in aspartate aminotransferase^{125,137} or creatine phosphokinase,^{124,126,140,141,144,147} but in most instances, these did not necessitate withdrawal of the drug. In a recent meta-analysis of studies on the treatment of nephrotic hyperlipidemia, HMG-CoA reductase inhibitors were found to be the most effective therapy.¹⁴⁹

Data from experimental studies in vitro and in animal models suggest that the pleiotropic effects of statins may have additional benefits by decreasing proteinuria and delaying the progression of renal disease.^{150,151} However, conclusive data to support these findings in humans are lacking. In a meta-analysis of 12 trials in which lipid-lowering agents were administered to patients with proteinuric renal diseases, a significant reduction in the rate of decrease of the GFR was observed that correlated with study duration.¹⁵² A nonsignificant trend toward a decrease in proteinuria was also found. A number of other small studies of up to 2 years' duration also demonstrated a decrease in proteinuria with statin treatment.^{124,146} However, this is not a consistent finding.^{138,140} More recently, a prospective, controlled study by Bianchi and colleagues¹⁵³ looked at the effects of treatment with atorvastatin for 1 year in a group of 56 patients with proteinuria and chronic kidney disease. A significant decrease in proteinuria and slowing of the rate of decrease in the GFR were observed that were additive to the effects of an ACEI or an ARB.

No large randomized trials have specifically looked at progression of renal disease as a primary outcome, but a slowing of the decrease in the GFR has been suggested in post hoc analyses of subgroups of patients in large cardiovascular trials. A recent meta-analysis of 15 placebo-controlled, randomized trials found a significant decrease in proteinuria with statins, the effect being more pronounced in subjects with higher baseline protein excretion.¹⁵⁴ A secondary analysis of data from the Cholesterol and Recurrent Events trial found that pravastatin significantly slowed the rate of decline in renal function in subjects with a GFR less than 40 mL/min and in those with a GFR less than 50 mL/min who also had proteinuria.¹⁵⁵ In contrast, an analysis of data from the PREVEND cohort study and the PREVEND-IT trial failed to demonstrate an effect of statin therapy on either proteinuria or GFR.¹⁵⁶ In a recent meta-analysis of 27 trials in 39,704 participants, a modest effect of statins in decreasing proteinuria and slowing the rate of loss of renal function was observed.¹⁵⁷ There was considerable heterogeneity among trials, and the observed decrease in the rate of loss of renal function was confined to patients with cardiovascular disease. No effect was seen in patients with other causes of chronic kidney disease, such as hypertension, diabetes mellitus, or glomerulonephritis.¹⁵⁷ The true role of statins as renoprotective agents awaits confirmation in long-term trials specifically designed to look at prespecified renal endpoints.

Finally, there is some evidence to suggest that antiproteinuric treatment with ACEIs may be accompanied by an improvement in lipid parameters. Keilani and colleagues¹⁵⁸ reported 13% and 15% decreases in total and LDL cholesterol, respectively, in a group of patients with moderate proteinuria without NS. A reduction in lipoprotein (a) also occurred, but only three patients had frankly elevated levels at the start of the trial. The combination of an ACEI and an NSAID effected decreases in total cholesterol, LDL cholesterol, and lipoprotein (a) in nine patients with nephrosis-range proteinuria.¹⁵⁹ These alterations in lipid parameters correlated with decreases in proteinuria.

A reasonable approach to the management of nephrotic hyperlipidemia is to institute therapy with an HMG-CoA reductase inhibitor in conjunction with a low-cholesterol diet. Modification of other risk factors, such as smoking and obesity, is also important. If this regimen is inadequate, a bile acid sequestrant may be added as long as triglyceride levels are not excessive. If triglycerides are very high and/or HDL levels are low, a fibric acid analogue such as gemfibrozil could be added. Although these strategies will undoubtedly lower lipid levels, whether they will translate into a decrease in cardiovascular morbidity or a slowing of progression of renal disease awaits confirmation in long-term controlled trials.

ABNORMALITIES OF CALCIUM HOMEOSTASIS

Hypocalcemia (both total and ionized) and secondary hyperparathyroidism have been variably described in NS. Potential mechanisms include decreased intestinal absorption of calcium and a blunted calcemic response to parathyroid hormone.¹ Moreover, levels of 25-hydroxycholecalciferol (25-OH-D), the precursor of the active vitamin, are decreased in most patients with NS, probably because of loss of this metabolite in the urine bound to its vitamin D

carrier protein.^{160,161} Levels of the physiologically active 1,25-dihydroxycholecalciferol (1,25-[OH]₂-D) are more variable, being normal in some studies and low in others.¹

Despite these alterations in calcium and vitamin D metabolism, studies have yielded conflicting data regarding the incidence of bone disease in patients with NS.^{161,162} In one study, bone structure was largely normal among patients with normal renal function. Severe demineralization and bone resorption occurred only in association with deterioration of renal function.¹⁶³ Nevertheless, bone abnormalities were more pronounced in patients with NS than in a control group with comparable azotemia but lacking proteinuria. Others have reported evidence of osteomalacia and secondary hyperparathyroidism even in patients with normal renal function.¹⁶⁴ A more recent study of 30 adults with NS and normal renal function documented normal bone histology in one third of patients and osteomalacia in 57% of the group.¹⁶¹ The presence of osteomalacia correlated with the degree of proteinuria and the duration of NS.¹⁶¹ It seems clear that the potential for osteomalacia exists in these patients and may increase as renal failure supervenes. The known deleterious effects of glucocorticoids on bone mineral density may be of relevance in patients who receive prolonged or frequent courses of steroids for treatment of NS. It is of interest in this regard that a recent study of bone density in a group of 60 children and adolescents with steroid-sensitive NS, who had received an average of 23,000 mg prednisone, failed to show evidence of osteoporosis.¹⁶⁵ Bone mineral content of the lumbar spine and of the whole body were not different from a group of 195 control subjects.¹⁶⁵

Management

Treatment with oral vitamin D therapy should be prescribed for patients with evidence of osteomalacia or secondary hyperparathyroidism, patients with persistently low serum ionized calcium levels, patients in whom progressive renal insufficiency is anticipated, and patients who have unremitting or frequently relapsing NS.¹⁶⁶ Unfortunately, there is little information available on the optimal formulation or dose for vitamin D replacement in NS. In one study, vitamin D₃ (25 mg) was administered daily for a period of 4 to 52 weeks to nine nephrotic patients with documented low levels of 25-OH-D and 1,25-(OH)₂-D.¹⁶⁷ Normalization of 25-OH-D levels occurred in eight of nine patients, and normalization of 1,25-(OH)₂-D levels in five patients in whom the baseline serum creatinine was normal. Serum calcium levels should be monitored closely in patients on vitamin D replacement therapy. Measurement of bone mineral density should be considered in patients with persistent NS, particularly if they have received high doses of corticosteroids or have additional risk factors for osteoporosis.

HYPERCOAGULABILITY AND THROMBOEMBOLISM

Numerous defects in coagulation factors, clotting inhibitors, the fibrinolytic system, and platelet function have been invoked to explain the hypercoagulable state that exists in patients with NS.¹⁶⁸⁻¹⁷¹ There is a distinct lack of uniformity among the various studies. In general, levels of fibrinogen, factor V, factor VII, and α₂-antiplasmin are increased,

whereas those of factor IX, factor XI, factor XII, antithrombin III, plasminogen, and α_1 -antitrypsin are decreased. Disturbances in platelet physiology that could promote clotting include increased aggregability, increased levels of β -thromboglobulin (a protein released at the time of platelet aggregation), and increased levels of von Willebrand's factor. The cause of enhanced platelet aggregability is most likely multifactorial, with hypoalbuminemia, hyperlipidemia, and hyperfibrinogenemia all playing a role.¹⁷² Despite these multiple abnormalities, a direct relationship has yet to be established between any specific defect and the occurrence of thromboembolic complications.¹⁷³

Approximately 20% (range, 8%–44%) of adult NS patients develop thromboembolic complications other than renal vein thrombosis (RVT). As many as 50% of these episodes are clinically silent.¹⁶⁸ Arterial thromboses occur much less frequently than venous thromboses and have been described in the pulmonary, femoral, mesenteric, and coronary arteries. The incidence of RVT varies in different series from 2% to 60%, with an average of 35%. RVT is most common in membranous nephropathy.¹⁷⁴ Chronic RVT is usually asymptomatic and can only be diagnosed with certainty by renal venography, although computed tomography is also useful diagnostically and is less invasive.¹⁷¹ Long-term follow-up of established cases indicates that chronic RVT is generally benign, with a low incidence of thromboembolic episodes in patients who are anticoagulated.^{174,175} Moreover, there appear to be no adverse effects on renal function or the degree of proteinuria.² Acute RVT is less frequent. Patients usually present with flank pain and tenderness, macroscopic hematuria, and deterioration in renal function. Routine venography is not recommended in NS patients. Venography should be reserved for patients with features suggestive of acute RVT, an unexplained rapid deterioration in renal function, or symptoms suggestive of an acute thromboembolic event such as pulmonary embolus.

Management

Management of the thrombotic tendency in NS involves preventive measures such as avoiding immobilization or volume depletion, both of which increase the risk of clotting. Patients with a history of thromboembolism before the onset of NS should receive prophylactic anticoagulation if they are immobilized or have other major risk factors for clotting. In patients who experience an episode of thrombus or embolus, anticoagulants should be continued for as long as the nephrotic state persists.¹⁶⁹ Intravenous heparin followed by warfarin is the standard treatment for acute RVT.^{169,174,175} The international normalized ratio must be carefully monitored in nephrotic patients as warfarin kinetics are affected by NS, and dose adjustment may be necessary with changes in serum albumin level.¹⁷⁶ Recent case reports describe successful treatment of RVT with low molecular weight heparin continued in the outpatient setting.^{177,178} Fibrinolytic therapy, both systemic and local, has been successfully used in isolated patients,^{179–182} but does not appear to be superior to standard anticoagulant therapy. A more recent report described successful treatment of RVT with percutaneous catheter-directed thrombectomy in seven cases of acute RVT followed by thrombolysis in five cases.¹⁸³ Such direct percutaneous approaches are probably best reserved for patients with acute symptomatic RVT.¹⁷¹

The issue of prophylactic anticoagulation in NS is controversial. Prophylaxis with the low molecular weight heparin enoxaparin was recently studied in 55 adult patients for periods of 2 to 48 months.¹⁸⁴ No thrombotic episodes occurred during therapy, as evidenced by renal vein Doppler ultrasonography, lower leg Doppler ultrasonography, and lung ventilation-perfusion scintigraphy. There were no documented adverse effects, and patients found self-administration of the once-daily dose to be tolerable. Some authors advocate the use of prophylaxis in patients with membranous nephropathy because these are the patients at highest risk of thrombotic complications.^{4,185,186} A recent study using a decision analysis model concluded that the benefits of prophylactic anticoagulation begun at the time of diagnosis of NS due to membranous nephropathy outweighed the risks of bleeding.¹⁸⁵ Despite the arguments in favor of prophylactic anticoagulation, its routine use in all nephrotic patients cannot be recommended. Further prospective, controlled studies are indicated to determine both the necessity and optimal prophylactic anticoagulant regimens for patients with NS.

INCREASED SUSCEPTIBILITY TO INFECTION

A number of immunologic abnormalities have been documented in patients with NS. These include depressed immunoglobulin levels due to urinary loss, impaired antibody generation, defective opsonization due to depressed levels of complement factor B, and abnormalities of cell-mediated immunity.¹ In many patients, nonspecific depression of immune responses may occur because of malnutrition, vitamin D deficiency, or immunosuppressive therapy. These abnormalities may result in an increased susceptibility to infection, with the peritoneum and lungs being the sites most frequently involved.

Before the introduction of antibiotics, pulmonary, meningial, or peritoneal infection with encapsulated organisms, such as *Streptococcus*, *Haemophilus*, and *Klebsiella* species, was a common cause of death, particularly in children. In recent years, the incidence of infection with these agents has decreased, although adult patients continue to display an increased incidence of infection with gram-negative bacteria.¹⁸⁷

Management

Aggressive antibiotic therapy should be instituted at the first suspicion of infection. Prophylactic use of antibiotics, pneumococcal vaccine, or intravenous administration of hyperimmunoglobulin should be considered in high-risk cases. Vaccination should be given whenever possible during periods of remission because NS may impair the antibody response to vaccination.¹⁸⁸ Despite an adequate initial response to vaccination, many vaccinated patients do not maintain adequate antibody titers over time.^{189,190} Nonetheless, pneumococcal vaccination is still recommended for children older than 2 years of age and for adults with severely depressed immunoglobulins, particularly if NS is likely to be persistent or if renal failure supervenes.^{1,2} Although intravenous immunoglobulin has been used in NS,¹⁸⁷ insufficient data preclude specific recommendations.

BACKGROUND

The term thrombotic microangiopathy (TMA) defines a lesion of vessel-wall thickening (mainly arterioles and capillaries), intraluminal platelet thrombosis, and partial or complete obstruction of the vessel lumina. Depending on whether renal or brain lesions prevail, two pathologically indistinguishable, but somehow clinically different, entities have been described: hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Injury to the endothelial cell is the central and likely inciting factor in the sequence of events leading to TMA. Loss of physiologic thromboresistance, leukocyte adhesion to damaged endothelium, complement consumption, abnormal von Willebrand factor (vWF) release and fragmentation, and

increased vascular shear stress may then sustain and amplify the microangiopathic process. Intrinsic abnormalities of the complement system and of the vWF factor pathway may account for a genetic predisposition to the disease that may play a paramount role in particular in familial and recurrent forms. Due to their poor outcome and response to treatment, these congenital (genetic) forms are considered separately from acquired forms, whose outcome is strongly dependent on the possibility to treat or remove the underlying cause. The pathogenesis of acquired forms is only briefly reviewed to provide the background to different specific treatments. Mechanisms of genetic forms are discussed in more detail because they have been clarified only recently and will certainly have major relevance in identifying specific treatment modalities in the next few years. Forms

Table 26-1 Classification of Thrombotic Microangiopathies

Forms	Clinical Features
Acquired	
Shigatoxin associated	HUS
Neuraminidase associated	HUS
Immune-mediated ADAMTS-13 defective activity associated	TTP (often recurrent)
Immune-mediated CFH defective activity associated	HUS (recurrent)
Pregnancy associated	HUS, TTP, HELLP syndrome
Systemic disease associated	HUS, TTP
Drug associated	HUS, TTP
Bone marrow and solid organ transplantation associated	HUS (de novo or recurrent)
Genetic	
CFH, CFI, MCP abnormalities associated	HUS (often recurrent and familial)
ADAMTS-13 deficiency associated	HUS, TTP (often recurrent and familial)
Abnormal cobalamin metabolism associated	HUS
Others	HUS, TTP (often recurrent and familial)
Idiopathic	HUS, TTP

CFH, complement factor H; CFI, complement factor I; HELLP, hemolysis, elevated liver enzymes, and low platelet count; HUS, hemolytic uremic syndrome; MCP, membrane cofactor protein; TTP, thrombotic thrombocytopenic purpura.

without a recognized genetic predisposition or precipitating agent are referred to as idiopathic forms and discussed separately from acquired and genetic forms (Table 26-1).

ACQUIRED

These are by far the most common forms of TMA. Toxins, autoantibodies, pregnancy, systemic diseases, and drugs have been associated with TMAs that may present with the clinical features of both HUS and TTP. In most of these cases, early recognition and removal or treatment of the underlying condition is therefore of paramount importance to achieve remission.

Shiga Toxin–Associated Thrombotic Microangiopathy

Shiga toxin (Stx)–associated HUS (Stx-HUS), the most frequent form of TMA, may follow infection by certain strains of *Escherichia coli* or *Shigella dysenteriae*, which produce a powerful exotoxin (Stx).¹ The term *Shiga toxin* was initially used to describe the exotoxin produced by *S. dysenteriae* type 1. Then, some strains of *E. coli* (mostly the serotype O157:H7) isolated from human cases with diarrhea were found to produce a toxin similar to the one of *S. dysenteriae*. This toxin was subsequently given different names such as Shiga-like toxin for its similarities with Stx or verotoxin for its cytopathic effect on Vero cells (i.e., African green monkey kidney cells). The terms Shiga-like toxin and verotoxin should now be abandoned and only the term Stx should be used to encompass the exotoxins produced both by *S. dysenteriae* and *E. coli*. After food contaminated by Stx-producing *E. coli* or

S. dysenteriae is ingested, the toxin is released in the gut and may cause watery or most often bloody diarrhea because of a direct effect on the intestinal mucosae. When Stx, via the intestinal mucosae, reaches the systemic circulation, full-blown HUS may develop. Stx-HUS is usually considered a disease with a good outcome, with complete recovery in approximately 90% of cases. However, a recent meta-analysis of 49 studies including 3476 patients showed that 12% of patients die during the acute phase of the disease or remain dialysis dependent, 16% have residual kidney insufficiency with glomerular filtration rate values ranging from 5 to 80 mL/min/1.73 m², 15% are proteinuric, and 10% are hypertensive.² Age younger than 2 years, severe gastrointestinal prodromes, elevated white blood cell count, and anuria early in the course of the disease are predictors of the severity of HUS. Anuria for more than 10 days or the need for dialysis in the acute phase, as well as proteinuria at 12-month follow-up have been associated with an increased risk of chronic renal failure in the long term. Patched cortical necrosis or involvement of more than 50% glomeruli are further predictors of poor outcome.

Diagnosis rests on detection of *E. coli* O157:H7 in stool cultures. Serologic tests for antibodies to Stx and O157 lipopolysaccharide can be done in research laboratories, and tests are being developed for rapid detection of *E. coli* O157:H7 and Stx in stools.

Undercooked ground beef is the most common source of infection, but ham, turkey, cheese, unpasteurized milk, juice, water, and fresh vegetables irrigated with contaminated water have also been implicated. Secondary person-to-person contact is an important way to spread infection in institutions, particularly day-care centers and nursing homes. Infected patients should be excluded from day-care centers until two consecutive

stool cultures are negative for *E. coli* O157:H7 to prevent further transmission. However, the most important preventive measure in child-care centers is supervised hand washing.

Supportive Therapy

In children, the mortality rate from typical Stx-HUS has significantly decreased over the past 40 years, probably as the result of better supportive management of anemia, renal failure, hypertension, and electrolyte and water imbalance. Intravenous isotonic volume expansion as soon as an *E. coli* O157:H7 infection is suspected, that is, within the first 4 days of illness, even before culture results are available, may limit the severity of kidney dysfunction and the need for renal replacement therapy.³ Bowel rest is important for the hemorrhagic colitis associated with Stx-HUS. Antimotility agents should be avoided because they may prolong the persistence of *E. coli* in the intestinal lumen and therefore increase patient exposure to Stx. The use of antibiotics should be restricted to the very limited number of patients presenting with bacteremia⁴ because in children with *E. coli* enteritis, they may increase the risk of HUS by 17-fold.⁵ A possible explanation is that antibiotic-induced injury to the bacterial membrane might favor the acute release of large amounts of preformed toxin. Alternatively, antibiotic therapy might give *E. coli* O157:H7 a selective advantage if these organisms are not as readily eliminated from the bowel as are the normal intestinal flora. Moreover, several antimicrobial drugs, particularly the quinolones, trimethoprim, and furazolidone, are potent inducers of the expression of the Stx 2 gene and may increase the level of toxin in the intestine. Although the possibility of a cause-and-effect relationship between antibiotic therapy and increased risk of HUS has been challenged by a recent meta-analysis of 26 reports,⁶ there is no reason to prescribe antibiotics because they do not improve the outcome of colitis, and bacteremia is rare in Stx-HUS. However, these considerations do not necessarily apply to many cases of bloody diarrhea, in particular in South America and India, that are precipitated by *E. coli* strains different from O157:H7 or by other bacteria, such as *Shigella* dysentery type 1. For instance, when hemorrhagic colitis is caused by *Shigella* dysentery type 1, early and empirical antibiotic treatment shortens the duration of diarrhea and decreases the incidence of complications and the risk of transmission by shortening the duration of bacterial shedding. Thus, in developing countries where *Shigella* is the most frequent cause of hemorrhagic colitis, antibiotic therapy should be started early and even before the involved pathogen is identified.

Careful blood pressure control and renin-angiotensin system blockade may be particularly beneficial long-term treatment for those patients who suffer chronic renal disease after an episode of Stx-HUS. A study in 45 children with renal sequelae of HUS followed for 9 to 11 years documented that early restriction of proteins and use of angiotensin-converting enzyme inhibitors may have a beneficial effect on long-term renal outcome, as documented by a positive slope of 1/Cr values over time in treated patients.⁷ In another study, treatment with angiotensin-converting enzyme inhibitors for 8 to 15 years after severe Stx-HUS normalized blood pressure, reduced proteinuria, and improved the glomerular filtration rate.⁸

Shiga Toxin Binding

An oral Stx binding agent composed of repeated synthetic carbohydrate determinants that mimic the Stx receptor linked to colloidal silica (Synsorb Pk) has been developed with the

rationale of inhibiting intestinal absorption of the toxin. However, after preliminary studies showing that the drug is well tolerated and effectively binds the toxin, a prospective, randomized, double-blind, placebo-controlled clinical trial of 145 children with diarrhea-associated HUS failed to demonstrate any beneficial effect of treatment on disease outcome.⁹ This may have been because the drug is only effective in the gut and in most cases, Synsorb was administered only after the onset of HUS and target organs had been already exposed to Stx. Alternatively, impaired gastrointestinal motility may have limited delivery of the drug to the distal intestine where *E. coli* localize, or the affinity of Synsorb may be too low to compete with endogenous receptors. Whatever the explanation, this study suggests that strategies aimed at interfering with gastrointestinal absorption of Stx may have limited ability to prevent or limit HUS in children with gastrointestinal O157:H7 infection unless given before the onset of HUS to all those affected by an outbreak of diarrhea.

Plasma Manipulation and Other Specific Treatments

No specific therapy aimed at preventing or limiting the microangiopathic process has been proved to affect the course of Stx-HUS in children. Two prospective, controlled trials found that plasma therapy may limit short-term renal lesions, but does not affect long-term renal outcome and patient survival^{10,11} (Table 26-2). Heparin and antithrombotic agents may increase the risk of bleeding and should be avoided. Whether tissue type plasminogen activator, discriminating between fibrin and fibrin-bound plasminogen, gives a better risk-benefit profile in the treatment of HUS is worth investigating.

The efficacy of specific treatments in adult patients is difficult to evaluate because most information is derived from uncontrolled series that may also include non-Stx-HUS cases (see Table 26-2). In particular, no prospective, randomized trials are available to definitely establish whether plasma infusion or exchange may offer some specific benefit compared with supportive treatment alone. However, comparative analyses of two large series of patients treated¹² or not treated¹³ with plasma suggest that plasma therapy may dramatically decrease overall mortality of Stx *E. coli* O157:H7-associated HUS. These findings lead us and others to consider plasma infusion or exchange suitable for adult patients, in particular, in those with severe renal insufficiency and central nervous system involvement.

Rescue Treatments

Bilateral Nephrectomy

In occasional patients, increased shear stress and platelet activation in the damaged renal microvasculature may sustain the microangiopathic process even after the precipitating factor has been exhausted.¹ In these rare cases, persistent thrombocytopenia associated with severe refractory hypertension and signs of hypertensive encephalopathy may put the patient in imminent danger of death. In such dramatic cases, bilateral nephrectomy was followed within 2 weeks by complete hematologic and clinical remission.¹⁴

The rationale of the procedure rests on evidence that removing the kidneys eliminates a major site of vWF fragmentation, which would limit platelet activation and protect patients from the further spreading of microvascular lesions.¹⁴ However, bilateral nephrectomy is irreversible and should be

Table 26-2 Controlled Studies of Specific Treatments of Different Forms of Thrombotic Microangiopathy

Ref.	Design	Clinical Features	No. of Patients	TREATMENT			Outcome
				Case	Controls		
Child Series							
Loirat et al ⁷⁸	Prospective, randomized, multicenter	HUS	33	Heparin, urokinase	Supportive		Comparable survival, clinical outcomes, and histologic changes in cases and controls
Van Damme-Lombaerts et al ⁷⁹	Prospective, randomized, monocenter	HUS	58	Heparin, dipyridamole	Supportive		Comparable survival, clinical outcomes, and histologic changes in cases and controls
Loirat et al ⁸⁰	Prospective, randomized, monocenter	HUS	79	FFP (10 mL/kg/day)	Supportive		Lower serum creatinine at 6 mo (63 ± 21 vs. 48 ± 13 $\mu\text{m/L}$, $P < .005$) and fewer cases of cortical necrosis (0 vs. 7, $P < .02$) in cases than in controls
Rizzoni et al ¹⁰	Prospective, randomized, multicenter	HUS	32	FFP (10–30 mL/kg/day)	Supportive		Comparable survival, clinical outcomes, and histologic changes in cases and controls
Gianviti et al ⁸¹	Retrospective, multicenter	HUS (with ARF)	33	PE (3–10 exch.)	Supportive		Less residual renal insufficiency (glomerular filtration rate < 80 mL/min) in cases than in controls (18% vs. 43%)
Adult Series							
Italian group ⁸²	Retrospective, multicenter	TTP	29	PE (3–15 exch.)	Steroids, antiplatelets		Less mortality (18% vs. 43%) and more remissions (86% vs. 57%) in cases than in controls
French group ⁸³	Retrospective, multicenter	HUS	53	PE (2–21 exch.)	Supportive		Less mortality (0% vs. 23%) and less end-stage renal disease (26% vs. 64%) in cases than in controls
Henon ⁸⁴	Prospective, randomized, multicenter	TTP (with ARF)	40	PE (3–35 exch.)	FFP, ASA, dipyridamole		Less mortality (15% vs. 43%) and more remissions (80% vs. 52%) in cases than in controls
Rock et al ²⁹	Prospective, randomized, multicenter	TTP	102	PE (3–36)	FFP, ASA, dipyridamole		Less mortality (22% vs. 37%) and more remissions (78% vs. 49%) in cases than in controls

ARF, acute renal failure; ASA, acetylsalicylic acid; exch., replacement of one plasma volume; FFP, fresh frozen plasma; HUS, hemolytic uremic syndrome; PE, plasma exchange; TTP, thrombotic thrombocytopenic purpura.

considered only for patients in whom all other approaches have failed. Potential candidates are patients who are plasma resistant (defined as > 20 procedures with no improvement of clinical and laboratory findings) or plasma dependent (patients who have to be continuously infused with plasma to remain in remission and in whom the platelet count invariably drops, with signs of hemolysis, within a few days after plasma is discontinued).

Nephrectomy should not be considered unless a renal biopsy specimen, obtained as soon as the platelet count increases, even transiently, with plasma to a level where the procedure is safe, shows chronic diffuse lesions associated with signs of the disease, meaning arteriolar thrombosis and myointimal proliferation. Finally, nephrectomy should be considered only in the presence of life-threatening signs such as major neurological dysfunction or coma or uncontrolled bleeding as a consequence of refractory thrombocytopenia.

Kidney Transplantation

Kidney transplantation should be considered as an effective and safe treatment for those children who progress to end-stage renal disease (ESRD). Indeed, the outcome of renal transplantation is good in children with Stx-HUS, recurrence rates range from 0% to 10%,^{15,16} and graft survival at 10 years is even better than in control children with other diseases.¹⁷

Neuraminidase-Associated Thrombotic Microangiopathy

This is a rare but potentially fatal disease that may complicate pneumonia or, less frequently, meningitis caused by *Streptococcus pneumoniae*. Neuraminidase produced by *S. pneumoniae*, by removing sialic acid from the cell membranes, exposes Thomsen-Friedenreich antigen to preformed circulating IgM antibodies.¹⁸ Then, binding of circulating preformed IgM antibodies to this cryptic antigen exposed on platelet and endothelial cell surface would cause platelet aggregation and endothelial damage. Binding of IgM antibodies to the antigen expressed on circulating erythrocytes may also explain why Coombs-positive hemolytic anemia is so frequently reported in patients with neuraminidase-induced HUS. The clinical picture is usually severe, with respiratory distress, neurological involvement, and coma.

Therapy

The outcome is greatly dependent on the effectiveness of antibiotic therapy. In theory, plasma, either infused or exchanged, is contraindicated because adult plasma contains antibodies against the Thomsen-Friedenreich antigen that may accelerate polyagglutination and hemolysis.¹⁸ Thus, patients should be treated only with antibiotics and washed red cells. In some cases, however, plasma therapy, occasionally in combination with steroids, has been associated with recovery.

Thrombotic Microangiopathy Associated with Immune-Mediated Defective Activity of Complement Regulatory Proteins

Recurrent, atypical HUS has been recently reported¹⁹ in three children with circulating IgG autoantibodies against complement factor H (CFH), a circulating glycoprotein that modu-

lates the activity of the alternative complement pathway (see “Thrombotic Microangiopathy Associated with Congenital Defects” and Chapter 30) (Fig. 26-1). Anti-CFH antibodies were captured by enzyme-linked immunosorbent assay using purified human factor H-coated plates. Subsequent studies in five unrelated patients found that the binding epitopes for CFH autoantibodies localize in the cell-binding C terminus of CFH.²⁰

Of interest, the children showed an increased titer of circulating antinuclear antibodies, a finding that supports the possibility of an autoimmune pathogenesis of the disease. One child had two recurrences with pancreas and liver involvement, progressed to ESRD, and eventually required a bilateral nephrectomy to control refractory hypertension. The other two children recovered from the first episode with plasma exchange, then had four and three relapses, respectively, and recovered again with plasma exchange. These two children were maintained on long-term therapy with a steroid and azathioprine, respectively.

Treatment

Available information is insufficient to provide clear guidelines for treatment of this rare form of HUS. Conceivably, however, when anti-CFH autoantibodies are detected, plasma exchange and steroids or other immunosuppressive agents should be considered with the rationale of removing the pathogenic antibody from the circulation as soon as possible and inhibiting its synthesis.

Thrombotic Microangiopathy Associated with Immune-Mediated Deficiency of von Willebrand's Factor-Cleaving Protease (ADAMTS-13) Activity

This is an immune-mediated, nonfamilial form of TMA that most likely accounts for the majority of cases so far reported as acute idiopathic or sporadic TTP. The disease is characterized by a severe deficiency of a plasma metalloprotease, ADAMTS-13, that in normal individuals cleaves ultralarge vWF multimers as soon as they are secreted²¹ and in TTP patients is inhibited by a specific autoantibody that develops transiently and tends to disappear during remission.^{22–25} These inhibitory anti-ADAMTS-13 antibodies, characterized either as IgG or IgM and IgA, have been detected in 50% to 90% of patients with acquired TTP.^{25,26} Recent studies found inhibitory anti-protease antibodies reacting against the cysteine-rich and spacer domains of recombinant ADAMTS-13 in all considered patients with acquired TTP.²⁵ In some cases, the antibodies were directed only against these epitopes, but in the majority of plasma samples from TTP patients, different combinations of antibodies against the propeptide, the Tsp-1, and the CUB domains²⁵ were found, suggesting a polyclonal autoantibody response.

Further evidence of the pathogenetic role of these autoantibodies is derived from finding that they usually disappear from the circulation when remission is achieved with effective treatment, and this occurs in parallel with the normalization of ADAMTS-13 activity. Although TTP associated with ADAMTS-13 inhibitors is usually sporadic, recurrent episodes have also been reported due to the reappearance of the inhibitor in the circulation several weeks or even months after the resolution of the presenting episode. Of note, autoantibodies

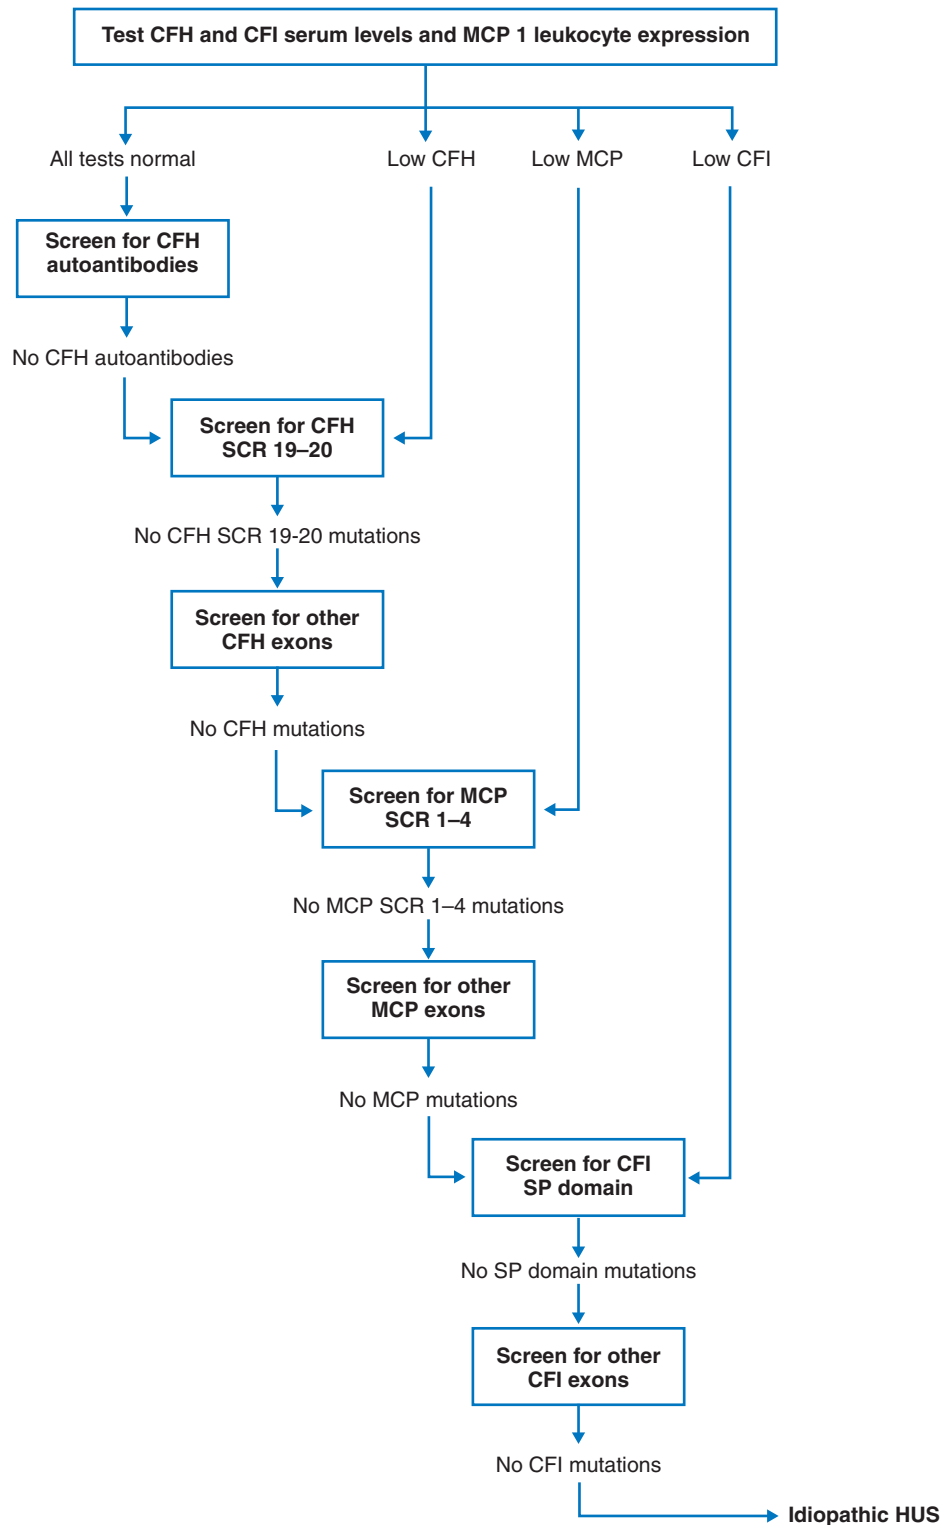

Figure 26-1 Flow diagram of the steps suggested to optimize the cost-effectiveness of screening for genetic defects in patients with hemolytic uremic syndrome not associated with Shiga toxin and suspected, genetically determined abnormalities in complement regulatory proteins. A preliminary screen for serum complement factor H (CFH) and complement factor I (CFI) levels by either enzyme-linked immunosorbent assay or RID, and for membrane cofactor protein (MCP) expression in peripheral blood leukocytes by fluorescence-activated cell sorter is recommended to identify which is the candidate gene to evaluate. If no abnormalities are detected, we suggest screening for anti-CFH autoantibodies and then if no autoantibodies are detected, looking for mutations of candidate genes, starting to evaluate the *CFH* gene, which is more frequently affected by pathogenic mutations, followed by *MCP* and *CFI* genes, respectively. Within each gene, the exons where the mutations tend to localize more frequently should be studied first. HUS, hemolytic uremic syndrome; RID, radial immunodiffusion; SCR, short consensus repeat; SP, serine protease.

against the ADAMTS-13 have also been observed in patients developing TTP during treatment with antiplatelet drugs such as ticlopidine (see “Drug-Associated Thrombotic Microangiopathy”).

The clinical picture is usually severe, with an abrupt onset of neurological signs, purpura, and fever.²⁷ Neurological symptoms usually dominate the clinical picture and may be fleeting and fluctuating, probably because of continuous thrombus formation and dispersion in the brain microcirculation. Coma and seizures complicate more severe forms.

Supportive Therapy, Plasma Manipulation, and Other Specific Treatments

In the early 1960s, TTP was almost invariably fatal, but now, thanks to earlier diagnosis, improved intensive care facilities, and new techniques such as plasma therapy, survival may reach 90%.^{28,29}

Plasma manipulation is a cornerstone of the therapy of the acute episode. Plasma may serve to induce remission of the disease by replacing defective protease activity. In theory, compared with infusion, exchange may offer the advantage of also rapidly removing anti-ADAMTS-13 antibodies. This, however, needs to be proved in controlled trials. In addition, corticosteroids might inhibit the synthesis of antiprotease autoantibodies. In a series of 33 patients with anti-ADAMTS-13 antibodies and undetectable ADAMTS-13 activity, combined treatment with plasma exchange and steroids was associated with disease remission in approximately 90% of cases.²⁶ The rationale of combined treatment is that plasma exchange will have only a temporary effect on the presumed autoimmune basis of the disease and additional immunosuppressive treatment may cause a more lasting response. Thirty of 108 patients with either TTP or HUS were reported to have recovered after treatment with corticosteroids alone. All of them, however, had mild forms, and none of them were tested for ADAMTS-13 activity.

Rescue Treatments

Plasma Cryosupernatant

Cryosupernatant fraction (i.e., plasma from which a cryoprecipitate containing the largest plasma vWF multimers, fibrinogen, and fibronectin has been removed) instead of fresh frozen plasma has been successful in treating a small number of patients who did not respond to repeated exchanges or infusions with fresh frozen plasma.³⁰ The rationale for this approach is that plasma cryosupernatant may provide the same beneficial factor(s) found in whole plasma (for instance, in this specific case, the defective/inhibited ADAMTS-13 activity), but does not contain those factors (including large vWF multimers) that may actually sustain the microangiopathic process until remission is achieved. Based on this, the use of plasma cryosupernatant has been suggested as first-line therapy. Results of preliminary uncontrolled studies seem encouraging.³¹

Rituximab

Recently, the infusion of rituximab, an antibody directed against B cells, has been proven to be effective in inducing remission in TTP patients with ADAMTS-13 antibodies refractory to any other treatment²⁵ and in maintaining patients in remission when used as prophylactic therapy. Longitudinal evaluation of ADAMTS-13 activity and autoantibody levels may help monitor patient response to treatment.

Splenectomy

Before the discovery of the efficacy of plasma exchange for the treatment of TTP, splenectomy was quite frequently performed, but most patients still died. More recent studies in patients refractory to plasma therapy cast further doubt on the efficacy of splenectomy because of high morbidity and mortality.^{28,32} However, the patients in these studies were unselected, and splenectomy might be expected to achieve persistent remission by removing a major site of antibody synthesis in those with autoantibodies against ADAMTS-13 that persist in the circulation despite plasma and immunosuppressive therapy. This appears to have been the case in two reports in which patients with autoimmune TTP who had failed to respond to plasma exchange and immunosuppression or had repeated relapses entered a stable remission with disappearance of the ADAMTS-13 protease inhibitor.^{22,33} These reports, however, are far from conclusive, and further studies with a larger number of patients are needed to assess the therapeutic value of this invasive procedure.

Platelet Transfusions

The severe thrombocytopenia in TTP has led many physicians to administer platelet transfusions with the aim of preventing severe bleeding complications. However, reports of sudden death, decreased survival, and delayed recovery after platelet transfusion dramatically document the danger of giving platelets to patients with active TTP. Thus, platelet transfusions are contraindicated in acute TTP, except in cases of life-threatening bleeding.

Pregnancy-Associated Thrombotic Microangiopathies

TMA associated with pregnancy includes TTP (usually in the early phases of pregnancy), HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) (usually near term), and HUS (usually postpartum).³⁴ The disease is considered a specific complication of pregnancy, but reports of women with familial recurrence or defective ADAMTS-13 activity without a demonstrable inhibitor provide convincing evidence that, at least in a proportion of cases, an underlying genetic predisposition plays a central role in the pathogenesis of TMA and pregnancy may just represent a precipitating event.³⁵ Changes observed during normal pregnancy, such as progressively decreasing fibrinolytic activity, loss of endothelial thrombomodulin, increasing levels of procoagulant factors, and decreasing ADAMTS-13 activity, may contribute to precipitate the disease in those at risk.

Thrombotic Thrombocytopenic Purpura

TTP develops during the antepartum period in 89% of cases, usually within 24 weeks. Later in the course of pregnancy, clinical features of TTP and preeclampsia may overlap. Despite limited experience, available series show that the maternal mortality rate has decreased from 68% to almost zero with the institution of plasma therapy.³⁴ Delivery is recommended only for those patients who do not respond to plasma therapy.

Measurement of plasma antithrombin III activity has been suggested as a useful tool to differentiate TTP and preeclampsia. Before gestational week 28 and when antithrombin III plasma activity is normal, TTP is most likely. Plasma therapy could be tried, and, if effective, it should be continued until

term and/or complete remission of the disease. Delivery can be considered as rescue after failure of plasma therapy. The role of other treatments often employed in idiopathic TTP remains elusive.

After week 34 of gestation, preeclampsia is most likely and is usually associated with decreased plasma antithrombin III activity. Delivery is the treatment of choice and is usually followed by complete recovery within 24 to 48 hours. Persistent disease may be an indication to attempt a course of plasma therapy. Between 28 and 34 weeks, the optimal treatment is controversial. It is some times held that delivery should always be considered as first-line therapy, whereas others believe that if there is no evidence of fetal distress and plasma antithrombin III activity is normal, a course of plasma therapy can be reasonably attempted before inducing delivery.³⁶

HELLP Syndrome

HELLP syndrome is simply a form of severe preeclampsia in which, in addition to hypertension and renal dysfunction, there is evidence of microangiopathic hemolysis and liver involvement. The syndrome is most common in white multiparous women with a history of poor pregnancy outcome. It arises in the antepartum period in 70% of cases. Symptoms usually arise within 24 to 48 hours postpartum, occasionally after an uncomplicated pregnancy.³⁴

Diagnosis is based on (1) hemolysis (defined as fragmented erythrocytes in the circulation and lactic dehydrogenase of at least 600 U/L), (2) elevated liver enzymes (serum glutamic oxaloacetic transaminase > 70 U/L), and (3) low platelet count ($<100 \times 10^3/\text{mm}^3$).³³ Overt disseminated intravascular coagulation is reported in 25% of cases. Intrahepatic hemorrhage, subcapsular liver hematoma, and liver rupture are rare life-threatening complications. The maternal and perinatal mortality rates range from 0% to 24% and from 7.7% to 60%, respectively. Most of the perinatal deaths are related to abruptio placentae, intrauterine asphyxia, and extreme prematurity. As many as 44% of the infants are growth retarded.

Termination of pregnancy is the only definitive therapy. Hydralazine or dihydralazine is the first-choice drug to control pregnancy-induced hypertension, and magnesium sulfate prevents and treats convulsions. Both peritoneal dialysis and hemodialysis have been used to treat acute renal failure. Platelet transfusions are needed for clinical bleeding or severe thrombocytopenia (platelet count $< 20,000/\mu\text{L}$).

In approximately 5% of patients with HELLP syndrome, symptoms and laboratory abnormalities do not improve after delivery. These are cases with central nervous system abnormalities associated with renal and cardiopulmonary dysfunction and activation of coagulation. Uncontrolled studies suggest that plasma exchange may help recovery in patients with persistent evidence of disease 72 hours or more after delivery. However, plasma therapy is ineffective during pregnancy and may increase fetal and maternal risk when used to delay delivery. Preliminary evidence suggests that, postpartum, corticosteroids may speed up disease recovery and, antepartum, may postpone delivery of preivable fetuses and reduce the mother's need for blood products.

Postpartum Hemolytic Uremic Syndrome

By definition, postpartum HUS follows a normal delivery by no more than 6 months.¹ The clinical course is usually fulminant. Supportive care including dialysis, transfusions,

and careful fluid management remains the most important form of treatment. Whether plasma therapy improves survival or limits renal sequelae has not been established so far. Antiplatelet agents, heparin, and antithrombotic therapy may enhance the risk of bleeding and have no proven efficacy.

Systemic Disease–Associated Thrombotic Microangiopathy

Prevention and treatment of TMA associated with systemic diseases largely rest on specific treatment of the underlying conditions.

Antiphospholipid Syndrome, Systemic Lupus Erythematosus, Scleroderma, and Malignant Hypertension

Plasma therapy should always be attempted in TMA associated with systemic diseases even if its efficacy in this setting is poorly defined. Regarding antiphospholipid syndrome, until the relationships between the various antiphospholipid antibodies identified so far and clinical manifestations of the disease are clarified, oral anticoagulation remains the only treatment of proven efficacy, even if concomitant thrombocytopenia may increase the risk of hemorrhagic complications, to prevent and treat micro- and macrovascular thromboses. Blood pressure control is the keystone of treatment of TMA associated with scleroderma crisis and malignant hypertension.

Human Immunodeficiency Virus

Both HUS and TTP are among the complications of acquired immunodeficiency syndrome (AIDS), which may account for as many as 30% of hospitalized HUS/TTP patients. Plasma manipulation appears to be the only feasible approach. Uncontrolled series provide evidence that the survival rate in patients with human immunodeficiency virus without AIDS is comparable with that of those with idiopathic TTP. By contrast, patients with AIDS associated with TTP almost invariably have a poor outcome and do not appear to benefit from plasma therapy.³⁶

Cancer

TMA complicates almost 6% of cases of metastatic carcinoma. The prognosis is extremely poor and most patients die within a few weeks. Therapy is minimally effective. Administration of blood products to correct symptomatic anemia often results in exacerbation of the syndrome, with rapid worsening of hemolysis, deterioration of renal function, and pulmonary edema.

Drug-Associated Thrombotic Microangiopathy

Mitomycin and Anticancer Drugs

A form of TMA resembling HUS has been described in cancer patients treated with mitomycin C. Disease manifestation is dose related, and renal dysfunction is reported in less than 2% of patients given a cumulative dose lower than 50 mg/m² and in more than 28% of those given more than 50 mg/m² or receiving more than one course of therapy.

Platinum- and bleomycin-containing combinations have also been reported to induce HUS. The fatality rate is close to 79%, and the median time to death is approximately 4 weeks. Patients surviving the acute phase often remain on long-term dialysis or die later of a recurrence of the tumor or metastases. The possibility of preventing the syndrome by giving steroids during mitomycin treatment has been suggested and needs to be confirmed in prospective, controlled trials. Plasma exchange is usually attempted, but its effectiveness is unproven. Regimens that contain platinum and bleomycin have also been reported to induce HUS.

Antiplatelet Drugs

TMA has been reported in 1 of every 1600 to 5000 patients treated with ticlopidine. Neurological abnormalities occur within 1 month of treatment in 80% of cases. The overall survival rate is 67% and is improved by early treatment withdrawal and plasma therapy. Generation of an autoantibody against ADAMTS-13 protease may be involved in the pathogenesis of ticlopidine-associated TTP. In seven patients who developed TTP 2 to 7 weeks after initiation of ticlopidine therapy, severely decreased levels of ADAMTS-13 activity were reported along with the appearance of IgG molecules in their blood, which inhibited ADAMTS-13 activity.³⁷ The deficiency resolved after ticlopidine therapy was discontinued and plasmapheresis was instituted. Eleven cases have been reported during treatment with clopidogrel, a new antiaggregating agent that has achieved widespread clinical use for its safety profile. All patients had neurological involvement and were treated with plasma exchange: eight fully recovered, two had relapses that rapidly recovered after retreatment with plasma exchange, and one died. Half the patients were concomitantly treated with cholesterol-lowering drugs. Conceivably, these drugs should be avoided in clopidogrel-treated patients.

Quinine

Quinine is one of the drugs more frequently associated with TMA. The disease typically occurs in patients presensitized by previous exposure to quinine and rapidly follows re-ingestion of the drug. Quinine is generally used to treat muscle cramps, but it is also contained in beverages (tonic water and bitter lemon drinks). Quinine-dependent antiplatelet, antierythrocyte, and antigranulocyte antibodies have been involved in the pathogenesis of the disease. Presenting symptoms are often severe, and death or irreversible kidney failure are common outcomes unless quinine is immediately withdrawn and plasma exchange is promptly provided. Avoidance of successive quinine use is necessary to prevent recurrences.

Interferon Alfa

Renal impairment is the predominant feature of TMA associated with interferon alfa. Recovery of the TMA has been reported to follow early discontinuation of the drug and prompt supportive therapy³⁸; however, the prognosis for renal recovery is poor, resulting in ESRD in approximately half of the cases. Because of the few cases reported, it is not possible to evaluate the effectiveness of specific therapies such as plasma exchange or infusion.

Bone Marrow and Solid Organ Transplantation–Associated Thrombotic Microangiopathy

Among acquired forms of HUS, post-transplantation HUS is being reported with continuously increasing frequency and appears to affect a progressively increasing number of patients worldwide. Albeit poorly defined, the incidence of the disease is remarkably higher in the transplant recipient than in the general population, most likely because of the clustering of several risk factors in this particular setting of patients. In renal transplants, HUS may ensue for the first time in patients who never had the disease (de novo post-transplantation HUS) or may affect patients whose primary cause of ESRD was HUS (recurrent post-transplantation HUS). Treatment of post-transplantation HUS rests on removal of the inciting factor(s), relief of symptoms, and plasma infusion or exchange. No other approach has proven effective.

De Novo Posttransplantation Hemolytic Uremic Syndrome

This form occurs in renal and extrarenal transplant recipients and is usually triggered by immunosuppressive drugs such as calcineurin inhibitors,²⁹ less frequently by virus infections, and, specifically in renal transplant recipients by acute vascular rejection. A peculiar form of de novo post-transplantation HUS may affect the recipients of a bone marrow transplant, usually in the setting of a graft-versus-host disease or of intensive graft-versus-host disease prophylaxis, including total body irradiation.

Therapy

Drug withdrawal or dose reduction is the first-line therapy for de novo cyclosporin A- or tacrolimus-associated forms, but is effective in less than 50% of cases.³⁹ A remarkably higher success rate (84%) has been reported with adjunctive plasma infusion or exchange. A similar response rate, but in much smaller series, has been reported with intravenous IgG infusion given with the rationale to neutralize hypothetical circulating cytotoxic or platelet agglutinating factors. Once remission is achieved, patient rechallenge with decreased doses of cyclosporin A or tacrolimus, with switching from one drug to the other one, or, finally, with replacement of both drugs with mycophenolate mofetil has been anecdotally reported to maintain adequate immunosuppression without further disease recurrences. Very recently, compassionate treatment with rapamycin has been associated with a remarkably good outcome in 15 patients with cyclosporin A- or tacrolimus-associated posttransplantation HUS, with no patient requiring rapamycin withdrawal because of disease recurrence.⁴⁰ Monoclonal anti-interleukin-2 receptor antagonists may also be a valid option to maintain adequate immunosuppression, avoiding the toxic effects of calcineurin inhibitors. The outcome of de novo forms occurring in the setting of viral infection parallels the response to treatment of the underlying disease. Despite intensive plasma therapy or rescue treatment with plasma cryosupernatant or protein A immune adsorption, the outcome of de novo forms complicating BMT is still dramatically poor, with a mortality rate closed to 90%. In addition to the severity of the microangiopathic process, quantified by serum lactate dehydrogenase levels and the percentage of circulating

fragmented erythrocytes, infection, progressive graft-versus-host disease or relapse of the underlying disease may account for such discouraging figures.

Recurrent Posttransplantation Hemolytic Uremic Syndrome

This form is most frequently reported in patients who progressed to ESRD because of non-Stx-HUS, in particular, in those with genetic forms. Whether the precipitating factors associated with the novo HUS may contribute also to disease recurrence on the kidney graft is still a debated question. This is consistent with, albeit not proved by, evidence that a precipitating factor is often observed or suspected in patients with recurrent disease.

Therapy

Recurrent forms usually do not respond to any type of therapy and are associated with a graft loss rate close to 100%. Based on these data, kidney transplantation should be considered as an effective and safe treatment of ESRD only for patients with Stx-HUS, but should be considered with extreme caution in those with non-Stx-HUS, in particular, in genetic forms. In particular, until new strategies to effectively limit or prevent recurrence become available, kidney transplantation is contraindicated in familial/relapsing forms and in all cases with a well-characterized genetic abnormality predisposing to the disease (see later).

GENETIC (THROMBOTIC MICROANGIOPATHY ASSOCIATED WITH CONGENITAL DEFECTS)

These forms are rare, often occur in families, occur mainly but not exclusively in children, and frequently relapse even after complete recovery of the presenting episode. Depending on the involved defect and the age at disease onset, these forms may present with the clinical features of HUS or TTP or both in different members of the same family or in different episodes in the same patient. ESRD, permanent neurological sequelae, or death is the outcome in the majority of cases.¹ Therapy seldom achieves persistent remission of the disease. Genetic counseling is therefore of paramount importance. In cases with recognized genetic mutations, antenatal diagnosis by amniocentesis or chorionic villus biopsy is possible and the carrier state can be identified.

Thrombotic Microangiopathy Associated with Genetic Abnormalities in Complement Regulatory Proteins

In 1998, Warwicker and colleagues⁴¹ studied three families with non-Stx-HUS and established linkage in the affected individuals to the regulator of complement activation gene cluster on human chromosome 1q32, which encodes for several complement regulatory proteins. The first examined candidate gene in this region was factor H (CFH), due to the fact that an association between familial HUS and CFH abnormalities had been reported previously.

Since the first report by Warwicker and colleagues, more than 100 different CFH mutations in patients with non-Stx-HUS⁴² have been described. In sporadic forms, the mutation was either

inherited from a clinically unaffected parent or, more rarely—only four cases reported—arose de novo in the proband.⁴³ The mutation frequency is approximately 30%.^{44,45}

CFH is a plasma glycoprotein that plays an important role in the regulation of the alternative pathway of complement. It serves as a cofactor for the C3b-cleaving enzyme complement factor I (CFI) in the degradation of newly formed C3b molecules and controls decay, formation, and stability of the C3b convertase C3bBb. CFH consists of 20 homologous short consensus repeats (SCRs). The complement regulatory domains needed to prevent fluid-phase alternative pathway amplification have been localized within the N-terminal SCR1-4.⁴⁶ The inactivation of surface-bound C3b is dependent on the binding of the C-terminal domain of CFH to polyanionic molecules, which increases CFH affinity for C3b and exposes its complement regulatory N-terminal domain.⁴⁷

The vast majority of CFH mutations in HUS patients are heterozygous and cause either single amino acid changes or premature translation interruptions, mainly clustering in the C-terminal domains, and are commonly associated with normal CFH plasma levels. Expression and functional studies demonstrated that CFH proteins carrying HUS-associated mutations have a severely reduced capability to interact with polyanions and with surface-bound C3b⁴⁷, which results in a lower density of mutant CFH molecules bound to endothelial cell surfaces and a diminished complement regulatory activity on their cell membranes.⁴⁷ In contrast, these mutants have a normal capacity to control activation of the complement in plasma, as indicated by data showing that they retain a normal cofactor activity in the proteolysis of fluid-phase C3b.

In a recent study,⁴⁸ a heterozygous hybrid gene derived from a crossing over between intron 21 of CFH and intron 4 of CFHR1 (CFH-related 1) was found in five patients. The hybrid gene consists of the first 21 exons of CFH (encoding SCRs 1–18 of CFH) and the last two exons of CFHR1 (encoding SCRs 4 and 5 of CFHR1). The protein product of the hybrid gene is identical to the CFH mutant S1191L/V1197A, which arises by gene conversion and lacks surface complement regulatory activity. The frequency of this abnormality in non-Stx-HUS patients is estimated to be approximately 6%.

Abnormalities in two additional genes encoding for complement regulatory proteins have been recently involved in predisposition to non-Stx-HUS. Two reports from independent groups described mutations in MCP (encoding membrane cofactor protein) in affected individuals of four families.^{49,50} MCP is a widely expressed transmembrane glycoprotein that serves as a cofactor for CFI to cleave C3b and C4b deposited on the host cell surface.⁵¹ To date, approximately 40 MCP mutations in non-Stx-HUS have been reported, with a mutation frequency of 10% to 15%.⁴⁵ Evaluation of mutant protein expression and function showed either severely decreased protein expression on the cell surface, decreased C3b binding capability, and/or capacity to prevent complement activation.⁴⁵

Twenty-four mutations in CFI, encoding a plasma serine protease that cleaves and inactivates C3b and C4b, have been reported in patients with non-Stx-HUS, with a frequency of 5% to 12% in different studies.^{45,52,53} All of them are heterozygous mutations, 80% cluster in the serine-protease domain and either cause greatly decreased protein secretion or result in mutant proteins with decreased cofactor activity.

The list of published and unpublished mutations in CFH, MCP, and CFI is continuously updated in the Factor H–HUS database (www.fh-hus.org). The database includes also CFH, MCP, and CFI single nucleotide polymorphisms.

More recently, two gain-of-function mutations in the gene encoding complement factor B (CFB), a zymogen that carries the catalytic site of the complement alternative pathway convertase, have been found in two families from a Spanish HUS cohort.⁵⁴

Although genotype-phenotype correlations are often inexact, analysis of published reports^{44,45,55,56} indicates that the course and outcome of non–Stx-HUS are influenced by the gene involved. Non–Stx-HUS associated with CFH mutations most often presents early in childhood, although adult onset is reported in approximately 30% of cases. The clinical course is characterized by a high rate of relapses and 60% to 80% of patients die or develop ESRD after the presenting episode or progress to ESRD as a consequence of relapses. Non–Stx-HUS associated with MCP mutations presents mostly in childhood; the acute episode is in general milder than in CFH mutation carriers, and 80% of patients undergo complete remission. Recurrences are very frequent, but their effect on long-term outcome is rather mild, with approximately 60% to 70% of patients remaining dialysis free even after several recurrences. However, there are some exceptions; a subgroup of patients lost renal function either during the first episode or later in life. The clinical course of patients with CFI mutations is more variable. The onset is in childhood in half of the patients. Fifty-eight percent of patients eventually develop ESRD.

Therapy

Genetic characterization of patients could potentially help in tailoring treatment. Plasma infusion or exchange has been used in patients with HUS due to CFH mutations, with the rationale to provide the patients with normal CFH to correct the genetic deficiency. In published studies, some patients with CFH mutations did not respond at all to plasma infusion and died or developed ESRD. Others required plasma infusion at weekly intervals to raise CFH plasma levels sufficiently to maintain remission.^{57,58} Stratton and Warwicker⁵⁹ were able to induce sustained remission in a patient with a CFH mutation with 3 months of weekly plasma exchange in conjunction with intravenous immunoglobulins. At 1 year after stopping plasma therapy, the patient remained disease free and dialysis independent. In our series,⁴⁵ approximately 50% of patients with CFH mutations treated with plasma underwent either complete or partial hematologic remission. However, half of the patients did not respond at all to plasma infusion and 20% died during an acute episode.

Because CFI and CFB are plasma proteins, plasma infusion and plasma exchange would be expected to be of value in patients with defects in the corresponding genes. Published data in small numbers of patients document that approximately half the patients with either CFI⁴⁵ or CFB mutations⁵⁴ underwent remission after plasma infusion, exactly as observed in patients with CFH mutations.

There is less rationale for using plasma in patients with MCP mutations because MCP is a transmembrane cell-associated protein and theoretically plasma infusion or exchange would

not correct the MCP defect. Published data^{45,50} indicate that the majority (70%–80%) of patients experienced remission after plasma infusion or exchange; however, complete recovery from the acute episode was also observed in 70% to 80% of patients not treated with plasma.

Transplantation

The role of kidney transplantation in patients with non–Stx-HUS who have progressed to ESRD is still a matter of debate. Actually, approximately 50% of the patients who underwent a renal transplantation had a recurrence of the disease in the grafted organ.⁵⁶ There is no effective treatment for recurrences, and graft failure occurs in more than 90% of patients. Genotyping for CFH, MCP, and CFI mutations should be performed in all patients with ESRD secondary to non–Stx-HUS being considered for transplantation to help determine graft prognosis. In patients with CFH mutations, the graft outcome is poor; the recurrence rate ranges from 30% to 100% according to different surveys and is significantly higher than in patients without CFH mutations.^{44,56,60} As CFH is mainly produced by the liver, kidney transplantation alone will not correct the CFH genetic defect. Simultaneous kidney and liver transplantation has been performed in two young children with non–Stx-HUS and CFH mutations, with the objective of correcting the genetic defect to prevent disease recurrences.⁵⁶ However, both cases treated with this procedure were complicated by premature irreversible liver failure. The patient in the first case recovered after a second uneventful liver transplantation. The child, who had experienced monthly recurrences before transplantation, has had no symptoms of HUS at more than 2 years of follow-up. The second patient died of fatal primary nonfunction of the liver graft followed by multiorgan failure. Increased susceptibility of the transplanted liver to ischemic or immune injury related to uncontrolled complement activation may have been responsible for the liver failure. Two more cases of combined kidney and liver transplantation in patients with CFH mutations have been subsequently reported.⁶¹ In both cases, the post-transplantation outcome was favorable with good renal and liver function recorded at 2-year follow-up. In those two cases, extensive plasma exchange was given before surgery to provide patients with enough normal CFH to prevent liver graft damage. Thus, in this setting, combined liver and kidney transplantation may be an effective way to gain independence from long-term dialysis and may be lifesaving in those infants who, on dialysis, have a poor life expectancy.

As CFI and CFB are plasma proteins, one could speculate that HUS recurrence may take place in the transplanted kidney, and patients may experience graft failure. The few data available are in line with this hypothesis, as graft failures for recurrence occurred in 7 of 8 patients with CFI mutations and in one patient with CFB mutation.^{45,62} Conversely, kidney graft outcome is favorable in patients with MCP mutations, as found in four patients who successfully underwent transplantation with no disease recurrence.⁵⁶ There is a strong theoretical rationale for this: MCP is a transmembrane protein highly expressed in the kidney. Transplantation of a kidney expressing normal MCP not surprisingly corrects the defects in these patients.

Thrombotic Microangiopathy Associated with Congenital Deficiency of ADAMTS-13

This rare form of TMA is associated with a congenital defect of ADAMTS-13, a plasma metalloprotease that cleaves ultra-large vWF multimers into smaller multimers. The defect was originally described in TTP^{21,22}; however, emerging data indicate that patients with HUS²⁴ may also have a complete lack of ADAMTS-13 activity, albeit less frequently. Thus, on clinical grounds, a possible congenital defect of ADAMTS-13 cannot be excluded only on the basis of predominant renal localization of disease manifestation. TMA associated with congenital ADAMTS-13 deficiency presents either in families or in patients with no familial history of the disease.^{21,22,24,63} In both cases, the disease is inherited as an autosomal recessive trait, as documented by ADAMTS-13 levels in healthy relatives of patients who fell into bimodal distribution with a group with half normal values, consistent with carriers, and the other half with normal values.⁶³

Recurrences are very frequent and may occur even after symptom-free periods of months or years. Although they are more frequent in adults, relapsing forms of TMA have also been reported in children with congenital ADAMTS-13 deficiency in whom renal symptoms are predominant.⁶⁴

To date, more than 50 ADAMTS-13 mutations have been identified in patients with familial TTP.^{63,65} Affected individuals within families were either homozygous for the same mutation or compound heterozygous for two different mutations, confirming that the disease was inherited as a recessive trait.

The mutations have been found along the entire ADAMTS-13 gene and no clustering is evident, although more than 70% of them are located from the metalloprotease through the Tsp-1-2 domains.²⁵ Studies on secretion and activity of the mutated forms of the protease showed that most of these mutations impair secretion from the cells.⁶⁶ In those cases in which the mutated proteins are secreted, their proteolytic activity is greatly decreased.⁶⁶

Therapy

At present, therapy of ADAMTS-13-associated TMA involves plasma infusion or exchange to replenish the active protease. Actually, providing just 5% of normal enzymatic activity may be sufficient to degrade large vWF multimers, which may be relevant to induce remission of the microangiopathic process, and this effect is sustained over time due to the relatively long half-life (2–4 days) of the protease. In two brothers with complete deficiency of the protease and relapsing TTP, disease remission was achieved by plasmapheresis and was concurrent with an almost full recovery of ADAMTS-13 activity. Both patients achieved a long-lasting remission, although protease activity decreased to less than 20% over 20 days after plasma therapy withdrawal.⁶⁷ One patient of ours with relapsing TTP due to congenital ADAMTS-13 deficiency⁶⁴ who had more than 100 relapses over 7 years was given different forms of treatment on different occasions: exchange, plasma infusion alone or plasma removed and replaced with albumin and saline. Clinical remission and normalization of platelet count within a few days were invariably obtained by plasma exchange or infusion, but plasma removal never increased the platelet count. Thus, plasma infusion is likely an established first-line treatment for HUS or TTP forms associated with congenital

ADAMTS-13 protease deficiency. Although individual attacks usually respond to treatment, long-term prognosis is invariably poor if therapy fails to achieve a lasting remission.

Thrombotic Microangiopathy Associated with Inborn Abnormal Cobalamin Metabolism

This is a rare autosomal recessive form of HUS associated with an inborn abnormality of cobalamin metabolism.⁶⁸ The disease manifests in the first days or months of life. Children fail to thrive, have poor feeding and vomiting, and may present neurological symptoms of fatigue, delirium, psychosis, and seizures. In cases with early onset, the disease has a fulminant evolution and occasionally involves the pulmonary vasculature, but when it occurs later in childhood, it may follow a more chronic course. The hallmarks of defective cobalamin metabolism are hyperhomocysteinemia and methylmalonic aciduria, and the extremely high homocysteine levels have been suggested to have a role in the pathogenesis of the vascular lesions. Without treatment, the disease is fatal, and it is likely that some children die undiagnosed.

Therapy

Treatment is directed at correcting the metabolic disorder as effectively as possible.⁶⁹ Daily intramuscular administration of hydroxycobalamin may reduce both homocysteine levels and methylmalonic aciduria, whereas oral hydroxycobalamin and cyanocobalamin are ineffective. Oral betaine further reduces serum homocysteine levels by activating betaine-homocysteine methyltransferase. Supplementation of folic acid to avoid folate deficiency induced by 5-methyltetrahydrofolate trapping and of L-carnitine to increase propionyl carnitine excretion has been recommended, but it is unclear whether they improve disease outcome. Despite treatment, the majority of children with early-onset disease die or have severe neurological sequelae. Intensified treatment in older children with less acute disease may achieve remission of the microangiopathic process and amelioration of the other clinical manifestations of the metabolic disorder. It is not known whether plasma therapy would improve disease outcome.

Other Genetic Forms

Conceivably, the mutations described account for approximately 50% of genetic forms of TMA. Patients with decreased C3 but no evidence of CFH, MCP, CFI, or CFB abnormalities have been described. In these rare cases, uncontrolled activation of the alternative complement pathway may be due to genetic defects in other complement regulatory proteins, including DAF, CR1, CR2, and C4 binding protein. Other cases may be associated with still unrecognized genetic defects. Among these are familial forms transmitted with a dominant or recessive pattern of inheritance that may manifest with the features of HUS or TTP in different members of the same family or in different recurrences in the same patient.

Therapy

Plasma infusion or exchange is the only therapy that may have some effect. Regardless of treatment, however, disease outcome is usually poor.

IDIOPATHIC

These are forms of unknown etiology with progressive renal function deterioration and neurological involvement that may resemble TTP. They may follow a progressive course to end-stage renal failure or death and very likely constitutes a disease closer to TTP that requires more specific therapies to stop the progression of the microangiopathic process. These cases recur more often after kidney transplantation.⁷⁰

Therapy

Plasma infusion and exchange have been retrospectively found to limit residual renal insufficiency or the risk of end-stage renal failure in children. Uncontrolled studies suggest that plasma infusion or exchange may markedly lower the mortality rate and risk of end-stage renal failure in adults.^{1,71} Intravenous immunoglobulins have been suggested to limit neurological involvement, but their effectiveness too is still unproven. Bilat-

eral nephrectomy (see “Shiga-Toxin–Associated Thrombotic Microangiopathy”) may be attempted as rescue therapy in patients with severe renal involvement, refractory hypertension/thrombocytopenia, and hypertensive encephalopathy.

SPECIFIC RECOMMENDATIONS

In addition to symptomatic treatment, various specific therapies have been suggested for the different forms of TMA (Tables 26-2, 26-3 and 26-4), but, until recently, no clear-cut guidelines were available to identify which patients should be treated, which therapies should be chosen, and how these should be administered. Over the past decade, however, the identification of at least two broad categories of patients, those with genetically determined and those with acquired immune-mediated disease, has allowed, at least in some circumstances, targeting the therapeutic intervention to specific pathogenic mechanisms and therefore to optimize the

Table 26-3 Specific Therapies Most Commonly Used in Thrombotic Microangiopathy, Doses, and Routes of Administration

Therapy	Dose	Route of Administration
Antiplatelet Agents		
Aspirin	325–1300 mg/day	Oral
Dipyridamole	400–600 mg/day	Oral
Dextran 70	500 mg bid	IV injection
Prostaglandin I ₂	10–20 ng/kg/min	Continuous IV infusion
Antithrombotic Agents		
Heparin	5000 U	IV bolus injection
	750–1000 U/hr	Continuous IV infusion
Streptokinase	250,000 U	IV bolus injection
	100,000 U/hr	Continuous IV infusion
Antioxidant Agents		
Vitamin E	1000 mg/m ² /day	Oral
Immunosuppressive Agents		
Prednisone	200 mg tapered to 60 mg/day, then 5 mg decrease per week	Oral during active disease, oral after remission
Prednisolone	200 mg tapered to 60 mg/day, then 5 mg decrease per week	IV during active disease, IV after remission
Immunoglobulins	400 mg/kg/day	IV infusion
Vincristine	1.4 mg/m ² on day 1	IV injection
	1 mg every 4 days	IV injection up to 4 doses
Fresh Frozen Plasma		
Infusion	20–30 mL/kg on day 1	IV infusion
	10–20 mL/kg/day	IV infusion until remission
Exchange	1–2 plasma volumes/day	IV until remission
Cryosupernatant	See plasma infusion/exchange	See plasma infusion/exchange
Sodium detergent treated	See plasma infusion/exchange	See plasma infusion/exchange

Table 26-4 Indications for Specific Therapy in the Different Forms of Thrombotic Microangiopathy

Disease	Comment
Acquired	
Shiga-toxin associated	
Childhood forms	No indication (possibly with the exception of plasma infusion/exchange for severe forms with anuria and neurological signs)
Adult forms	Plasma infusion/exchange (to minimize the risk of sequelae)
Neuraminidase associated	Possible indication for plasma infusion/exchange (combined with steroids to minimize adverse reactions)
Immune-mediated defective CFH activity	Plasma infusion/exchange combined with steroid or immunosuppressive therapy
Immune-mediated defective ADAMTS-13 activity	Plasma infusion/exchange combined with steroid or immunosuppressive therapy (life saving)
Pregnancy associated	
TTP	Plasma infusion/exchange (life saving)
HELLP syndrome	Plasma infusion/exchange (in selected cases and after delivery)
Postpartum HUS	Plasma infusion/exchange (often ineffective)
Systemic disease associated	Plasma infusion/exchange (combined with treatment of underlying disease)
Drug associated	Plasma infusion/exchange (combined with drug withdrawal)
Transplant associated	Plasma infusion/exchange (often ineffective)
Genetic	
CFH, CFI, CFB abnormalities	Plasma infusion/exchange (often ineffective)
MCP abnormalities	Probably no indication for plasma infusion/exchange (relatively good outcome also with conservative therapy alone)
ADAMTS-13 deficiency	Plasma infusion/exchange (life saving)
Abnormal cobalamin metabolism	Correction of the metabolic abnormalities; possible indication for plasma infusion/exchange
Others	Plasma infusion/exchange (often ineffective)
Idiopathic	Plasma infusion/exchange (often ineffective)

CFB, complement factor B; CFH, complement factor H; CFI, complement factor I; HELLP, hemolysis, elevated liver enzymes, and low platelet count; HUS, hemolytic uremic syndrome; MCP, membrane cofactor protein; TTP, thrombotic thrombocytopenic purpura.

risk-benefit profile of intervention. Thus, plasma exchange is especially beneficial for patients with immune-mediated deficiency of ADAMTS-13 or factor H because it provides an excess of the plasma components that may saturate and neutralize the autoantibody activity and partially restore their circulating levels while removing the autoantibody from the circulation. Similar considerations apply to steroids, vincristine, immunoglobulins, immunosuppressants, and splenectomy. In particular, steroids have been extensively used in the past to treat patients with so-called idiopathic TTP or with atypical forms of HUS, with inconsistent results. Although these treatments may have a role in immune forms of TMA by inhibiting the production of the autoantibody and, in combination with plasma exchange, effecting clearance of the autoantibody from the circulation, they definitely have no role in the treatment of genetic forms. Trials that included both the immune and genetic forms of TMA invariably diluted the

potential benefits of steroids or immunosuppressive therapy in subjects with immune-mediated disease. This may explain the inconclusive results of previous studies in HUS and TTP. Future studies should likely focus on the role of steroids as first-line therapy for immune-mediated forms and on vincristine, high-dose immunoglobulins, or other immunosuppressants as second-line therapy, with splenectomy being considered only rarely as rescue therapy for those patients with refractory disease and life-threatening thrombocytopenia or neurological involvement. Conversely, patients with genetically determined ADAMTS-13 deficiency may benefit from both plasma infusion or exchange because both procedures may re-place the defective activity, with the exchange procedure offering the possibility of supplying larger amounts of plasma without the risk of fluid overload. This applies also to patients with forms of HUS associated with genetic abnormalities of circulating complement regulators such as factors H and I.

Conversely, there is less rationale or evidence for plasma therapy, either as infusion or exchange, in forms associated with abnormalities of membrane-bound regulatory proteins such as MCP.

Finally, when a given intervention is being considered in an individual patient, the risks and benefits of add-on therapy with a specific treatment should always be evaluated compared with conservative therapy alone. Thus, the use of invasive and potentially toxic treatments such as plasma exchange or immunosuppressive agents aimed at stopping the microangiopathic process should be restricted to cases that, without intervention, are expected to have a poor outcome. The risk of sensitization, which may limit the possibility of a successful transplantation in those progressing to ESRD, should also be taken into account at the time the option of plasma therapy is being considered. Along this line, conservative therapy alone is the intervention of choice in most cases of childhood STx-HUS, which usually recover spontaneously. Similarly, waiting before considering plasma therapy is the best strategy in cases associated with MCP mutations because these forms appear to have a high rate of spontaneous remission that does not appear to be appreciably increased by plasma therapy.

Whenever indicated, specific therapy should be started as soon as diagnosis is established to speed up disease recovery and minimize morbidity and mortality. Treatment should be continued until complete disease remission is achieved.

Platelet count and serum lactate dehydrogenase are the most sensitive markers for monitoring the response to therapy. In conditions associated with decreased platelet production (cancer- or AIDS-associated TMA), serum lactate dehydrogenase concentration is a more reliable indicator of disease activity than platelet count. In pregnancy-associated TMA, monitoring serum transaminases may be helpful.

Screening and Diagnosis

Understanding of the genetic basis of non-STx-HUS has its implications for patient management, in particular, in the perspective of kidney transplantation for those who progress to ESRD; thus the demand for genetic screening has been progressively increasing. However, a full analysis for mutations in the four complement proteins so far recognized to be involved in the disease is extremely expensive and time-consuming. To optimize cost-effectiveness of genetic studies and guarantee timely delivery of the results, an initial screen based on protein levels (either serum levels or surface expression) appears a rational approach to rapidly identify the gene likely involved (see Fig. 26-1). Even when complement regulator levels are normal, both the titer of anti-CFH antibodies and possibly involved genes should be studied according to the expected frequency of mutations. Thus, the CFH gene should be considered first because it may be mutated in approximately 30% of cases, followed by MCP and CFI genes, which may be mutated in approximately 10% and 2% to 5% of cases, respectively. Then, to minimize cost and detection time, the exons where the mutations are more frequently identified within a given gene should be studied first: thus, the analysis of CFH gene should start with the study of the SCRs 19 and 20, where the majority of CFH mutations tend to cluster; the same applies to SCRs 1 to 4 of MCP, where 90% of

mutations are identified, and to the serine protease domain, which accounts for 60% of CFI mutations.

Plasma Manipulation

The infusion is intended to deliver the equivalent of one plasma volume (≈ 30 mL/kg of body weight) over the first 24 hours and approximately 20 mL/kg of body weight daily thereafter. To avoid fluid overload, diuretics or ultrafiltration may be employed. The exchange procedure is usually intended to replace one to two plasma volumes every day.

Two procedures are available for plasma separation in the setting of plasma exchange: filtration and centrifugation. The total extracorporeal volume of the plasma circuit affects the choice of the procedure. It is estimated that the total extracorporeal volume should not exceed 8% to 10% of total blood volume of the patient (taken as 100 mL/kg in infants < 10 kg and 80 mL/kg in children > 10 kg). Thus, the filtration system, which has an extracorporeal volume less than 100 mL, is preferred for small children and in patients with cardiovascular instability. Plasma centrifugation is the standard procedure for all other cases.

Other Specific Treatments

In a large series of TTP patients,²⁹ 200 mg/day of oral prednisone (or 200 mg/day of intravenous prednisolone in patients with evidence of hepatic dysfunction) were given until complete normalization of the markers of hemolysis, when corticosteroids were rapidly tapered to 60 mg/day and then more slowly by 5 mg/week. In HELLP syndrome, dexamethasone was given, 10 mg intravenously every 12 hours until delivery and for 36 hours thereafter.

The recommended initial dose of vincristine is 1.4 mg/m² (not to exceed 2 mg) by intravenous injection, followed by 1 mg intravenously every 4 days until complete remission is achieved. Because of its severe neurotoxicity, the drug should be used with caution.

Antiplatelet agents have been given by a variety of schedules. Dipyridamole (400 mg/day) and aspirin (325 mg/day) are usually given for at least 2 weeks and until disease remission.²⁸

Prostaglandin I₂ (epoprostenol), infused at the recommended doses of 10 to 20 ng/kg/min, may cause hypotension, headache, facial flushing, and diarrhea. Stable analogues have recently been developed, but their effectiveness remains to be investigated in controlled trials.

The suggested doses of antithrombotic agents used in HUS are given in Table 26-3. Oral vitamin E is usually given, 1000 mg/m²/day until complete remission of the disease. Other antioxidants available for trial include allopurinol, desferoxamine, and superoxide dismutase.

Rescue Treatments

When cryosupernatant fraction (i.e., plasma from which the cryoprecipitate containing the largest plasma vWF multimers, fibrinogen, and fibronectin has been removed) is used, during the infusion or exchange procedure, patients should be given the same volumes as stated previously for whole plasma (see Table 26-2).

Bilateral nephrectomy and splenectomy are irreversible procedures and should be considered only for patients at imminent

risk of death or with disabling disease. In patients at increased risk of bleeding because of severe refractory thrombocytopenia, platelet transfusion may be indicated before surgery.

FUTURE DIRECTIONS

Acquired Forms

Research efforts are aimed at identifying more specific approaches that may interfere with the causes of endothelial injury and the sequence of events triggered by endothelial damage. Along this line, several agents aimed at interrupting the pathogenic cascade starting with the ingestion of Stx-producing *E. coli* strains and eventually culminating in full-blown HUS are currently under investigation.¹ Molecular decoys such as orally administered nonpathogenic recombinant *E. coli*, genetically engineered to display a Stx receptor on the surface,^{72–74} have been successfully used to bind and inactivate the toxin in the intestines of mice. In another study, a plant-based oral vaccination with nicotiana tabacum cells transfected with the gene encoding inactivated Stx2 fully protected mice from challenge with a lethal dose of the toxin.⁷⁵ Yet another approach is to use Stx inhibitors; among them is STARFISH, an oligobivalent, water-soluble carbohydrate ligand that can simultaneously engage all five B subunits of Stx, which might help to prevent toxin that already has entered the circulation from binding to specific receptors.⁷⁶ Others have ameliorated disease in pigs by injection of toxin-neutralizing antibodies.⁷⁷ Although natural infection with *E. coli* O157 does not confer immunity and no human vaccine is currently available, Shiga toxoid vaccines have been shown effective in preventing related diseases in animals.

At present, however, prevention remains the most efficient strategy to decrease the morbidity and mortality associated with Stx-*E. coli* infection. A multifaceted approach is required including novel ways of decreasing Stx-*E. coli* carrier rate in livestock and implementing a zero-tolerance policy for contaminated foods and beverages. Generalized pasteurization of ground beef through irradiation will probably help to limit/prevent *E. coli* O157 and other food-borne pathogen infections.

Agents to prevent shear-induced, vWF-mediated platelet aggregation in vitro may hold promise in the therapy of TMA, in which high shear stress forces in damaged microvessels may sustain vWF-mediated intravascular platelet thrombosis. These agents include aurin tricarboxylic acid, a potent inhibitor of large vWF multimers binding to the platelet surface glycoprotein Ib receptor that is now under investigation as an arterial antithrombotic agent; recombinant fragments of the vWF monomer competitively block the binding of vWF multimers to GPIb, as do monoclonal antibodies to the arginine-glycine-aspartate-binding region for glycoprotein IIb/IIIa on monomeric subunits of vWF multimers.

An alternative approach is aimed at identifying the plasma component(s) that might induce remission of HUS and TTP (examples of these might be ADAMTS-13 and CFH, found to be defective in some forms of TMA). A plasma fraction that substantially retains the beneficial activity of whole plasma would reduce the total amount of plasma proteins infused, limiting the risk of allergic reactions and fluid overload. The active plasma fraction in lyophilized form could be made available to centers that lack facilities for plasma exchange: It

would allow better and more prompt treatment of the disease at considerably lower cost and would limit the risk of viral infection. Novel techniques such as the solvent-detergent virus inactivation method by which viruses are inactivated by a lipid solvent and detergent that disrupt the lipid envelope are under evaluation to assess the possibility of limiting viral contamination of plasma without lowering its effectiveness.

Clinical trials to assess the effectiveness of these treatments are, however, difficult to design properly. In view of the good outcome of childhood diarrhea-associated HUS, trials invariably require several hundreds of patients to ensure that they have the power to demonstrate an additional beneficial effect of the treatment under evaluation compared with supportive therapy alone. Conversely, adult HUS and TTP patients are often so ill that treatments are usually attempted in combination, thus confounding data interpretation. This may explain why, so far, the majority of information on the treatment of TMA comes from retrospective and often uncontrolled trials rather than from prospective, randomized trials.

Genetic Forms

New information derived from recent genetic studies will perhaps open the perspective on new specific treatments for patients with genetic forms of HUS and TTP. Specific replacement therapies with recombinant factor H and ADAMTS-13 could become a viable alternative to plasma treatment. This is reasonably feasible for patients with ADAMTS-13 gene mutations because even low (5% of normal) vWF-cleaving protease activity may be sufficient to degrade large vWF multimers. Finally, the full definition of factor H and ADAMTS-13 gene sequence will soon render gene therapy a realistic option for patients with inherited HUS or TTP.

FUTURE DIRECTIONS 318

Acute interstitial nephritis (AIN) leads to renal failure following persistent autoimmunity in the tubulointerstitium. Since the classic description of AIN by W.T. Councilman in 1898,¹ the epidemiology of the disorder has changed significantly and so have the therapeutic implications. In the preantibiotic era, AIN was a complicating feature of scarlet fever, diphtheria, tuberculosis, or other infections, whereas today it is far more likely to result from an immunologic response to drug therapy, except perhaps in children or renal transplant recipients in whom infectious AIN is still seen. The role of the immune system in the pathophysiology of AIN was established more than 30 years ago through experiments in animal models, and the rationale for current therapy largely rests on these classic studies. Unfortunately, randomized, controlled trials of various therapies are notably absent from the medical literature. Therefore, one must consider therapeutic options based on knowledge of the pathophysiology of this disease.

Retrospective series suggest that among patients with acute renal failure, AIN accounts for the primary process in 1% to 4% of all cases or 10% to 15% of those in which a biopsy was performed.^{2,3} It is likely that this is an underestimate due to underreporting and the avoidance of renal biopsy in presumed cases of AIN, a practice that we discourage. Some estimate that almost 25% of patients with end-stage renal disease suffer from primary tubulointerstitial injury.⁴ Furthermore, a recent case series of adult AIN at a tertiary referral center suggests that the burden of AIN may be increasing, as the annual incidence increased from 1% to 4% over the 12 years analyzed.² This increase probably reflects a growth in the polypharmacy of patient care.⁵

Although a complete discussion of the histology and pathophysiology of AIN is beyond the scope of this chapter, many aspects of this disease resemble characteristics of other forms of autoimmune tissue injury. A nephritogenic immune response is initiated when the host reacts to a foreign antigen (e.g., a hapten-protein conjugate⁶), loses tolerance to a self-antigen (e.g., the glycoprotein 3M-1 in the case of antitubular basement membrane [TBM] disease⁷), responds to a neoantigen produced by a toxic insult, or identifies a self-antigen as foreign due to molecular mimicry with an infectious agent.⁸ Mononuclear cells, primarily CD4⁺ helper T cells and macrophages, infiltrate the interstitium and effect the immune response by inducing a

delayed-type hypersensitivity response with the release of inflammatory mediators and by stimulating CD8⁺ T cell-mediated cytotoxicity.⁴ Although not absolute, parenchymal eosinophils suggest the presence of drug-induced AIN. If neutrophils predominate, one should search for an infectious cause. Tubulitis, characterized by disruption of the TBM and lymphocytic invasion, is more common. The parenchymal inflammation is accompanied by interstitial edema and distortion of the normal architecture. With continued injury, tubular epithelial cells undergo epithelial-mesenchymal transition and join the pool of fibroblasts that produce extracellular matrix and subsequent renal fibrosis.⁹ Immune deposits are rarely observed by immunofluorescence or electron microscopy, except in the rare cases of anti-TBM disease in which the TBMs demonstrate linear staining with IgG antibodies.

For the purposes of therapy, AIN may be classified into three major categories: (1) drug-induced AIN, accounting for approximately 70% of cases in recent series; (2) infectious causes, accounting for approximately 8%; and (3) systemic immune disorders among the remainder.¹⁰ A large number of drugs have been associated with AIN, and many have reasonable foundation based on pathophysiology. For example, it was demonstrated in 1975 that methicillin forms a hapten conjugate with proteins along the TBM, leading to a drug-induced form of anti-TBM disease and AIN.⁶ The contribution of a detrimental immune response in drug-induced AIN is also suggested by the observations that a reaction to a given drug only occurs in a small percentage of the population, is not dose dependent, is occasionally associated with extrarenal signs and symptoms of hypersensitivity, and usually recurs with rechallenge.¹¹ Exciting recent data support a direct link between drugs and the immune response; peripheral T cells isolated from patients with AIN activate and proliferate *ex vivo* when incubated with a specific drug from their regimen.¹² A comprehensive listing of offenders may be found elsewhere, but commonly implicated drugs include β -lactam antibiotics, sulfonamides, nonsteroidal anti-inflammatory drugs, proton pump inhibitors, anticonvulsants, rifampin, allopurinol, cimetidine, and thiazides.^{11,13,14}

Infection-related AIN may result from multiple pathogens, but viruses (including BK virus in transplant recipients), leptospirosis, legionella, diphtheria, and tuberculosis are among

some of the most frequently seen. AIN may also be observed in conjunction with Sjögren's syndrome, systemic lupus erythematosus, and sarcoidosis. When found in association with uveitis, although not always temporally concordant, it is classified as tubulointerstitial nephritis-uveitis syndrome. Although these causes may seem disparate, the common denominator is the putative role of the immune response in renal inflammation and subsequent destruction. Therefore, attempts at therapeutic intervention have focused on immunomodulators.

CLINICAL APPROACH

Renal fibrosis may develop within 2 weeks of the onset of AIN, and the extent of tubulointerstitial fibrosis correlates with renal survival. This provides the rationale for early definitive diagnosis and treatment.⁴ The diagnosis of AIN is suggested by the classic presentation of a patient who has defervesced in response to antibiotic therapy for an infectious illness and then develops a recrudescence of fever associated with a skin rash and a decline in renal function. Although methicillin tended to produce this monomorphic clinical picture, the classic triad of fever, rash, and eosinophilia is found in less than 5% of patients in the current era.² Urinary eosinophils detected with Hansel stain and gallium scintigraphy have been proposed to aid in the diagnosis of AIN, but neither is sensitive nor specific enough for routine clinical use. The difficulty in making a clinical diagnosis of AIN is highlighted in a retrospective study by Buysen and colleagues.¹⁵ In a biopsy series of 25 clinically suspected cases of AIN, the diagnosis was confirmed in 11 (44%). They also reviewed the clinical charts of 18 biopsy-proven AIN cases and discovered that the diagnosis had been clinically suspected in only 11 (61%). This bedside error rate demonstrates the potential value of a renal biopsy in establishing the diagnosis, as long as the patient can undergo the procedure without excessive risk and would be a suitable candidate for immunosuppressive therapy. Histological examination of renal tissue with specific attention to the degree of inflammation and tubulointerstitial fibrosis may provide prognostic information and influence the choice or timing of therapy.

THERAPY

The use of immunosuppressive drugs in the treatment of AIN remains controversial because there are no prospective, randomized, controlled trials that evaluate this therapeutic option. Given the varied causes of AIN, the relative scarcity of clinical cases, and the ethical dilemma of withholding potentially beneficial drug therapy from a patient who does not improve after withdrawal of the putative offending agent, it seems unlikely that any such trials will be conducted in the future. Current recommendations for therapy, therefore, are based on numerous case reports and several small, retrospective case series that demonstrate the occasional benefit of immunosuppression. The collective experience is greatest with corticosteroids, and few human data have been published for other immunomodulating drugs such as mycophenolate mofetil (MMF), cyclosporine, and cyclophosphamide.

Withdrawal of the Offending Agent

The initial treatment of AIN is not controversial. Every effort must be made to remove the suspected offending agent immediately after making a diagnosis. In the case of infection-associated AIN, treatment of the underlying infection is analogous to the discontinuation of a medication in drug-induced AIN. The duration of renal injury has been shown to affect the renal outcome; one study reported that AIN patients who suffered acute renal failure for 2 weeks or less had a significantly better renal outcome than those who had ARF for 3 weeks or more (serum creatinine ~ 1 mg/dL vs. ~ 3 mg/dL at the end of follow-up).¹⁶ Similarly, continued exposure to a drug responsible for AIN can result in significant irreversible damage, including the need for long-term dialysis.¹⁷⁻¹⁹

Even though the prompt withdrawal of the offending agent often leads to clinical improvement, it is not known whether this acute improvement suggests the cessation of indolent injury. It is certainly plausible that the destructive immune response is perpetuated by a proinflammatory cytokine milieu that lingers for varying periods of time after the antigen has been removed. Furthermore, the nature and course of the immune response may vary depending on the target moiety. For example, in the era of methicillin-induced AIN, complete recovery of renal function was the rule with the serum creatinine returning to baseline in approximately 90% of reported patients even though the mean duration of renal failure was 1.5 months.¹¹ In the recent summary by Baker and Pusey¹⁰ of three modern series totaling 128 patients, however, only 64% made a full recovery (serum creatinine < 1.5 mg/dL), 23% made a partial recovery, and 13% remained on renal replacement therapy at the end of follow-up. Whether this difference in prognosis is inherent to the antigen is speculative, but the modern experience supports our belief that AIN can no longer be considered a benign disease.

Corticosteroids

Corticosteroids have been used as immunosuppressive agents for several decades. They effectively attenuate the inflammatory response by suppressing both the innate (macrophage and dendritic cell-mediated) and adaptive (T and B cell-mediated) immune response. Upon binding to glucocorticoid receptors, the receptor-corticosteroid complex translocates to the nucleus, binds to specific DNA sequences (glucocorticoid response elements) that reside in the promoter regions of glucocorticoid-regulated gene products, and recruits coactivator or corepressor proteins, all of which modulate the transcription of inflammatory mediators. By this mechanism, transcription of I κ B is up-regulated, leading to the inhibition of the proinflammatory transcription factor nuclear factor- κ B. Interestingly, the receptor-corticosteroid complex also directly interacts with nuclear factor- κ B, preventing the transcription of cytokines such as interleukin-1, -2, and -6 and tumor necrosis factor α . Corticosteroids also attenuate the production of inflammatory prostaglandins by inhibiting nuclear factor- κ B-mediated transcription of cyclooxygenase-2 and through the up-regulation of annexin I (lipocortin-1) and mitogen-activated protein kinase phosphatase 1, two proteins that inhibit cytosolic phospholipase A_{2a}. Last, corticosteroids exert posttranslational effects such as reducing the mRNA stability of inflammatory cytokines and chemokines.²⁰ These

mechanisms provide the scientific rationale for using these drugs to treat AIN.

Perhaps the most often quoted study that demonstrates a beneficial effect of corticosteroids in AIN is a retrospective review by Galpin and colleagues²¹ of 14 patients with methicillin-induced AIN (8 biopsy proven). In addition to the withdrawal of methicillin, eight patients received prednisone (mean oral dose, 60 mg/day) for a mean duration of 9.6 days. Compared with the six patients who did not receive prednisone, those in the treated group were more likely to return to their previous normal serum creatinine level (six of eight treated vs. two of six not treated) and achieved their new baseline with greater rapidity (9.3 days vs. 54 days).

Following this report, Linton and colleagues²² published their experience with nine cases of drug-induced AIN. Withdrawal of the inciting drug led to improvement in only two cases. The seven nonresponders were treated with prednisone 60 mg/day for periods of 6 to 12 days, and all exhibited a prompt diuresis and improvement in renal function within 2 days of initiating steroid therapy. Within 10 days, all treated patients returned to their previous baseline level of renal function. Several other reports describe a similar brisk response to the initiation of steroids in AIN. Pusey and colleagues²³ treated seven episodes of biopsy-proven AIN with high-dose intravenous methylprednisolone (500–1000 mg/day) in a regimen similar to that used for the treatment of acute renal allograft rejection. All patients responded with a remarkable diuresis and/or improvement in renal function within 72 hours of treatment without major side effects. In two additional episodes not treated with steroids, one patient was left with advanced, chronic renal failure and the other achieved normal renal function more slowly than those in the steroid-treated group.

A larger case series evaluated 27 patients with biopsy-proven AIN (15 drug induced, 9 associated with infection, and 3 idiopathic). Seventeen of these patients improved with drug discontinuation or treatment of the associated infection. Ten demonstrated continued renal decline after 5 to 20 days (mean, 10 days) and were then treated with three daily doses of intravenous methylprednisolone or a 3- to 4-week course of oral prednisone (40–60 mg/day). Six (60%) of these patients achieved a normal serum creatinine at a mean of 1 month, and the remaining had a partial improvement in renal function. A plot of renal function over time demonstrates a dramatic correlation between the initiation of steroids and the improvement in serum creatinine in every patient treated.¹⁵

Enriquez and colleagues²⁴ observed a similar temporal association of steroid administration and improved renal function. A woman with acute renal failure due to biopsy-proven idiopathic AIN demonstrated rapid improvement in renal function after treatment with three boluses of intravenous methylprednisolone (1000 mg daily) followed by 1 mg/kg/day of oral prednisone. Renal function worsened when steroids were discontinued (serum creatinine: 1.7–5.0 mg/dL), but improved again following their reintroduction. This pattern repeated during the second steroid taper, and the patient again responded favorably to steroids. Eventually, steroids were successfully discontinued and renal function remained stable for an additional year of follow-up with a serum creatinine of 0.9 mg/dL. In a separate dramatic case report, a patient who had been hemodialysis dependent for more than 3 months due to AIN was treated with high-dose methylpred-

nisolone; surprisingly, renal function improved and dialysis was discontinued.²⁵

Not all reports describe a beneficial effect of corticosteroids on the prognosis of AIN.^{2,19,26,27} The largest published series to date that specifically addresses the role of corticosteroid therapy in the management of AIN is a retrospective analysis by Clarkson and colleagues.² Reviewing 2598 adult native renal biopsy specimens at a tertiary referral center over a 12-year period, the authors identified 42 patients with AIN. Patients were excluded if they had findings consistent with acute pyelonephritis, a connective tissue disorder, or sarcoidosis or were found to have a coexisting glomerular disease (except minimal change disease, which is associated with nonsteroidal anti-inflammatory–induced AIN). As expected in a retrospective study of this duration, steroid regimens varied but were initiated within 4 days of renal biopsy and typically comprised intravenous methylprednisolone (500 mg for 2–4 days) followed by oral prednisone (0.75 mg/kg/day tapered over 3–6 weeks). Twenty-six of 42 (60%) patients received corticosteroid therapy, and the remainder received supportive care. Although not a randomized study, the reported baseline characteristics between the conservatively managed and corticosteroid-treated groups were similar. No difference in median serum creatinine was observed between the two groups at 1, 6, and 12 months after diagnosis.²

It is important to recognize that although corticosteroid therapy may be associated with side effects such as hypertension, hyperglycemia, psychiatric disturbance, weight gain, and increased risk of infection, none of the studies described herein reported major adverse events due to corticosteroid use. Therefore, we believe that the risk-benefit ratio favors a corticosteroid trial for most patients with biopsy-proven AIN who fail to show an improvement in renal function within days of discontinuing the offending agent. Clinical judgment is required in cases in which this risk-benefit ratio may be higher, such as those already showing marked interstitial fibrosis and/or minimal active inflammation at the time of biopsy. If renal biopsy is absolutely contraindicated, an empirical trial of corticosteroids may be reasonable if the history and evaluation are strongly suggestive of AIN and removal of the inciting agent does not produce a satisfactory clinical response.

Mycophenolate Mofetil

It is somewhat surprising that the largest reported human experience with immunomodulatory agents other than corticosteroids for AIN is a retrospective, single-center study of MMF use in eight patients.²⁸ MMF is widely used in solid-organ transplantation and has been shown to reduce the incidence of acute rejection in renal allograft recipients.²⁹ It is a prodrug of mycophenolic acid (MPA), an inhibitor of the rate-limiting enzyme inosine monophosphate dehydrogenase in the *de novo* pathway of purine synthesis. Since T and B cells are more dependent on this pathway than most other cells, they are especially prone to the antiproliferative effects of MPA. Moreover, MPA is an especially potent inhibitor of type II inosine monophosphate dehydrogenase, which is expressed in activated lymphocytes. It also induces apoptosis of activated T cells and suppresses the expression of cell adhesion molecules, thereby decreasing mononuclear cell recruitment to sites of inflammation.³⁰

Preddie and colleagues²⁸ published the first case series of MMF use in steroid-dependent biopsy-proven AIN. These eight patients received at least 6 months of steroids (in one or two courses) and experienced a worsening of the serum creatinine when steroids were tapered or discontinued. Acute interstitial nephritis was attributed to drugs in two patients, mixed connective tissue disease in one, and an idiopathic cause in three; granulomatous interstitial nephritis was observed in the remaining two patients, associated with sarcoid in one and with perinuclear antineutrophil cytoplasmic antibody seropositivity in the other. MMF was initiated at 500 to 1000 mg twice daily and titrated to 1000 mg twice daily as tolerated by the leukocyte count and gastrointestinal side effects. Renal function improved in six of the eight patients, defined as a decrease in serum creatinine of at least 0.3 mg/dL, and the remaining two experienced no significant change in function. At the most recent follow-up before the authors published their experience (mean, 28 months; range, 14–40), all had discontinued corticosteroids and five patients had discontinued MMF as well. In another isolated case report, a pediatric patient with renal-limited sarcoidosis was maintained successfully on MMF after induction therapy with corticosteroids.³¹ Although we do not recommend MMF for initial treatment of AIN, it may find future use in select cases characterized by a relapsing steroid-responsive pattern.

Cyclophosphamide and Cyclosporine

Not all patients with AIN experience improved renal function after removal of the offending agent and a trial of corticosteroids. In these unfortunate circumstances, there are no published human trials or case series to guide further therapy with alternative immunomodulatory agents. Convincing experimental evidence in animal models and anecdotal human reports, however, suggest that cyclophosphamide and cyclosporine may have a role in the treatment algorithm for select cases of steroid-resistant AIN.

Cyclophosphamide is an alkylating agent that gained popularity in the 1970s for the treatment of lupus and vasculitis. It forms covalent bonds and cross-links a variety of macromolecules, with DNA likely being the most important. Cross-linking DNA impairs replication and transcription and ultimately leads to cell death or dysfunction. This makes cyclophosphamide one of the most potent immunosuppressant drugs available, but also one that carries a substantial risk of toxicity.

The level of evidence available for cyclophosphamide use in AIN comes primarily from experimental animals. Brown Norway rats immunized with rabbit renal TBMs provide an experimental model of severe tubulointerstitial nephritis. The appearance of anti-TBM antibodies is followed by an intense mononuclear cell infiltrate (mainly T cells and macrophages) within several weeks. Agus and colleagues³² demonstrated that treatment with daily oral cyclophosphamide beginning at the time of immunization prevented the development of anti-TBM antibodies and histologic lesions. More important, when therapy was initiated after established interstitial disease, progression of histologic lesions halted. With administration early in the course of established disease, there was even a trend toward regression of histological severity and decreased serum creatinine. To extrapolate this rat model of anti-TBM disease to human AIN is not easy, but the study does provide

a rationale for a therapeutic trial in select cases. The published use of cyclophosphamide in human AIN consists of anecdotal experience mainly in the setting of sarcoidosis and a single case report of presumed drug-induced granulomatous AIN in the setting of concomitant chronic lymphocytic leukemia.³³ In the latter case, the authors assumed their regimen of corticosteroids and a single dose of intravenous cyclophosphamide treated the patient's AIN and chronic lymphocytic leukemia, respectively. The patient, who was dialysis dependent due to acute renal failure, recovered her renal function after 6 weeks of hemodialysis and achieved a baseline serum creatinine of 2.8 mg/dL 9 months after diagnosis.³³ It is unknown what effect the cyclophosphamide had, if any, on the course of AIN in this case.

A full discussion of the use of cyclophosphamide is beyond the scope of this chapter, and the reader is referred to Chapter 10 (“Immunosuppressive Agents for the Therapy of Glomerular and Tubulointerstitial Disease”) for additional information. The patient should be made aware of the risks of cyclophosphamide therapy, including teratogenicity, hematologic toxicity, infection, malignancy (bladder cancer being the most common tumor associated with daily oral therapy), hemorrhagic cystitis, alopecia, and gonadal toxicity (in both men and women, with the incidence among women increasing with age).³⁴ Some physicians will bank sperm or eggs if the patient is of child-bearing age. These risks increase with cumulative dose and length of treatment and must be reflected in the risk-benefit ratio for an individual patient.

The risk of malignancy secondary to cyclophosphamide therapy is difficult to quantify, as retrospective analyses are plagued by confounding variables such as concomitant carcinogenic drug exposure, other therapies (e.g., external radiation), and the oncogenic potential of the underlying disease process. Noting these limitations, a case-control study of breast cancer patients suggests that even after adjustment for radiation exposure, a cumulative dose of cyclophosphamide greater than 20 g may be associated with an increased risk of hematological malignancy.³⁵ Most reports of malignancy, however, report greater cumulative doses and durations of therapy than we would suggest for treating AIN. For example, in a retrospective study of 119 patients with rheumatoid arthritis, the mean total dose and duration of cyclophosphamide was 74.9 g over 43.8 months in those who developed a subsequent malignancy compared with 45.8 g over 28.1 months in control patients.³⁶ In a National Institutes of Health cohort of 145 patients with Wegener's granulomatosis treated with oral cyclophosphamide, eight patients (6%) developed transitional-cell carcinoma of the bladder. The duration from initiation of therapy to diagnosis of bladder cancer ranged from 7 months to 17 years, and seven of the eight patients had received a total of more than 100 g of cyclophosphamide.³⁷ Regarding the treatment of AIN, if a comparatively short course of cyclophosphamide successfully improves renal function in a patient with severe renal dysfunction after other therapies have failed, the benefit of avoiding the morbidity and mortality of end-stage renal disease may outweigh the potential therapeutic risks. Generally, we attempt oral cyclophosphamide 2 mg/kg/day and stop therapy if the serum creatinine does not decrease by 6 to 8 weeks. If the patient responds, a reasonable approach would be to continue therapy for 4 months, at which time an alternative agent (such as MMF) could be substituted to minimize cyclophosphamide exposure.

Cyclosporin A has been used in transplantation and immune-mediated diseases since the 1980s. This fungus-derived endecapeptide binds to cyclophilin, and the resulting complex subsequently inhibits the serine/threonine phosphatase calcineurin. The loss of calcineurin's phosphatase activity prevents the translocation of cytosolic nuclear factor of activated T cells to the nucleus for transcription of interleukin-2, thereby inhibiting T-cell activation.³⁴ The effectiveness of cyclosporine to treat established AIN was tested in the Brown Norway rat model of anti-TBM disease described previously.³⁸ Similar to cyclophosphamide, multiple investigators have demonstrated that cyclosporine halts disease progression, even when initiated after disease is established, by inhibiting the cell-mediated immune response.^{38–40}

Cyclosporine has been used in a few cases of the tubulointerstitial nephritis-uveitis syndrome, but these reports do not provide adequate data to assess renal response; in fact, with the exception of one case, most attribute renal improvement to preceding courses of corticosteroids.^{41–43} One case report of a severe vancomycin-associated hypersensitivity reaction with skin rash and visceral involvement (hepatitis and acute renal failure with pyuria, eosinophiluria, and low-grade proteinuria) attributed a dramatic clinical improvement to a 5-day course of cyclosporine (100 mg twice daily) after 3 weeks of steroid administration had failed. The skin rash resolved within a week and was accompanied by a slow, but stable, improvement in renal function. The patient, who had been dialysis dependent for 6 weeks at the time of cyclosporine initiation, was able to discontinue renal replacement therapy 5 weeks later and had a serum creatinine of 1.0 mg/dL 20 months after initial presentation.⁴⁴ Although the rapid resolution of skin lesions was temporally related to cyclosporine treatment, it is speculative as to whether the drug also led to the improvement in renal function. In addition, when contemplating the use of cyclosporine, the drug's nephrotoxic potential must be considered as well as its proclivity to stimulate the renal fibrogenesis that one is attempting to suppress.⁴⁵

SPECIFIC RECOMMENDATIONS

It is important to establish a definitive diagnosis of AIN early in its course. There are no clinical, laboratory, or imaging features with adequate sensitivity or specificity to rule out the diagnosis. With a good clinical story, we favor the use of early renal biopsy if the procedure and the use of immunosuppressive therapy are not contraindicated by the patient's general medical condition. In addition to providing the diagnosis, histologic analysis may guide therapy. For example, the presence of a diffuse cellular infiltrate or granulomatous inflammation may encourage the use of immunosuppressive agents, whereas the presence of significant fibrosis may favor withholding potentially toxic therapy.

As outlined in Figure 27-1, the putative agent(s) responsible for the inflammatory response must be discontinued or treated as soon as the diagnosis is suspected.

In patients who do not demonstrate substantial improvement within several days of removing the inciting agent, we recommend a trial of corticosteroids (Table 27-1). Prednisone 1 mg/kg/day (maximum 80 mg/day) should be initiated, preceded in severe cases by pulse high-dose intravenous methylprednisolone (250–1000 mg/day for 1–3 days) at the clinician's

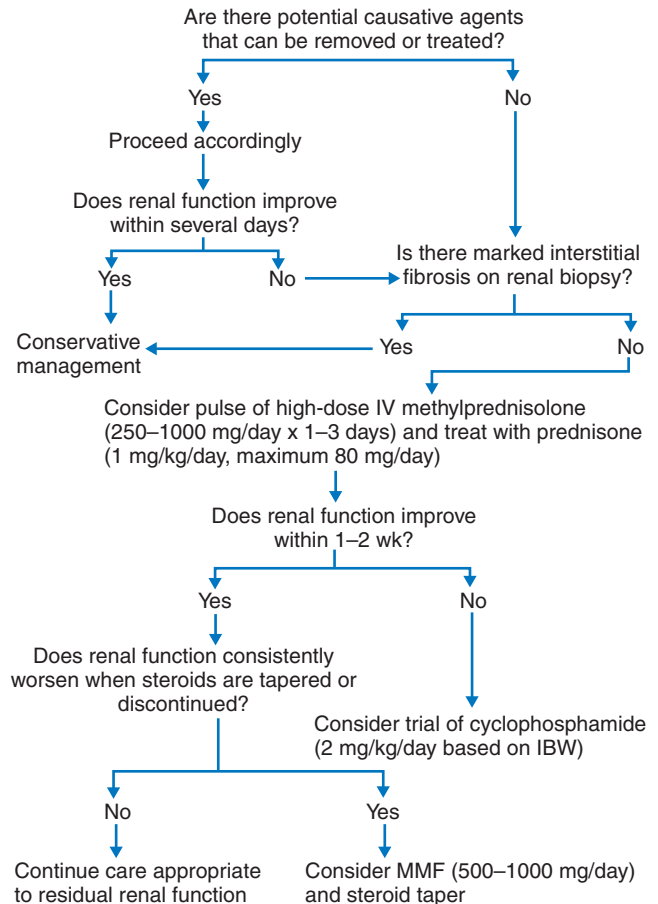

Figure 27-1 Suggested treatment algorithm for acute interstitial nephritis. IBW, ideal body weight. See text for details.

discretion. If renal function improves within 7 to 10 days, the drug should be continued for approximately 2 months and then tapered over the next several weeks.

If renal function improves with steroid use but repeatedly worsens during the taper or with discontinuation, MMF may be administered as a steroid-sparing alternative. We recommend an initial dose of 500 mg twice daily, titrated to 1000 mg twice daily if gastrointestinal symptoms and the leukocyte count permit.

In cases of severe AIN that do not respond to corticosteroid therapy within 1 to 2 weeks, cyclophosphamide may be considered if histologic examination of the renal parenchyma suggests potential salvage. In these difficult cases, we suggest the addition of oral cyclophosphamide (2 mg/kg/day based on ideal body weight) with steroids. In nonresponders, the drug should be discontinued after 6 to 8 weeks to minimize toxicity. In responders, there are no data to guide duration of therapy, but it would not be unreasonable to continue cyclophosphamide for 4 months, at which time a switch to another immunosuppressant agent, such as MMF, could be considered, akin to induction and maintenance therapy for lupus nephritis. In our opinion, corticosteroids may be maintained at lower doses (20–40 mg/day) while initially treating with cyclophosphamide. Vigilance for leukopenia, infections, and microscopic hematuria is exceedingly important.

Supportive therapy for patients with acute renal failure includes dialysis as necessary. For patients who recover partial

Table 27-1 Immunosuppressive Drugs and Level of Evidence for Use in Acute Interstitial Nephritis

Drug	Initial Dose / Route / Duration*	Level of Evidence
Methylprednisolone	250 to 1000 mg/day for 1–3 days (IV), followed by oral prednisone	Retrospective case series
Prednisone	1 mg/kg/day (max. 80 mg daily; oral) for 7–10 days, frequently assessing for response	Retrospective case series
Mycophenolate mofetil	500 mg twice daily, titrating to 1000 mg twice daily, as steroids are tapered	Retrospective case series (relapsing steroid-responsive cases only)
Cyclophosphamide	2 mg/kg/day (based on IBW; oral) for 6–8 weeks, frequently assessing for response and toxicity	Experimental animal data; anecdotal human reports
Cyclosporine	3 mg/kg/day in divided doses twice daily (based on IBW; oral) for 4–6 weeks, frequently assessing for response and toxicity	Experimental animal data; anecdotal human reports

*Initial doses and therapeutic trial durations are provided; see text for details. Given the lack of adequate evidence regarding the use of immunosuppressant drugs in AIN, the treating physician must rely on clinical judgment, involve the patient in the decision making, and individualize therapy. IBW, ideal body weight.

renal function, appropriate attention should be given to chronic kidney disease care, including the use of renin-angiotensin system blockade, in an attempt to obviate renal progression.

FUTURE DIRECTIONS

We have witnessed an impressive growth of knowledge in the field of immunology over the past several years, and many new immunomodulatory agents have entered routine clinical use, testing, or active development. Given that not one randomized, controlled trial has been performed for AIN therapy to date, however, we are not optimistic that these new agents will take positions outside of the occasional case report or small series. Because tubulointerstitial fibrosis is the final common pathway to all chronic kidney diseases, it is likely that the development of drugs targeting fibrogenesis will have more of an impact on the prognosis of these patients. For example, we are encouraged by recent elegant work that suggests that bone morphogenic protein-7 administration reverses transforming growth factor β_1 -mediated epithelial-mesenchymal transition and renal pathology in an animal model of chronic kidney disease.⁴⁶ Other mediators of transforming growth factor β signaling may also hold promise, such as a transforming growth factor β type I receptor kinase (ALK5) inhibitor that ameliorated fibrosis in an animal model of obstructive nephropathy.⁴⁷ These approaches are far from routine clinical application but hold considerable promise for the future.

TREATMENT OF THE DIABETIC PATIENT WITH END-STAGE RENAL DISEASE 329

CONCLUSION 330

Diabetic nephropathy (DN) is the single most common cause of end-stage renal disease (ESRD) in the United States and Europe. According to the World Health Organization, more than 171 million people worldwide have diabetes mellitus (DM) (www.who.int/diabetes/facts/world_figures/en, accessed June 2007) and approximately 30% to 40% will develop DN.¹ Many of these patients will reach ESRD, although in the United States, the number of patients entering the Medicare ESRD program with DM appears to have plateaued.² Many patients with early DN die of cardiovascular events before reaching ESRD. DM and chronic kidney disease (CKD) are independent risk factors for increased cardiovascular (CV) morbidity and mortality. Patients with DM and CKD have even higher mortality rates than patients without DM and CKD.³ The CV risk associated with CKD is present with an estimated glomerular filtration rate (GFR) as high as 60 mL/min, and the risk increases with declining renal function.⁴ This chapter reviews strategies to care for the patient with DN and impede the devastating progression of DN.

PREVENTION

The clinical course of DN has been best defined in patients with type 1 DM, as the time of onset of the disease in these patients is so readily apparent. Studies of type 2 DM and nephropathy are less readily defined; however, the reported experience in the type 2 diabetics seen in Native Americans, specifically the Pima Indians of Arizona, would indicate that the clinical course in these patients who develop type 2 DM at an early age mirrors that of the type 1 population.⁵⁻⁷ The natural history of DN is summarized in Figure 28-1. After a period of glomerular hyperfiltration, the earliest clinically detectable stage of DN is microalbuminuria. Generally, patients have the onset of abnormal urine albumin excretion from 5 to 10 years after the onset of DM. Microalbuminuria is defined as the excretion of small amounts of albumin,

below the level that can be detected by a traditional urinary dipstick evaluation. This level is quantified (Table 28-1) and arbitrarily determined to be clinically relevant if within the range of 20 to 200 mg albumin per gram of creatinine in a spot urine specimen or 30 to 300 mg of albumin in a 24-hour urine collection. When microalbuminuria is the result of DM, it progresses to overt nephropathy, defined by urinary albumin excretion rates of 300 mg or more in 24 hours, in up to 50% of patients in 5 to 10 years.⁸⁻¹² Clinical predictors of the development of microalbuminuria and progression to overt nephropathy include increased age, male gender, African American or Hispanic race, smoking, increased body mass index, elevated glycosylated hemoglobin, presence of proliferative diabetic retinopathy, duration of DM, dyslipidemias, and systolic hypertension.¹³⁻¹⁷ Once albuminuria is established, if untreated, a decrease in GFR of up to 50% will occur within 2 years.¹⁸

With the advent of medications that slow progression of DN, the primary cause of death has shifted from renal failure to CV disease. Patients with DM who have never had a CV event are at greater risk of having one than a patient without DM but with a known history of a CV event.¹⁹ The risk of a CV event is higher in a diabetic patient with nephropathy and progressively increases as GFR decreases.²⁰⁻²² Treatment that prevents the progression of renal disease becomes the cornerstone of therapy for delaying ESRD with all of its attendant CV risks.

Glycemic Control for the Prevention of Diabetic Nephropathy

Poorly controlled glucose carries an inherent risk of complications in patients with DM. Impaired fasting glucose is an established risk factor for developing CV complications.^{19,23} Furthermore, data from observational studies have demonstrated a consistent association of poorly controlled blood sugars and the development and progression of DN.²⁴⁻²⁷

Figure 28-1 Typical natural history of diabetic nephropathy for a patient with type 2 diabetes mellitus. Glomerular filtration rate (GFR) is elevated at the onset of diabetes mellitus. Structural changes follow. With the development of microalbuminuria, there is typically an increase in blood pressure, and advancing structural damage appears in the kidney and vasculature elsewhere. With progression to overt proteinuria, the GFR starts to decrease usually in a linear fashion and, without intervention, the patient reaches end-stage renal failure. The risk of cardiovascular death is present early in the course of diabetic nephropathy and progresses as the renal disease advances. GBM, glomerular basement membrane. (Modified from Lewis JB: Diabetic nephropathy in patients with type II diabetes. *Geriatr Nephrol Urol* 1999;9:168.)

Treating poorly controlled glucose is therefore essential, and several studies have evaluated the impact of intensive glycemic control on preventing the complications of DM.

Two clinical trials have examined the hypothesis that intensive blood glucose control could slow or prevent the development of complications of DM including nephropathy.^{28,29} The Diabetes Control and Complications Trial²⁸ was a prospective trial randomizing 1441 patients with type 1 DM to conventional versus intensive blood glucose control. The patients were followed for an average of 6.5 years and achieved mean hemoglobin A1C values of 7.2% and 9.1% for the intensive and conventional arms, respectively. Patients in the intensive group had a significantly lower incidence of developing microalbuminuria and overt albuminuria compared with the conventional group. Interestingly, the beneficial effect persisted even after the trial ended, when, on long-term follow-up, the group of patients in the intensive arm during the study period had a sustained beneficial effect on preventing the development of microalbuminuria, overt albuminuria, and

hypertension despite a lack of persistent difference in achieved hemoglobin A1C values on follow-up.^{30,31} The Diabetes Control and Complications Trial was a landmark study demonstrating conclusively that intensive blood glucose control in patients with type 1 DM will slow or prevent the development of DN as well as other complications of DM.

This same hypothesis was tested in the United Kingdom Prospective Diabetes Study (UKPDS) in patients with type 2 DM.²⁹ The investigators randomized 3867 patients with newly diagnosed type 2 DM to receive intensive therapy with oral hypoglycemic agents or insulin versus conventional therapy with diet alone. The average hemoglobin A1C values achieved were 7.0% in the intensive arm versus 7.9% in the conventional arm. Patients randomized to the intensive therapy group had a significant decrease in any diabetes-related endpoint, but no statistically significant decrease in the development of microalbuminuria, albuminuria, or twofold increase in the serum creatinine. However, renal function was tested infrequently. These data did not demonstrate a positive effect of aggressive glycemic control in the prevention of DN in type 2 DM in the UKPDS population. In another study of intense glucose control in 110 Japanese patients with type 2 DM, intensive insulin therapy reduced the development of microalbuminuria and overt albuminuria compared with less intensive insulin therapy.³² This effect persisted at follow-up of 8 years.^{32,33}

Although the optimal level of glycemic control is unknown, the current American Diabetes Association guidelines recommend that the hemoglobin A1C level be kept at less than 7% in patients with type 1 and 2 DM.³⁴

Control of Blood Pressure for the Prevention of Diabetic Nephropathy

Profound evidence exists of the importance of blood pressure control and choice of antihypertensive therapy in patients with existing DN (see “Therapy of Diabetic Nephropathy”). The answer to the question of whether patients with established type 1 or 2 DM are less likely to develop progressive nephropathy if their blood pressure is well controlled is not as clear. Observational studies have linked the presence of hypertension and uncontrolled blood pressure to the development of microalbuminuria or proteinuria in patients with DM.^{8,9,16,17,24,27} Randomized, controlled trials have had conflicting results. Embedded within the UKPDS study was a trial comparing two levels of blood pressure control with regard to the development of macrovascular and microvascular complications in 1148 hypertensive patients with type 2 DM and a normal GFR.³⁵ During the

Table 28-1 Categories of Urinary Protein Excretion

	Dipstick Protein	24-Hour Protein	24-Hour Albumin	Spot Collection	Timed Collection
Normal	Negative	<150 mg	<30 mg	<30 μ g albumin/mg creatinine	<20 μ g/min
Microalbuminuria	Negative	150–500 mg	30–300 mg	30–300 μ g albumin/mg creatinine	20–200 μ g/min
Overt nephropathy	1(+) to 4(+)	\geq 500 mg	\geq 300 mg	\geq 300 μ g albumin/mg creatinine	\geq 200 μ g/min

mean follow-up of 8.4 years, the mean blood pressure in those patients with more active blood pressure control (mean achieved blood pressure, 144/82 mm Hg) was lower than the group with less tight control (mean achieved blood pressure, 154/87 mm Hg). The risk of any complication or death from diabetes, myocardial infarction, and the composite of microvascular complications was less with lower systolic blood pressure.³⁶ This study was unable to demonstrate a statistically significant benefit of lower blood pressure on the renal endpoints of proteinuria or twofold increase in the serum creatinine. However, it is important to emphasize that the UKPDS was not designed as a trial to examine renal endpoints.

The Appropriate Blood Pressure in Diabetes study³⁷ was carried out to determine the importance of blood pressure control in an attempt to prevent the onset of progressive renal dysfunction. The investigators randomized 480 normotensive patients with type 2 DM to intensive blood pressure or moderate blood pressure control and observed these patients over 5 years. There was a significant decrease in the development of albuminuria in the group randomized to the intensive therapy. However, the primary endpoint of the study was a change in creatinine clearance, and no difference was noted between the groups.

As noted below, intensive blood pressure control is an important therapeutic goal in the diabetic population, particularly with respect to the prevention of CV events and treatment of the course of established renal disease. However, the value of blood pressure control as a preventive measure with respect to the onset of nephropathy remains an open question.

Blockade of the Renin-Angiotensin System to Prevent Diabetic Nephropathy

Before the onset of microalbuminuria, the initial mechanism in the development of DN is renal hypertrophy, hyperfunction, and glomerular hyperfiltration. Evidence derived from the measurement of glomerular hemodynamic parameters in experimental diabetes in the rat reveals increased intraglomerular pressures from the direct transmission of pressure along a dilated afferent arteriole as well as vasoconstriction due to the effects of increased angiotensin II on the efferent arteriole. Blockade of the angiotensin II effect on the efferent arteriole with angiotensin-converting enzyme (ACE) inhibitors leads to an improvement in the elevated intraglomerular pressure, which may well account for the preservation of glomerular structure and function in DM.³⁸⁻⁴¹

In view of the apparent central role of angiotensin II antagonism in the interruption of a pathogenic pathway in DM, which can result in glomerular damage, the question has arisen whether blockade of the renin-angiotensin system (RAS) prevents the development of clinically detectable DN. The Bergamo Nephrologic Diabetes Complications Trial^{42,43} was a multicenter, controlled trial designed to investigate whether blood pressure control and choice of blood pressure agent could prevent the onset of microalbuminuria in patients with hypertension and type 2 DM. A total of 1204 patients were randomized to receive the ACE inhibitor trandolapril, the calcium channel blocker verapamil, a combination of trandolapril and verapamil, or placebo and followed for a median of 3.6 years. The primary outcome of developing microalbuminuria was the defined endpoint of the development of DN, and this was less in the groups receiving trandolapril. The verapamil arm was equivalent to placebo. A post hoc analysis

revealed that treatment with the ACE inhibitor trandolapril prevented microalbuminuria independent of blood pressure control.⁴³ This study supports the recommendation that treatment of patients with type 2 DM without clinically detectable DN with an ACE inhibitor is effective in reducing the development of early nephropathy.

Cardiovascular Risk Reduction

Patients with DM, and even more so for patients with DN, are prone to CV complications and death. Targeting a global decrease in CV risk, especially early in the course of the disease, is instrumental in promoting the long-term health of these patients. Unfortunately, although there is much evidence demonstrating the benefit of a variety of interventions to reduce CV events in patients with DM, patients with DN are typically excluded from these trials. However, the Steno-2 trial evaluated such an approach for patients with type 2 DM and microalbuminuria.⁴⁴ One hundred sixty patients were randomly assigned to either an intensified treatment plan of lifestyle modification, smoking cessation, pharmacologic therapy for hyperglycemia, hypertension, dyslipidemia, microalbuminuria, and aspirin or conventional therapy and followed for an average of 7.8 years. Patients who received intensive therapy had a significant decrease in CV death and events, peripheral vascular disease, urinary albumin excretion, as well as retinopathy and neuropathy. Although this study was not designed to detect which therapy was responsible for the greatest effect, clearly an organized global approach to decrease in CV risk was beneficial.

More specific therapy of blocking the RAS for decreasing CV events has also been tested. The Heart Outcomes Prevention Evaluation trial was a randomized, controlled study of patients with vascular disease or DM performed in an attempt to ascertain a CV effect of the ACE inhibitor ramipril versus placebo. Compared with placebo, treatment with ramipril significantly reduced the primary outcome of a composite of myocardial infarction, stroke, or death from CV causes over a 5-year period.⁴⁵ The trial enrolled 9297 patients, 3577 (38%) of whom had DM. The MICRO-Heart Outcomes Prevention Evaluation substudy of the Heart Outcomes Prevention Evaluation trial examined these 3577 patients for the same primary outcome with the addition of the development of overt nephropathy. The study was halted early because of the consistent benefit of ramipril for all CV outcomes as well as nephropathy.⁴⁶ Additional evidence was supplied by the Reduction in End-Points in Non-Insulin Dependent Diabetes Mellitus with the Angiotensin II Antagonist Losartan trial investigators.⁴⁷ In this study, over a follow-up period of 3.4 years, 1513 patients with overt DN from type 2 DM were randomized to receive angiotensin antagonism with losartan 100 mg/day or placebo. The primary outcome of the composite of doubling of the serum creatinine, ESRD, or death was significantly lower in the group assigned to losartan. A secondary analysis of this study^{48,49} demonstrated that albuminuria was the strongest predictor of CV outcome. There was an 18% decrease in CV risk for every 50% decrease in albuminuria, and a 27% decrease in heart failure risk for every 50% decrease in albuminuria. This lends additional support for the cardioprotective role of blockade of the RAS and decrease in albuminuria in the patient with DN.

Patients with DM have the same risk of cardiac mortality as patients with known coronary artery disease.¹⁹ As patients with CKD and ESRD from DN have an even greater risk,^{3,50} it remains essential to reduce this risk with lifestyle modification, smoking cessation, aspirin, and pharmacologic therapy for hyperglycemia, hypertension, dyslipidemia, and albuminuria.

THErapy OF DIABETIC NEPHROPATHY

The natural history of DN has been altered by therapeutic interventions that reduce the malignant course and delay the progression to ESRD. Blockade of the RAS, blood pressure control, and blood glucose control all have a role in maintaining preservation of renal function. As the nephropathy progresses, treating the sequelae of CKD and adjusting medications for the decrease in GFR become important aspects of patient care. With these therapies, there has been a remarkable decrease in new onset ESRD from DN since 1995.^{2,51}

Blood Pressure Control

Initial studies of blood pressure reduction in patients with DN were performed with small numbers of patients but demonstrated an overall benefit of blood pressure control. In 1982, Mogensen⁵² evaluated the effects of blood pressure control on progression of DN. He reported that lowering blood pressure from a mean of 162/103 mm Hg to 144/95 mm Hg in six patients reduced the rate of loss of GFR from 1.23 mL/min/month to 0.49 mL/min/month. Others confirmed these findings.^{53–55} In 1987, Parving and colleagues⁵⁴ reported that treating blood pressure from a mean of 143/96 mm Hg to 129/84 mm Hg in 11 patients with type 1 DM and DN decreased the rate of GFR decline from 0.89 mL/min/month to 0.22 mL/min/month.

These promising results suggested further study would be necessary to determine the optimal blood pressure range to prevent the pathologic progression of DN. The UKPDS randomized patients to two different blood pressure goals and found an impressive risk reduction in CV and diabetes-related events with the lower achieved blood pressure (144/82 mm Hg), but was unable to detect a renoprotective effect of being randomized to the lower blood pressure.^{35,54} However, this may have reflected the limitation of study design in the UKPDS. A further trial,³⁷ the Appropriate Blood Pressure in Diabetes study, not only demonstrated a decrease in the development of albuminuria, but also a decrease in the progression to overt nephropathy in the group that achieved a mean blood pressure of $128 \pm 0.8/75 \pm 0.3$ mm Hg. Finally, a smaller study⁵⁶ investigated the effects of lowering blood pressure in patients with type 1 DM and advanced DN by randomizing them to a mean arterial pressure of 92 mm Hg or less versus 100 to 107 mm Hg. Patients were followed for 2 years, and those randomized to the lower mean arterial pressure goal experienced an improvement in proteinuria from an average of 1043 mg/day to 535 mg/day compared with the group with the higher mean arterial pressure goal that developed an average increase in urinary protein excretion from 1140 mg/day to 1723 mg/day. Based on this randomized study, renal remission was achieved, defined as a 24-hour urine protein excretion of less than 500 mg/day coupled with a loss of GFR of less than 2 mL/min per year. Blood pressure control was achieved using

ramipril, which was titrated up to a dose of 20 mg/day before the addition of other antihypertensive agents. Therefore, those patients with the best outcome had better blood pressure control and were on average treated with the higher dose of the ACE inhibitor.

The Irbesartan Diabetic Nephropathy Trial (IDNT) revealed that the application of angiotensin receptor blockade in patients with overt nephropathy significantly slowed the rate of progression to loss of renal function in type 2 DM (see later).⁵⁷ When the impact of the patients' blood pressure at the time of entry into the study was examined, it was clear that patients who entered the study with more poorly controlled blood pressure were more likely to develop renal failure. Despite this relationship between the lack of historical blood pressure control and an adverse renal outcome, it was demonstrated in the IDNT that the achieved blood pressure had a more profound effect on outcome than did the baseline blood pressure.⁵⁸ Hence, despite a history of undertreatment of the blood pressure, achieving blood pressure control was an important and effective therapeutic goal.

Intensive blood pressure control therefore has substantial benefits for treatment of nephropathy in patients with DM; however, how far should the clinician attempt to lower it? Is there CV harm in lowering blood pressure too much? In 1988, the concept of the J curve was introduced.⁵⁹ This was based on the fact that lowering blood pressure diminished CV disease and death, but there was a definable plateau where blood pressure control lacked a benefit for CV mortality. In fact, decreasing the diastolic blood pressure below this plateau was associated with an increase in mortality. This relationship between blood pressure control and clinical outcome therefore was depicted graphically as a U- or J-shaped curve and was compatible with the observation that during diastole, lower blood pressures could limit coronary perfusion.^{59,60} This concept is essential to apply to patients with DM and DN who have a well-established CV risk. Attempting to control the systolic pressure in this population can lead to the potential danger of decreasing diastolic pressure too far. The post hoc analysis of the IDNT confirmed the J-curve relationship in the patient with DN, as a plateau was reached in the development of renal outcomes at a systolic blood pressure of less than 130 mm Hg, and, more importantly, all-cause mortality increased below a systolic blood pressure of 120 mm Hg.⁵⁸ In this same population of overt DN, CV deaths and congestive heart failure events increased at an achieved systolic blood pressure of less than 120 mm Hg, and the relative risk of a myocardial infarction was higher in those patients who achieved a lower diastolic blood pressure.⁶¹ An additional trial, not a post hoc analysis, was performed by Osher and colleagues.⁶² The investigators attempted to treat patients with DM and hypertension to the blood pressure goal of less than 130/85 mm Hg as recommended by the most recent Joint National Commission on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.⁶³ The diastolic blood pressure goal was achieved in 90% of the patients and the systolic goal in 33%. The achievement of a diastolic blood pressure of less than 70 mm Hg was more likely in patients who were older, had a higher systolic blood pressure, or a history of coronary artery disease.

Treatment of blood pressure in the patient with DN should therefore be targeted between the range of 120 to

130/80 to 90 mm Hg, with care to not excessively lower the diastolic pressure.

Blockade of the Renin-Angiotensin System

Angiotensin receptor blockers (ARB) and ACE inhibitors block the deleterious renal effects of angiotensin II while simultaneously lowering blood pressure, and, as lowering blood pressure has been shown to improve renal outcomes, debate could exist as to which effect is renoprotective. The first large human clinical trial to examine this hypothetical effect of renoprotection with RAS blockade in DN was in 409 patients with type 1 DM and overt DN.⁶⁴ Overt DN was defined as the excretion of 500 mg proteinuria/day or more and serum creatinine of 2.5 mg/dL or less. The patients were randomized to receive captopril 25 mg three times daily or placebo, and blood pressures were similar in the two groups. The results were a dramatic 43% decrease in the doubling of serum creatinine (Fig. 28-2) as well as a statistically significant decrease in time to death, dialysis, or transplantation with captopril compared with placebo. Thus, in patients with type 1 DM and DN, ACE inhibitors provide renoprotection superior to that with blood pressure treatment alone.

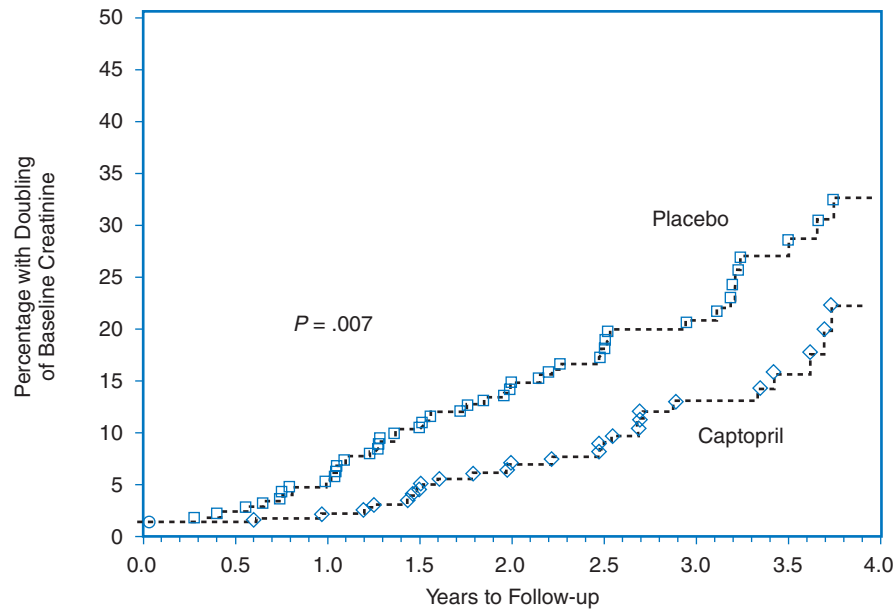

The data in DN associated with type 2 DM is also compelling. The Effect of Irbesartan in the Development of Diabetic Nephropathy in Patients with Type 2 Diabetes investigators⁶⁵ randomized 590 patients with type 2 DM and microalbuminuria to receive either placebo, irbesartan 150 mg, or irbesartan 300 mg for 2 years. The primary endpoint of albuminuria more than 200 mg/day was statistically lower ($P < .001$) in the irbesartan 150-mg group and 300-mg group compared with the placebo group, with the greatest decrease at the highest

dose (Fig. 28-3). This study demonstrated not only the importance of blockade of the RAS for the renal outcome, but also the importance of dose on efficacy, with the higher dose being more efficacious.

More advanced DN from type 2 DM was studied by the IDNT group,⁵⁷ who randomized 1715 hypertensive patients with overt DN (median baseline serum creatinine, 1.67 mg/dL; median baseline urinary protein excretion, 2.9 g/24 hr) to receive one of three treatment regimens: (1) irbesartan 300 mg/day, (2) amlodipine 10 mg/day, or (3) placebo. Patients were followed for an average of 2.6 years. Antihypertensive agents with the exception of ACE inhibitors, ARBs, and calcium channel blockers were used as needed in each group to target a blood pressure of less than 135/85 mm Hg. The primary composite endpoint of doubling of the serum creatinine, development of end-stage renal disease, or death was significantly lower in the irbesartan arm compared with the amlodipine or placebo arm. Blood pressure control was similar in all three arms and equivalent in the amlodipine and irbesartan groups.

Similar results were demonstrated in the Reduction in End-Points in Non-Insulin Dependent Diabetes Mellitus with the Angiotensin II Antagonist Losartan trial,⁴⁷ in which randomization to angiotensin antagonism with losartan produced a decrease in the primary outcome of the composite of doubling of the serum creatinine, ESRD, or death. The benefit was greater than that attributed to blood pressure decrease alone. These two independent trials gave extraordinarily similar results, providing remarkable attestation for the use of ARBs for renoprotection in overt DN from type 2 DM.

These data established the blood pressure-independent effects of renoprotection with blockade of the RAS for DN in patients with type 1 and 2 DM. Figure 28-4 represents renal

Figure 28-3 Incidence of progression to diabetic nephropathy during treatment with 150 mg/day irbesartan, 300 mg/day irbesartan, or placebo in hypertensive patients with type 2 diabetes and persistent microalbuminuria. The difference between the placebo group and the 150-mg group was not significant ($P = .08$ by the log-rank test), but the difference between the placebo group and the 300-mg group was significant ($P < .001$ by the log-rank test). (From Parving HH, Lehnert H, Brochner-Mortensen J, et al: The effect of irbesartan on the development of diabetic nephropathy in patients with type 2 diabetes. *N Engl J Med* 2001;345:870.)

outcomes from the IDNT, stratified by treatment assignment and systolic blood pressure quartiles.⁵⁸ It is apparent that, in addition to randomization to the irbesartan group, the lower quartiles of achieved systolic blood pressure were associated with improved renal outcomes. Thus, blood pressure control

Figure 28-4 Simultaneous impact of quartile of achieved systolic blood pressure (BP) and treatment modality on the relative risk for reaching a renal endpoint (doubling of baseline serum creatinine or end-stage renal disease, defined as serum creatinine ≤ 6.0 mg/dL or renal replacement therapy). Avg, average. (From Pohl MA, Blumenthal S, Cordonnier DJ, et al: Independent and additive impact of blood pressure control and angiotensin II receptor blockade on renal outcomes in the irbesartan diabetic nephropathy trial: Clinical implications and limitations. *J Am Soc Nephrol* 2005;16:3031.)

and inhibition of the RAS offer independent and additive effects to prevent progression of DN.

In addition to blood pressure, proteinuria is reduced in patients with DN treated with RAS blockade. In the IDNT, baseline proteinuria was a strong and linear determinant of developing a renal endpoint (Fig. 28-5A). More importantly, improved renal outcomes were associated with a decrease in proteinuria (see Fig. 28-5B).⁶⁶ Data from the Reduction in End-Points in Non-Insulin Dependent Diabetes Mellitus with the Angiotensin II Antagonist Losartan trial also demonstrated a significant decrease in proteinuria in those patients assigned to losartan.⁴⁷ The baseline proteinuria was predictive of a renal endpoint and ESRD, and decrease in the protein excretion was associated with fewer renal outcomes and ESRD.⁴⁹ This emphasizes that proteinuria may be another potential target for therapy in DN, as more evidence is emerging for the association of proteinuria as an independent modifiable risk factor for progression of advanced DN.^{48,49}

Blockade of the RAS with ACE inhibitors or ARBs has been well established in slowing the progression of DN, and therapies that antagonize this system further by other maneuvers have been evaluated. Most of these trials are small in sample size and/or contain confounding variables. Higher doses of ARBs than those approved by the U.S. Food and Drug Administration have been shown to decrease microalbuminuria to a greater degree than the accepted doses.⁶⁷ Studies of combining ACE inhibitors and ARBs have shown a decrease in proteinuria below what was established with either agent alone.⁶⁸⁻⁷⁵ Blockade of aldosterone receptors with spironolactone⁷⁶ and eplerenone⁷⁷ has been shown in small trials to reduce proteinuria in patients with DN independent of their effects on blood pressure. The renin inhibitor aliskiren, currently approved by the U.S. Food and Drug Administration for control of blood pressure, has preliminarily shown reduction in proteinuria additive to the effects of RAS blockade by losartan.⁷⁸ At present, however, no study of these alternative and novel maneuvers to block the RAS has been shown to be associated with a decrease in the rate of decline of renal function. Proteinuria reduction alone has been associated with improved renoprotection, and therefore long-term studies with further blockade of other agents that interfere with the RAS to document significant delay in the progression to ESRD are eagerly anticipated.

Care must be taken to monitor and treat the potential development of hyperkalemia when using any agent to block the RAS. Given the fact that many of these patients have a decreased GFR or even hyporeninemic hypoaldosteronism, maximally blocking the RAS at multiple sites may lead to an increased incidence of hyperkalemia. The rigorous nature of follow-up in a clinical trial typically would follow this closely; however, widespread application of clinical trial data to patients in the general public who may not meet criteria for the study and/or may not follow up as closely can be dangerous,⁷⁹ especially with the known consequence of sudden death seen with hyperkalemia. It is prudent to check the serum potassium 7 to 14 days after establishing therapy with these agents.

Overwhelming evidence from statistically valid clinical trials supports blockade of the RAS with ACE inhibitors or ARBs to decrease the rate of progression of DN. They are considered the first-line therapy for the patient with microalbuminuria or overt DN. Evidence exists proving a beneficial effect of ACE inhibition in patients with overt nephropathy from type 1 DM

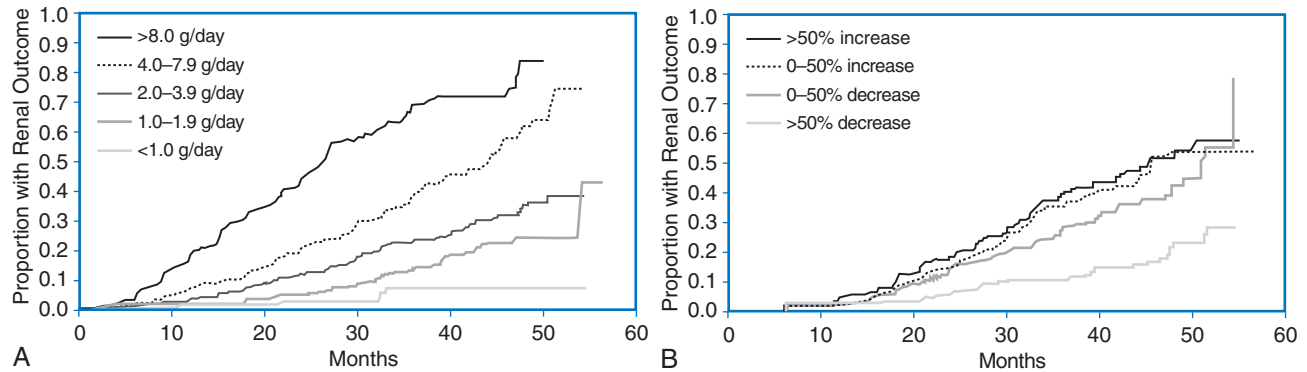

Figure 28-5 **A**, Kaplan-Meier analysis of doubling of baseline serum creatinine level, serum creatinine level of 6.0 mg/dL, or the development of end-stage renal disease by baseline proteinuria values. **B**, Kaplan-Meier analysis of doubling of baseline serum creatinine level, serum creatinine level of 6.0 mg/dL, or the development of end-stage renal disease by level of proteinuria change in the first 12 months. (**B**, From Atkins RC, Briganti EM, Lewis JB, et al: Proteinuria reduction and progression to renal failure in patients with type 2 diabetes mellitus and overt nephropathy. *Am J Kidney Dis* 2005;45:283, 285.)

and reduction in albuminuria in DN from type 2 DM. Evidence of angiotensin II blockade with ARBs proves the beneficial effect in patients with microalbuminuria and overt nephropathy from type 2 DM. Further evidence and safety data must exist before recommending the use of additional novel maneuvers to block the RAS in patients with DN.

Diet

The modern diabetic diet of low fat, low sodium, moderately low protein, and high fiber has been shown to decrease blood pressure in patients with type 2 DM and hypertension.⁸⁰ This has not been formally evaluated for patients with DN. Studies on dietary protein restriction have had mixed results.⁸¹⁻⁸⁵ Due to the dietary restrictions of fat and simple carbohydrates in diabetic patients, restricting protein may increase the risk of protein malnutrition. A reasonable recommendation is to follow a low sodium (<2 g/day) diet with moderate protein intake (0.8 g/kg/day).

Treating Chronic Kidney Disease and Avoiding Acute Kidney Injury

In addition to focusing on slowing or reversing the progression of DN, care must be taken to treat the sequelae of CKD. This therapy is beyond the scope of this chapter and can be reviewed in Part XII: Chronic Renal Failure and Its Systemic Manifestations. However, certain precautions are unique to evaluating the diabetic patient. As the GFR decreases, dosing for insulin and other oral hypoglycemic agents with renal excretion needs adjustment. Metformin should be held when the creatinine clearance decreases to less than 60 mL/min as the risk of type B lactic acidosis develops.⁸⁶ Diabetic patients, and especially those with DN, are at increased risk of developing acute kidney injury.⁸⁷ These acute insults can often lead to an irrecoverable loss of renal function and have a direct correlation with a higher mortality.⁸⁸ It is sensible to avoid, if possible, situations that may cause acute kidney injury, such as iodinated contrast exposure, atheroemboli, and nonsteroidal anti-inflammatory agents, as these may accelerate the progression of CKD. As the diabetic patient has a

high risk of vascular disease and congestive heart failure, control of coronary risk factors and volume status is prudent. Finally, dialysis education, preparation for transplantation, or palliative care should begin early in the course of CKD in patients with diabetes to allow for an informative and effective evaluation.⁸⁹

Future Strategies

Despite the established therapies for reducing progressive nephropathy, the patient with diabetes is still at risk of eventual renal failure and CV complications. New medications to reduce and perhaps reverse this risk may be developed in the future. One such drug is sulodexide, a glycosaminoglycan that has shown promise in pilot studies to reduce albuminuria in patients with DN.⁹⁰ Endothelin antagonism is another novel target for treatment of DN; however, trials with these agents were recently halted due to side effects associated with the use of the study drug. Inhibitors of transforming growth factor β , such as pirfenidone, may have promise in inhibiting fibrosis in the kidney as DN progresses.^{91,92} Ruboxistaurin, a protein kinase C inhibitor, has also been shown to decrease proteinuria in patients with DN in preliminary pilot studies.⁹³ Agents that reduce or inhibit glycosylation end products also show promise.⁹⁴⁻⁹⁷ In light of limitations of maximally blocking the RAS system, such as hyperkalemia, these future therapies for DN are attractive. There must be further study with rigorous clinical trials and safety data must exist before recommendation of these novel therapies in addition to RAS blockade.

TREATMENT OF THE DIABETIC PATIENT WITH END-STAGE RENAL DISEASE

Hemodialysis, peritoneal dialysis, renal transplantation, and palliative care are all options for the diabetic patient with ESRD. These are discussed in detail in Parts XIII and XIV. The choice of renal replacement therapy is individualized for each patient, but the treating physician and the patient should be aware of the specific risks that a diabetic patient carries.

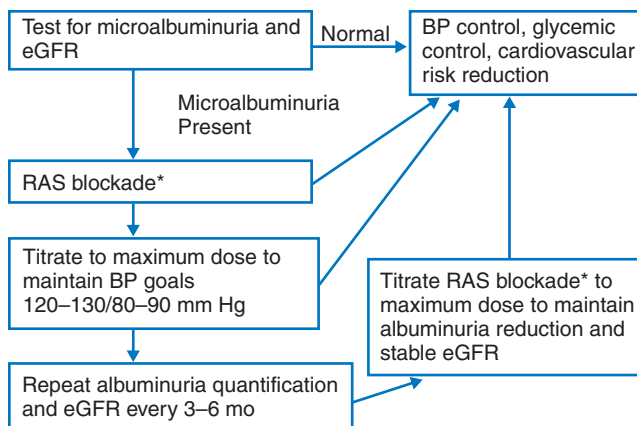

The diabetic patient with ESRD has a higher morbidity, mostly from cardiac and vascular disease, compared to a non-diabetic patient with ESRD.⁵¹ Furthermore, mortality is nearly double for a diabetic with ESRD compared with a nondiabetic with ESRD.^{3,51} Although kidney transplantation is associated with an improved mortality, no proven difference in overall mortality exists between those patients on hemodialysis versus peritoneal dialysis.⁵¹ The studies evaluating a difference in dialysis modality for the mortality of diabetic patients have demonstrated conflicting results,^{98–103} which can be explained by the nature of their observational and/or retrospective study designs. To date, there has not been an appropriately powered randomized trial to define a difference in mortality with respect to modality of dialysis for patients with DM and ESRD.

Other practical factors are involved when choosing the dialysis modality for the patient with DN. Blindness from proliferative diabetic retinopathy may limit a patient's ability to perform peritoneal dialysis.¹⁰⁴ Rates of recurrent peritonitis are also higher in patients with DM.¹⁰⁴ Patients with DM have an accelerated course to peritoneal membrane failure.¹⁰⁵ Systemic glucose absorption from the dialysate may lead to worsening hyperglycemia and increasing insulin requirements in patients undergoing peritoneal dialysis. In patients undergoing hemodialysis, the preponderance of vascular disease in those with diabetes limits the maturity and increases the rate of complications of vascular access.¹⁰⁶ The increased rate of cardiac disease, left ventricular hypertrophy, and autonomic insufficiency observed in patients with diabetes can contribute to intradialytic hypotension, arrhythmias, or even sudden death on hemodialysis.¹⁰⁴ Therefore, the choice of dialysis modality in diabetic patients with ESRD should remain individualized.

Transplantation in patients with DM remains an attractive alternative to dialysis. In patients with type 1 DM, pancreas transplantation is a viable option to restore euglycemia. Survival for patients with diabetes with a renal transplant is markedly higher than survival on dialysis. The survival for diabetic patients undergoing renal transplantation is approximately 80% at 5 years,² and the unadjusted 5-year patient survival rate is 83.4% for diabetics undergoing living donor transplantation in the United States (the scientific registry of transplant recipients, www.ustransplant.org, accessed June 2007). This is a lower percentage compared with those reported for living donation or renal failure from other etiologies, such as polycystic kidney disease (94.5%) or glomerular disease (94.1%) at 5 years. These less favorable results are chiefly due to the increased CV disease in diabetic patients. However, according to the U.S. Renal Data Systems report, the survival rate of patients with DM on dialysis is approximately 25% at 5 years,² an astounding difference compared with transplantation. This cannot be entirely explained by selection bias, as those patients who are eligible for transplantation but remain on the transplantation waiting list have a lower survival compared with transplant recipients, but a higher survival than those on dialysis who are not on the waiting list.¹⁰⁷

CONCLUSION

The management of the patient with diabetes is complex and suited to a multidisciplinary approach. Glycemic and blood pressure control is necessary to assist in the prevention of DN.

*Provided no contraindication: persistent hyperkalemia, angioedema, prerenal azotemia, pregnancy

Figure 28-6 Treatment algorithm for diabetic nephropathy. BP, blood pressure; eGFR, estimated glomerular filtration rate; RAS, renin-angiotensin system blockade.

Once nephropathy has developed, substantial evidence exists for blockade of the RAS to delay the onset of ESRD as first-line therapy. Blood pressure control clearly remains important as the disease progresses. Exciting novel therapies beyond blockade of the RAS are eagerly anticipated and must be tested through rigorous clinical study for safety and efficacy. Treating the sequelae of CKD and preparing the patient for ESRD become more relevant as the GFR decreases. Throughout the entire course of DM and DN, CV risk reduction for this high-risk population remains vital. The therapies discovered in the past 30 years have helped improve the devastating progression of DN (Fig. 28-6).

Abnormalities of the serum sodium concentration (S_{Na}) are the most common electrolyte disorders encountered in clinical medicine.¹ Collectively referred to as the dysnatremias, they represent disturbances in the control of the body's relative amount of water to sodium. In some settings, treatment must be prompt and judicious, because symptoms may be life-threatening and inappropriate therapy can be deleterious. Skilled management of these disorders requires an understanding of the normal control of the serum sodium, the pathologic settings in which dysnatremias occur, and the ability to quantify the disturbances in order to prescribe safe and effective treatment.

PLASMA SODIUM CONCENTRATION

The plasma sodium value only reflects the relative amount of sodium to water.² It cannot therefore be used to assess total body sodium (TB_{Na}). The S_{Na} is determined by TB_{Na} , total body potassium (TB_K), and total body water (TBW):

$$S_{Na} = \frac{(TB_{Na} + TB_K)}{TBW} \quad (\text{Eq. 29-1})$$

Careful analysis by Nguyen and Kurtz³ has led to more sophisticated formulas describing how the S_{Na} is established, but this simple equation is still very useful in clinical evaluation of the patient. From Equation 29-1, it can be seen that

hyponatremia can occur as a consequence of a decrease in the body's content of monovalent cations, an increase in TBW, or a combination of these. Overall, the dysnatremias should be viewed primarily as disturbances in water balance, with a variable component of negative solute balance.

The sodium concentration is a primary determinant of plasma osmolality (P_{osm}):

$$P_{osm} = 2[Na] + \text{glucose}/18 + \text{BUN}/2.8 \quad (\text{Eq. 29-2})$$

where BUN represents blood urea nitrogen. Normally, the osmolality of body fluids can be estimated as twice the S_{Na} plus approximately 10 mOsm to account for other solutes. The addition of solutes to the extracellular fluid will increase its measured osmolality. However, the permeability of a solute across cell membranes determines whether it will cause water to be redistributed between the intracellular and extracellular compartments. Solutes that are permeable across cell membranes, such as urea, ethanol, methanol, and ethylene glycol, do not induce water movement and thus cause hyperosmolality without cellular dehydration. In contrast, the addition of impermeable solutes such as glucose (in an insulinopenic state) or mannitol establishes an effective gradient for water to leave the cell. This process lowers the S_{Na} , producing a translocational hyponatremia in the setting of either an isotonic or even hypertonic state, and leads to cellular dehydration. Conversely, when hyponatremia occurs as a consequence of an

increase in TBW (hypotonic hyponatremia), water flows into cells causing increased cell volume and decreased intracellular osmolality.

THERAPEUTIC APPROACH TO THE HYPONATREMIC PATIENT

Although most hyponatremic patients are asymptomatic, severe hyponatremia is a medical emergency that may lead to cerebral edema, tentorial herniation, and death.⁴⁻⁶ Surveys of severe symptomatic hyponatremia suggest high mortality rates in the absence of aggressive intervention.⁷ In some patients, however, the treatment itself may result in central nervous system demyelination, producing permanent neurological sequelae or even death. Safe treatment therefore requires an understanding of cerebral adaptation to hypotonicity and knowledge of the patient groups at greatest risk of poor outcomes.

Cerebral Adaptation to Hypotonicity

Due to the unyielding confines of the skull, the brain is the primary site of symptoms in acute hyponatremia. Decreases in extracellular osmolality cause water to flow into the intracellular space, and the resultant cellular edema within the fixed volume of the cranium produces an increase in intracranial pressure. Fortunately, the brain possesses adaptive mechanisms that defend against such increases in intracranial pressure, making overt neurological manifestations infrequent.⁸ The first protective mechanism, occurring early in hyponatremia (1–3 hours), involves a decrease in cerebral extracellular fluid volume. As cellular volume expands, the resultant increase in interstitial pressure stimulates flow of extracellular fluid into the cerebrospinal fluid, which is shunted into the systemic circulation, effectively relieving some of the elevation of intracranial pressure. This mechanism protects against mild acute changes in hyponatremia. A second protective mechanism involves a reduction in intracellular solutes. This starts approximately 3 hours after the onset of hypotonicity with the loss of cellular potassium. This is followed over the next 72 hours by the loss of organic solutes, including glutamate, taurine, myo-inositol, and glutamine.⁹ Although some of the osmolyte losses occur within 24 hours, the loss of such solutes becomes more marked in subsequent days and accounts for almost complete restoration of cerebral water.

The benefits afforded by cerebral adaptation are also the source of the problems encountered in the treatment of hyponatremia. The increase in plasma tonicity that accompanies correction of chronic hyponatremia requires a reversal of the adaptive process to prevent cellular dehydration. The rate at which the brain reverses this process and restores lost solutes is of great pathophysiologic importance. Although brain sodium and chloride levels recover rapidly, the reaccumulation of osmolytes is considerably delayed. The process of increasing or restoring cellular electrolytes and accumulating organic osmolytes in the face of increasing extracellular sodium concentration is less efficient in brains previously adapted to hypotonic conditions compared with those in normonatremic states. This is reflected by the greater cerebral water loss sustained by adapted brains.¹⁰

Correction of chronic hyponatremia with resultant cerebral dehydration correlates with the delayed appearance of severe neurological deficits and the pathologic finding of foci of demyelination. This finding, called the osmotic demyelination syndrome (ODS), was initially observed in the central basis pontis but also occurs elsewhere throughout the central nervous system. The typical clinical presentation is for patients to show an initial improvement in mental status after the start of correction, with subsequent deterioration and development of (1) motor abnormalities, sometimes progressing to flaccid quadriplegia and even respiratory paralysis; (2) pseudobulbar palsy; and (3) mental status or behavioral changes, including progressive loss of consciousness. The diagnosis of this ODS is made through confirmation of foci of demyelination on head computed tomography or magnetic resonance imaging, although the radiographic findings may lag behind clinical findings by several weeks. Although survival without residual deficits is becoming more common, ODS frequently has a fatal course within 3 to 5 weeks, making this a dreaded complication of therapy. It must be noted that the diagnosis of ODS is made primarily based on clinical findings because the radiographic features can be absent.

RISK FACTORS FOR NEUROLOGICAL COMPLICATIONS OF HYPONATREMIA AND ITS CORRECTION

Mortality estimates of inpatient hyponatremia range from 10% to 50%, although the contribution of the hypotonicity to poor outcome is difficult to separate from other underlying causes. Oh and colleagues¹¹ suggest that most patients dying of complications related to acute hyponatremia may already be brain dead at the time of diagnosis, further supporting need for careful monitoring and a high index of suspicion in making the diagnosis.

Symptoms of hyponatremia, such as gastrointestinal complaints, lethargy, apathy, agitation, and cramps, occur most commonly with rapid decreases in S_{Na} to less than 125 mEq/L. Seizures and coma usually result from rapid decreases to levels below 110 mEq/L. Conversely, hyponatremia usually needs to be present for at least 72 hours to set the stage for complications related to treatment. Despite these generalizations, there is tremendous variation in the physiologic responses to water intoxication and the likelihood of suffering complications during correction. Clinical surveys and experimental data suggest that there are subgroups of patients at greatest risk of either acute cerebral edema or osmotic demyelination (Box 29-1).

Risk Factors for Acute Cerebral Edema

Hypoxia

The combination of hyponatremia and hypoxia may be particularly dangerous.^{12,13} In experimental animals, hypoxia abrogates the volume adaptive response to hyponatremia, therefore resulting in increased brain edema.¹⁴ Patients with symptomatic hyponatremia and hypoxia who are corrected at

Box 29-1 Patient Groups at Increased Risk of Neurological Complications of Hyponatremia

Acute Cerebral Edema	Osmotic Demyelination
Hypoxic patients	Alcoholics
Postoperative	Malnourished patients
premenopausal women	Hypokalemic patients
Elderly women on thiazide diuretics	Burn patients
Polydipsic patients	Patients with previous hypoxic episodes
Children	Elderly women on thiazide diuretics
Marathon runners	Serum Na < 105 mEq/L

rates slower than 0.55 mEq/L/hr may have greater mortality than those corrected faster,¹³ even though this rate of correction is similar to what is commonly recommended for patients with chronic hyponatremia.

Hospital-Acquired Hyponatremia in Premenopausal Women

In the hospital setting, hyponatremic premenopausal women are more symptomatic at higher sodium levels than other groups and appear to be at increased risk of neurological complications related to acute hyponatremia. Although hyponatremia appears to develop with almost equal frequency in men and women, Ayus and colleagues¹⁵ reported that of 307 men with postoperative hyponatremia, only one had an outcome of permanent cerebral dysfunction or death; in contrast, 33 of 367 women with hyponatremia had such outcomes. Experimental data support gender differences in arginine vasopressin (AVP) release and its cerebral action, including the process of cerebral adaptation. In female rats, AVP decreases high-energy phosphates and pH in the brain and increases mortality relative to male rats. Some of these effects may be related to female sex hormones, which can stimulate release of AVP, compared with male sex hormones, whose action may be inhibitory.¹⁶ Studies in rabbits suggest that cellular adaptation may be less efficient in females than in males, perhaps due to decreased potassium extrusion. Synaptosomes obtained from females demonstrated lower levels of sodium transport and Na⁺/K⁺-ATPase activity than those obtained from males.¹⁷

Patients on Thiazide Diuretics

Thiazide diuretics are a common cause of hyponatremia. These agents reduce electrolyte-free water clearance by inhibiting sodium reabsorption in the early distal tubule and also induce sodium, potassium, and magnesium losses. They may also directly stimulate thirst. Occasionally, thiazides can cause severe hyponatremia, with levels below 115 mEq/L. The majority of affected patients reach these levels within 2 weeks of starting the diuretic, although approximately one third require fewer than 5 days.¹⁸ These patients seem to have a predisposition to thiazide-induced hyponatremia, as challenge with the drug can rapidly reinduce the hypotonic state.

Sonnenblick and colleagues¹⁸ reported 12 deaths in a group of 129 patients with diuretic-induced severe hyponatremia. These deaths were directly related to the hyponatremia and were associated with a lower mean sodium level on presentation (103 mEq/L) compared with those patients who recovered (108 mEq/L). In most studies, the patients at greatest risk are elderly women with low body mass. This may be related to decreased body water at the start of therapy, but possibilities also include altered hypothalamic responses and intrarenal water excretion defects in this group. Of note, some elderly women may have a habitually increased water intake and low solute intake as described by the “tea and toast” diet. Low solute excretion impairs the ability to excrete the ingested water load, resulting in hyponatremia.

Polydipsia

Polydipsia, particularly in psychiatric patients, is a common cause of hyponatremia. Approximately 6% to 17% of all chronically ill psychiatric patients exhibit features of polydipsia, consuming 4 to 25 L of water per day. Most of these patients have schizophrenia, although associations with affective disorders, mental retardation, and alcoholism are also observed. Only a subgroup of polydipsic patients becomes hyponatremic; estimates range from 25% to 50%.¹⁹ Hyponatremic patients who compulsively drink water frequently have increased circulating levels of AVP and defects in intrarenal water handling. These abnormalities may be related to antipsychotic medications, but some evidence suggests the presence of defects in water homeostasis even in the absence of pharmacotherapeutic agents.²⁰ Excessive water intake also increases the risk of hyponatremia in marathon runners.²¹

Children

Children are at risk of becoming hyponatremic because of either excessive dietary intake of hypotonic fluids (such as plain water or diluted formula) or the inappropriate use of hypotonic fluids during hospital admission.²² Use of hypotonic fluids in children may overestimate their requirements and also may not take into account nonosmotic release of vasopressin due to stimuli such as pain and nausea.²³ In the United States, hyponatremia is the primary cause of nonfebrile seizures and may also cause respiratory failure. Keating and colleagues²⁴ reviewed 34 cases of water intoxication in infants and found that an inability to pay for formula was the most common reason given by caretakers for diluting the formula or substituting water.

Risk Factors for Osmotic Demyelination

Several factors appear to increase the treated individual's susceptibility to ODS (see Table 29-1). First, ODS is rarely observed in patients with S_{Na} of more than 120 mEq/L and occurs only if hyponatremia has been present for at least 24 hours and probably for 48 hours. Serum sodium less than 105 mEq/L also increases the risk of this complication. In addition, severely hyponatremic patients with alcoholism, malnutrition, or hypokalemia as well as elderly women taking thiazide diuretics appear to be at increased risk of osmotic demyelination.²⁵ Hypoxia or anoxia may also contribute.¹⁴

TREATMENT STRATEGIES IN HYPONATREMIA

The optimal treatment of hyponatremia involves attention to four factors: (1) the presence of symptoms, (2) the duration of the hypo-osmolality, (3) the volume status, and (4) the degree of hyponatremia.

Urine electrolytes and calculation of electrolyte-free water clearance can help predict how the kidney will handle the salt and water administered during therapy and the changes in serum sodium that ensue. If the urine sodium concentration (U_{Na}) is less than 10 mEq/L, the kidney is sodium avid and the patient will likely retain any sodium that is administered. Conversely, if U_{Na} is more than 50 mEq/L, the kidney will likely excrete any administered sodium, and the concentration at which it excretes this sodium will determine the change in the patient's S_{Na} .

For patients who are euvolemic and who will likely excrete the administered sodium, the electrolyte-free water clearance can be calculated to predict the resultant change in the relative amount of TBW to sodium. Urine flow (V) can be divided into two components. The first component is the urine volume needed to excrete electrolytes at the concentration of electrolytes in plasma (i.e., isotonic). The second component is any remaining urine volume, which represents electrolyte-free water (cH_2Oe). Because sodium and potassium contribute to the osmolality of urine and sodium is the primary determinant of osmolality in serum, the fraction of urine volume that is isotonic can be calculated as:

$$\frac{(U_{Na} + U_K)}{S_{Na}} \quad (\text{Eq. 29-3})$$

The electrolyte-free water can therefore be calculated as:

$$cH_2Oe = V \left[1 - \frac{(U_{Na} + U_K)}{S_{Na}} \right] \quad (\text{Eq. 29-4})$$

The cH_2Oe is negative when $U_{Na} + U_K > S_{Na}$, indicating that the kidney is producing urine with an electrolyte concentration greater than that of plasma. Formation of urine with this composition will tend to decrease the S_{Na} . Conversely, if $U_{Na} + U_K < S_{Na}$, cH_2Oe is positive and S_{Na} will increase.

Treatment of Acute Symptomatic Hyponatremia

In view of the potentially life-threatening complications of acute hyponatremia as described previously, there is a wide consensus that rapid correction of hyponatremia is indicated in patients in whom hyponatremia has developed in less than 48 hours (Fig. 29-1). Generally, the presence of symptoms indicates that hyponatremia has developed too quickly for the adaptive mechanisms to compensate, and symptomatic patients have probably developed hyponatremia over a short period. Because patients who have acutely developed hyponatremia have not had time to adapt to the change in tonicity, they also are at less risk of developing complications from correction of the hyponatremia (ODS).

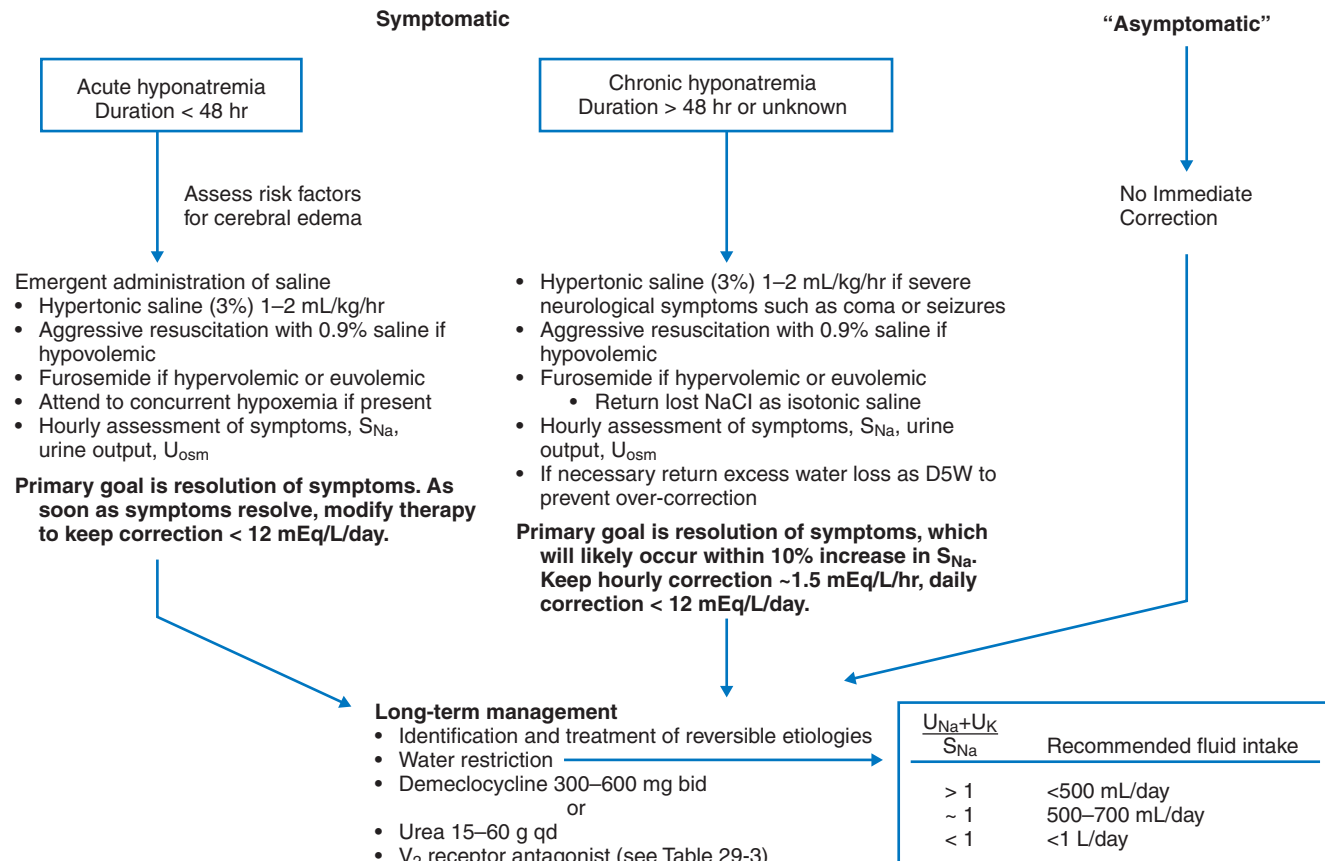

Figure 29-1 Treatment of severe (<125 mEq/L) euvolemic hyponatremia. S_{Na} , serum sodium concentration; U_K , urine potassium concentration; U_{Na} , urine sodium concentration.

Therapy should be initiated immediately in symptomatic patients, particularly in those at increased risk of complications, such as those with hypoxia. For patients with hyponatremia of less than 48 hours' duration and/or risk factors for the development of cerebral edema, treatment is aimed at achieving the following (Box 29-2):

1. Initial sodium administration should increase the serum sodium by approximately 2 mEq/L/hr. A rapid increase in the S_{Na} can be achieved by administering hypertonic saline (3% saline contains 513 mEq/L of Na). Hypertonic saline is often started at 1 to 2 mL/kg/hr. The primary goal for the administration of 3% saline is not the restoration of a sodium deficit but the rapid reversal of potentially life-threatening cerebral edema.
2. For patients in whom the duration is known to be less than 48 hours, full correction is probably safe, but probably should be continued only until symptoms resolve. After that, correction can be slowed to keep the total daily correction at less than 12 mEq/L.
3. Address and correct concurrent hypoxemia.

A clinical case is described to illustrate the approach to such a patient and to highlight the following principles:

1. In the setting of antidiuresis, $U_{Na} + U_K$ can exceed 150 mEq/L, and the electrolyte-free water clearance is negative. Thus, if isotonic saline is infused, the body may excrete the infused sodium in a more concentrated form, possibly even worsening the hyponatremia.
2. The administration of hypertonic saline with furosemide ensures electrolyte-free water excretion while preventing volume expansion.

Case History

A 31-year-old, 60-kg woman with normal preoperative laboratory values underwent an elective hysterectomy with minimal intraoperative blood loss. During a 4-hour period encompassing the surgery and recovery room care, she received 2 L of 0.9% normal saline. Thereafter, 125 mL/hr of 0.45% normal saline was administered. Her total urine output for the 12 hours after surgery was 1500 mL. The patient suffered progressively worsening abdominal pain and intermittent vomiting, for which she received meperidine (Demerol) and prochlorperazine (Compazine).

At 30 hours postoperatively, mental status changes developed and S_{Na} was 114 mEq/L. Her intravenous orders were changed to 200 mL/hr of 0.9% normal saline for 5 hours, during which time the patient's urine output was 750 mL, U_{Na} was 140 mEq/L, and U_K was 60 mEq/L. The patient then had a seizure and respiratory arrest. The repeat S_{Na} was 112 mEq/L.

Case Analysis

Because preoperative S_{Na} was 140 mEq/L and preoperative TBW was 30 L (50% of body weight), rearranging Equation 29-1 gives

$$\begin{aligned} TBW_{Na} + TBW_K &= S_{Na} \times TBW \\ &= 140 \times 30 \\ &= 4200 \text{ mEq} \end{aligned}$$

Postoperatively, when S_{Na} was 114 mEq/L (assuming solute balance), the patient's new TBW would have been:

$$\begin{aligned} TBW &= \frac{(U_{Na} + U_K)}{S_{Na}} \\ &= \frac{4200 \text{ mEq}}{114 \text{ mEq/L}} \\ &= 36.8 \text{ L} \end{aligned}$$

Therefore, a rough estimate of positive water balance would have been $36.8 - 30 = 6.8$ L.

Even after the patient's hyponatremia was recognized and the hypotonic fluids were replaced by isotonic saline, the patient's S_{Na} continued to decrease. The following table is an analysis of water and solute balance during the 5 hours of isotonic saline infusion.

	Water (L)	Solute (Na + K) (mEq)
Intake (0.9% saline at 200 mL/hr)	1.00	150 Na
Output	0.75	105 Na + 45 K
Balance (intake - output)	+0.25	0

Box 29-2 General Guidelines for the Treatment of Symptomatic Hyponatremia

Acute Hyponatremia (duration < 48 hr)

Increase S_{Na} rapidly by ~2 mEq/L/hr until resolution of symptoms
 Full correction probably safe but not necessary
 Limit correction to 12 mEq/24 hr
 Treat coexistent hypoxia

Chronic Hyponatremia (duration > 48 hr)

Initial rapid increase in S_{Na} by 10% or 10 mEq/L
 Perform frequent neurological evaluations; correction rate may be reduced with improvement in symptoms
 At no time after initial increment should correction exceed rate of 1.5 mEq/L/hr or total increment of 12 mEq/L/day
 Hypotonic fluids, and even DDAVP, should be administered to prevent correction in excess of desired daily goal

The sum of urinary cations ($U_{Na} + U_K$) should be less than the concentration of infused sodium to ensure excretion of electrolyte-free water. DDAVP, 1-desamine-8-D-arginine vasopressin; U_{Na} , urine sodium concentration; U_K , urine potassium concentration.

The resultant TBW is now $36.8 + 0.25 = 37.05$ L. The S_{Na} , assuming essentially unchanged solute balance, would be

$$\begin{aligned} S_{Na} &= \frac{(TB_{Na} + TB_{K})}{TBW} \\ &= \frac{4200 \text{ mEq}}{37.05 \text{ L}} \\ &= 113 \text{ mEq/L} \end{aligned}$$

This example illustrates that, in a patient with high AVP levels, the infusion of isotonic saline not only fails to correct hyponatremia but can further aggravate it. The correction of hyponatremia requires the excretion of electrolyte-free water, that is, the sum of urinary sodium and potassium must be less than the sodium of the infusing fluid.

The administration of furosemide promotes such electrolyte-free water excretion. When combined with the infusion of hypertonic saline, S_{Na} can be promptly increased. The following table illustrates what would have happened if the patient had received 100 mL/hr of 3% saline for 2 hours and 40 mg furosemide, with urine output of 1000 mL, U_{Na} 70 mEq/L, and U_{K} 30 mEq/L.

	Water (mL)	Solute (Na + K) (mEq)
Intake (3% saline at 100 mL/hr)	200	100 Na
Output	1000	70 Na + 30 K
Balance (intake - output)	-800	0

Therefore, TBW is $36.8 - 0.8 = 36$ L. Because solute balance is unchanged:

$$\begin{aligned} S_{Na} &= \frac{(TB_{Na} + TB_{K})}{TBW} \\ &= \frac{4200 \text{ mEq}}{36 \text{ L}} \\ &= 117 \text{ mEq/L} \end{aligned}$$

Thus, rather than decreasing, the patient's S_{Na} has increased and has done so at an acceptable rate (~ 2 mEq/L/hr).

Treatment of Chronic Symptomatic Hyponatremia

Symptomatic hyponatremia that has persisted for longer than 48 hours or is of unknown duration must be treated with great caution. Neurological symptoms, such as depressed sensorium or seizures, reflect cerebral dysfunction and the need for some correction, yet overly rapid correction puts the patient at risk of osmotic demyelination (see Fig. 29-1). Various studies have attempted to resolve whether it is the rate or magnitude of correction that determines the risk of complications (Table 29-1). However, these two variables are not readily dissociated because a rapid correction rate is usually accompanied by a greater absolute magnitude of correction over a given time period.

Several animal studies indicate that the daily absolute change may be the primary determinant of the risk of osmotic demyelination and that correction by less than 25 mEq/L in the first 24 hours correlates best with survival. Soupart and colleagues²⁶ showed that in rats corrected over 48 hours, 95% of the hyponatremic animals developed brain lesions when the daily absolute change in S_{Na} reached 20 mEq/L/day. Below this limit, the incidence and severity of brain lesions were very low, even in the group corrected rapidly with bolus injections. In another study, hyponatremic rats treated with rapid correction (2.7 mEq/L/hr) but an absolute change in S_{Na} of less than 25 mEq/L/day had a lower mortality rate (95% survival) compared with rats treated with rapid correction and an absolute change in S_{Na} of more than 25 mEq/L/day (15% survival).²⁷ Verbalis and Martinez²⁸ have shown that in rats with hyponatremia of 19 days' duration, demyelination might be a function of both the rate and magnitude of correction. Demyelination was not observed in any rats in which the maximal correction rate was less than 2.5 mEq/L/hr and the magnitude of increase in S_{Na} was less than 25 mEq/L/day. If either of these limits was exceeded, the demyelination rate was 60%.

What is known about this subject in humans? Obviously, the potentially severe consequences make controlled clinical trials in humans impossible. Most retrospective studies indicate that demyelinating lesions are rare in patients who are corrected at a rate less than 0.5 mEq/L/hr and a magnitude less than 12 mEq/L/day (see Table 29-1). Sterns and colleagues²⁹ reported eight hyponatremic patients who developed the ODS after being corrected by more than 12 mEq/L in 24 hours. In a subsequent study, Sterns²⁵ reviewed 54 patients with chronic hyponatremia who underwent treatment. Seven of these patients developed neurological complications after treatment. Those who developed neurological complications had experienced a wide range of corrections (<0.7 mEq/L/hr in three patients), but all had been corrected by more than 12 mEq/L in 24 hours (mean correction, 17 mEq/L in 24 hours). In another retrospective study of 56 patients, 14 developed neurological complications, although there were no neurological complications in patients corrected by less than 0.55 mEq/L/hr and less than 12 mEq/L/day.³⁰ In a retrospective analysis of the literature, Ayus and colleagues³¹ initially found that patients treated slowly (<0.7 mEq/L/hr) had a greater mortality than those corrected at a rate of 2 mEq/L/hr. However, this was based on case reports that may have included patients with acute hyponatremia, and the deaths were typically due to brain edema and herniation as one would expect with acute hyponatremia corrected too slowly.⁴ In a combined prospective and retrospective analysis of patients with demyelinating lesions, Ayus and colleagues³² later showed that an increase in S_{Na} of more than 25 mEq/L in the initial 48 hours was the primary risk factor for the development of cerebral lesions.

A more recent study by Ayus and Arief³³ also highlights the risks of delaying therapy in symptomatic patients. The outcomes of 53 postmenopausal women with chronic symptomatic hyponatremia were compared based on whether they were treated promptly with saline, treated with saline only after the onset of respiratory insufficiency, or treated with fluid restriction only. The group treated promptly had no long-term neurological sequelae, whereas those whose treatment was delayed until after the onset of respiratory insufficiency had significant morbidity and mortality, particularly in the group treated by fluid restriction alone. Thus, although the rate and magnitude of correction must be controlled, treatment should be initiated promptly.

Table 29-1 Studies of Patients with Chronic Hyponatremia

Ref.	Type of Study	No. of Patients	Initial S _{Na} (mEq/L)	Rate of Correction (mmol/L/hr)	Magnitude of Correction (mmol/L/day)	No. of Patients with Neurological Complications
Sterns et al ²⁹	Retrospective	8 (duration of hyponatremia uncertain)	107		Average 21.5, all corrected > 12	8
	Literature review	51				22/38 of those corrected >12 mmol/L/day; 0/13 corrected <12 mmol/L/day
Sterns ²⁵	Retrospective	54 chronic cases	107	0.59	17 in those with neurological complications	7 (2 had demyelination)
		10 acute cases (defined as 2–4 days)	105	1.57		None
Ayus et al ³²	Prospective	33 (30 of whom had hyponatremia for > 24 hr)	108 ± 1	1.3 ± 0.2 (in 5 patients, correction was 1.6–4.7)	20 ± 1 (2 acute patients were corrected to 27 and 38 mmol/L, raising the average)	None
	Retrospective	12 (four with hepatic encephalopathy and only mild hyponatremia)	107 ± 4	1 ± 0.2	37 ± 3 (over 41 ± 3 hr)	8
	Literature review	17	107 ± 2	0.7 ± 0.1	27 ± 2 (over 39 ± 4 hr)	17 (11 with evidence of demyelination)
Sterns et al ³⁰	Retrospective	56	<105	No complications if <0.55	No complications if <12 mmol/L/day	14
	Prospective	17	111	0.7	14	None
		22	103	0.8	22	14 died or had permanent neurological sequelae
		14	109	0.1	3	11 died, three had permanent neurological sequelae

The question of whether the process that leads to brain demyelination is reversible has significant clinical importance. This issue has been studied by Soupart and colleagues.³⁴ Hyponatremic rats were submitted to an excessive correction (>25 mEq/L) with hypertonic saline during a single intra-peritoneal infusion. This osmotic stress was maintained for 12 hours. Next, hypotonic fluid was administered to maintain the total magnitude of correction at less than 20 mEq/L/day. Mild brain lesions were noted in 20% of the treated group and in 100% of the control rats that did not receive hypotonic fluids. This experiment implies that, at least in animals, subsequent brain damage can be prevented in asymptomatic rats by early lowering of S_{Na} , provided that the final correction is maintained at less than 20 mEq/L/day. Soupart and colleagues³⁵ have also published a case report of a patient with chronic symptomatic hyponatremia who received hypotonic fluid and 1-desamine-8-D-arginine vasopressin (DDAVP) to lower the serum sodium after she had initially been overcorrected. The patient was reported to have had neurological deterioration after the overcorrection, but after the sodium was relowered and allowed to correct slowly, she recovered without neurological deficits. Other similar reports have also been published.^{36,37}

The rate at which S_{Na} will increase depends on the rate of administration and electrolyte content of infused fluids as well as on the rate of production and electrolyte content of urine. The initial increment may be achieved with cautious infusion of hypertonic or normal saline and furosemide, with frequent determinations of S_{Na} and urinary electrolytes. Hypertonic saline is rarely needed in this clinical setting and should be reserved for patients who have seizures. A number of formulas have been put forth to predict the change in serum sodium that would ensue with various saline infusion rates.^{3,38,39} These formulas may be helpful as a guide to initial therapy, but because they fail to account for ongoing renal and extrarenal losses, their use is limited.⁴⁰ Recent attempts to determine the validity of the Adroque-Madias formula³⁸ revealed that it accurately predicts changes in S_{Na} under most clinical settings with a tendency to underestimate the achieved S_{Na} concentration, sometimes by significant amounts.⁴¹ If correction occurs at an inappropriately rapid rate, free water should be administered. After the desired increment is attained, therapy can continue in the form of water restriction.

These data lead us to propose the following guidelines for treating chronic hyponatremia (see Fig. 29-1 and Box 29-2).

1. Correction of S_{Na} should be undertaken without delay in symptomatic patients, particularly those experiencing seizures. Because cerebral water is only increased by approximately 10% in severe chronic hyponatremia, S_{Na} should be increased by 10% or approximately 10 mEq/L over approximately 8 to 12 hours, followed by water restriction. Rapid correction of S_{Na} should only continue until symptoms resolve or until this 10% change is achieved.
2. After the initial correction, the rate should not exceed 1 to 1.5 mEq/L/hr and probably should be less than 0.5 mEq/L/hr.
3. S_{Na} should not be increased by more than 12 mEq/L/day.
4. If the patient has reached the desired rate or magnitude of correction yet is excreting hypotonic urine, hypotonic fluids and even DDAVP can be administered to prevent correction in excess of the desired daily goal. Calculation of the

electrolyte-free water and attention to urine volume can be used to predict the patient's free water requirement.

Example

A 50-kg man with altered mental status is found to have an S_{Na} of 110 mEq/L. The initial goal of therapy is to increase the patient's S_{Na} by 10% or to approximately 120 mEq/L. If the patient is thought to be euvolemic, correction can be achieved via electrolyte-free water excretion without a significant change in total body osmoles.

For men, $TBW \cong 0.6 \times \text{weight (kg)}$. Because the osmoles remain constant, Equation 29.1 can be rearranged to yield:

$$\frac{\text{Desired } S_{Na}}{S_{Na}} = \frac{TBW}{\text{Desired TBW}}$$

Because $TBW = 0.6 \times 50 = 30 \text{ L}$,

$$\begin{aligned} \text{Desired TBW} &= \frac{S_{Na} \times TBW}{\text{Desired } S_{Na}} \\ &= \frac{110 \times 30}{120} \\ &= 27.5 \text{ L} \end{aligned}$$

Therefore, 2.5 L of electrolyte-free water must be excreted. If the water is to be excreted over 10 hours, the urine should contain 250 mL/hr of electrolyte-free water. This can be achieved by administering furosemide and replacing any sodium, potassium, and excess free water lost in the urine. The balance during the first 2 hours is shown in the following table.

	Water (mL)	Solute (Na + K) (mEq)
Intake (500 mL normal saline + 100 mL D5W with 20 mEq KCl)	600	75/20
Output	1000	75/20
Balance	-400	0

D5W, 5% dextrose in water.

Continuing to replace urine electrolyte or excess electrolyte-free water losses, the balance during the subsequent 2 hours is shown in the following table.

	Water (mL)	Solute (Na + K) (mEq)
Intake (400 mL normal saline + 100 mL D5W with 20 mEq KCl)	500	60/20
Output	800	60/25
Balance	-300	-5

D5W, 5% dextrose in water.

The patient's TBW has decreased by approximately 700 mL, total body osmoles are essentially unchanged, and one can estimate S_{Na} as approximately 113 mEq/L.

Asymptomatic Euvolemic Hyponatremia

Even those hyponatremic patients who appear asymptomatic may have subtle neurological findings. For example, one study of such patients found that rigorous examination often detected unsteady gait or attention deficits, and they had a significantly increased risk of falls.⁴² Nevertheless, patients without obvious deficits should be corrected very cautiously as cerebral adaptation has likely occurred (see Fig. 29-1). Nonedematous asymptomatic hyponatremia should invoke a search for reversible causes. If indicated, thyroid or glucocorticoid replacement should be initiated. If the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is present, identification of reversible causes should be undertaken with subsequent removal of offending agents. If the aforementioned strategies are not attainable, then fluid restriction should be prescribed. An initial restriction of 1 L/day is often prescribed. In most patients, this will be adequate to allow net free water excretion. In some patients, however, such an intake still exceeds insensible and urinary losses and does not result in improvement. Furst and colleagues⁴³ described a patient whose S_{Na} decreased from 121 to 117 mEq/L over 24 hours even though his fluid intake was limited to 1 L/day. This patient had a U_{Na} of 100 mEq/L and a U_K of 66 mEq/L and produced 900 mL of urine over the 24 hours. Using Equation 29-4, net electrolyte-free water can be calculated as follows:

$$\begin{aligned} cH_2Oe &= V \left[1 - \frac{(U_{Na} + U_K)}{S_{Na}} \right] \\ &= 0.9 \left[1 - \frac{(100 + 66)}{121} \right] \\ &= -0.33 \text{ L} \end{aligned}$$

Unless his intake is less than insensible losses plus electrolyte-free water excretion (which is negative in this case), his S_{Na} will decrease even more. The authors therefore propose guidelines for therapy based on urine and serum electrolytes (incorporated in Fig. 29-1).

Restricting fluid intake to 1 L/day or less is difficult to attain in the outpatient setting, and pharmacologic therapy may be necessary. SIADH impairs the renal capacity for urine dilution, but pharmacologic agents that impair urinary concentration increase free water excretion.

Lithium carbonate and demeclocycline hydrochloride have been used in the treatment of chronic hyponatremia. The nephrotoxicity and unwanted central nervous system effects of lithium have limited its usefulness. Demeclocycline, however, is safer and effective for the treatment of SIADH.⁴⁴ Administered in doses of 300 to 600 mg twice daily, demeclocycline interferes with the renal action of AVP and promotes maximal water diuresis after 1 to 2 weeks of therapy. To ensure adequate gastrointestinal absorption, the drug should be given at least 1 to 2 hours after eating, and antacids that contain aluminum, calcium, or magnesium

should be avoided. Once diuresis begins, the dose may be tapered to 150 to 300 mg twice daily to minimize toxicity. Additionally, water intake should be allowed to increase, thus preventing diabetes insipidus-induced dehydration. Nephrotoxicity may be observed in patients with liver disease. Azotemia independent of renal function may result from mild antianabolic effects. It may be associated with severe photosensitivity and should not be used in pregnant patients or children due to abnormalities in bone or enamel formation.

Urea has also been used in the treatment of SIADH.⁴⁵ Assume that a patient has an S_{Na} of 134 mEq/L, a fixed urine concentration of 800 mOsm/day, an obligatory solute load of 500 mOsm/day, a dietary sodium intake of 100 mmol/day, and a potassium intake of 40 mmol/day. Calculation of the volume required to excrete the daily solute load at baseline reveals:

$$\begin{aligned} V &= \frac{\text{solute excretion}}{U_{Osm}} \\ &= \frac{500 \text{ mOsm/day}}{800 \text{ mOsm/kg H}_2\text{O}} \\ &= 0.625 \text{ L/day} \end{aligned}$$

Urinary sodium and potassium concentrations can be determined as follows:

$$\begin{aligned} U_{Na} &= 100 \text{ mmol}/0.625 \text{ L} = 160 \text{ mmol/L} \\ U_K &= 40 \text{ mmol}/0.625 \text{ L} = 64 \text{ mmol/L} \end{aligned}$$

These values may then be inserted into Equation 29-4 to compute the electrolyte-free water clearance:

$$\begin{aligned} cH_2Oe &= V \left[1 - \frac{(U_{Na} + U_K)}{S_{Na}} \right] \\ &= 0.625 \left[1 - \frac{(160 + 64)}{134} \right] \\ &= -0.418 \text{ /day} \end{aligned}$$

The negative value for excretion of electrolyte-free water clearance implies net free water absorption, which could worsen hyponatremia.

Under the same conditions, administration of urea (30 g/day) adds approximately 500 mOsm/day to the obligatory solute load that must be excreted. This has a profound effect on electrolyte-free water clearance:

Volume required for excretion of solute load

$$\begin{aligned} &= \frac{1000 \text{ mOsm/day}}{800 \text{ mOsm/kg H}_2\text{O}} \\ &= 1.25 \text{ L/day} \end{aligned}$$

As a result of the increased volume for solute clearance, urinary electrolyte concentrations decrease:

$$\begin{aligned} U_{Na} &= \frac{100 \text{ mmol}}{1.25 \text{ L}} = 80 \text{ mmol/L} \\ U_K &= \frac{40 \text{ mmol}}{1.25 \text{ L}} = 32 \text{ mmol/L} \end{aligned}$$

Note the resultant changes in electrolyte-free water clearance:

$$\begin{aligned} cH_2O_e &= V \left[1 - \frac{(U_{Na} + U_K)}{S_{Na}} \right] \\ &= 1.25 \left[1 - \frac{(80+32)}{134} \right] \\ &= -1.25 (1-0.83) = 0.21 \text{ L/day} \end{aligned}$$

Thus, the administration of urea has altered this patient's water handling from net reabsorption to excretion of electrolyte-free water. Without altering urinary concentration, the increase in urine flow allows for more liberal water intake without the danger of worsening hyponatremia. Urea administration at doses more than 60 g is limited by gastrointestinal adverse effects such as gastric distress and diarrhea. A similar effect can be obtained by increasing salt intake (200 mEq/day) in combination with furosemide. Because this combination is likely to result in high potassium losses, serum potassium needs to be monitored and potassium replacement should be provided.

More recently, several small nonpeptide vasopressin antagonists have been developed that block the function of AVP at the V_2 receptor (Table 29-2). Several studies have demonstrated that they can induce a water diuresis and effectively increase the S_{Na} in patients with SIADH.^{46,47} In the recently published Study of Ascending Levels of Tolvaptan in Hyponatremia I and II (SALT I/II) trials, 91 patients with SIADH were treated with tolvaptan for 30 days, and the S_{Na} in these patients increased by a greater degree than those who received placebo.⁴⁸ In another study,⁴⁹ patients received the oral vasopressin antagonist sataxaptan for 1 year without any major side effects. Conivaptan is the only drug in this class to have U.S. Food and Drug Administration approval for the treatment of euvolemic hyponatremia.^{50,51} It can only be administered intravenously, and it also blocks the V_1 receptor. As there is not yet much experience with these agents, they should be initiated at the lowest available dose. The urine osmolality can be monitored, and the dose can gradually be increased. These drugs should permit easing of the free water restriction and may increase the achievable S_{Na} . At this time, they appear to be safe, and ODS has not been reported. However, with further experience, possible adverse effects may emerge as the use of the drug increases.

Hypovolemic and Hypervolemic Hyponatremia

Hypovolemic hyponatremia results from the loss of both water and solute, with a greater relative loss of solute. The nonosmotic release of AVP in response to reduced effective circulating volume perpetuates the hyponatremia by producing antidiuresis. Patients with this type of hyponatremia are usually asymptomatic, probably because the losses of sodium and water limit the development of cerebral edema. The cornerstone of therapy is the administration of isotonic saline while also treating the underlying disturbance (Box 29-3). Resolution of the volume disturbance removes the stimulus for AVP and restores normal S_{Na} .

Hypervolemic hyponatremia is observed when both water and solute are increased, but water is increased to a greater extent. This condition is very difficult to treat because it often reflects severe irreversible dysfunction of the liver, heart, or kidney. In heart failure, cirrhosis, and nephrotic syndrome, decreased effective arterial volume results in the nonosmotic stimulation of AVP and an increase in thirst. Therefore, compliance with water restriction is difficult. Diuretics are the primary therapeutic agents for edema, but caution must be used in selecting the appropriate regimen. Whereas thiazide diuretics impair urinary dilution and may exacerbate hyponatremia, loop diuretics increase free water excretion and can improve S_{Na} . Correction of the underlying disturbances is usually not attainable.

The vasopressin antagonists can be employed to induce a water diuresis in patients with nonosmotic release of AVP. These agents can reduce the total body water and reduce the need for free water restriction. Because it blocks both the V_1 and V_2 receptors (see Table 29-2), Conivaptan has vasodilatory and aquaretic effects, both of which may be beneficial in congestive heart failure (CHF), although its vasodilatory effects are probably inappropriate for patients with cirrhosis.⁵² It has been shown to decrease the pulmonary capillary wedge pressure in patients with CHF,⁵³ and currently it is approved by the U.S. Food and Drug Administration for the treatment of hypervolemic hyponatremia. The oral V_2 receptor antagonists lixivaptan⁵⁴ and tolvaptan^{48,55} have also successfully been used to induce a water diuresis in patients with CHF. In the recently published Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (EVEREST) trial, patients with CHF and hyponatremia who received tolvaptan had significant increases in their S_{Na} .⁵⁶ However, the drug did not alter long-term all-cause

mortality, cardiovascular mortality, or CHF hospitalizations in the full study cohort, most of whom were not hyponatremic. Vasopressin antagonists have also been successfully used to increase the serum sodium concentration in patients with cirrhosis and dilutional hyponatremia.⁵⁷

Patients with cirrhosis and CHF typically have only mild hyponatremia, and the optimal S_{Na} is not known. The increased TBW associated with hyponatremia in these conditions contributes to vascular congestion,⁵⁸ however, and may also limit the use of diuretics. Furthermore, there is evidence that correction of hyponatremia can improve symptoms and mortality, even beyond the benefits attributable to improvements in the volume status.⁵⁹ Thus, there is reason to expect that the use of vasopressin antagonists may improve outcomes in these patients, but conclusive clinical trials have not yet been performed and the target S_{Na} has not been determined.

THE HYPERNATREMIC PATIENT

Hypernatremia is defined as S_{Na} greater than 146 mEq/L. The presence of hypernatremia implies both extracellular hyperosmolality and, more importantly, hypertonicity, which produces central nervous system injury through cell shrinkage. The reported incidence of hypernatremia ranges from 0.65% to 2.23% of all hospitalized patients. Morbidity and mortality estimates in hypernatremic adults range from 42% to more than 70%, with approximately 10% mortality in chronic hypernatremia compared with 75% mortality in severe acute elevations of S_{Na} (>160 mEq/L). Unfortunately, even in survivors, neurological sequelae are common, especially in children in whom two thirds may show long-term deficits. As with hyponatremia, correcting hypernatremia too rapidly may be as dangerous as allowing the condition to persist.

TREATMENT OF THE HYPERNATREMIC PATIENT

Cerebral Response to Hypernatremia

Cellular dehydration is the primary basis of brain injury, as fluid shifts from the cellular compartment into the extracellular fluid. Neurological symptoms ensue, with initial changes in sensorium potentially culminating in seizures, coma, or death. Although alterations of cellular fluid and solute balance likely contribute to these signs and symptoms, pathologic evidence demonstrates

a variety of underlying anatomic derangements. Loss of brain cell volume places mechanical stress on cerebral vessels and supporting tissues, potentially leading to damage of vascular structures. This is supported by autopsy evidence of hypernatremia-related capillary and venous congestion, subcortical and subarachnoid bleeding, and venous sinus thrombosis.⁶⁰

Cellular adaptation to extracellular hypertonicity results in an increase in intracellular osmolality. This is achieved through events that mirror those described previously for adaptation to hyponatremia. Within seconds, the brain is protected from severe water loss by an increase in cellular sodium, potassium, and chloride content.⁶⁰ Thereafter, cerebral dehydration is further attenuated by the accumulation of osmolytes such as glutamine, glycerolphosphorylcholine, and myo-inositol.⁶¹ As cellular adaptation requires a period of days to reach full effect, the rate and severity of developing hypernatremia alter the degree of cell shrinkage and injury. Because it also takes several days for cells to reverse the accumulation of these organic osmolytes, treatment of chronic hypernatremia requires a gradual reduction of extracellular fluid tonicity to avoid treatment-induced cerebral edema.

Prevention

Hypernatremia occurs in predictable clinical settings (Box 29-4). Elderly persons, hospitalized patients receiving hypertonic infusions, those suffering increased insensible losses or undergoing osmotic losses, those with diabetes, and patients with previous symptoms of polydipsia and polyuria should invoke a high index of suspicion when displaying neurological alterations, especially in periods of stress.

Geriatric patients have impaired thirst responses, decreased urinary concentrating ability, and lower baseline levels of TBW. As a result, elderly patients are the group most likely to develop severe hypernatremia in the outpatient setting, and hypernatremia in the elderly accounts for 1% to 2% of all hospital admissions.⁶² The most common scenario is that of a debilitated patient with a febrile illness. Increased insensible losses are not compensated because of impaired access to free water. Recognition of mental status changes in settings of increased insensible losses should prompt close attention to S_{Na} and increased administration of free water.

Hospitalized patients are also susceptible to the development of hypernatremia. Individuals developing hypernatremia during hospital admission are more likely to be younger and to have an iatrogenic cause.⁶³ In a careful survey of hyponatremia in the intensive care unit, Polderman and colleagues⁶⁴ noted

Box 29-4 Patient Groups at Increased Risk of Development of Severe Hypernatremia

- Elderly patients
- Hospitalized patients
 - Hypertonic infusions
 - Tube feedings
 - Osmotic diuretics
 - Lactulose
 - Mechanical ventilation
- Patients with decreased baseline levels of consciousness
- Patients with uncontrolled diabetes
- Patients with underlying polyuric disorders

that those who acquired the electrolyte disorder in the hospital had longer stays in the intensive care unit and higher mortality. Inpatients with high insensible losses (e.g., patients on mechanical ventilators) develop hypernatremia due to restricted access to water and inadequate fluid prescriptions. Hypertonic fluid administration (e.g., sodium bicarbonate) and osmotic diuretics including mannitol and urea may also result in hypertonicity. Hyperosmolar tube feedings may induce diarrhea and gastrointestinal water losses, and the large daily osmolar load may lead to increased electrolyte-free water losses. Pavlevsky and colleagues⁶³ noted that despite frequent S_{Na} measurements, treatment of hypernatremia was often delayed. Of patients with S_{Na} values more than 150 mEq/L, 50% did not receive hypotonic fluid within 24 hours of becoming hypernatremic and only 36% were corrected within 72 hours.

Patients with both type 1 and 2 diabetes frequently develop hypernatremia in the setting of diabetic ketoacidosis or hyperosmotic nonketotic coma. In both disorders, a relative deficiency in insulin with respect to increased basal requirements produces hyperglycemia and glucosuria. The ensuing osmotic diuresis and decreased fluid intake produce a state of hypovolemic hypernatremia. The S_{Na} must be interpreted with caution because it may not reflect the actual degree of hyperosmolality. Hyperglycemia leads to the translocation of cellular water into the extracellular fluid and may cause a dilutional hyponatremia. New-onset hyperglycemia associated with decreases in mental status should invoke prompt evaluation and therapy of both volume and free water deficits. However, the simultaneous

administration of both insulin and free water can lead to a rapid decrease in extracellular osmolality and can result in cerebral edema.⁶⁵ To prevent an excessively rapid decrease in serum osmolality, isotonic fluids can be used until the serum glucose is only mildly elevated, at which point hypotonic saline can be administered to start correcting the free water deficit.⁶⁶

Polyuric patients should undergo evaluation for defects in urinary concentration because previous knowledge of such disorders can avert serious hypernatremia. In diabetes insipidus, patients compensate for water losses by consuming large amounts of water, thus maintaining relatively normal osmolality. If an illness increases water losses or restricts access to water, hypernatremia will result. Patients at risk of diabetes insipidus include those with central nervous system disease or trauma and those receiving lithium or amphotericin B.

TREATMENT STRATEGIES IN HYPERNATREMIA

The keys to detection and treatment of hypernatremia are (1) recognition of symptoms, when present; (2) correct identification of the underlying defects of water metabolism; (3) correction of volume disturbances; and (4) correction of hypertonicity (Fig. 29-2). Treatment should be initiated promptly to avoid worsening of hypernatremia and increased risk of poor outcome. Once the condition has been stabilized, steps may be taken for long-term prevention.

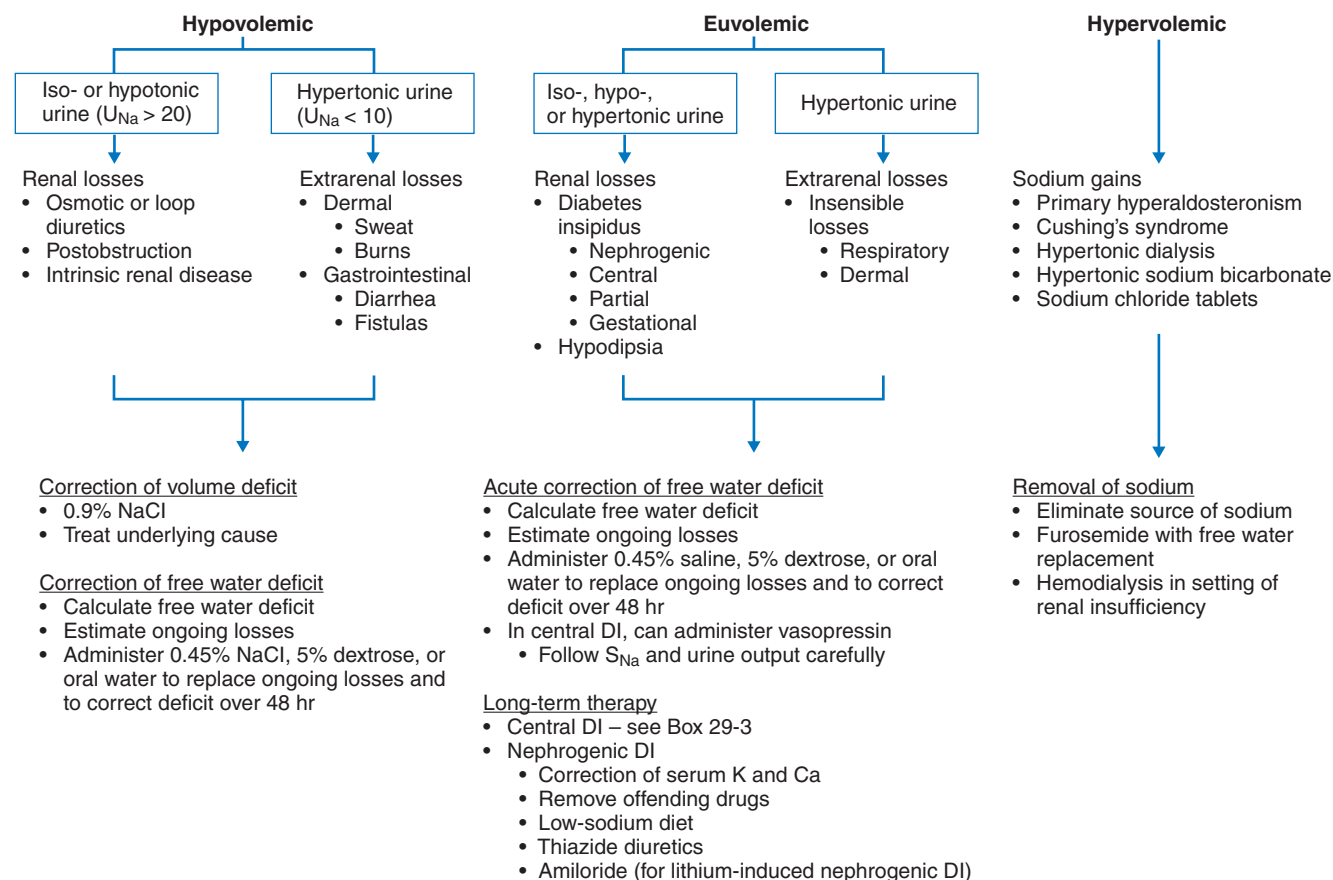

Figure 29-2 Therapeutic approach to hypernatremia. DI, diabetes insipidus.

Box 29-5 General Guidelines for the Treatment of Symptomatic Hypernatremia

Correct at rate of 2 mEq/L/hr
 Replace half calculated water deficit over first 12–24 hr
 Replace remaining deficit over the next 24 hr
 Perform serial neurological examinations; prescribed rate of correction can be decreased with improvement in symptoms
 Perform measurements of serum and urine electrolytes every 1–2 hr

Early signs and symptoms of hypernatremia are nonspecific and primarily manifest as changes in mental status. These include restlessness, irritability, lethargy, confusion, and somnolence. Progression of neurological injury may produce muscular twitching, hyperreflexia, seizures, coma, or even death. If corresponding mechanisms are intact, patients may complain of intense thirst. As previously asserted, mental status changes related to hypernatremia may be difficult to differentiate from neurological manifestations of other underlying illnesses. Therefore, a high index of suspicion is required for consistent diagnosis.

The rate of correction of hypernatremia depends on its rate of development and on the presence or absence of symptoms. As a general rule, the rate of correction should parallel the rate of development. Cerebral adaptation to chronic hypernatremia results in the generation of organic intracellular solutes.⁶¹ If extracellular tonicity is rapidly decreased, water moves into brain cells producing cerebral edema. A slower rate of correction likely prevents these events by allowing time for dissipation of these solutes. Two studies in children suggest that correction of hypernatremia should occur at 0.5 mEq/L/hr or less.^{67,68} No seizures occurred in those corrected at this rate, whereas seizures occurred in nearly 20% of the patients in the group corrected more rapidly. If symptoms are present and the time course of hypernatremia is acute, then rapid correction with resolution of hypernatremia over several hours is appropriate. It is generally recommended that half of the deficit be replaced in 12 to 24 hours as the neurological status is carefully monitored (Box 29-5). Thereafter, the remaining deficit can be corrected during the ensuing 48 hours. The maximum correction rate should not exceed 2 mEq/L/hr. Because ongoing fluid losses are difficult to estimate, frequent determinations of S_{Na} should be made during the course of treatment.

Therapy, like diagnosis, is categorized by extracellular volume status. The chief goals are initial correction of underlying volume disturbances and subsequent correction of hypertonicity.

Euvolemic Hypernatremia

The guiding principles in the treatment of euvolemic hypernatremia are (1) restoration of the water deficit and (2) decrease in ongoing losses of hypotonic fluids.

The presence of such losses is not always obvious. The measurement of urinary osmolality can suggest the excretion of isotonic or even hypertonic urine despite continued electrolyte-free water losses.

For example, a patient has the following laboratory values: $S_{Na} = 146$ mEq/L, $U_{osm} = 320$ mOsm/kg H_2O , $S_{osm} = 310$ mOsm/kg, $U_{Na} = 40$ mEq/L, $U_K = 30$ mEq/L, and urine volume = 2 L. U_{osm} greater than S_{osm} might suggest that no free water is being excreted. However, using Equation 29-4, calculation of electrolyte-free water clearance reveals the following:

$$cH_2O_e = V \left[1 - \frac{(U_{Na} + U_K)}{S_{Na}} \right]$$

$$cH_2O_e = V \left[\frac{70}{146} \right]$$

$$= 2 \text{ L} \times 0.52 = 1.04 \text{ L}$$

Therefore, this individual is excreting more than 1 L of electrolyte-free water during the period of this urine collection. If this water is not replaced, S_{Na} will increase further. Replacement can be with oral cold water or infusion of 5% dextrose in water.

The water deficit can be calculated based on the S_{Na} and the assumption that 60% of body weight is water.

$$\text{Water deficit} = 0.6 \times \text{Body weight} \times \left[\frac{S_{Na}}{140} - 1 \right]$$

For example, the water deficit of a 70-kg male with an S_{Na} of 156 mEq/L would be

$$0.6 \times 70 \times \left[\frac{156}{140} - 1 \right] = 4.8 \text{ L}$$

This is the net positive water balance that needs to be achieved over approximately 48 hours, not including ongoing losses that must also be replaced, as estimated by the electrolyte-free water clearance. The water deficit can be replaced orally or parenterally, using solutions such as 0.45% sodium chloride or 5% dextrose in water (see Box 29-4 and Fig. 29-2). Central diabetes insipidus may be treated by hormone replacement or pharmacologic agents (Table 29-3). In acute settings where renal water losses are extensive, aqueous vasopressin is preferable. Its short duration of action allows for more careful monitoring and decreases the likelihood of complications such as water intoxication. An initial dose of 5 μg may be given subcutaneously, with quantification of its effect on S_{Na} and urine output used to guide additional dosing. Vasopressin activates vascular V_1 receptors and may produce coronary spasm, uterine contraction, gastrointestinal cramping, and pallor. Caution must therefore be used in patients with known coronary artery disease or peripheral vascular disease. In chronic settings, DDAVP is the agent of choice because of its long half-life, diminished V_1 receptor stimulation, and its availability in an oral formulation. It is conveniently administered intranasally in doses of 10 to 20 μg every 12 to 24 hours, and a single dose may induce antidiuresis for 8 to 12 hours. It is also available in 0.1- or 0.2-mg tablets, which can be started at 0.05 mg every 12 to 24 hours and titrated depending on the response. DDAVP may also be given intravenously or subcutaneously, especially during periods of upper respiratory disease or surgery. For patients who are converted from the intranasal to the

Table 29-3 Therapeutic Regimens for the Treatment of Diabetes Insipidus

	Drug	Dose
Complete central diabetes insipidus	DDAVP	10–20 μ g intranasally every 12–24 hr 0.1–0.8 mg orally in divided doses; start with 0.05 mg orally every 12 hr and adjust as needed
Partial central diabetes insipidus	DDAVP	10–20 μ g intranasally every 12–24 hr
	Aqueous vasopressin	5–10 U SC every 4–6 hr
	Chlorpropamide	250–500 mg/day
	Clofibrate	500 mg tid to qid
	Carbamazepine	400–600 mg/day
Nephrogenic diabetes insipidus	Thiazide diuretics	25–50 mg/day
	NSAIDs	Indomethacin 1–2 mg/kg/day
	Amiloride (for lithium-related disease)	5 mg/day
Gestational diabetes insipidus	DDAVP	As above

DDAVP, 1-desamine-8-D-arginine vasopressin; NSAIDs, nonsteroidal anti-inflammatory drugs.

injectable form, the dose should be reduced to 10% of the intranasal administration. Dosing regimens need to be tailored individually, with a bias toward undertreatment. The lowest dose that decreases polyuria to acceptable levels should be used, and the return of polyuria should be noted before repeat dosing to prevent hyponatremia. The drug appears to be safe for use in pregnancy and is resistant to degradation by increased circulating vasopressinases. DDAVP is usually tolerated extremely well, but in very large doses may cause hypertension, headache, and abdominal cramping. Unfortunately, the agent is very expensive, and adjunctive measures may be used to decrease the required dose.

When the quantity of DDAVP available for treatment is limited and in cases of partial central diabetes insipidus, circulating AVP may be increased by pharmacologic agents that potentiate its release. These drugs include chlorpropamide, clofibrate, and carbamazepine. When used alone, these agents are not usually adequate to control polyuria, but when combined with hormonal therapy, decreased solute intake, or diuretic administration, they prove very useful in the treatment of diabetes insipidus. It is interesting that chlorpropamide has been used to normalize S_{Na} by increasing water intake and has also been used to treat primary polydipsia. Although other agents such as thioridazine and benzodiazepines appear to increase water intake, they are not of practical use.

Nephrogenic diabetes insipidus does not respond to increased circulating levels of AVP. Initial therapeutic maneuvers should be focused on identifying reversible etiologies of impaired water conservation and, if possible, correcting them. This includes treatment of hypokalemia, hypercalcemia, or the withdrawal of drugs such as lithium, demeclocycline, glyburide, or colchicine. Because of its therapeutic benefits, lithium may be difficult to discontinue in some bipolar patients. In such cases, amiloride may attenuate water losses by blocking entry of lithium into the collecting tubule cell.⁶⁹ Thiazide diuretics may

decrease polyuria related to nephrogenic diabetes insipidus by reducing the delivery of dilute urine to the distal collecting tubule. This seems to occur by inducing mild extracellular fluid volume contraction with a decreased glomerular filtration rate and increased proximal tubular reabsorption, and by diminishing sodium reabsorption in the diluting segment of the distal nephron. Another method of reducing renal water losses is by reducing oral solute intake in the form of a low-sodium diet. The polyuria of congenital nephrogenic diabetes insipidus may be attenuated by nonsteroidal anti-inflammatory drug-mediated inhibition of cyclooxygenase. Potential future therapies may include agents that modulate the insertion of aquaporin-2 into the tubular epithelial cells.⁷⁰

A rare form of diabetes insipidus may occur during pregnancy. This is related to the production of a vasopressinase by the placenta.⁷¹ These patients respond to treatment with DDAVP, which is not subject to degradation by the enzyme.

Hypovolemic Hyponatremia

When hyponatremia coexists with low TB_{Na} and physical evidence of hypovolemia, the primary goal is fluid resuscitation because the extracellular fluid volume contraction may be more life threatening than the hypertonicity. Such patients should receive initial therapy with normal saline or other plasma expanders until signs of hypovolemia are no longer present. In states of hyponatremia, isotonic saline is actually hypotonic compared with the existing extracellular fluid and can lower plasma osmolality, although not significantly. Serial examinations of volume status should demonstrate the return of normal neck veins and improvement of orthostatic hypotension or tachycardia. Once intravascular volume depletion has been corrected, administration of 0.45% saline or 5% dextrose may be used for further correction of hypertonicity.

Hypervolemic Hyponatremia

When the patient is hypervolemic and hyponatremic, the therapeutic goal is to remove the excess sodium. Natriuresis is likely to be present if renal function is normal but can be further enhanced by diuretics such as furosemide with 5% dextrose. Care must be taken not to reduce S_{Na} too rapidly with concomitant diuretic and hypotonic fluid administration. The rate of urine flow and calculation of electrolyte-free water clearance can help estimate free water requirements. If renal function is impaired, volume overload and hypertonicity may require treatment by dialysis.

CONCLUDING REMARKS	365

BRIEF OVERVIEW OF K⁺ PHYSIOLOGY

It is important to recognize at the outset that hyperkalemia or hypokalemia are common laboratory findings in a heterogeneous group of disorders. Therefore, it is not appropriate to have a “one-size-fits-all” recommendation for therapy that will apply to all patients with these electrolyte disorders. Accordingly, our objective is to provide an approach to therapy that is based on the pathophysiology of the disorder in an individual patient.^{1,2} There are three areas of emphasis: First, one must define and deal with emergencies that are present when the patient seeks medical attention (with regard to the dyskalemias, the dangers usually are due to cardiac arrhythmia or respiratory muscle weakness). Second, one needs to anticipate and prevent risks that may be caused by the initial therapy. Third, in the long term, measures need to be taken to return the potassium (K⁺) level in body compartments to normal and reverse the abnormal physiologic processes. Overviews of two aspects of K⁺ physiology are outlined briefly to provide the background needed for the design of therapy: first, the events at the interface between the extracel-

lular fluid (ECF) and the intracellular fluid (ICF) compartments (control of the transcellular distribution of K⁺) and second, the concepts concerning the regulation of renal K⁺ excretion.

Interface between Extracellular Fluid and Intracellular Fluid

K⁺ ions are retained inside cells by a negative voltage. When this voltage becomes more negative, K⁺ will shift into cells; the converse is also true. The electrogenic cation pump, the Na⁺/K⁺-ATPase (Na/K-ATPase) generates this negative voltage by pumping out three Na⁺ ions while importing only two K⁺ ions; hence, there is an export of one third of a positive charge per Na⁺ that exits from the cell via this pump.³ It follows that an abnormal shift of K⁺ across cell membranes can be anticipated when the activity of the Na/K-ATPase deviates from its expected physiology; this is usually due to altered hormone levels. The main hormones that cause a shift of K⁺ into cells are β₂-adrenergic agonists, insulin, and thyroid hormone; aldosterone may also cause a shift of K⁺ into cells when given to

patients who lack this hormone. The Na/K-ATPase is activated directly by β_2 -adrenergics, which phosphorylate the Na/K-ATPase, whereas thyroid hormone increases the number of the Na/K-ATPase units in the cell membrane. Flux through the Na/K-ATPase will increase substantially when more Na^+ enters cells. For this to result in an increase in the negative voltage inside cells, the entry of Na^+ must be electroneutral; this occurs when Na^+ enters the cell via the Na^+/H^+ ion exchanger (NHE) (Fig. 30-1).⁴

It appears that the NHE is normally inactive in cells; this can be deduced from the fact that the concentrations of its substrates (Na^+ in the ECF compartment and H^+ in the ICF compartment) are considerably higher than those of its products (Na^+ in the ICF compartment and H^+ in the ECF compartment) at steady state (see Fig. 30-1). There are two major activators of the NHE: insulin and a higher concentration of H^+ in the ICF compartment.

Renal Regulation

Control of the rate of K^+ excretion occurs primarily in the late cortical distal nephron, including the cortical collecting duct (CCD).⁵ The excretion of a large quantity of K^+ requires a high flow rate in the CCD. A lumen-negative transepithelial voltage must be generated and open K^+ channels must be present in the apical membranes of the principal cells in this nephron segment to secrete K^+ . To generate this voltage, the

Figure 30-1 Na/K-ATPase activity and the creation of an intracellular negative voltage. The Na/K-ATPase generates the electrical driving force for K^+ entry into cells providing that the source of the Na^+ pumped out was either Na^+ that existed in cells or Na^+ that entered cells in an electroneutral fashion via the NHE (Na^+/H^+ ion exchanger). Two hormones that cause more Na^+ pumping by the Na/K-ATPase are shown; the first is insulin, which activates the NHE, and the second is catecholamines (β_2 -adrenergic actions), which activate the Na/K-ATPase by phosphorylation. The increase in negative voltage in cells will diminish the exit of K^+ from cells via K^+ channels. ADP, adenosine diphosphate; ATP, adenosine triphosphate. (From Halperin ML: *The ACID Truth and Basic Facts: With a Sweet Touch, an enLYTEment*, 5th ed. Toronto, Ontario: RossMark Medical Publishers, 2004, with permission.)

reabsorption of Na^+ must occur at a faster rate than the accompanying anion (chloride [Cl^-]).² The pathway for Na^+ reabsorption is via an epithelial Na^+ channel (ENaC) in the apical membrane of principal cells.⁶ Stimulation of the reabsorption of Na^+ and/or the secretion of K^+ is influenced to a major extent by the hormone aldosterone,⁷

CLINICAL ASSESSMENT OF THE CONCENTRATION OF K^+ IN THE CORTICAL COLLECTING DUCT

The two parameters affecting the net secretion of K^+ in the CCD can be assessed in a semiquantitative fashion as illustrated in Figure 30-2 (Equation 30-1).⁸ To estimate the concentration of K^+ in fluid traversing the terminal CCD ($[\text{K}^+]_{\text{CCD}}$), one needs to adjust the measured concentration of K^+ in the urine (U_{K}) for the reabsorption of water in the medullary collecting duct. This can be done by dividing U_{K} by the ratio of the urine osmolality to osmolality in fluid exiting the terminal CCD (equal to the plasma osmolality when vasopressin acts) (Equation 30-1). A

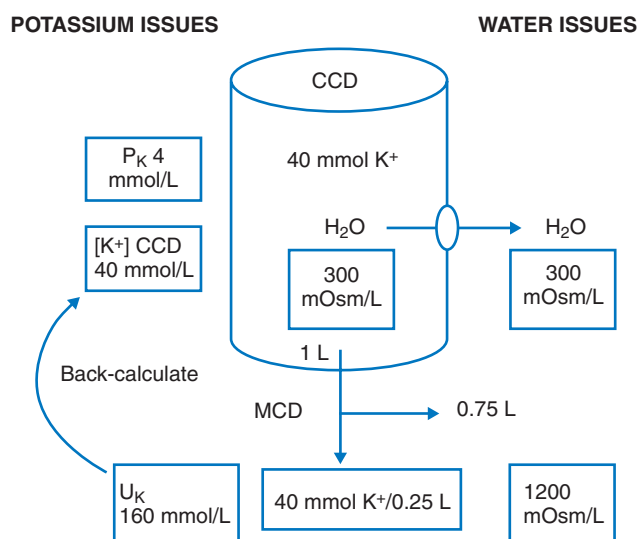

Figure 30-2 Assessment of components of K^+ excretion in the cortical collecting duct (CCD). The barrel-shaped structures represent the CCD and the arrow below it is the medullary collecting duct (MCD). In this example, the luminal K^+ concentration in the CCD is 40 mmol/L or 10-fold greater than the peritubular K^+ concentration of 4.0 mmol/L (equal to the plasma potassium concentration [P_{K}]). When 1 L of fluid traverses the MCD and 75% of the water is reabsorbed, if no K^+ is reabsorbed or secreted in the MCD, the potassium concentration in the urine (U_{K}) and the urine osmolality are both fourfold higher (U_{K} increases from 40 to 160 mmol/L; urine osmolality increases from 300 mOsm/kg H_2O (equal to the plasma osmolality when vasopressin acts) to 1200 mOsm/kg H_2O). This should be taken into account in assessing the $[\text{K}^+]_{\text{CCD}}$. Similarly, an estimate of the minimum flow rate in the terminal CCD can be obtained by dividing the osmole excretion rate by the plasma osmolality. (From Halperin ML: *The ACID Truth and Basic Facts: With a Sweet Touch, an enLYTEment*, 5th ed. Toronto, Ontario: RossMark Medical Publishers, 2004, with permission.)

similar calculation is done to estimate the flow rate in the terminal CCD (Equation 30-2). One premise in these calculations is the absence of a large reabsorption of osmoles in the medullary collecting duct. While this is true for electrolyte, it may be not the case for urea, as recent findings suggest that the amount of urea that is delivered to the distal convoluted tubule is about threefold larger than that excreted in the urine. Although there are no normal values for the excretion of K^+ in steady state because normal subjects excrete all the K^+ that they ingest, there are expected responses in the presence of hypokalemia or hyperkalemia; the expected value in a patient with hypokalemia is less than 15 mmol/day ($U_K/U_{\text{creatinine}} < 1.5$ in mmol/mmol terms), and in a patient with hyperkalemia is more than 200 mmol/day ($U_K/U_{\text{creatinine}} > 20$ in mmol/mmol terms)

$$[K^+]_{\text{CCD}} = U_K/(U/P)_{\text{osm}} \quad (\text{Eq. 30-1})$$

$$\text{Flow rate}_{\text{CCD}} = \text{osmole excretion rate}/P_{\text{osm}} \quad (\text{Eq. 30-2})$$

Hypokalemia with a High $[K^+]_{\text{CCD}}$

The usual value for the $[K^+]_{\text{CCD}}$ is less than 6 and that for the transtubular potassium gradient is less than 2 if hypokalemia is of nonrenal origin. A $[K^+]_{\text{CCD}}$ that is inappropriately high for the presence of hypokalemia indicates a higher luminal negative voltage in CCD due to a higher rate of electrogenic Na^+ reabsorption (and/or an altered K^+ conductance). We divide these patients into two subgroups based on their renal handling of Na^+ .¹ The first one is a primary lesion affecting Na^+ where the reabsorption of Na^+ is accelerated. In this setting, the effective arterial blood volume is expanded, renin activity in plasma is low (with exception of conditions such as renal artery stenosis and renin-secreting tumors), and there is an ability to have low concentrations of Na^+ and Cl^- in the urine, but only when the ECF volume is contracted. In the second subgroup, there is slower reabsorption of Cl^- . It is characterized by a contracted effective arterial blood volume and high renin activity in plasma.

Faster Reabsorption of Na^+

When there is an increase in the number of open ENaC units in the luminal membrane of the cortical distal nephron, the lumen could become more electronegative. Causes of an overabundance of active ENaCs in the luminal membrane of principal cells include an inborn error (e.g., Liddle syndrome), the presence of too much aldosterone (e.g., primary hyperreninemic hyperaldosteronism, primary hyperaldosteronism, glucocorticoid-remediable aldosteronism, and drugs or hormones that have mineralocorticoid actions). Cortisol may act as a mineralocorticoid when there is insufficient activity of the enzyme 11β -hydroxysteroid dehydrogenase in principal cells, which converts intracellular cortisol to its inactive metabolite cortisone.⁹ This occurs when there is massive overproduction (or administration of large doses) of cortisol, when inhibitors of this enzyme are present (e.g., by glycyrrhizic acid from licorice¹⁰ or carbenoxolone) or if there are inborn errors that diminish the activity of 11β -hydroxysteroid dehydrogenase (apparent mineralocorticoid excess).

Slower Reabsorption of Cl^-

A slower Cl^- type of lesion may be due to a low distal delivery of Cl^- to the CCD or the presence of luminal HCO_3^- and/or an alkaline luminal fluid, which seems to decrease the reabsorption of Cl^- in the CCD.¹¹ A slower Cl^- type of lesion may

also be due to a large increase in the delivery of Na^+ and Cl^- to the CCD along with a retained stimulus for the reabsorption of Na^+ via ENaCs due to the continuing presence of aldosterone (a low effective arterial blood volume); hence, the rate of reabsorption of Na^+ by ENaCs exceeds that for Cl^- (see Fig. 30-2). Examples include the use of diuretics or diseases such as Bartter and Gitelman's syndromes in which there is inhibition of $NaCl$ reabsorption at a site upstream of a CCD.

Hyperkalemia with a Low $[K^+]_{\text{CCD}}$

The usual value for the $[K^+]_{\text{CCD}}$ is greater than 30 and that of the transtubular potassium is greater than 7 gradient if hyperkalemia is of nonrenal origin. The $[K^+]_{\text{CCD}}$ that is inappropriately low for the presence of hyperkalemia usually indicates that there is a smaller negative luminal voltage in CCD, which is almost always due to a decreased electrogenic reabsorption of Na^+ ; rarely, the major problem can be lower K^+ conductance in these nephron segments. We divide patients into two subgroups based on their renal handling of Na^+ . In the first subgroup, the Na^+ reabsorption is slower in the CCD in which the effective arterial blood volume is contracted, the renin activity in plasma is high, and there is an inability to have low concentrations of Na^+ and Cl^- in the urine when the effective arterial blood volume is contracted. In the second subgroup, there is faster reabsorption of Cl^- . It is characterized by an expanded effective arterial blood volume, low renin activity in plasma, and an ability to have low concentrations of Na^+ and Cl^- in the urine when the effective arterial blood volume is contracted.

Slower Reabsorption of Na^+

This disorder can be seen in a number of settings. Examples include when there is an inborn error that decreases the availability of ENaCs (e.g., pseudohypoaldosteronism type I), low production of aldosterone (e.g., Addison's disease), drugs that interfere with the synthesis of aldosterone (e.g., nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, heparin, and ketoconazole), blockers of the aldosterone receptor in principal cells of the cortical distal nephron (e.g., spironolactone), ENaCs inhibited by luminal acting K^+ -sparing diuretics (e.g., amiloride, triamterene), and when certain drugs block ENaCs (e.g., trimethoprim and pentamidine).

Faster Reabsorption of Cl^-

There are two possible reasons for having the reabsorption of Na^+ fail to exceed that of Cl^- in the late cortical distal nephron. First, there could be an increased permeability for Cl^- in the late cortical distal nephron (i.e., a Cl shunt disorder).¹² Examples may include the hyperkalemia in some patients with type 2 diabetes mellitus and patients on cyclosporine or tacrolimus. Second, there could be an enhanced reabsorption of Na^+ and Cl^- in the distal convoluted tubule, which diminishes the delivery of Na^+ and Cl^- to the late cortical distal nephron (called Gordon's syndrome). The molecular basis for this latter disorder has been attributed to deletions in the genes encoding for WNK kinase-1 and WNK kinase-4 (WNK stands for "with no lysine" [K is the abbreviation for lysine]).¹³

HYPOKALEMIA

General Considerations for the Treatment of Hypokalemia

Causes of hypokalemia are listed in Box 30-1. The steps to take in the treatment of patients with an emergency related to hypokalemia are illustrated in Figure 30-3.

Box 30-1 Causes of Hypokalemia

Decreased Intake of K⁺

Rarely a primary cause unless K⁺ intake is very low and duration is prolonged
Can augment the degree of hypokalemia if there is ongoing K⁺ loss

Shift of K⁺ into Cells

Hormones (insulin and β-adrenergics are the most important ones)
Metabolic alkalosis
Anabolic state (e.g., recovery from diabetic ketoacidosis)
Other (anesthesia, hereditary hypokalemic periodic paralysis)

Increased Urine K⁺ Loss

High [K⁺]_{CCD}
Faster reabsorption of Na⁺ in the CCD
Constitutively active epithelial Na⁺ channel (ENaC) (e.g., Liddle syndrome), artificial ENaC (e.g., amphotericin B)

Medical Emergencies

There are two potentially life-threatening circumstances that require aggressive therapy: The most common is a cardiac arrhythmia and the other is extreme weakness involving the respiratory muscles, especially when respiratory acidosis or metabolic acidosis (e.g., distal renal tubular acidosis due to a low rate of secretion of H⁺ or an accelerated secretion of HCO₃⁻ in the distal neph-

High aldosterone levels

Cortisol acts as a mineralocorticoid

Low 11β-hydroxysteroid dehydrogenase activity (apparent mineralocorticoid excess), inhibitors of 11β-hydroxysteroid dehydrogenase (e.g., licorice), very high cortisol level (e.g., corticotropin-producing tumor)

Relatively slower reabsorption of Cl⁻ in the CCD

Delivery of Na⁺ without Cl⁻ to the CCD and a contracted effective arterial blood volume

Inhibition of Cl⁻ reabsorption in the CCD (e.g., bicarbonaturia)

High delivery of Na⁺ and Cl⁻ to the CCD and a maximum rate of Na⁺ reabsorption that exceeds that for Cl⁻ (e.g., states with inhibition of NaCl reabsorption of an upstream nephron segment plus effective arterial blood volume contraction, e.g., use of diuretics, Bartter or Gitelman's syndrome)

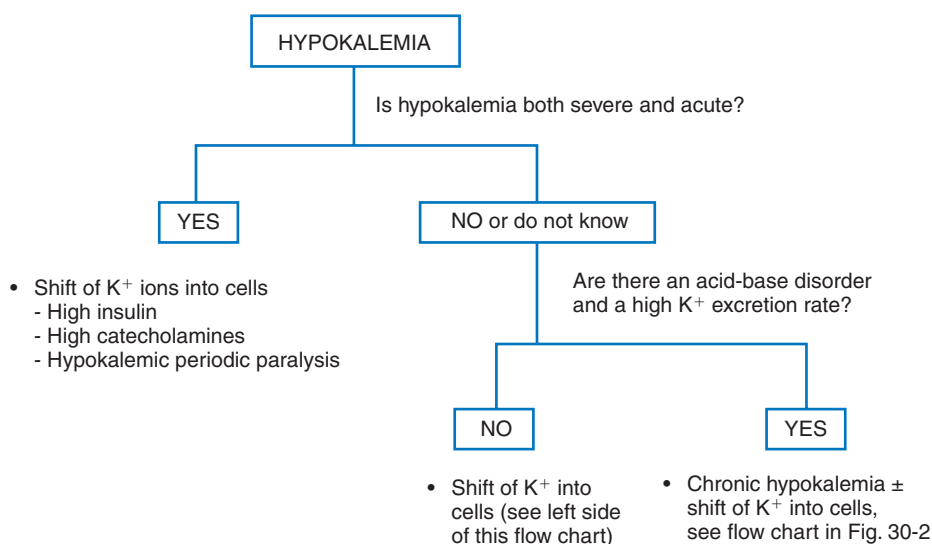

Figure 30-3 Initial approach to the patient with hypokalemia. The initial aim is to determine whether there is a major component of shift of K⁺ into cells. This is suggested from the time course and a clinical history of the presence of factors associated with a shift of K⁺ into cells. Laboratory assessment of the rate of excretion of K⁺ and the presence of an acid-base disorder help to confirm this diagnosis. (From Halperin ML: *The ACID Truth and Basic Facts: With a Sweet Touch, an enLYTEment*, 5th ed. Toronto, Ontario: RossMark Medical Publishers, 2004, with permission.)

ron or severe diarrhea) is present. Having decided that hypokalemia requires urgent therapy, enough K^+ must be given to increase the plasma K^+ concentration (P_K) quickly and to a high enough level (~ 3.0 mM) to avert these dangers; the total K^+ deficit should be replaced *much* more slowly. Because large doses and a high concentration of K^+ may need to be infused at the outset, K^+ must be administered via a large central vein and the patient should be connected to a cardiac monitor. Unless otherwise indicated, the infusion should not contain glucose or HCO_3^- because this may lead to a shift of K^+ into cells, which may aggravate an already severe degree of hypokalemia.

Illustrative Example

A patient fell from a great height and sustained a serious head injury.¹⁴ While in the intensive care unit, his P_K decreased to 1.3 mmol/L over 30 minutes, and this led to a ventricular tachycardia. This sudden and marked shift of K^+ into cells was likely due to the extreme adrenergic response from the head injury and the administration of adrenergic agents to support his hemodynamic state. In this setting, we would try to increase his P_K by 1 mmol/L in 1 minute, recognizing the fact that the increase would be much smaller in the interstitial fluid bathing cardiac myocytes. Therefore, we would infuse 3 mmol K^+ /min for the first 5 minutes (blood volume: 5 L; cardiac output: 5 L/min; 60% of blood volume is plasma, i.e., 3 L). At this time, we would decrease the rate of infusion of K^+ to 1 mmol/min and measure the P_K (stopping the infusion for 60 seconds to avoid a spuriously high P_K). If the electrocardiographic changes did not improve and there was little increase in the P_K , we would repeat this procedure.

No Medical Emergency

The initial emphasis in our approach to patients with hypokalemia is to determine whether there is an important shift of K^+ into cells; the steps to take are shown in Figure 30-3. Conversely, if the problem is due to an excessive excretion of K^+ , the diagnostic approach differs and the steps are illustrated in Figure 30-4. In both of these categories, there is no generic therapy for hypokalemia because this is a finding rather than a specific disease. There is a different emphasis in the therapy of patients who have hypokalemia due to a shift of K^+ into cells (Fig. 30-5). Because these patients do not have a large deficit of K^+ , we begin by discussing our management of these patients. This is followed by general comments about replacing a large deficit of K^+ and concluded with a discussion of specific therapy for some of the common disorders that are associated with hypokalemia.

Hypokalemic Periodic Paralysis

Typically, these patients have very low rates of K^+ excretion and they do not have an acid-base disorder.¹⁵ In the Western world, most cases of hypokalemic periodic paralysis are sporadic or familial and therapy is simply to infuse enough KCl to increase the P_K to more than 3.0 mmol/L. A high-carbohydrate meal or an adrenergic surge may precipitate the attack. In contrast, Asian patients are most frequently young males who have hyperthyroidism. Other causes of an attack of hypokalemic periodic paralysis include a high and prolonged adrenergic surge, the use of amphetamines, or a very large intake of beverages containing caffeine.¹⁶ The most important issue for therapy is to decide whether an adrenergic

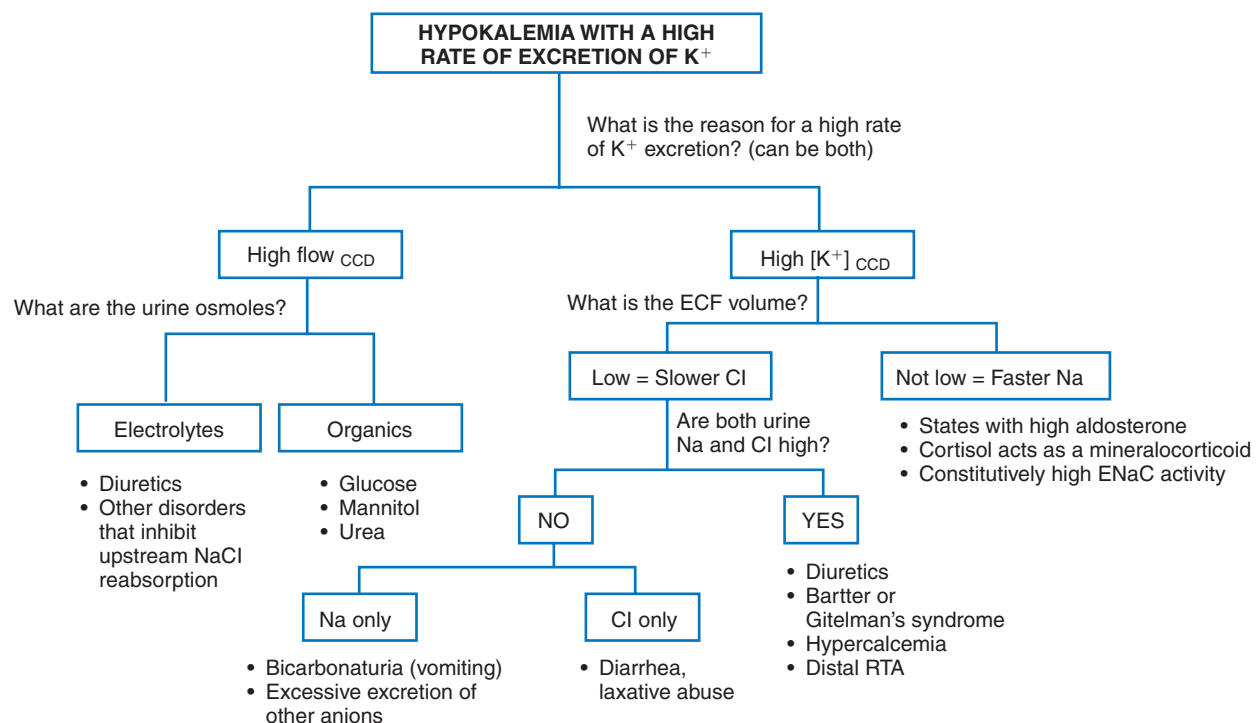

Figure 30-4 Renal causes of hypokalemia and a low rate of excretion of K^+ . Assessment of the components of K^+ excretion in the cortical collecting duct (CCD) is obtained by back-calculating the flow rate and the concentration of K^+ in the urine to values in fluid traversing the terminal CCD, as shown in Figure 30-2. A list of likely causes of a high rate of excretion of K^+ is provided below the diagnostic categories. ECF, extracellular fluid; ENaC, epithelial Na channel; RTA, renal tubular acidosis. (From Halperin ML: *The ACID Truth and Basic Facts: With a Sweet Touch, an enLYTEnment*, 5th ed. Toronto, Ontario: RossMark Medical Publishers, 2004, with permission.)

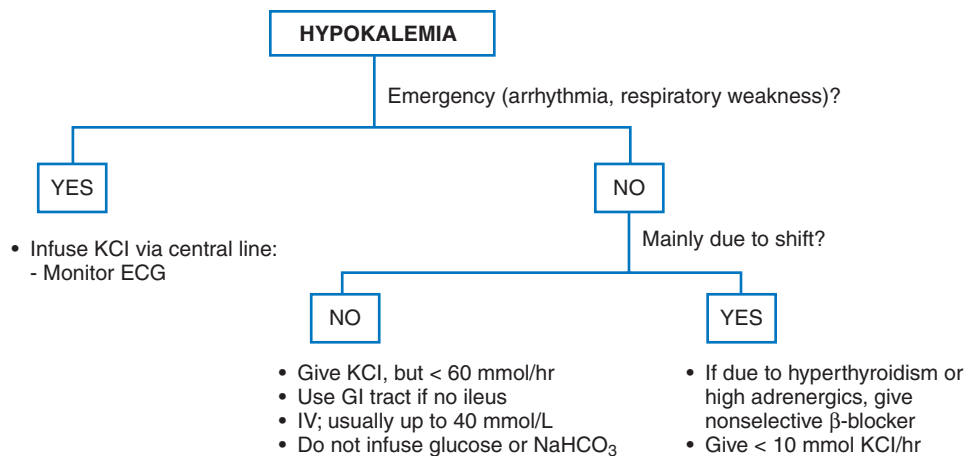

Figure 30-5 Treatment of the patient with hypokalemia. If an emergency is present (usually cardiac), intravenous KCl must be given promptly, and this usually means via a central vein. The electrocardiogram (ECG) must be monitored to guide therapy. Longer term strategies are to determine whether there is an important shift of K^+ into cells, especially if its cause is too much adrenaline or hyperthyroidism as the treatment now is with a nonselective β -blocker and much lower doses of KCl. In other settings, the goal is to administer sufficient KCl, and the oral route is preferred. If given in a peripheral vein, the K^+ should not exceed 40 mmol/L. In either case, and the amount given should not usually exceed 60 mmol/L/hr. Substances that cause K^+ to shift into cells such as glucose, via the release of insulin and $NaHCO_3$, should not be given at this stage of therapy. GI, gastrointestinal. (From Halperin ML: *The ACID Truth and Basic Facts: With a Sweet Touch, an enLYTement*, 5th ed. Toronto, Ontario: RossMark Medical Publishers, 2004, with permission.)

surge may be the cause of the hypokalemia. This is suggested by findings such as tachycardia and a wide pulse pressure on physical examination. Plasma phosphate levels are usually low. If that were the case, we would administer a nonselective β -blocker (propranolol 3 mg/kg) as their first-line treatment, especially if the patient had thyrotoxic hypokalemic periodic paralysis because it can cause a prompt increase in P_K (within 2 hours).¹⁷ If effective, much smaller doses of KCl may be needed for therapy. In retrospective, case-controlled studies, rebound hyperkalemia (>5.0 mmol/L) was observed in 30% to 70% of patients with thyrotoxic hypokalemic periodic paralysis if more than 90 mmol of KCl were given within 24 hours or at a rate of more than 10 mmol/hr.¹⁸ Hence we prefer to give less than this amount unless the P_K fails to increase to a safe level of approximately 3 mmol/L. Acetazolamide may be useful to prevent attacks of hypokalemic periodic paralysis patients with the sporadic or familial types of this disorder; nevertheless, its mechanism of action is not clear.

Specific Issues in K^+ Replacement Therapy

Magnitude of the K^+ Deficit

It is common practice to infer that there is a deficit of 100 to 400 mmol K^+ if the P_K has decreased from 4.0 to 3.0 mmol/L and that a P_K of 2 mmol/L suggests that there is a much greater deficit of K^+ (as high as 800 mmol in a 70-kg adult). However, this is not supported with solid data because a component of the hypokalemia is due to a shift of K^+ into cells in many patients. In our view, there is no useful quantitative relationship between P_K and the total body K^+ deficit in an individual patient. Hence, careful monitoring of P_K during replacement of the K^+ deficit is mandatory.

Route of K^+ Administration

The oral route is the preferred one to administer K^+ . Certain factors may necessitate using the intravenous route, including the urgency of therapy, the level of consciousness, and the presence of gastrointestinal problems. As a rule, the concentration of K^+ should not be more than 40 mmol/L if infused peripherally because higher K^+ concentrations may irritate veins with a lower rate of blood flow; the rate of administration of K^+ should not exceed 60 mmol/hr in most settings.

K^+ Preparations

Most preparations that are in tablet form release K^+ slowly (Table 30-1). Although usually well tolerated, they occasionally cause ulcerative or stenotic lesions in the gastrointestinal tract due to a high local K^+ concentration. Oral KCl can also be given in a crystalline form (e.g., salt substitutes such as Co-salt (equal amounts of NaCl and KCl), which provide 14 mmol K^+ /g); this is generally well tolerated and is an inexpensive form of K^+ supplementation.

For electroneutrality, a deficit of K^+ must be accompanied by the loss of Cl^- or HCO_3^- or a gain of Na^+ . With a KCl deficit (e.g., due to chronic vomiting or diuretic use), KCl is needed; in contrast, with a $KHCO_3$ deficit (e.g., due to diarrhea), K^+ with HCO_3^- (or a HCO_3^- equivalent, e.g., citrate) is needed. A note of caution is necessary: The administration of HCO_3^- may cause a shift of K^+ into cells in certain settings. Therefore, in a patient who is markedly hypokalemic and acidemic, KCl should be given initially; alkali in the form of $NaHCO_3$ may then be administered after the P_K approaches a safer level (>3 mmol/L). In conditions in which K^+ loss is matched by Na^+ retention (e.g., in a patient with primary hyperaldosteronism), K^+ is usually given as KCl while measures are taken to ensure that NaCl

Table 30-1 Commonly Used Potassium Supplements

	K ⁺ Salt	Unit
Oral Preparations		
Apo-K	KCl	8 mEq/tablet

will be excreted. The need for K⁺ as its phosphate salt is most evident when there is rapid anabolism; examples include patients on nutritional support or those in the acute recovery phase of a catabolic disorder such as diabetic ketoacidosis. If given, phosphate should not be administered too rapidly (<50 mmol in 8 hours) because a large phosphate load has the risk of inducing metastatic calcification and hypocalcemia. We give K⁺ as KCl in the treatment of patients who have diabetic ketoacidosis and rely on the patient's diet to supply the phosphate needed for the anabolic phase of the illness, which occurs later.

Although it may seem reasonable on superficial analysis to increase the intake of K⁺-rich foods (e.g., bananas, fruit juice), this is not an effective way to replace a K⁺ deficit. A few centimeters of banana provides only about 1 mmol of K⁺, so it will take a true banana lover to consume enough bananas to provide 50 mmol K⁺ each day. The calories in this quantity of bananas could add 22.5 to 45 kg to the patient's body weight in a year. Conversely, a large amount of K⁺ can be obtained through dietary means by ingesting vegetables, which have a high ratio of potassium to calories.

Adjuncts to Therapy

Administering K⁺-sparing diuretics to patients with hypokalemia can decrease renal loss of K⁺. However, this is only useful on a long-term therapy basis and not during the treatment of acute hypokalemia, when the rate of K⁺ excretion is usually less than 10 mmol/hr. Amiloride and triamterene are better tolerated than spironolactone because they lack the gastrointestinal and hormonal complications of spironolactone (amenorrhea, gynecostasia, decreased libido). Eplerenone is a highly selective mineralocorticoid receptor antagonist that is associated with a lower incidence of endocrine side effects, but is also significantly more expensive than spironolactone.¹⁹ When using the ENaC blockers amiloride and triamterene, the patient should have a low intake

of NaCl because this leads to a lower delivery of osmoles to the CCD and thereby a lower flow rate.²⁰ With a lower flow rate, the concentration of the drug near the ENaC will be higher. There is an important note of caution; hyperkalemia can develop when K⁺ is given along with K⁺-sparing diuretics, especially if other conditions that may compromise K⁺ excretion are present; it should also be recognized that these drugs have a long half-life.

Risks of Therapy

With prolonged hypokalemia, the CCD may become hyporesponsive to the kaliuretic effect of aldosterone (probably due to fewer luminal K⁺ ion channels for the secretion of K⁺); this would allow aldosterone to continue to be a NaCl-retaining hormone while diminishing its kaliuretic effect.²¹ Hence, it is important to monitor the P_K frequently during the treatment of hypokalemia.

Hyperkalemia has been observed in approximately 4% of patients taking K⁺ supplements. The risk is highest in patients with renal failure and diabetes mellitus. The simultaneous use of angiotensin-converting enzyme inhibitors, β-blockers, or nonsteroidal anti-inflammatory drugs may also predispose to the development of hyperkalemia.

Specific Causes of Hypokalemia

A summary of the causes of hypokalemia is provided in Box 30-1. We only comment briefly on those that are common or because new strides have been made in understanding their pathophysiology, which have implications for therapy. A summary of the specific issues in therapy of these disorders is provided in Table 30-2.

Diuretic-Induced Hypokalemia

When hypokalemia develops in this setting, it is usually modest in degree.²² A decrease in P_K to less than 3 mmol/L occurs in less than 10% of patients on the usual doses of thiazide-type diuretics and usually occurs in the first 2 weeks of therapy. Although there is some controversy, it is our view that patients with chronic diuretic-induced hypokalemia, even if it is mild in degree, should be treated.

There are several ways to minimize the degree of diuretic-induced hypokalemia. First, give the lowest effective dose of diuretic because the risk of hypokalemia is dose dependent. In most patients with essential hypertension, 12.5 to 25 mg of hydrochlorothiazide produces as great a decrease in blood pressure as higher doses. Second, the intake of K⁺ should not be low. Salt substitutes such as Co-salt (14 mmol K⁺/g) are an inexpensive way to provide K⁺ while decreasing the intake of Na⁺. Third, lowering the rate of K⁺ excretion can minimize the degree of hypokalemia. This may be achieved in part by limiting the intake and thereby the excretion of NaCl to approximately 100 mmol/day. The renal loss of K⁺ can be reduced with the use of K⁺-sparing diuretics. Nevertheless, their dose may need to be adjusted independently because a higher distal flow rate lowers the luminal concentration of this class of drugs and hence they become less effective blockers of ENaCs. Therefore, we do not favor the use of tablets of combination of thiazide or a loop diuretic plus a K⁺-sparing diuretic.

Primary Hyperaldosteronism

This should be suspected when there is both hypertension and hypokalemia with renal K⁺ wasting in patients who have low

Table 30-2 Specific Issues in Therapy of Some Disorders of Hypokalemia

Disorder	Specific Issues in Therapy
Diuretic-induced hypokalemia	Use lowest effective dose of diuretics K supplements (e.g., Co-salt) Restrict NaCl intake to <100 mmol/day Add K ⁺ -sparing diuretics
Primary hyperaldosteronism	Unilateral adrenal adenoma: laparoscopic adrenalectomy Bilateral adrenal hyperplasia: mineralocorticoid receptor antagonists (preferred), ENaC blockers
Barter and Gitelman's syndromes	K ⁺ supplements, in frequent divided doses K ⁺ -sparing diuretics: may aggravate salt wasting, high doses of amiloride needed Mg supplements if hypomagnesemia ACE inhibitors, ARBs: limited by hypotension Prostaglandin inhibitors: risk of chronic renal dysfunction with prolonged use
Glucocorticoid-remediable aldosteronism	Glucocorticoids
Liddle syndrome	ENaC blockers, high doses required
Apparent mineralocorticoid excess	Mineralocorticoid receptor antagonists ENaC blockers; must have low intake of NaCl

For details, see the text.

ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; ENaC, epithelial Na⁺ channel

plasma renin activity. A poorly explained fact is that a significant number of patients with primary hyperaldosteronism do not have hypokalemia. Laparoscopic unilateral adrenalectomy is generally the preferred treatment in a patient with an adrenal adenoma.²³ If successful, it should induce a marked reduction in aldosterone secretion, a decrease in blood pressure, and correction of the hypokalemia. Notwithstanding, hypertension persists in as many as 40% to 65% of patients after unilateral adrenalectomy, especially those with a family history of hypertension and those who were taking two or more antihypertensive medications prior to surgery.²⁴ In patients with bilateral adrenal hyperplasia or those with an adrenal adenoma but who are not candidates for surgery, medical therapy is the preferred treatment.²⁵ The goals of therapy, however, are not only to control blood pressure and correct the hypokalemia, but also to reverse the unwanted effects of hyperaldosteronism on the heart. The administration of a mineralocorticoid receptor antagonist (spironolactone or eplerenone) is the preferred therapy. Amiloride is an alternative in those who are intolerant of these drugs. The issue about the need for a low intake of NaCl to decrease the flow rate in CCD applies in this setting.

Barter Syndrome and Gitelman's Syndrome

The current therapy for both Bartter and Gitelman's syndromes includes KCl supplements, K⁺-sparing agents, and the use of angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers. Correction of hypokalemia in these patients is rather difficult, even with large K⁺ supplements.²⁰ One might be able to maintain a somewhat higher P_K in these patients by giving the same daily amount of K⁺ supplements but using a more frequent dosing schedule. This is perhaps because a large dose of K⁺ may induce a sufficient increase in the P_K to cause the insertion of K⁺ channels into the luminal membrane in CCD cells and hence an

increase in K⁺ secretion.^{26,27} Hypomagnesemia may be a contributing factor in the enhanced kaliuresis in some patients with Gitelman's syndrome.²⁸ Again, correction of hypomagnesemia with oral magnesium is usually difficult and also limited by gastrointestinal side effects. K⁺-sparing diuretics (amiloride, spironolactone) may help conserve K⁺. A common clinical observation is that even high doses of amiloride fail to curtail the excessive kaliuresis in patients with Bartter and Gitelman's syndromes. Part of the explanation of this diminished effect could be related to the higher flow in the CCD due to inhibition of NaCl reabsorption in upstream nephron segments. This higher volume delivery to the CCD lowers the concentration of ENaC blockers, thus diminishing their effectiveness.²⁰ A potential concern using these agents in patients with Bartter or Gitelman's syndromes is that they may aggravate their salt wasting. This may become evident if, for example, dietary salt intake is decreased or there is a nonrenal cause of the loss of NaCl. Angiotensin-converting enzyme inhibitors have been used to decrease levels of angiotensin II and aldosterone with variable success; if effective, hypotension becomes an important concern. In prenatal Bartter syndrome, prostaglandin E₂ synthesis can be reduced with cyclooxygenase inhibitors such as indomethacin.²⁹ Inhibition of prostaglandin E₂ synthesis attenuates salt wasting with hypokalemia and minimizes the systemic symptoms of prostaglandin excess. Caution is advised using these agents in the neonatal period as acute renal failure and patent ductus arteriosus are documented complications. Because of the potential for causing chronic renal dysfunction, the lowest possible effective dose of these drugs should be used.

Glucorticoid-Remediable Aldosteronism

Glucorticoid-remediable aldosteronism is an autosomal dominant form of hypertension caused by a chimeric gene, which results in aldosterone synthesis being under the control of

corticotropin rather than its normal regulator, angiotensin II.³⁰ In this disorder, exogenous glucocorticoids may suppress the release of corticotropin and thereby the secretion of aldosterone.

Liddle Syndrome

Liddle syndrome is an autosomal dominant disorder that is caused by mutations in either the β or the γ subunit of the ENaC that leads to its defective degradation and thereby an increased number of active ENaC units in the luminal membrane of principal cells in the CCD.³¹ The channel is amiloride and triamterene sensitive providing that their concentrations are high enough in luminal fluid, explaining the efficacy of these K^+ -sparing diuretics in the treatment of this syndrome. Conversely, aldosterone receptor antagonists are not effective in these patients.

Apparent Mineralocorticoid Excess

Apparent mineralocorticoid excess is the result of a mutation in the gene encoding for 11β -hydroxysteroid dehydrogenase type 2,³² the enzyme responsible for converting cortisol to its inactive metabolite, cortisone, in principal cells of the CCD. This enzyme is inhibited by glycyrrhetic acid in licorice. These patients can be treated with ENaC blockers (e.g., amiloride, triamterene), with the same caveat for the need for salt restriction noted previously. In contrast to patients with Liddle syndrome, patients with apparent mineralocorticoid excess usually have a good response to spironolactone.

HYPERKALEMIA

The steps to identify the major diagnostic categories for patients with hyperkalemia are summarized in Figure 30-6. It is necessary to make the specific diagnosis because the mode

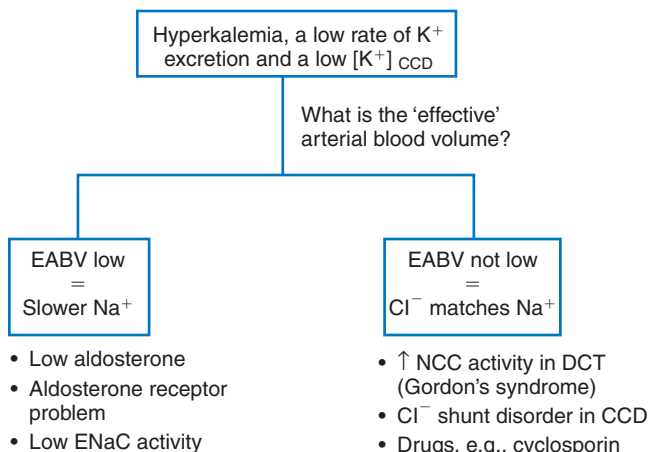

Figure 30-6 Renal causes for hyperkalemia and a low rate of excretion of K^+ . For details, see legend to Figure 30-4. A list of likely causes of a low rate of excretion of K^+ is provided below the diagnostic categories. CCD, cortical collecting duct; DCT, distal convoluted tubule; EABV, effective arterial blood volume; ENaC, epithelial Na^+ channel; Na^+ - Cl^- cotransporter. (From Halperin ML: *The ACID Truth and Basic Facts: With a Sweet Touch, an enLYTEnment*, 5th ed. Toronto, Ontario: RossMark Medical Publishers, 2004, with permission.)

and emphasis of therapy are strongly influenced by the diagnostic category.

General Considerations for Treatment of Hyperkalemia

Medical Emergencies

The major danger for the patient with hyperkalemia is a cardiac arrhythmia. Because minor electrocardiographic changes may progress rapidly to a dangerous arrhythmia, any patient with an electrocardiographic abnormality related to hyperkalemia should be treated as a medical emergency. We would also treat patients with a severe degree of hyperkalemia (e.g., $P_K > 7.0$ mmol/L) aggressively, even in the absence of electrocardiographic changes. A note of caution, however, is needed: a severe degree of hyperkalemia is well tolerated in certain settings such as extremes of exercise (the supermarathon) and in infants.

The steps to take in the treatment of patients with an emergency related to hyperkalemia are discussed below and are illustrated in Figure 30-7.

Antagonize the Cardiac Effects of Hyperkalemia

Calcium is the best agent and its effects should be evident within minutes. It is usually given as 20 to 30 mL of a 10% calcium gluconate solution (two to three ampoules) or 10 mL of 10% calcium chloride (one ampoule). Both solutions are equally effective, but the former is safer than the latter in case of infiltration of the needle during an intravenous infusion because at high concentrations calcium gluconate is mostly undissociated, whereas calcium chloride is nearly completely dissociated. Once calcium gluconate enters the circulation and gets diluted greatly, it also becomes mostly dissociated. This dose can be repeated in 5 minutes if electrocardiographic changes persist. The effect may last 30 to 60 minutes. Extreme caution should be exerted using Ca^{2+} in patients on digitalis because hypercalcemia may precipitate digitalis toxicity.

Induce a Shift of K^+ into the Intracellular Fluid

Use of Insulin

Many studies support the use of insulin in the treatment of acute hyperkalemia in patients with end-stage renal disease (ESRD).³³⁻³⁶ For example, Blumberg and colleagues³³ studied 10 patients with ESRD on hemodialysis after an overnight fast before their regularly scheduled hemodialysis. The patients were treated on different occasions with approximately 20 units of intravenous regular insulin plus glucose, $NaHCO_3$ at 4 mmol/min, epinephrine 0.05 μ g/kg/min, or hemodialysis. The P_K was followed for 60 minutes. Hemodialysis was the most effective modality that lowered the P_K , decreasing it from 5.6 to 4.3 mmol/L. Insulin with glucose also caused the P_K to decrease rapidly from 5.6 to 4.7 mmol/L. Of note, epinephrine caused only a minor decrease in the P_K . Intravenous $NaHCO_3$ failed to lower the P_K . Large doses of insulin are needed for maximal K^+ shift into cells. In the study by Blumberg and colleagues,³³ 20 units of regular insulin were given to increase the plasma insulin level to 300 to 400 mU/L. One cannot overemphasize the need to give enough glucose to prevent the development of hypoglycemia and to monitor blood glucose levels for a sufficient period of time.

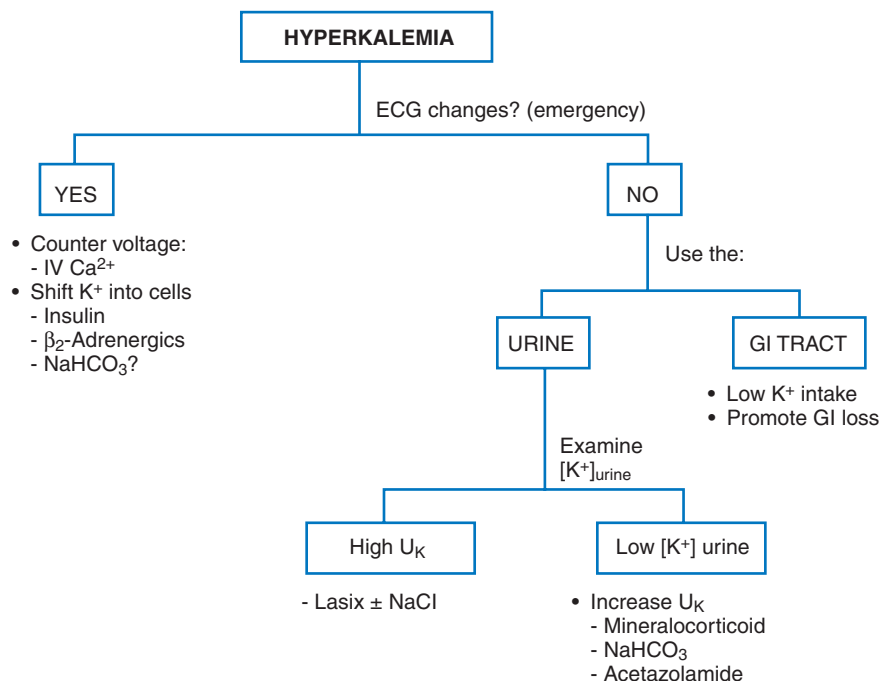

Figure 30-7 Treatment of the patient with hyperkalemia. If an emergency is present (usually cardiac), intravenous Ca^{2+} must be given. This treatment should act promptly. Efforts are now made to shift K^+ into cells with insulin and glucose. Longer term strategies are to limit the intake of K^+ , increase its excretion in the gastrointestinal (GI) tract, and promote its excretion in the urine. In this latter context, examine the potassium concentration in the urine (U_K) and flow rate to decide leverage for therapy (see Fig. 30-2 for details). ECG, electrocardiogram; ICF, intracellular fluid. (From Halperin ML: *The ACID Truth and Basic Facts: With a Sweet Touch*, an eLYTEment, 5th ed. Toronto, Ontario: RossMark Medical Publishers, 2004, with permission.)

We recommend insulin with glucose as initial therapy to induce a shift of K^+ into cells in the emergency treatment of hyperkalemia. Although some suggest treating nondiabetic, hyperkalemic patients with a bolus of glucose without exogenous insulin, we believe that this strategy is unwise because the high levels of insulin required to induce an adequate shift of K^+ into cells might not be achieved without giving insulin. In addition, hypertonic glucose may cause K^+ to shift out of cells in patients with inadequate insulin reserves, leading to a paradoxical increase in the P_K .³⁷

β_2 -Adrenergic Agonists

β_2 -Agonists stimulate the Na/K-ATPase via a cyclic adenosine monophosphate-dependent pathway (see Fig. 30-1). The ability of β_2 -adrenergic stimulation to lower the P_K in patients with renal failure has been demonstrated in a number of studies.^{34–36,38,39} Montoliu and colleagues³⁸ gave 20 patients on maintenance hemodialysis 0.5 mg albuterol intravenously over 15 minutes, which caused the mean P_K to decrease from 5.6 to 4.5 mmol/L within 30 minutes. Of note, eight of these patients developed tremors and six had minor ill-defined discomfort. In a second part of the study, consecutive patients with acute or chronic renal failure were given intravenous albuterol (0.5 mg over 15 minutes). Their mean P_K decreased from 7.0 to 5.6 mmol/L within 30 minutes, and the effect was sustained for 3 hours. Reversal of the electrocardiographic manifestations of hyperkalemia was documented in most of the patients, and only minor adverse effects were noted. It was recognized, however, that there was considerable individual variation in the response of the P_K to albuterol, although the data for individual patients were not shown.

A number of studies have examined nebulized β_2 -agonists as therapy for hyperkalemia. In a study by Allon and colleagues,⁴⁰ 10 hyperkalemic ESRD patients on hemodialysis were treated with 10 mg of nebulized albuterol, 20 mg of nebulized albuterol, or placebo on three separate occasions. After the administration of albuterol, the P_K decreased within 30 minutes and this decrease was sustained for at least 2 hours. The maximum decreases in P_K were 0.6 mmol/L with the 10-mg dose and 1.0 mmol/L with the 20-mg dose. However, two of the 10 patients were resistant to the hypokalemic effects of albuterol. There was a minimal increase in heart rate and a notable absence of cardiovascular adverse effects.

Although these studies suggest that β_2 -agonists are effective in rapidly lowering the P_K , we do not recommend their use as preferred therapy in the emergency treatment of hyperkalemia for two reasons. First, they are not effective in a significant proportion of patients; 20% to 40% of patients studied had a decrease in P_K of less than 0.5 mmol/L. It is unclear why some patients do not exhibit a decrease in P_K after the administration of β_2 -agonists, and it is not possible to predict which patients will respond. Second, we are concerned about the safety of these drugs in the doses used for the treatment of hyperkalemia, which are four to eight times those prescribed for the treatment of acute asthma. Although no severe adverse events were reported in the studies noted here, most were performed in stable patients with a mild degree of hyperkalemia before their regular hemodialysis session. A number of these studies excluded patients on β -blockers and selected those with no significant coronary heart disease or unstable heart rhythms. Therefore, the safety of these agents was determined in a group of patients who

may not resemble the general ESRD population, which has a high prevalence of cardiac disease.

Whether the effect of nebulized β_2 -agonists in lowering P_K is additive to that of insulin has been examined by Allon and Copkney.³⁴ In a crossover design, 12 patients on maintenance hemodialysis who had predialysis P_K values that were greater than 5 mmol/L received 10 units of regular insulin plus glucose as an intravenous bolus or 20 mg of nebulized albuterol over 10 minutes, or both. Insulin decreased P_K in 15 minutes and albuterol decreased P_K within 30 minutes. There was a similar decrease in P_K with insulin (0.65 mmol/L) or albuterol (0.66 mmol/L). However, four of 10 patients treated with albuterol had a mean decrease in P_K of less than 0.5 mmol/L. There was a substantially greater decrease in P_K with the combined regimen (1.2 mmol/L) compared with either agent alone. One should note, however, that only 10 units of intravenous regular insulin were given in this study, the plasma insulin level was only 40 mU/L at 60 minutes, and the magnitude of the decrease in P_K was lower than that observed in other studies when higher doses of insulin were used. Blumberg and colleagues³³ administered 20 units of intravenous insulin and achieved a similar decrease in P_K (~1 mmol/L) as Allon and Copkney³⁴ with their combined therapy of 10 units of intravenous insulin and albuterol. Thus, it remains uncertain whether β_2 -agonists would have a P_K -lowering effect additive to that of insulin if insulin were given at the higher doses.

NaHCO₃

The first step in the action of NaHCO₃ is to decrease the concentration of H⁺ in the ECF compartment and thereby promote the exit of H⁺ and entry of Na⁺ into cells via the NHE (see Fig. 30-1). However, because the NHE is normally inactive in most cell membranes, this will not cause a decrease in the P_K . Thus, only if the NHE were active would the administration of NaHCO₃ have the potential to lower the P_K . One major activator of the NHE is intracellular acidosis because H⁺ ions are not only a substrate for the NHE, but they also bind to a modifier site that activates it.

The potential value of NaHCO₃ for therapy of patients with a severe degree of hyperkalemia is not clear. NaHCO₃ therapy did not lower the P_K acutely in a number of studies.^{33,41,42} In more detail, Blumberg and colleagues³³ administered 100 to 215 mmol of intravenous NaHCO₃ as either an isotonic or a hypertonic solution to 10 patients with ESRD on hemodialysis who had mild hyperkalemia (mean P_K close to 5.5 mmol/L). Although the mean plasma HCO₃⁻ concentration increased from 21 to 34 mmol/L, there was no change in P_K after 60 minutes, a time frame during which this intervention must have a significant effect if it were to be used in a potentially life-threatening situation. In a subsequent study, Blumberg and colleagues⁴¹ infused 390 mmol of NaHCO₃ over 6 hours in 12 patients with ESRD on hemodialysis. There was a moderate decrease in P_K from 6.0 to 5.4 mmol/L, but only after 4 hours of starting the NaHCO₃ infusion. It is noteworthy that the studies that found a lack of effect of NaHCO₃ were performed in stable hemodialysis patients without significant acidosis. In other words, these studies examined the effect of NaHCO₃ when the NHE was presumably in an inactive mode. The question remains as to whether NaHCO₃ would be effective in pa-

tients with a more significant degree of acidosis, when the NHE is likely to become activated. There are limited data in the literature to answer this question. A report by Schwarz and colleagues⁴³ described four uremic patients with P_K values ranging from 5.9 to 8.5 mmol/L associated with electrocardiographic changes attributable to hyperkalemia and a profound degree of acidosis (plasma HCO₃⁻ 1.3–7.3 mmol/L). In all four patients, an infusion of 150 to 400 mmol NaHCO₃ caused a significant decrease in the P_K and improvement of their electrocardiogram. Although it is difficult to draw definite conclusions, this study identifies a potential value for NaHCO₃ in certain settings. Accordingly, we would administer NaHCO₃ to treat dangerous hyperkalemia in patients with significant acidosis, but we would not use it as the only emergency therapy to shift K⁺ into cells. However, the excessive administration of NaHCO₃ should be avoided due to the risk of inducing hypernatremia, ECF volume expansion, carbon dioxide retention, and a decrease in ionized serum calcium, which may aggravate the effect of hyperkalemia.

Studies that examined the combined use of NaHCO₃ with insulin have also produced conflicting results. Allon and Shanklin³⁵ found that the addition of NaHCO₃ did not enhance the P_K -lowering effects of insulin in their study of eight patients on hemodialysis. In this study, the mean P_K before therapy was 4.5 mmol/L and the mean plasma HCO₃⁻ was 22 mmol/L. In contrast, Kim⁴⁴ compared insulin, NaHCO₃, or both in eight patients with a predialysis P_K of more than 6 mmol/L. There was no change in the P_K with NaHCO₃ as the sole therapy after 60 minutes, and insulin caused the P_K to decrease from 6.3 to 5.7 mmol/L. The combination of insulin and NaHCO₃ led to the greatest decline in P_K (from 6.2 to 5.2 mmol/L). It is unclear why Kim⁴⁴ found a synergistic effect of NaHCO₃ with insulin, yet Allon and Shanklin³⁵ did not; it should be noted, however, that the patients studied by these authors were not hyperkalemic.

No Medical Emergency: Removal of K⁺ from the Body

It is important to appreciate that to lower the P_K from 7.0 to 6.0 mmol/L requires very much less K⁺ loss than that needed to lower the P_K from 6.0 to 5.0 mmol/L. Hence, it is important to cause even a small K⁺ loss when there is a severe degree of hyperkalemia.

Diuretics and/or Mineralocorticoids

There are two aspects to consider in this context. If the excretion of K⁺ is low because of a low urine volume with a high concentration of K⁺, a loop diuretic may be able to induce a kaliuresis by increasing the flow rate in the CCD. One can avoid unwanted ECF volume contraction by replacing the NaCl lost in the urine. Conversely, if the urine K⁺ concentration is unduly low, giving a mineralocorticoid (100 μ g of fludrocortisone acetate) and inducing bicarbonaturia with the carbonic anhydrase inhibitor acetazolamide may cause substantial kaliuresis (the HCO₃⁻ lost in the urine might need to be replaced).

Cation-Exchange Resins

A cation-exchange resin is a cross-linked polymer with negatively charged structural units. The resin can exchange bound Na⁺ (Kayexalate) or Ca²⁺ (calcium resonium) for cations

including K^+ . The purpose of using resins is to enhance the elimination of K^+ from the gastrointestinal tract. The cation-exchange resin Kayexalate contains 4 mEq of Na^+ /g. This Na^+ is theoretically exchangeable for 4 mEq of K^+ . Thus, 30 g Kayexalate could theoretically remove 120 mEq of K^+ . However, this degree of exchange does not occur at the Na^+ and K^+ concentrations found in the gastrointestinal tract. In more detail, Emmet and colleagues⁴⁵ examined the *in vitro* binding characteristics of Kayexalate and found that the Na^+ and K^+ concentrations at which 50% of Na^+ is exchanged for K^+ were 65 and 40 mmol/L, respectively. With a higher concentration of Na^+ and/or a lower concentration of K^+ , less exchange would be expected to take place. If one considers the concentrations of Na^+ and K^+ in the duodenum (110 and 15 mmol/L, respectively), jejunum (140 and 5 mmol/L, respectively), ileum (130 and 20 mmol/L, respectively), and rectum (10 and 80 mmol/L, respectively),⁴⁶ it seems that the only favorable location for the exchange of Na^+ for K^+ is in the lumen of the rectum. Because there is little absorption of K^+ in the rectum, there is no significant advantage to having the K^+ in its luminal fluid excreted in an ionic form or bound to a resin. Furthermore, normal fecal K^+ excretion is approximately 9 mmol/day; subjects with ESRD excrete only slightly more K^+ (an extra 2–3 mmol/day) in their feces than do normal subjects.

In humans, active secretion of K^+ in the gastrointestinal tract occurs in the rectosigmoid portion of the colon. One possible theoretical benefit for the use of cation-exchange resins is if they were to lower the K^+ concentration in luminal water, thereby enhancing the net secretion of K^+ in this portion of the colon. However, a number of factors limit the magnitude of this process. Other cations are available to exchange for resin-bound Na^+ apart from K^+ , including NH_4^+ , Ca^{2+} , and Mg^{2+} . The concentration of NH_4^+ in stool water may be high in patients with ESRD as a result of their high blood urea levels and because of bacterial urease activity in the lumen of the gastrointestinal tract. Cations such as Ca^{2+} and Mg^{2+} have an even greater affinity for the resin than K^+ because of their divalent positive charge. In addition, resins are usually given with cathartics because of their tendency to cause constipation, which can increase the concentration of Na^+ in stool water, leading to conditions even more unfavorable for the exchange of Na^+ for K^+ . Colonic secretion of K^+ in normal subjects is approximately 4 mmol/day. It has been suggested that patients with ESRD have enhanced colonic secretion of K^+ that is perhaps mediated by aldosterone.^{47,48} Balance data are conflicting, and the evidence of increased removal of K^+ by the gastrointestinal tract in patients with ESRD is not convincing.⁴⁹ Even if there were an adaptive increase in colonic K^+ secretion, stool volume will be limiting for the total removal of K^+ . If one assumes a transepithelial voltage as high as 90 mV (measured values are significantly lower, close to 40 mV), and a P_K of 5 mmol/L, the concentration of K^+ in stool water would be close to 100 mmol/L. With a usual stool weight of 125 g/day, of which 75% is water, only 10 mmol of K^+ will be excreted. In experiments in which dialysis bags were placed into the rectum of patients with chronic renal failure,⁴⁸ the rate of net K^+ secretion was 1.5 $\mu\text{mol/hr/cm}^2$ of rectal surface area. Thus, with an average rectal surface area of 100 cm^2 , the net K^+ secretion would be only 4 mmol/day. If, however, this high rate of K^+ secretion could be present unabated throughout the entire colon, fecal K^+ excretion could be as high as 70 mmol/day if stool volume were not limiting. Thus, from a theoretical point of view, resins would

seem of little use in inducing a loss of K^+ from the gastrointestinal tract unless lowering of the stool K^+ concentration plays an important role in this process and, more importantly, the patient has diarrhea.

Two reports are commonly cited to support the use of resins for treatment of hyperkalemia.^{50,51} Although the authors of both studies concluded that resins were useful for treating hyperkalemia, it is difficult to determine their exact role. It should be noted that several doses were given, sometimes for a number of days, and that the effect on P_K was noted after 1 to 5 days. Furthermore, it is not clear whether the effect was due to the resin or merely to the induction of diarrhea with hypertonic glucose or other cathartics.

Two studies have reexamined the effect of cathartics and/or resins on fecal K^+ excretion. First, Emmett and colleagues⁴⁵ gave nine normal human subjects 60 or 120 g sorbitol, 100 mmol sodium sulfate, or eight phenolphthalein/docusate tablets; each with and without 30 g Kayexalate. Stool water and Na^+ and K^+ concentrations were followed over the next 12 hours. Phenolphthalein resulted in the highest stool K^+ excretion rate (37 mmol in 12 hours) compared with the other laxatives. The addition of 30 g Kayexalate to phenolphthalein increased stool K^+ excretion only modestly to 49 mmol in 12 hours. The addition of the resin to sorbitol or sodium sulfate did not significantly increase stool K^+ excretion compared with either laxative alone. The results of this study suggest that the majority of K^+ excretion with cathartics and resins is due to the induction of diarrhea. Second, Gruy-Kapral and colleagues⁵² studied the effect of a single dose of cathartic and/or resin on fecal K^+ excretion and the P_K in patients with renal failure. The results of the study support the argument that resins do not contribute to fecal K^+ excretion above the induction of diarrhea alone and that single-dose resin/cathartic therapy is of no value in the management of acute hyperkalemia.

In summary, we do not recommend the use of resins for acute hyperkalemia. In the setting of chronic hyperkalemia, the addition of resins to cathartics adds little to the induction of diarrhea alone. One other point merits emphasis: there is convincing evidence that the hypertonic sorbitol may cause colonic necrosis.⁵³

Dialysis

Hemodialysis is more effective than peritoneal dialysis for removing K^+ . Removal rates of K^+ can approximate 35 mmol/hr with a dialysate bath K^+ concentration of 1 to 2 mmol/L. A glucose-free dialysate is preferable to avoid the glucose-induced release of insulin and the subsequent shift of K^+ into cells, lessening the removal of K^+ .

Specific Causes of Hyperkalemia

As mentioned earlier, hyperkalemia is a laboratory finding and not a specific disorder. Hence, the settings where hyperkalemia is present are heterogeneous in pathophysiology, and thus the treatment for each group is different. Accordingly, they are discussed under separate headings.

Syndrome of Hyporeninemic Hypoaldosteronism

Patients in this diagnostic category are heterogeneous with regard to the pathophysiology of their disorder and therefore require different approaches to the treatment of their hyperkalemia.⁵⁴

Group with a Low Capacity to Produce Renin

The basis of this group of disorders may be destruction of or a biosynthetic defect in the juxtaglomerular apparatus. The net result is hyporeninemia and thereby a low plasma aldosterone level. Accordingly, there is a relatively slower reabsorption of Na^+ in the CCD. Hyperkalemia will develop if there is a sufficiently large intake of K^+ such that an increase in the P_K must be present to permit the kidneys to excrete the daily K^+ load because of the chronic low aldosterone levels. The effective arterial blood volume will tend to be low. With respect to treatment, patients with this group of disorders are expected to have a significant decrease in their P_K due to an increase in their $[\text{K}^+]_{\text{CCD}}$ after the administration of exogenous mineralocorticoids for several days (e.g., fludrocortisone 100 $\mu\text{g}/\text{day}$). The administration of diuretics to these patients will aggravate the degree of contraction of their effective arterial blood volume.

Group with Low Stimulus to Produce Renin

There are two subtypes in this group of patients.

Enhanced Reabsorption of Na^+ and Cl^- in the Distal Convoluted Tubule This is due to an abnormal regulation of the signal system that affects the distribution of the Na^+ , Cl^- cotransporter in this nephron segment with more active units ending up in the luminal membrane. This seems to be the underlying pathophysiology in patients with pseudohypoaldosteronism type II (Gordon's syndrome).⁵⁵ When there is an enhanced upstream reabsorption of Na^+ and Cl^- , this results in a low delivery of Na^+ and Cl^- to the CCD, which compromises the ability of this nephron segment to reabsorb Na^+ faster than Cl^- and thereby leads to a diminished excretory capacity for K^+ . ECF volume expansion is a hallmark of the pathophysiology and results in hyporeninemia and thus a lower than expected plasma aldosterone level given the hyperkalemia. These patients do not have an appreciable increase in their K^+ excretion with exogenous mineralocorticoids, but their K^+ excretion should increase when thiazide diuretics are given (higher Na^+ and Cl^- delivery to the CCD) if ENaCs are open. Of note, mineralocorticoids may aggravate the hypertension in patients who have excessive reabsorption of Na^+ and Cl^- in the distal convoluted tubule.

Cl Shunt Disorder This subtype is most commonly seen in patients with diabetic nephropathy. Although the basis of the disorder remains to be established, it is possible that the reabsorption of Na^+ and Cl^- may be augmented in the distal convoluted tubule or these patients may have a Cl shunt disorder in the CCD.⁵⁶ With the former pathophysiology, the ideal treatment would be with a thiazide diuretic as described above. Conversely, patients with a Cl shunt have a significant increase in their K^+ excretion with the induction of bicarbonaturia (perhaps secondary to the inhibition of the reabsorption of Cl^- in the CCD).¹¹ Hence, inducing bicarbonaturia with acetazolamide may increase K^+ excretion; HCO_3^- loss may have to be replaced to avoid the development of metabolic acidosis.

Cyclosporine-Induced Hyperkalemia

Hyperkalemia develops in some patients receiving cyclosporine after organ transplantation. Even though cyclosporine can lead to inhibition of Na/K -ATPase in vitro, we favor the hypothesis that the pathophysiology of hyperkalemia in these

patients resembles a Cl shunt disorder in the CCD.⁵⁷ A kaliuresis could be enhanced in these patients with the administration of a loop diuretic to increase the flow rate in the CCD or the administration of acetazolamide to induce bicarbonaturia.

Trimethoprim-Induced Hyperkalemia

Trimethoprim and pentamidine cause hyperkalemia by blocking ENaCs in the CCD.⁵⁸ Although frequently reported in patients who have acquired immunodeficiency syndrome and have received high doses of trimethoprim for the treatment of *Pneumocystis carinii* pneumonia, trimethoprim causes an increase in P_K even when used in conventional doses. Patients with acquired immunodeficiency syndrome might also have other causes that make them prone to the development of a more severe degree of hyperkalemia (shift of K^+ from cells, decreased K^+ excretion because of low flow in the CCD due to a low rate of delivery of osmoles (NaCl and urea) to the CCD²).

Use of a loop diuretic may help by increasing the volume delivered to the CCD, which will lower the concentration of trimethoprim in its lumen; enough NaCl administration will be required to defend ECF volume. Because trimethoprim only blocks ENaCs when the drug is in its charged (protonated) form, increasing luminal fluid pH in the CCD should decrease the cationic form of trimethoprim and minimize the antidiuretic effect of this drug.⁵⁹ Inducing bicarbonaturia with acetazolamide and the use of a loop diuretic are rational therapeutic options in a patient with hyperkalemia in whom continuation of trimethoprim is necessary. However, sufficient NaCl and NaHCO_3 would need to be given to avoid a contracted ECF volume and metabolic acidosis, respectively.

Addison's Disease

Adrenal crisis is an emergency that requires immediate restoration of the intravascular volume (intravenous saline) and correction of the cortisol deficiency (administer dexamethasone or hydrocortisone). Beware of increasing the plasma sodium concentration too rapidly if hyponatremia is present because of the risk of osmotic demyelination in a catabolic patient. Both expansion of the effective arterial blood volume and the administration of cortisol can lead to a decrease in the circulating level of vasopressin. Therefore, we prefer to give 1-desamine-8-D-arginine vasopressin at the outset to avoid a large water diuresis. Water intake must be restricted while DDAVP acts.

Patients with chronic adrenal insufficiency should receive replacement therapy with both a glucocorticoid and a mineralocorticoid.⁶⁰ For the former, hydrocortisone 25 mg (15 mg in the morning and 10 in the afternoon) is usually given. For mineralocorticoid replacement, fludrocortisone in a single dose of 50 to 200 μg is usually used. Dose adjustments are made based on patients' symptoms, ECF volume status, blood pressure measurements, and P_K .

It is interesting to note that a lack of hyperkalemia is not uncommon because almost one third of patients with Addison's disease did not have high P_K values. Hence, this should not be an absolute diagnostic criterion.⁶¹

CONCLUDING REMARKS

Hyperkalemia and hypokalemia are common electrolyte disorders that may cause life-threatening cardiac arrhythmias. Therefore, our approach to therapy emphasizes first measures to deal

with an emergency related to hypokalemia or hyperkalemia. In the long term, the design of appropriate therapy requires an understanding of the pathophysiology of the disorder in the individual patient because hypokalemia and hyperkalemia are not specific diagnoses, but rather findings in a heterogeneous group of disorders.

PATHOPHYSIOLOGY OF ACID-BASE DISORDERS

Definition and Fundamental Concepts

Metabolic acidosis occurs when there is increased production of endogenous acid (e.g., lactic acid and ketoacids), loss of bicarbonate (HCO_3^-) in diarrhea, or a sustained inability to generate new bicarbonate by the kidney (renal failure and renal tubular acidosis). Metabolic acidosis is recognized by the co-occurrence of acidemia ($\text{pH} < 7.35$) and a low serum bicarbonate concentration (total CO_2 concentration). Metabolic acidosis may also be recognized by an elevated anion gap (AG), even in the face of normal values for pH and HCO_3^- in plasma. Two broad types of metabolic acidoses are recognized by consideration of the AG: (1) high AG acidoses and (2) normal AG or hyperchloremic acidoses.¹ The AG is defined as:

$$\text{AG} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-) = 10 \text{ mEq/L (range, 8–12 mEq/L)}$$

A flow diagram outlining the diagnostic approach to metabolic acidosis, in which the initial consideration is the AG, is displayed in Figure 31-1.

When there is a primary decrease in plasma $[\text{HCO}_3^-]$, an increase in alveolar ventilation and thereby a decrease in Paco_2 (respiratory compensation) are expected because the medullary chemoreceptors are stimulated by acidemia to invoke an increase in ventilation. The ratio of $[\text{HCO}_3^-]$ to Paco_2 and the subsequent pH will be returned toward, but not to, normal. This hypocapnic response to acidemia is predictable in simple acid-base disturbances and blunts the magnitude of the decline in blood pH that would occur otherwise.¹

Respiratory and metabolic compensation can be predicted for metabolic and respiratory acid-base disturbances from the

formulas in Table 31-1. The degree of respiratory compensation expected in uncomplicated or “simple” metabolic acidosis was derived empirically and can be predicted from the relationship:

$$\text{Paco}_2 = (1.5 \times \text{HCO}_3^-) + 8 \pm 2 \text{ mm Hg.}$$

The diagnostic approach to the patient with a low HCO_3^- is outlined in Figure 31-1. Thus, in a patient with metabolic acidosis and a plasma $[\text{HCO}_3^-]$ of 12 mEq/L, a Paco_2 between 24 and 28 mm Hg would be anticipated. Values for Paco_2 less than 24 or more than 28 mm Hg denote a mixed disturbance (metabolic acidosis and respiratory alkalosis, or metabolic acidosis and respiratory acidosis, respectively). Although this relationship is reliable, the Paco_2 can be estimated more conveniently by adding 15 to the patient’s serum $[\text{HCO}_3^-]$.

Renal Response to Acidosis

The kidneys regulate plasma $[\text{HCO}_3^-]$ through three processes: (1) reabsorption of the filtered HCO_3^- ; (2) excretion of titratable acidity; and (3) biochemical synthesis and excretion of NH_4^+ . The sum of the last two processes represents net acid excretion (net acid excretion = titratable acidity + $\text{NH}_4^+ - \text{HCO}_3^-$). Approximately 80% to 90% of the filtered HCO_3^- is reabsorbed in the proximal tubule. Under normal conditions, the distal nephron reabsorbs the remainder of the filtered HCO_3^- (5%–10%). The quantity of acidic amino acids produced on a daily basis from metabolism and digestion of dietary protein is approximately 40 to 60 mEq. Thus, an equal amount of acid must be secreted by the collecting duct to prevent the development of chronic positive hydrogen ion balance and metabolic acidosis. NH_4^+ excretion, a major component of net acid excretion, is regulated by both NH_4^+ production and NH_4^+ transport within the kidney.^{1,2}

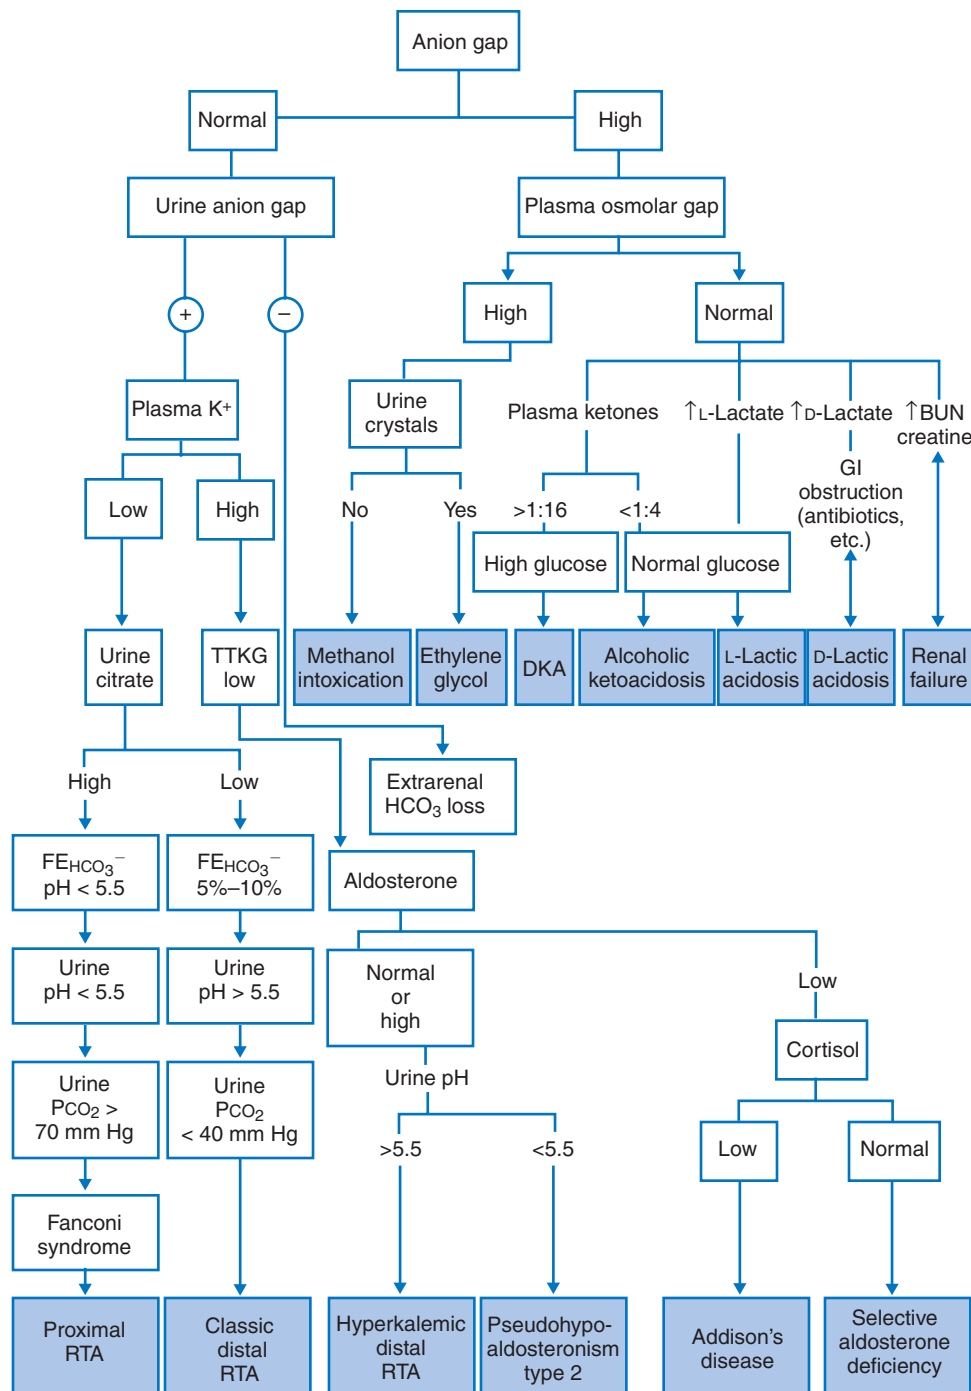

Figure 31-1 Flow diagram of approach to metabolic acidosis. The anion gap is the entry point and divides the types of metabolic acidoses into high anion gap and normal anion gap categories. Final diagnoses are displayed in shaded boxes. BUN, blood urea nitrogen; DKA, diabetic ketoacidosis; $FE_{HCO_3^-}$, fractional excretion of bicarbonate; GI, gastrointestinal; RTA, renal tubular acidosis; TTKG, transtubular potassium.

Because the filtered load of phosphate is relatively constant, the 20 to 30 mEq excreted as titratable acid daily (primarily phosphate) is fixed and not subject to the robust regulatory mechanisms governing ammoniogenesis and ammonium excretion. Therefore, for practical purposes, NH_4^+ excretion is the most sensitive index of the kidney's response to systemic acidosis.

When renal function is normal, the kidney responds to chronic metabolic acidosis by increasing NH_4^+ production and excretion; therefore, NH_4^+ production and excretion are much less than normal in the face of chronic renal failure, hyperkalemia, and renal tubular acidosis (RTA). Therefore, a normal renal response to metabolic acidosis must be distinguished from a subnormal response to determine whether the kidney is

Table 31-1 Respiratory and Metabolic Compensation

Disorder	Prediction of Compensation
Metabolic acidosis	$P_{aCO_2} = (1.5 \times [HCO_3^-]) + 8$ or P_{aCO_2} will ↓ 1.25 mm Hg per mmol/L ↓ in $[HCO_3^-]$ or $P_{aCO_2} = [HCO_3^-] + 15$
Metabolic alkalosis	P_{aCO_2} will ↑ 0.75 mm Hg per mmol/L ↑ in $[HCO_3^-]$ or P_{aCO_2} will ↑ 6 mm Hg per 10 mmol/L ↑ in $[HCO_3^-]$ or $P_{aCO_2} = [HCO_3^-] + 15$
Respiratory alkalosis	
Acute	$[HCO_3^-]$ will ↓ 2 mmol/L per 10 mm Hg ↓ in P_{aCO_2}
Chronic	$[HCO_3^-]$ will ↓ 4 mmol/L per 10 mm Hg ↓ in P_{aCO_2}
Respiratory acidosis	
Acute	$[HCO_3^-]$ will ↑ 1 mmol/L per 10 mm Hg ↑ in P_{aCO_2}
Chronic	$[HCO_3^-]$ will ↑ 4 mmol/L per 10 mm Hg ↑ in P_{aCO_2}

responding appropriately or is responsible for the acidosis. NH_4^+ excretion can be estimated from a spot urine sample by consideration of the urine anion gap (UAG) and/or the urinary osmolal gap. The UAG, a commonly applied surrogate for the measurement of $[NH_4^+]_u$, is defined as the difference between the concentrations of chloride (Cl^-) and the sum of the urinary cations Na^+ and K^+ , that is, $UAG = [Na^+ + K^+]_u - [Cl^-]_u$. In chronic metabolic acidosis of nonrenal origin (such as diarrhea), the expected response by the kidney is to increase NH_4^+ production and excretion. The increase in $[NH_4^+]_u$ in the urine in this condition is detected, clinically manifested as an increase in the UAG (i.e., the urinary Cl^- exceeds the sum of urinary $Na^+ + K^+$). In contrast, in hyperchloremic metabolic acidosis of renal origin (i.e., RTA), the UAG is expected to be zero or positive, denoting no increase in, or minimal, NH_4^+ in the urine, signifying an inappropriate renal response to the metabolic acidosis or a tubular defect in H^+ secretion.² Caution is warranted with this test because ketonuria or the presence of drug anions or toxins (such as toluene metabolites) in the urine invalidates this method.

The urinary NH_4^+ may be estimated more precisely from the measured urine osmolality (U_{osm}), urine $[Na^+ + K^+]$, and urine urea and glucose:

$$\text{Urinary } NH_4^+ = 0.5(U_{osm} - 2[Na^+ + K^+] + [\text{blood urea nitrogen}/2.8] + [\text{glucose}/18])$$

If the difference in measured and calculated osmolality were 150 mOsm/kg H_2O , the ammonium concentration would be 150×0.5 or 75 mEq/L. Values less than 20 mEq/L suggest impaired ammonium excretion.

CLINICAL EXAMPLES OF METABOLIC ACIDOSIS

Clinical Settings for Mixed Acid-Base Disorders

Mixed acid-base disorders are commonly observed in patients in critical care units and may lead to dangerous extremes of pH or, conversely, a normal pH in the face of grossly abnormal values for P_{aCO_2} and HCO_3^- . Mixed acid-base disorders can be distinguished from simple (single) disturbances by prediction of the respiratory compensatory response (as explained previously), by comparison of the decrease in AG with the increase in serum HCO_3^- , or by the use of clinical nomograms.

High Anion Gap Acidosis (Anion Gap > 12 mEq/L)

There are five major causes of a high AG acidosis: (1) ketoacidoses, (2) L-lactic acidosis, (3) acute and chronic renal failure, (4) ingested drugs and toxins, and, rarely (5) gastrointestinal overproduction of organic acids (D-lactic acidosis) (Box 31-1 and Fig. 31-2).³ Identification of the underlying cause of a high AG acidosis is facilitated by consideration of the clinical setting and associated laboratory values. Initial screening to differentiate the high AG acidoses should include the following:

1. A careful history or other evidence of drug or toxin ingestion;
2. Arterial blood gas measurement to detect coexisting respiratory alkalosis;
3. Oxalate crystals in the urine plus an osmolal gap in the patient with a high AG acidosis suggest ethylene glycol ingestion;
4. Historical evidence of diabetes mellitus (diabetic ketoacidosis);
5. Evidence of alcoholism or increased levels of β -hydroxybutyrate (alcoholic ketoacidosis);
6. Observation for clinical signs of uremia and determination of blood urea nitrogen and creatinine (uremic acidosis);

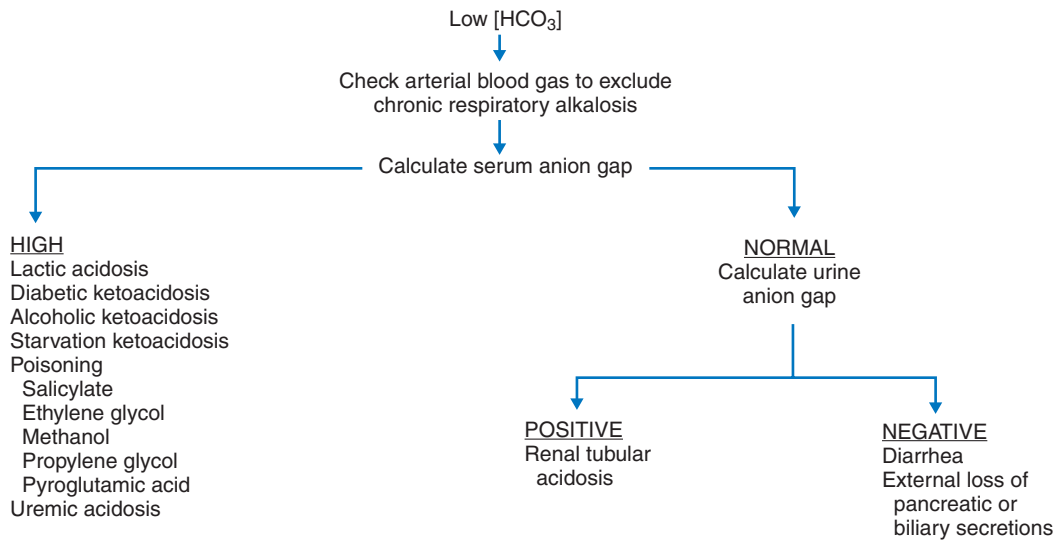

Figure 31-2 Diagnostic path for the patient presenting with low bicarbonate.

- Recognition of the numerous settings in which L-lactate levels may be increased (hypotension, cardiac failure, drugs, leukemia, cancer);
- Appreciation of the possibility of accumulation of D-lactate in the presence of low gastrointestinal motility, gastrointestinal obstruction, gastrointestinal pouches, antibiotic therapy, and bacterial overgrowth;

The distinguishing features of high AG acidoses are outlined in Figure 31-2.

Diabetic Ketoacidosis

Pathophysiology

Diabetic ketoacidosis is due to increased fatty acid metabolism and accumulation of acetoacetate and β -hydroxybutyrate, the consequences of insulin deficiency and relative excess of glucagon. An absence of insulin stimulates lipolysis and fatty acid release, whereas glucagon stimulates the hepatic metabolism of fatty acids to ketoacids.

Key Diagnostic Points

Diabetic ketoacidosis (most often in insulin-dependent diabetes mellitus) is seen in association with an intercurrent illness, particularly infections, which increase insulin requirements temporarily and acutely. The diagnosis is confirmed by the concurrence of a metabolic acidosis, strongly positive plasma ketones in undiluted serum, hyperglycemia, extracellular fluid (ECF) volume depletion, and Kussmaul's respiration. Although hyperchloremic acidosis may occur in patients who remain euolemic, the majority of patients will have an AG acidosis, a consequence of buffering by bicarbonate of the H^+ from ketoacids released into the plasma.

Therapeutic Options

Therapy consists of insulin to inhibit ketoacid production and intravenous fluids for ECF volume restoration and correction of electrolyte deficits. Low-dose intravenous insulin therapy (0.1 U/kg/hr) reduces plasma glucose, smoothly corrects the ketonemia, lowers the elevated AG, and repairs the acidosis. Although regular insulin may also be administered intramus-

cularly (0.2 mg/kg initially, then 6 units every hour), it should be noted that intramuscular insulin may not be effective in volume-depleted and/or hypotensive patients, as is often the case in ketoacidosis. Most, if not all, patients with diabetic ketoacidosis require correction of the ECF volume depletion that predictably accompanies the osmotic diuresis and ketoacidosis. Initiate therapy with IV isotonic saline at a rate of 1000 mL/hr. The usual ECF deficit in adults is in the range of 3 L of isotonic saline. When the pulse and blood pressure have stabilized and the corrected serum $[Na^+]$ is 130 to 135 mEq/L, switch to 0.45% NaCl. Ringer's lactate should be avoided. If the blood sugar decreases to less than 250 to 300 mg/dL, 0.45% NaCl with 5% dextrose should be administered.⁴

Total body potassium depletion is usually present. Nevertheless, the serum potassium is usually elevated at admission, indicating that potassium replacement therapy must be individualized. Normal or decreased $[K^+]$ on admission, which is found in certain patients (e.g., where vomiting was a prominent prodromal symptom), indicates severe potassium depletion. Potassium depletion occurs as a result of osmotic diuresis, decreased dietary intake, and vomiting, which accompanies diabetic ketoacidosis. Administration of saline, insulin, and alkali will cause the potassium level to decrease further by enhancing renal K^+ excretion. Frequent monitoring (hourly) of the serum potassium is mandatory and a precise recipe is difficult to provide. Caution should be exercised in the presence of hyperkalemia, especially in the patient with renal insufficiency; withhold potassium as long as the serum level is more than 5.0 mEq/L. Nevertheless, when urine output has been established, 20 mEq KCl may be administered in each liter of intravenous fluid as long as the plasma $[K^+]$ is less than 3.8 mEq/L. Monitor and record plasma concentrations of K^+ , glucose, HCO_3^- , Na^+ , and Cl^- hourly.

Controversial Points

The routine administration of phosphate (usually as potassium phosphate) is not advised because of the potential for hyperphosphatemia and hypocalcemia. A significant number of patients with diabetic ketoacidosis will display hyperphosphatemia before initiation of therapy. In virtually all patients, the increased phosphate concentration on admission is followed by

a decrease in plasma phosphate levels within 2 to 6 hours after initiation of therapy. In this circumstance, phosphate should be replaced as neutral potassium phosphate (10–20 mmol per liter of intravenous fluids) unless hyperkalemia coexists, in which case neutral sodium phosphate should be used. Bicarbonate therapy is usually not necessary unless the acidosis is very severe (pH < 7.0 and Paco_2 is low). In general, the increase in AG above normal represents potential bicarbonate or that bicarbonate that will be realized when circulating ketones are metabolically converted to bicarbonate following primary therapy (insulin). Nevertheless, during therapy it is difficult to predict to what extent ketones will be converted back to bicarbonate before being lost in the urine when glomerular filtration rate is normalized. If exogenous bicarbonate is administered, that amount of bicarbonate will be added to that produced endogenously so that an “overshoot alkalosis” may develop. Therefore, a prudent goal is to administer small amounts of bicarbonate (50–100 mEq IV in 250 mL of 0.25% NaCl) until the pH reaches approximately 7.2 or $[\text{HCO}_3^-]$ is 10 to 12 mEq/L. Because bicarbonate therapy has been associated with cerebral edema in children with diabetic ketoacidosis, it should be avoided in young children except for extreme acidemia (pH < 7.0) and then in very small amounts. Bicarbonate has never been demonstrated to improve the outcome in diabetic ketoacidosis. With exogenous bicarbonate therapy, additional potassium will be needed.⁴

Alcoholic Ketoacidosis

Pathophysiology and Diagnostic Points

This relatively common but underappreciated disorder occurs in alcoholics, particularly binge drinkers. Ketoacidosis develops when alcohol consumption is abruptly curtailed, usually as a result of vomiting or abdominal pain. In association with starvation and metabolism of ethanol (which inhibits gluconeogenesis), the glucose concentration is frequently low or normal. When ECF volume depletion is pronounced, the acidosis may be severe. The AG value is increased because of increased ketones, predominantly β -hydroxybutyrate. Mild lactic acidosis may coexist because of alteration in the redox state caused by ethanol or severe hypoxia. The nitroprusside ketone reaction (Acetest) can detect acetoacetic acid but not β -hydroxybutyrate, so the initial degree of ketosis and ketonuria may not be appreciated. Typically, insulin levels are low and levels of triglyceride, cortisol, glucagon, and growth hormone are increased, leading to ketoacidosis.

Therapeutic Options

The mainstay of therapy is intravenous normal saline to expand the ECF. Glucose is necessary if hypoglycemia is present. Insulin is obviously contraindicated, illustrating why the diagnosis of alcoholic ketoacidosis must not be mistaken for diabetic ketoacidosis. Intravenous replacement of potassium, phosphate, and magnesium deficits, as well as vitamin supplementation (thiamine 100 mg IV), are usually necessary and should be given as needed later in the course, particularly in the face of chronic alcoholism and malnutrition. Hypophosphatemia usually emerges several hours after admission, so the need for therapy can be overlooked, especially if the serum phosphate concentration on admission is normal. Profound hypophosphatemia may provoke aspiration, rhabdomyolysis, and coagulopathy. Phosphate should be replaced as either neutral sodium or potassium phosphate 10 to 20 mmol per liter of intravenous fluids, as dictated

by plasma $[\text{K}^+]$. Upper gastrointestinal hemorrhage, pancreatitis, and pneumonia may accompany alcoholic ketoacidosis.⁴

L-Lactic Acidosis

Pathophysiology

L-Lactic acidosis occurs in a diverse group of disorders that are recognized by an increase in plasma L-lactate concentration (normal venous levels < 1.8 mmol/L or 16 mg/dL). Brain, muscle, gastrointestinal tract, skin, and red cells produce lactate, whereas the liver is the major organ that participates in lactate disposal. Lactate synthesis is altered by changes in systemic pH, which control the rate of glycolysis by acting on the rate-limiting enzyme, phosphofructokinase. Acidosis decreases while alkalosis increases lactate production. The major determinants of plasma L-lactate levels include the concentration of pyruvate, the reduced nicotinamide adenine dinucleotide-to-oxidized nicotinamide adenine dinucleotide ratio, and the pH. Clinically significant L-lactic acidosis (plasma L-lactate > 4.0 mmol/L) is most often the result of tissue hypoxia; other causes include metabolic disorders, drugs, toxins, or hereditary defects. The accumulation of L-lactate may be secondary to an obvious cause of tissue hypoxia, for example, cardiac arrest, cardiogenic shock hemorrhage, sepsis, carbon monoxide poisoning, severe asthma, and severe anemia; this is called type A L-lactic acidosis. Conversely, type B L-lactic acidosis may accompany disorders in which tissue hypoperfusion or hypoxia are absent, such as diabetes mellitus, ethanol poisoning, liver failure, mitochondrial diseases, thiamine deficiency, malignancies, and drug and toxin overdose (e.g., metformin, salicylates, cocaine, fructose, cyanide, nonnucleoside reverse transcriptase inhibitors, nitroprusside). Lactic acidosis in combination with respiratory alkalosis can be observed early in the development of septic shock and may be one of the few harbingers of this entity.⁵

Treatment

The basic principle of therapy is that the underlying condition initiating the disruption in normal L-lactate metabolism must first be corrected. Every attempt should be made to restore tissue perfusion. Vasoconstricting agents should be administered only when absolutely necessary and at the lowest feasible dose because they potentiate the hypoperfused state. Alkali therapy is generally recommended for acute severe acidemia (pH < 7.15) to improve cardiac function and lactate utilization. However, the use of bicarbonate therapy is of only marginal value. Excess bicarbonate may depress cardiac performance and can even exacerbate the acidemia through increased phosphofructokinase activity. Thus, attempts to normalize the pH or $[\text{HCO}_3^-]$ by exogenous bicarbonate therapy is deleterious.⁵ One approach is to provide, by slow infusion over 30- to 40-minute intervals, sufficient bicarbonate to increase the arterial pH to no more than 7.2, that is, correct $[\text{HCO}_3^-]$ to 8 mEq/L. Despite initial enthusiasm for the use of dichloroacetate, a beneficial effect has not been substantiated. Similarly, no benefit is derived from administration of THAM (tromethamine). Thiamine should also be administered (50–100 mg) in patients with chronic malnutrition or alcoholism.

Fluid overload occurs with excessive bicarbonate therapy because the amount required is often massive when production of lactic acid is relentless. This complication may require slow continuous ultrafiltration, continuous venovenous hemodialysis, or acute intermittent hemodialysis. There is no evidence from controlled studies that would support one form

of renal replacement therapy over the others. Theoretically, all three should correct volume overload, remove lactate, and add bicarbonate. It has been the author's experience that continuous renal replacement therapy is more successful in controlling these parameters but offers no documentable improvement in overall mortality. Lactate-containing dialysate should be avoided, which obviates the use of typical peritoneal dialysis solutions. Unabated severe L-lactic acidosis in patients receiving large amounts of bicarbonate carries a very high mortality. If the underlying cause of the L-lactic acidosis can be corrected, the blood lactate will be reconverted to bicarbonate. Bicarbonate derived from lactate conversion in addition to any new bicarbonate generated by renal mechanisms during acidosis and from exogenous alkali therapy are additive and may result in an "overshoot" alkalosis.

D-Lactic Acidosis

Pathophysiology

D-Lactate, which is not an endogenous metabolite in vertebrates, is produced by bacterial overgrowth in the gastrointestinal tract in association with jejunoileal bypass, intestinal obstruction, antibiotic therapy, or decreased gastrointestinal motility. The diagnosis of D-lactic acidosis requires measurement of D-lactate levels specifically because it is not measured as L-lactate. The acid-base disturbance may consist of both an increased AG and hyperchloremia.⁶

Treatment

Because the potential danger in D-lactic acidosis is from accumulation of toxic products and not the acidosis, initial therapy should include (1) cessation of feeding, (2) eradication of bacterial overgrowth by administration of appropriate oral antibiotics (metronidazole or neomycin) or intravenous vancomycin, and (3) enhanced gastrointestinal motility. Longer term therapy may necessitate reversal of intestinal bypass if stasis and bacterial overgrowth persist or are recurrent.

Drug-Induced Acidosis

Salicylates

Aspirin overdose usually gives rise to a complex acid-base disturbance, in which respiratory alkalosis predominates (due to stimulation of respiration by salicylates) and a high AG may occur concomitantly. Only a portion of the increased AG can be attributed to the increased plasma salicylate concentration, for example, a toxic salicylate level of 100 mg/dL can only account for an increase in AG of 7 mEq/L. Lactic acid production is also often increased, partly as a direct effect of the drug and partly as a result of the decrease in P_{CO_2} induced by salicylate.^{3,4}

Treatment

The initial step in therapy should include vigorous gastric lavage followed by activated charcoal administration via a nasogastric tube. The mainstay of therapy is an alkaline diuresis to allow the relatively impermeant anionic form of salicylate to be trapped in tubular fluid and excreted in the urine. To facilitate removal of salicylate, intravenous sodium bicarbonate in amounts adequate to alkalinize the urine and maintain urine output is necessary (urine pH > 7.5). An alkaline diuresis may be induced by infusion of half-isotonic saline plus two ampoules of sodium bicarbonate (7.5% = 44.6 mEq or 8.4% = 50 mEq). Although this form of therapy is straightforward in acidotic patients, alkalemia from respiratory alkalosis

may make this approach hazardous. Arterial pH should be monitored and not allowed to increase to more than 7.55. Acetazolamide in small doses (250 mg) is recommended only when an alkaline diuresis cannot be achieved or when the pH exceeds 7.55 because larger doses may result in systemic metabolic acidosis if sodium bicarbonate is not given concomitantly. Moreover, acetazolamide and salicylates compete for binding sites on albumin. Coexisting metabolic acidosis greatly impedes salicylate clearance and enhances salicylate entry into the central nervous system and must be avoided. Hypokalemia may occur as a result of alkaline diuresis from either sodium bicarbonate or acetazolamide and should be treated promptly. If renal failure prevents rapid clearance of salicylate or if salicylate levels remain in the toxic range (>40–50 mg/dL), hemodialysis against a bicarbonate dialysate (35 mEq/L) should be performed.

Toxin-Induced Acidosis: Ethylene Glycol and Methyl Alcohol and the Osmolal Gap

Pathophysiology

Plasma osmolality (mOsm/kg H₂O) is calculated according to the following expression:

$$P_{osm} = 2Na^+ + \text{glucose}/18 + \text{blood urea nitrogen}/2.8,$$

where blood urea nitrogen and glucose are expressed in milligrams per deciliter. The calculated and determined osmolality should agree to within 10 to 15 mOsm/kg. When the measured osmolality exceeds the calculated osmolality by more than 15 to 20 mOsm/kg, one of two circumstances prevails: (1) the serum sodium may be spuriously low, as occurs with hyperlipidemia or hyperproteinemia (pseudohyponatremia), or (2) osmolytes other than sodium salts, glucose, or urea have accumulated in plasma. Examples include the accumulation of solutes that can increase plasma osmolality, such as the alcohols ethylene glycol and methyl alcohol. Less commonly, mannitol or retained radiocontrast agents increase the osmolal gap. In these examples, the difference between the calculated osmolality and the measured osmolality is proportional to the concentration of the unmeasured solute (osmolal gap). With an appropriate clinical history and index of suspicion, the osmolal gap becomes a very helpful screening tool in poison-associated AG acidosis.⁴

Ethylene Glycol

Diagnostic Points Ingestion of ethylene glycol (commonly used in antifreeze) leads to a metabolic acidosis and severe damage to the central nervous system, heart, lungs, and kidneys. Ethylene glycol (molecular mass 62 d) increases the osmolal gap (>10 mOsm/kg H₂O). The increased AG and osmolal gap are attributable to ethylene glycol and its metabolites oxalic acid, glycolic acid, and other organic acids. Lactic acid production increases secondary to inhibition of the tricarboxylic acid cycle and altered intracellular redox state. Diagnosis is facilitated by recognizing oxalate crystals in the urine, the presence of an osmolal gap in serum, and a high AG acidosis. Ethylene glycol ingested as antifreeze may be detected in the urine sample by use of Wood's light. Treatment should not be delayed while awaiting measurement of ethylene glycol levels in this setting. Propylene glycol, used as a vehicle for certain intravenous medications (e.g., lorazepam) has been associated with toxin-induced metabolic acidosis. Pyroglutamic acidosis has also been observed in critically ill patients receiving acetaminophen.⁴

Treatment

The principles of treatment of ethylene glycol intoxication (and propylene glycol intoxication) are to stop production of toxic metabolites by competitive inhibition of alcohol dehydrogenase using intravenous administration of fomepizole or ethanol, coupled with removal of the accumulated toxins. Immediate therapy is necessary to prevent irreversible central nervous system and renal toxicity. Ethanol (20% solution) 0.6 g/kg IV is given over 30 to 45 minutes followed by a maintenance infusion of 5% ethanol 110 mg/kg/hr to produce a serum ethanol level of 100 to 150 mg/dL. A saline or osmotic diuresis should be initiated and the patient given thiamine and pyridoxine supplements, fomepizole or ethanol, and hemodialysis. During dialysis, it is necessary to increase the rate of ethanol infusion. The intravenous administration of the alcohol dehydrogenase inhibitor fomepizole (4-methylpyrazole) (7 mg/kg as a loading dose) or ethanol serves to lessen toxicity because they compete with ethylene glycol for metabolism by alcohol dehydrogenase. Fomepizole, although expensive, offers the advantage of a predictable decrease in ethylene glycol levels without the adverse effects, such as excessive obtundation, associated with ethanol infusion.

Methyl Alcohol

Ingestion of methyl alcohol, as wood alcohol or paint thinners, causes metabolic acidosis and severe optic nerve and central nervous system manifestations when methyl alcohol is metabolized to formaldehyde and formic acid. Lactic acid, ketoacids, and other unidentified organic acids may contribute to the acidosis.⁴

Diagnostic Points Nausea, vomiting, and abdominal pain are usually present. Lactic acids and ketoacids as well as other unidentified organic acids may contribute to the high AG. Because of its high retention and low molecular mass (32 d), an osmolal gap is usually present.

Treatment The treatment of methyl alcohol intoxication is generally similar to that for ethylene glycol intoxication, including ethanol or fomepizole administration, general supportive measures, volume expansion, and hemodialysis. Initiation of a saline diuresis is less of an issue with methyl alcohol than with ethylene glycol intoxication because renal toxicity is not a direct effect of methyl alcohol intoxication and crystals are not present in the urine.⁴

Acute and Chronic Renal Failure**Pathophysiology**

Progressive renal insufficiency will eventually convert the hyperchloremic acidosis of moderate renal insufficiency to the typical high AG acidosis of advanced renal failure. Low glomerular filtration, continued reabsorption of organic anions, and low NH_4^+ excretion all contribute to the pathogenesis of this metabolic disturbance. As functional renal mass is compromised in the relentless progression of renal disease, the number of functioning nephrons eventually becomes insufficient to maintain NH_4^+ excretion to the extent necessary to balance net acid production. Thus, $[\text{HCO}_3^-]$ declines but rarely decreases to less than 15 mEq/L, and the AG rarely is more than 20 mEq/L. The acid retained in patients with chronic renal disease is buffered in part by alkaline salts derived from bone, resulting in

loss of bone calcium carbonate that contributes to the skeletal demineralization seen with renal acidosis. In addition, chronic acidosis increases urinary calcium excretion to a level proportional to the degree of cumulative acid retention and is corrected with repair of the acidosis.⁷

Treatment

Both uremic acidosis and hyperchloremic acidosis of renal insufficiency require oral alkali replacement to maintain $[\text{HCO}_3^-]$ between 20 and 24 mEq/L. This can usually be accomplished with relatively modest amounts of alkali (1–1.5 mEq/kg/day). Sodium citrate (Shohl's Solution or Bicitra) has been shown to enhance the absorption of aluminum from the gastrointestinal tract and should never be administered to patients receiving aluminum-containing antacids because of the risk of aluminum intoxication. If hyperkalemia persists, furosemide (60–80 mg/day) should be added.

Hyperchloremic Metabolic Acidosis (Normal Anion Gap Acidosis)**Pathogenesis and Differential Diagnosis**

Alkali may be lost from the gastrointestinal tract (diarrhea) or from the kidneys (RTA). In these disorders (Box 31-2), reciprocal changes in chloride and bicarbonate result in a normal AG. In a pure form of simple hyperchloremic acidosis, therefore, the increase in chloride above the normal value equals approximately the decrease in bicarbonate. The absence of such a relationship suggests a mixed disturbance. Diarrhea results in the loss of large quantities of HCO_3^- and further HCO_3^- depletion occurs by its reaction with organic acids. Instead of an acid urine pH, as often anticipated with diarrhea, a pH of 6.0 is usually observed because metabolic acidosis and hypokalemia increase renal NH_4^+ synthesis and excretion, thus providing more urinary buffer, which increases urine pH. Metabolic acidosis due to gastrointestinal losses with a high urine pH can be differentiated from RTA because urinary NH_4^+ excretion is low in RTA and high in patients with diarrhea. Urinary NH_4^+ levels can be estimated by calculating the UAG or the urine osmolal gap (see previously). With extrarenal bicarbonate loss, $[\text{Cl}^-]$ in urine exceeds $[\text{Na}^+ + \text{K}^+]$ in urine. If urine $[\text{Na}^+ + \text{K}^+]$ exceeds $[\text{Cl}^-]$, urine $[\text{NH}_4^+]$ is low, a finding compatible with RTA. The distinguishing features of hyperchloremic acidosis are outlined in Table 31-2.²

Hyperchloremic Acidosis of Chronic Renal Failure**Pathophysiology**
