The publisher's policy is to use permanent paper from mills that operate a sustainable forestry policy, and which has been manufactured from pulp processed using acid-free and elementary chlorine-free practices. Furthermore, the publisher ensures that the text paper and cover board used have met acceptable environmental accreditation standards.

Contents

Contributors, viii

Preface, xiv

Section 1: Physiology

- 1 Structure–Function Relationships: the Pathophysiology of Airflow Obstruction, 3
Dennis E. Niewoehner
- 2 The Physiology of Breathlessness, 20
Donald A. Mahler
- 3 The Physiology of Muscle, 26
Ghislaine Gayan-Ramirez and Marc Decramer
- 4 Exercise Limitations and Cardiopulmonary Exercise Testing in COPD, 40
Norman R. Morris, Lewis Adams, Bruce D. Johnson and Idelle M. Weisman
- 5 Clinical Assessment of Control of Breathing, 63
Joseph Milic-Emili and Antonia Koutsoukou
- 6 Physiology and Pathobiology of the Lung Circulation, 75
Norbert F. Voelkel
- 7 Sleep in Patients with COPD, 80
Mark W. Elliott
- 8 The Physiology of Cough, 90
Marian Kollarik and Bradley J. Undem
- 9 The Physiology of Gas Exchange, 102
Robert Rodriguez-Roisin, Andrés Echazarreta, Federico P. Gómez and Joan Albert Barberà

Section 2: COPD and Allied Conditions

- 10 The Natural History of COPD, 117
Jørgen Vestbo
- 11 Cystic Fibrosis, 124
Marcus P. Kennedy and Michael R. Knowles
- 12 Bronchiectasis and COPD, 139
Robert Wilson
- 13 Obliterative Bronchiolitis, 148
Hélène Levrey Hadden and Marshall I. Hertz
- 14 Asthma, 154
Diana C. Grootendorst and Klaus F. Rabe
- 15 COPD: Clinical Presentation and Evaluation, 167
Bartolome R. Celli
- 16 Monitoring and Outcomes, 181
Paul W. Jones

Section 3: Host Defences and Inflammation

- 17 Mucociliary Clearance, 191
Souheil El-Chemaly, Adam Wanner and Matthias Salathe
- 18 Mucosal Immunity, 201
Hugues Chanteux, Charles Pilette and Yves Sibille
- 19 COPD and Pulmonary Surfactant, 212
Carola Seifart and Bernd Muller
- 20 The Macrophage and its Role in the Pathogenesis of COPD, 219
Kellie R. Jones and Jordan P. Metcalf

- 21 Eosinophils and COPD, 233
Andrew J. Wardlaw
- 22 Airway Epithelial Defence, Repair and Regeneration, 245
Christelle Coraux, Jean-Marie Tournier, Jean-Marie Zahm and Édith Puchelle
- 23 The Role of the Neutrophil in the Pathogenesis of COPD, 255
Ian S. Woolhouse and Robert A. Stockley
- 24 Lymphocytes, 269
Simonetta Baraldo, Maria Elena Zanin, Renzo Zuin and Marina Saetta
- 25 Cytokines, 275
Jack A. Elias and Robert J. Homer
- 26 Leukotrienes in COPD: The Unexploited Potential, 285
Sven-Erik Dahlén
- 27 Cigarette Smoking, Emphysema and Lung Endothelium, 300
Stephanie A. Nonas, Irina Petrache and Joe G.N. Garcia
- 28 Mesenchymal Cells of the Lung, 308
Stephen I. Rennard and J. Graham Sharp

Section 4: Pathogenesis

- 29 Lung Development, 319
Cheng Chen, David Warburton and Wei Shi
- 30 Animal Models, 341
Piero A. Martorana, Monica Lucattelli, Barbara Bartalesi and Giuseppe Lungarella
- 31 Proteinases and COPD, 349
Anita L. Sullivan and Robert A. Stockley
- 32 Oxidants, 367
William MacNee
- 33 Cigarette Smoke-Induced Disease, 385
Stephen I. Rennard and Lisa M. Hepp
- 34 COPD and Air Pollution, 397
Kenneth Donaldson, Andrew Churg and William MacNee
- 35 Viruses in COPD, 408
Sam Hibbitts and Colin Gelder
- 36 Bacteria, 419
Sanjay Sethi
- 37 Genetic Factors, 436
Craig P. Hersh and Edwin K. Silverman

- 38 α_1 -Antitrypsin Deficiency, 447
Loufi S. Aboussouan and James K. Stoller
- 39 Body Weight and Systemic Effects, 460
Emile F.M. Wouters
- 40 Lung Connective Tissue, 467
Sarah E. Dunsmore and Geoffrey J. Laurent

Section 5: Clinical Considerations and Complications

- 41 Aerosols and Delivery Systems, 483
Stephen P. Newman
- 42 Gastro-oesophageal Reflux, 499
John K. DiBaise
- 43 Upper Airway Diseases, 513
Maria Rappai and Richard deShazo
- 44 Acute Pulmonary Embolism, 528
Victor F. Tapson
- 45 COPD and Lung Cancer, 538
Stephen G. Spiro and Frank McCaughan
- 46 Infection Management and Airflow Obstruction, 546
Alan M. Fein, Jill P. Karpel and Antonio Anzueto
- 47 Mechanical Ventilation for Exacerbation of COPD, 559
Andrea Rossi, Guido Polese and Lorenzo Appendini
- 48 Comorbidity, 569
Martin Sevenoaks and Robert A. Stockley

Section 6: Current and Future Treatment

- 49 Primary Care, 579
Daryl Freeman and David Price
- 50 Pulmonary Rehabilitation, 585
Richard ZuWallack
- 51 Social Support, 595
Robin Stevenson
- 52 Long-Term Invasive Mechanical Ventilation, 601
Gerard J. Criner
- 53 Smoking Cessation, 608
Philip Tønnesen
- 54 Oxygen Therapy in COPD, 622
Brian Tiep and Rick Carter
- 55 Surgical Therapy for COPD, 636
Fernando J. Martinez

- 56 Anticholinergics in COPD, 657
Theodore J. Witek, Jr
- 57 β_2 -Agonists, 669
Malcolm Johnson
- 58 Corticosteroids, 685
Olof Selroos
- 59 Phosphodiesterase 4 Inhibitors in the Treatment of COPD, 708
Hermann Tenor, Daniela S. Bundschuh, Christian Schudt, Dirk Bredenbröcker and Armin Hatzelmann
- 60 Antibiotic Therapy in Patients with COPD, 728
Michael S. Niederman
- 61 Antioxidants, 747
Claudio F. Donner
- 62 Mucolytics for COPD, 756
Duncan F. Rogers and Bruce K. Rubin
- 63 End-of-Life and Palliative Care for Patients with COPD, 769
John E. Heffner and Ann L. Heffner
- 64 Economic Burden of COPD, 779
David H. Au and Sean D. Sullivan
- 65 Pharmacoepidemiology of COPD, 792
Joan B. Soriano
- 66 Social and Behavioural Impact of COPD – Research Opportunities, 805
Suzanne S. Hurd and Claude Lenfant
- 67 Guidelines, 811
Peter M.A. Calverley
- Section 7: Pharmacotherapy:
Developing Therapies**
- 68 Protease Inhibitors, 823
Philip Davies, Malcolm MacCoss and Richard Mumford
- 69 Retinoids, 845
Stephen R. Tudhope
- 70 Chemokines in COPD, 859
Peter J. Barnes
- Index, 867
- Colour plate section falls between pp. 354 and 355*

Preface

In recent years COPD has become widely recognised as a major healthcare problem. This has led to an increase in interest of the clinical manifestations, management and pathophysiology of the condition. The increase in interest has been mirrored by dramatic increase in publications and research into COPD. Following on from this there has also been an increase in books dedicated to COPD.

Several years ago Steve Rennard and I noted that although there were several textbooks on COPD there were many facets of the condition that required alternative literature searches and turning to more books, particularly those of basic physiology. With this in mind we perceived that there was a need for a comprehensive textbook that covered normal and abnormal physiology, the latter being particularly related to COPD patients and that a spectrum from basic to clinical science was missing. Therefore we embarked upon a project to produce as comprehensive a book as possible.

However, it became clear that such a book would be extensive and would require the involvement of more editors. For this reason we were very pleased that we persuaded both Bart Celli and Klaus Rabe to join us in this task. The complexities resulted in a long gestation period, however the persistence of all of the editors and publishers eventually led to the development of this text. We recognize that any book of this sort should be regarded as a 'work in progress', since the field of COPD research is advancing steadily, but we greatly appreciate the work of the authors of the chapters to keep the book as up to date as possible.

We hope this text will provide background and update necessary for physicians/scientists/healthcare workers with an interest in COPD.

SECTION 1

Physiology

CHAPTER 1

Structure–function relationships: the pathophysiology of airflow obstruction

Dennis E. Niewoehner

A decrease in maximal expiratory flow rates is the cardinal physiological abnormality associated with chronic obstructive pulmonary disease (COPD). Expiratory flow obstruction is deemed to be so important that the presence and severity of COPD is commonly defined in terms of the forced expiratory pressure in 1 second (FEV_1) and of the ratio of the FEV_1 to the forced vital capacity (FVC) [1]. The morphological features thought responsible for expiratory airflow obstruction also play a prominent part in the causation of other physiological derangements in COPD, such as hyperinflation and uneven ventilation. These various functional abnormalities largely reflect the passive mechanical properties of the lung, namely the elastic behaviour of lung parenchyma and airways, and the flow-restrictive characteristics of the bronchial tree. The pathological lesions found in the lungs of COPD patients have been described in some detail, and they can be broadly classified into those that principally affect lung elastic recoil (emphysema) and others that primarily affect the flow-restrictive properties of the bronchi and bronchioles (airways disease). Ideally, an expert pathologist would be able to estimate accurately the degree of airflow obstruction from a comprehensive quantitative assessment of the diseased lung. This can be accomplished in rather broad terms, but the state-of-the-art falls well short of the ideal. The physiologist's assessment of disease severity in the individual case may be markedly discrepant from that of the pathologist. These failures reflect our incomplete understanding of basic pathophysiology in COPD, as well as the formidable methodological problems in studying an organ so structurally and functionally complex as the lung. This chapter describes some of the interrelationships of pathology with physiology in COPD.

Pathology

Emphysema

Patients with symptomatic COPD nearly always have some emphysematous involvement of their lungs, although the extent may vary widely among patients who have the same degree of spirometric impairment. Patients are sometimes labelled with a clinical diagnosis of 'emphysema', but this usage is discouraged because emphysema has a stricter, pathological definition. An expert committee has defined emphysema as 'a condition characterized by abnormal enlargement of the airspaces distal to the terminal bronchiole, accompanied by destruction of their walls, and without obvious fibrosis' [1]. Enlargement of the parenchymal airspaces within the gas exchange region of the lung (alveolus, alveolar duct and respiratory bronchiole) is the seminal feature of emphysema (Fig. 1.1). Airspace enlargement may be caused by actual departitioning and fenestration of the alveolar walls or by a simpler structural rearrangement of the normal acinus. Airspace enlargement is a normal feature of the ageing lung ('senile emphysema'), and it may also be observed in diseases such as interstitial fibrosis. Focal areas of fibrosis may be found in many lungs that are judged to have predominantly emphysema, particularly of the centriacinar subtype. Consequently, it may be difficult to ascertain the presence of mild grades of emphysema in the lungs of older patients, and in some instances there may be confusion as to whether airspace enlargement should be attributed to emphysema or to a separate disease process.

Pathologists recognize two principal subtypes of emphysema. Centriacinar, or centrilobular, emphysema is characterized grossly by discrete, enlarged airspaces, usually measuring 1–10 mm in diameter, which tend to be most prominent in the upper lobes. Microscopically, these

Figure 1.1 Macroscopic sections of inflation-fixed lungs comparing a normal subject (a) with a COPD patient having moderately severe emphysema (b). The emphysema has both centriacinar and panacinar features.

lesions may be seen in the proximal parts of the respiratory bronchiole, which is the partially alveolated airway immediately distal to the terminal bronchiole. Alveolar structures in the more distal acinus are usually well preserved, although very large centriacinar emphysema lesions may obliterate much of the acinus. Focal areas of inflammation, fibrosis and carbonaceous pigment are commonly present in adjacent alveolar and bronchiolar walls.

As the name implies, panacinar, or panlobular, emphysema, more uniformly involves the entire acinus. Macroscopically, mild panacinar emphysema appears as a subtle diffuse enlargement of airspaces, which resembles the aged lung. With progression of the disease, single lesions coalesce to form airspaces measuring millimeters to centimeters in diameter; large bullae may form in severe cases. Microscopically, alveolar ducts are diffusely enlarged, and adjacent alveoli become effaced to the extent that individual units cannot be identified. Panacinar emphysema involves all regions of the lung, and some patients, particularly those with severe α_1 -antitrypsin deficiency, may exhibit a basal predominance.

When lung sections are appropriately stained, a dense

labyrinth of elastic fibres becomes visible within alveolar walls and around peripheral airways (Fig. 1.2). This intricate elastic fibre network helps maintain normal parenchymal structure and contributes importantly to the lung's distinctive elastic recoil properties. The prevailing theory is that emphysema develops from an elastase–antielastase imbalance causing damage to the elastic fibres within the lung parenchyma. Despite their presumed importance in the pathogenesis of emphysema, surprisingly little is known about the state of elastic fibres and other extracellular matrix components in severe human emphysema. Existing studies are mostly descriptive and such basic information as the elastin content of the emphysematous lung is not available.

Emphysema is an anatomical entity, so that estimates of prevalence and severity can be directly made only from specimens obtained by surgical resection or at autopsy. Because reliable estimates of emphysema severity require that specimens be fixed in a uniformly inflated state, whole lungs or lobes are generally more satisfactory than smaller lung samples. The most widely used and accepted method for estimating emphysema severity utilizes a standard panel

Figure 1.2 Thick histological section of normal human lung stained for elastic fibres. Elastic fibres appear as a lacy network of thin dark lines when an alveolar wall is viewed *en face*. Thicker elastic fibres surround the ostia connecting alveolar ducts with individual alveoli. Elastic fibres are major contributors to lung elastic recoil.

that depicts whole lung sections with increasing degrees of emphysema [2]. The lung section in question is subjectively scored by direct comparison against the panel. Determination of a mean linear intercept (average distance between alveolar walls) is the preferred method for evaluating emphysema severity from histological sections. This method has the advantage of being truly quantitative, but it is time and resource intensive and, because of sampling issues, it is limited in its capability for distinguishing mild emphysema from normal lung [3]. Milder forms of emphysema may be focal in their distribution, and can usually be best appreciated from visualization of whole-lung slices. Estimates of emphysema severity by the picture panel and the mean linear intercept methods are generally in good agreement, but for most purposes the picture panel method is considered the gold standard.

There is now good evidence that reliable estimates of emphysema severity may be made indirectly from computed tomography (CT). Studies to date have consistently shown a good correlation between regions of reduced lung tissue density found on CT scan and the presence of anatomical emphysema [4]. CT scans are highly specific, but they lack sensitivity in detecting very mild grades of emphysema. This is an evolving technology, with issues relating to sensitivity, specificity and standardization currently being addressed.

Airways disease

Much confusion attends the terminology associated with airways disease in COPD. The term ‘chronic bronchitis’ has been widely used but with a variety of meanings. Strictly

speaking, ‘chronic bronchitis’ refers to an inflammatory condition involving the bronchi, which are the more central, larger and cartilage-containing airways. (The more peripheral airways without cartilage are termed bronchioles.) However, pathologists sometimes refer to bronchial mucous gland enlargement as ‘chronic bronchitis’. To complete this rather illogical pattern, the term has also been used to define a ‘clinical disorder characterized by excessive mucus secretion in the bronchial tree, manifested by chronic or recurrent productive cough on most days for a minimum of 3 months per year for not less than 2 successive years’ [5]. Experts arrived at this definition when excess mucus secretion was thought to have a central role in the development of airflow obstruction in COPD. This is no longer thought to be the case, but the definition persists to the bewilderment of several generations of medical students and residents. To avoid this confusion, all pathological changes within the bronchial tree that have been implicated in the pathophysiology of COPD will be called simply ‘airways disease’. For reasons that will later become evident, it is appropriate to distinguish pathological changes that primarily involve the central bronchi from those found in the peripheral bronchioles.

Central airways disease

Mucus lines the airway lumens of the bronchial tree and serves an important role in host defence against the environment. Mucous glands, containing both mucous and serous cells, are found between the epithelial basement membrane and the cartilage plates of the central bronchial tree. Mucus is actively secreted into the bronchial lumen via specialized ducts. Modest enlargement of the bronchial mucous glands is found in the lungs of many patients with COPD but not all. Bronchial mucous gland enlargement correlates with cough and excess sputum production [6]. The Reid Index was the first described method for quantifying the degree of mucous gland enlargement [7]. In this technique, the width of the mucous gland is compared with the width of the bronchial wall between the basal lamina and the perichondrium. This method has been largely supplanted by better methods which quantify area proportions. The volume of bronchial mucous gland may increase by 50–100% in selected cases of severe COPD (Fig. 1.3).

In addition to the mucous glands, mucus-secreting goblet cells are found in airway epithelium at all levels of the conducting airways. The population of epithelial goblet cells may expand in the larger airways of COPD patients, but existing studies are mostly descriptive. Epithelial metaplasia and loss of cilia have also been described. It is not clear whether the proportions of smooth muscle and cartilage are abnormal in lungs of COPD patients. COPD is commonly associated with a low-grade inflammatory response within the epithelium and submucosa of the more central

Figure 1.3 Histological section of a cartilaginous bronchus from a COPD patient with chronic cough and sputum production shows marked mucous gland enlargement. Mucous glands normally occupy but a small part of the area between cartilage and epithelium. A low-grade inflammatory reaction commonly accompanies mucous gland enlargement.

bronchi. Neutrophils, macrophages and CD8⁺ T lymphocytes are the predominant inflammatory cells [8].

Peripheral airways disease

The pathological changes seen in the peripheral airways of COPD patients are multiple and relatively non-specific

(Fig. 1.4). The earliest abnormalities seen in lungs from young smokers are focal collections of brown-pigmented macrophages in the proximal respiratory bronchioles [9]. In older patients with established COPD, the walls of membranous bronchioles frequently contain a low-grade inflammatory response that includes scattered neutrophils, macrophages and lymphocytes [10]. Additional abnormalities include fibrosis, goblet cell and squamous cell metaplasia of the lining epithelium, smooth muscle enlargement and scattered aggregations of mucus within the lumen. Most of this pathology can probably be directly attributed to the toxic effects of cigarette smoke, but peripheral airways in the lungs of elderly lifelong non-smokers may exhibit some of the same abnormalities [11].

Measurements in lungs obtained at surgery and at autopsy indicate that the internal calibre of fully distended peripheral bronchioles is smaller in COPD patients compared with normal subjects [11,12]. In addition, the walls of bronchioles from COPD patients are abnormally thickened, with the increased width being caused by epithelial, smooth muscle and connective tissue elements [13]. Abnormally thickened airway walls may take on added functional significance at smaller lung volumes, because the peripheral airways shorten and narrow as the lung deflates. Figure 1.5 illustrates this point. In the example shown, the abnormal airway has a wall that is twice the

Figure 1.4 Normal terminal bronchiole from a human lung is a thin-walled structure with an internal diameter of approximately 0.5 mm (a). Section through the junction of a membranous and respiratory bronchiole from the lung of a young adult shows the typical inflammatory lesion caused by cigarette smoking (b). Clusters of brown-pigmented macrophages are visible in the respiratory bronchiole and a few mixed inflammatory cells are present within the walls of the membranous bronchiole. In patients with established COPD, membranous bronchioles may exhibit thickened walls and narrowed distorted lumens (c).

Figure 1.5 External airway diameter decreases as lung volume becomes smaller. Because the volume of the airway wall remains constant, the wall becomes thicker at smaller lung volumes, with a disproportionate reduction in the calibre of the lumen. At very small lung volumes, longitudinal folds may develop along the inner wall of the airway. Abnormally thick airway walls, as occurs in COPD, may exaggerate this effect.

normal thickness. For the same change in external diameter, the lumen of the abnormal airway wall narrows to a far greater extent because the constant volume of excess tissue tends to bulge inward. This effect is greatly magnified at very small lung volumes, where the development of longitudinal folds along the inner surface may predispose to complete airway closure.

The accurate assessment of diverse pathological features that are widely distributed among tens of thousands of individual airways presents a formidable problem. Standardized scoring systems and direct quantitative approaches that measure the dimensions and volume components of the airways have largely supplanted earlier descriptive studies [11,12,14]. However carefully they are performed, assessments of airways in fixed tissues may poorly reflect their functional behaviour during the respiratory cycle. There have been efforts to image airways with CT and ultrasound during life [15,16]. These methods are interesting and promising, but they have yet to be fully validated. The major issue is whether they are capable of adequately resolving the dimensions of the smaller airways.

Physiological abnormalities

Lung elastic recoil

Lung elastic recoil refers to the lung's intrinsic tendency to deflate after it has been inflated. This relationship is commonly expressed by plotting lung volume as a function of transpulmonary pressure under the condition of no airflow

Figure 1.6 Lung volume as a function of lung elastic recoil pressure in a normal subject and in a COPD patient with extensive emphysema. At any particular lung volume, lung elastic recoil pressure is reduced with emphysema. In addition, the pressure–volume curve in the emphysema patient exhibits greater concavity towards the pressure axis. RV, residual volume; TLC, total lung capacity.

(Fig. 1.6). Transpulmonary pressure is defined as the pressure differential between the inside and the outside of the pleura. Pressure in the pleural space may be roughly estimated from a balloon catheter placed in the mid-oesophagus. In normal young adults, transpulmonary pressure at total lung capacity (TLC) is typically in excess of 35 cm H₂O and at functional residual capacity (FRC) is approximately 5 cm H₂O. Lung elastic recoil is sometimes defined in terms of compliance, defined as the change in lung volume relative to the change in pressure. The pressure–volume relationship is curvilinear through its entirety, and as a result, compliance has a unique value at each lung volume. There has been some success in fitting empirical mathematical models to the pressure–volume curve so that the entire relationship can be described by estimation of one or two parameters [17,18]. For most purposes lung elastic recoil can be adequately described in terms of the transpulmonary pressure at some specified lung volumes, TLC and FRC being most commonly used.

Loss of lung elastic recoil is one of the distinguishing features of ageing. This occurs in a manner so predictable that age can be estimated with fair accuracy from the pressure–volume characteristics of a postmortem lung [17]. Age-related losses in lung elasticity probably explain much of the decrease in spirometric function that occurs with advancing age.

Lung elastic recoil may be divided into two components: one resulting from tissue elasticity and a second attributable

to the air–liquid interface at the alveolar surface. Tissue elasticity arises from the rich network of elastic fibres within lung parenchyma, from other components of the extracellular matrix, and from the geometrical arrangements of these elements. Isolated elastic fibres behave much like rubber bands, snapping back to their original position upon being stretched to twice their resting length. Alveolar structures are sufficiently small that surface tension at the air–liquid interface creates significant pressure within the alveolar spaces, even in the presence of the surface tension-lowering substance, surfactant. This relationship is defined by the law of Laplace, which states that the pressure within a wetted sphere is proportional to the tension within the lining liquid film and inversely proportional to the radius of curvature. Comparing pressure–volume curves from air- and fluid-filled lungs delineates the contribution of tissue elements and of surface tension. Both make substantial contributions in the human lung. Hence, damage to matrix elements and loss of alveolar surface area would both be expected to reduce lung elastic recoil.

Because damage to elastic fibres and loss of alveolar surface area are the characteristic pathological features of emphysema, a decrease in lung elastic recoil would be anticipated. This prediction has been fully confirmed and Figure 1.5 illustrates the typical abnormality. Compared with normal, the severely emphysematous lung exhibits a substantial loss in elastic recoil pressure at all lung volumes. In addition, the pressure–volume curve in severe emphysema exhibits a shape change, being somewhat more convex with respect to the pressure axis. These altered lung elastic properties might be viewed as the primary functional defect associated with human emphysema.

Airflow resistance

The human bronchial tree is a complex structure. Starting with the trachea, conducting airways branch in an irregularly dichotomous pattern. Different pathways from trachea to terminal membranous bronchiole may encompass as few as 10 generations or as many as 25. Further branching occurs within the partly alveolated respiratory bronchioles distal to the terminal bronchiole. The internal diameter of the adult trachea is approximately 2 cm. Airway calibre decreases with each succeeding generation to a miniscule 0.5 mm at the level of the terminal bronchiole. Because there are approximately 50 000 terminal bronchioles in each human lung, total cross-sectional area at this level of the bronchial tree exceeds that of the trachea by about two orders of magnitude. Hence, the velocity of airflow during the breathing cycle is substantially larger in the central airways compared with the peripheral airways.

A pressure differential is necessary to generate airflow through a cylinder. The ratio of the longitudinal pressure

difference to the flow rate defines airflow resistance. The magnitude of airflow resistance varies with the flow profile (laminar versus non-laminar), the physical properties of the gas and the dimensions of the cylinder. The many airways comprising the bronchial tree can be viewed as resistive elements existing in series and in parallel.

As is true for lung parenchyma, airways exhibit intrinsic elastic behaviour which allows them to widen or narrow in response to traction and pressure differentials. Because of the cartilaginous rings within their walls, proximal bronchi are relatively rigid structures. However, the membranous posterior portion is easily deformed, and it will bow inward to occlude the airway lumen when subjected to large compressive pressures. Peripheral bronchioles have little inherent rigidity. The relatively thin, cartilage-free walls of these airways are embedded within lung parenchyma, and they depend upon the tethering effect from alveolar wall attachments to maintain patent lumens. The outward tension exerted by alveolar walls is a function of lung volume; the bigger the volume, the larger the lung elastic recoil, and the greater the tension within each alveolar attachment. If the lung were to exhibit perfect isotropy, a 50% reduction in lung volume would be associated with a 21% reduction in airway calibre.

Assessment of airflow resistance requires simultaneous measurements of airflow at the mouth and of pressure differential between the mouth and the alveolus. Alveolar pressures can be estimated either with an oesophageal balloon or by a plethysmographic method. Figure 1.7 compares

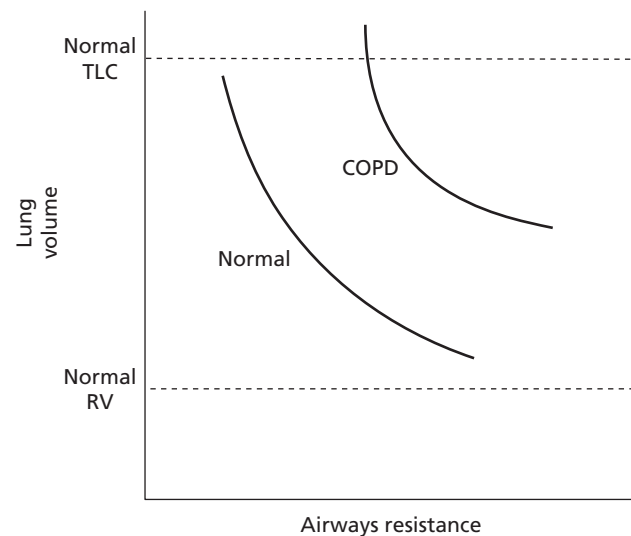

Figure 1.7 Lung volume as a function of airways resistance in a normal subject and in a COPD patient. In both patients airways resistance increases as lung volume becomes smaller. At any given lung volume, airways resistance is considerably larger in the COPD patient. RV, residual volume; TLC, total lung capacity.

typical airflow resistance as a function of lung volume in a normal subject with that in a COPD patient with emphysematous lungs. There is a strong volume dependence of airflow resistance in both subjects, this reflecting the decrease in lung elastic recoil and consequent reduction in airway calibre at smaller lung volumes. Airflow resistance is substantially higher at comparable lung volumes in the patient with COPD, and this might be attributed to two distinct mechanisms. At the same lung volumes, lung elastic recoil would be less in the emphysematous lungs, with the expectation that airways would be narrower and airflow resistance would be higher. It is possible to negate this effect by comparing airflow resistance in different lungs at the same lung elastic recoil pressures. Under these conditions, airflow resistance is still substantially higher in COPD compared with normal. This strongly suggests structural and functional abnormalities inherent to the conducting airways cause increased airflow resistance in COPD.

The dominant site of airflow resistance within the pulmonary airways is not intuitively obvious. The bronchial tree is a complex structure and pathological changes have been described at all levels in lungs from patients with COPD. The peripheral bronchioles are much smaller than the proximal bronchi, but there are a great many of them. Total cross-sectional area at the level of the terminal bronchiole is larger than the trachea by orders of magnitude. However, this tells us little about the relative flow-resistive properties at the two levels, because area changes as the square of airway radius while resistance changes as the fourth power or higher.

Studies with a retrograde catheter in excised animal and human lungs provide an invaluable clue to the site and nature of increased airflow resistance in COPD [19,20]. The catheter was placed at a site in the bronchial tree where airflow resistance in airways less than 2 mm diameter could be partitioned from resistance in airways with a diameter of greater than 2 mm. The first studies were performed in normal dogs and they yielded results that at the time were considered rather surprising [19]. The peripheral component accounted for only approximately 10% of total airflow resistance, a value much smaller than had been suggested by earlier studies.

Retrograde catheter studies of central and peripheral airflow resistance were subsequently made in postmortem lungs from subjects with and without COPD [20]. As was the case in dog lungs, the peripheral component of total airflow resistance in normal human lungs appeared quite low, representing only 10–20% of the total. In lungs from COPD patients, the central component of airflow resistance was only slightly increased from that in normal lungs. However, the peripheral component was increased by factor of between 10 and 20. These observations added enormously to our understanding of the pathophysiology

of COPD, because they indicated that it was disease in the distal airways and not the large bronchi that was principally responsible for increased airflow resistance in COPD.

The partitioning of airflow resistance in normal and diseased human lungs also led to a novel idea about the natural history of COPD, which in turn spawned a large and mostly futile research effort. The retrograde catheter studies indicated peripheral airflow resistance was negligible in normal lungs, but predominant in severe COPD. Therefore, early stages of the disease might be associated with pathological changes in the peripheral airways that had minimal effect on standard tests of lung function, such as the FEV_1 . It was further reasoned that these early changes might better be detected with more sensitive, non-standard tests. Considerable effort was expended in developing and evaluating newer, so-called ‘tests of small airways disease’, including the frequency dependence of dynamic lung compliance, the single breath nitrogen washout test, and spirometry with exotic gas mixtures. These tests have long been abandoned, because a variety of epidemiological and pathological–physiological correlative studies indicated that these newer, specialized tests offered little advantage over the FEV_1 in detecting the earliest stages of COPD [21–24].

These newer tests failed in part because they were based on a faulty rationale. Studies by other investigators indicated that the original retrograde catheter studies were subject to methodological errors that led to a systematic underestimate of peripheral airflow resistance in both normal and COPD lungs [25,26]. Repeat measurements in human lungs indicated that the peripheral component represents approximately 90% of total airflow resistance in the normal lung [27]. Additionally, studies in normal postmortem lungs demonstrated a remarkably good correlation between total airflow resistance and the diameter of the peripheral airways, but not with the diameter of the proximal airways [28].

These findings have important implications regarding our understanding of COPD. They lend strong support to the concept that the peripheral airways, and not the central airways, are principally responsible for the increased airflow resistance in COPD. If the peripheral airways determine levels of ventilatory function in the normal lung, it logically follows that relatively minor pathological changes in those same airways take on added functional significance in disease states.

Maximal expiratory airflow limitation

Spirometry is recommended as the single best test for the diagnosis of COPD. During this procedure maximal expiratory airflow is measured as a function of time, and the result is graphically displayed as either a volume–time or flow–volume plot. The two plots contain identical

Figure 1.8 Expiratory flow–volume loops as a function of absolute lung volume in a normal subject and in a patient with COPD. This figure illustrates the cardinal functional abnormalities associated with COPD, expiratory airflow limitation and hyperinflation. FVC, forced vital capacity; RV, residual volume.

information. The most common parameters extracted from the spirogram are the FEV_1 and the FVC. The expiratory flow rate between 200 and 1200 mL of the FVC, the mid-expiratory forced expiratory flow rate between 25% and 75% of the FVC, and other less frequently used spirometric parameters contain little additional diagnostic information and have fallen out of favour. A decrease in the FEV_1 , best expressed as the percentage of predicted, and a decrease in the ratio of the FEV_1 to the FVC (FEV_1/FVC) are the hallmark spirometric abnormalities of COPD.

Figure 1.8 shows representative flow–volume curves from a normal subject and from a patient with COPD. At any given fraction of VC, maximal expiratory flow rates are smaller in the COPD patient. In this example, flow rates are shown as a function of absolute lung volume to illustrate another of the cardinal physiological abnormalities in COPD. The COPD patient exhibits hyperinflation in that both the TLC and residual volume (RV) are shifted to larger lung volumes.

Forced expiratory flow–volume curves exhibit a phenomenon that is termed airflow limitation. The principle can be demonstrated by having a normal subject perform a series of full inspiratory and expiratory breathing manoeuvres between RV and TLC, each with a different strength of effort. Figure 1.9 depicts these graded efforts (*a* increasing through *e*) as a family of flow–volume loops. Greater effort during the inspiratory phase yields larger flow rates, and these increases are roughly proportional at all lung volumes. On the expiratory cycle, greater effort also generates larger flow rates, but only at the higher lung volumes. At intermediate and low lung volumes, airflow

Figure 1.9 A normal subject performed a series of full inspiratory and expiratory manoeuvres with graded effort (*a–e*). On the expiratory limbs, flow rates are independent of effort at smaller lung volumes. This phenomenon, described as ‘flow limitation’ or ‘effort-independence’, is not seen with inspiratory manoeuvres.

increases with added effort, but only up to a certain point. At that point the tracing superimposes those from other individual efforts. Over the lower two-thirds of the vital capacity a ceiling becomes evident, beyond which airflow does not increase further however great the expiratory effort. Expiratory flow rates at these lung volumes are sometimes described as being ‘flow limited’ or ‘effort independent’.

The principle of flow limitation can be demonstrated in somewhat better detail from what are called isovolume pressure–flow diagrams (Fig. 1.10). Inspiratory and expiratory flow are plotted as a function of alveolar pressure at specified lung volumes. The pressure differential between the mouth and the alveolar space, or driving pressure, generates airflow through the bronchial tree. Alveolar pressure is negative with respect to the mouth during inspiration and positive with expiration. During inspiration, airflow remains linear with driving pressure at each of the indicated lung volumes, meaning that airflow resistance remains nearly constant. Hence, inspiratory flow is largely limited by the magnitude of the applied pressure, which is largely a function of respiratory muscle strength. Differences in

Figure 1.10 Relationship of inspiratory and expiratory airflow rates to alveolar pressure at various lung volumes. With inspiration, flow increases proportionally to alveolar pressure. With expiration, flow increases with alveolar pressure only to a certain point, beyond which flow remains constant despite greater alveolar pressures. This effect, flow limitation, is most pronounced at smaller lung volumes.

the slopes of the pressure–flow relationships at the three different lung volumes indicate that airflow resistance becomes greater as lung volumes become smaller.

The patterns obtained during expiration are qualitatively different in that relationships between the pressure differential and airflow are curvilinear rather than linear. This is most obvious at smaller lung volumes where a fairly sharp inflection occurs at a relatively low driving pressure. Beyond this inflection, the relationship assumes a plateau shape, meaning that airflow is independent of changes in driving pressure. In other words, greater expiratory effort creates greater airflow resistance with no increase in airflow. Limitations to expiratory airflow are set by the mechanical properties of lung parenchyma and bronchial tree.

The relevance of expiratory airflow limitation to clinical disability can be appreciated by comparing flow–volume loops from a COPD patient with that of a normal subject. Figure 1.11 shows inspiratory and expiratory flow–volume loops during tidal breathing at rest and with maximal effort in the two subjects. Note that the normal subject has enormous reserve and from the resting state is able to increase minute ventilation by a large factor in response to increased metabolic demands. Consequently, ventilation is not a limiting factor, even with very vigorous exercise. In contrast, maximal inspiratory and expiratory flow rates are much smaller in the patient with COPD, expiration typically being more severely affected than inspiration. Most importantly, a large portion of the expiratory flow–volume loop

Figure 1.11 Inspiratory and expiratory flow–volume loops in a normal subject and in a patient with severe COPD. The outer loops represent maximal efforts and the loops represent tidal breathing. In the patient with COPD, expiration is flow limited even during a tidal breath.

obtained during tidal expiration superimposes that from a forced expiration. Severe COPD patients exhibit flow limitation even while meeting the minimal ventilatory requirements of the resting state. These patients have only limited capability for increasing minute ventilation in response to exercise. Their only effective strategy for increasing minute

ventilation is to shift tidal breathing to larger lung volumes where higher expiratory flow rates can be achieved. Clinical studies have shown that hyperinflation is a common response to increased workload in COPD patients [29]. Unfortunately, this compensatory mechanism comes with a price, because the lung and the thoracic cage both become stiffer at larger volumes. This increases the elastic workload of the respiratory muscles and is an important component in generating the sensation of breathlessness.

Mechanism of expiratory airflow limitation

Models of varying complexity have been used to analyse the physical behaviour of the lung in an effort to explain flow limitation during forced expiratory manoeuvres. A relatively simple model is described that provides some insight into this mechanism. The interested reader is referred elsewhere for more detailed and rigorous approaches to the subject [30–32].

The model shown in Figure 1.12 includes an expandable balloon to represent lung parenchyma. The balloon is contained within a box that depicts the thoracic cage. The space between the box and the balloon may be viewed as the pleural space. An airway with semi-rigid walls connects the balloon to the exterior. Up or down movement of the piston, representing the function of respiratory muscles, activates the model by altering intrapleural pressure (Ppl). The centrally directed arrows on the interior of the balloon symbolize lung elastic recoil.

Figure 1.12(a) shows the model at a fixed volume with no airflow. Under these static conditions, there is no gradient along the length of the airway and alveolar pressure (Palv) is equal to the reference pressure at the airway opening (Pao). The intrapleural pressure required to keep the lung statically inflated (arbitrarily chosen to be -10 cm H₂O in this example) is equal in magnitude but opposite in sign to the lung elastic recoil pressure (Pel). Hence, Palv is the algebraic sum of Ppl and Pel.

Downward motion of the piston creates a more negative Ppl. Palv now becomes negative with respect to Pao and air flows into the lung. On expiration, muscles relax and the lung typically contracts passively because of its inherent elastic recoil. As Ppl becomes less negative (-10 cm H₂O increasing to -5 cm H₂O), Palv becomes positive with respect to Pao and the lung exhales air (Fig. 1.12b). During the normal tidal breathing cycle, Ppl fluctuates by only a few centimetres H₂O and it remains negative even during expiration. As a result, pressure at each point within the conducting airway remains positive with respect to Ppl during the entire inspiratory and expiratory cycle. Consequently, an outwardly directed transmural pressure gradient expands the airway along its entire length, an effect that is greater during inspiration.

However, a forced expiratory effort creates a strongly positive Ppl that reverses the usual transmural pressure gradient along a segment of the airway. Figure 1.12(c) illustrates these pressure relationships during a submaximal forced expiration. Respiratory muscles generate sufficient force to increase Ppl to $+10$ cm H₂O. From the algebraic sum of Ppl and Pel, Palv now becomes $+20$ cm H₂O. The alveolar driving pressure dissipates along the length of airway lumen and at some point becomes equal to Ppl so that the transmural pressure gradient is zero. This is sometimes described as the 'equal-pressure point' (EPP). The EPP has no fixed anatomical site. Direct measurements suggest that the EPP is located in the central cartilaginous airways during the early stages of the maximal expiratory manoeuvre, but then migrates peripherally at lower lung volumes. Downstream from the EPP, intraluminal pressures become negative with respect to Ppl, creating a compressive force on the airway. Because the airway is not a rigid tube, compressive pressures narrow the lumen to some degree, thereby increasing airflow resistance. The length of compressed airway is referred to as the 'flow-limiting segment'.

Figure 1.12(d) illustrates the same relationships but with a more forceful expiratory effort. In this example, Ppl increases to $+20$ cm H₂O and the alveolar driving pressure, Palv, now enlarges to $+30$ cm H₂O. Because of the higher Ppl, compressive transmural pressures downstream from the EPP are now twice as large as in Figure 1.12(c). This further narrows the airway lumen with a corresponding increase in airflow resistance. In other words, greater expiratory effort increases the pressure head between alveolus and airway opening, but it also increases flow resistance because of greater compression of the airway downstream from the EPP. The result is little net change in expiratory airflow. This type of feedback mechanism for limiting flow is sometimes referred to as a Starling resistor, of which there are examples in other organ systems. It bears emphasizing that these relationships are exceedingly complex when analysed from first principles and no physical law requires that changes in Palv and airflow resistance need be strictly proportional. However, empirical observations indicate that these changes are roughly proportional in most human subjects.

The illustrated model permits some insight into other factors that might influence the flow-limiting airway segment. It is intuitively evident that a less rigid airway would narrow to a greater extent in response to the same transmural compressive pressure differential. Other conditions being equal, excessively compliant central airways would fix maximal expiratory airflow at a lower level. It is unclear from existing studies whether bronchial compliance is abnormal in well-defined patients with COPD.

Airflow resistance in more distal portions of the conducting airways may accentuate compressive effects on the

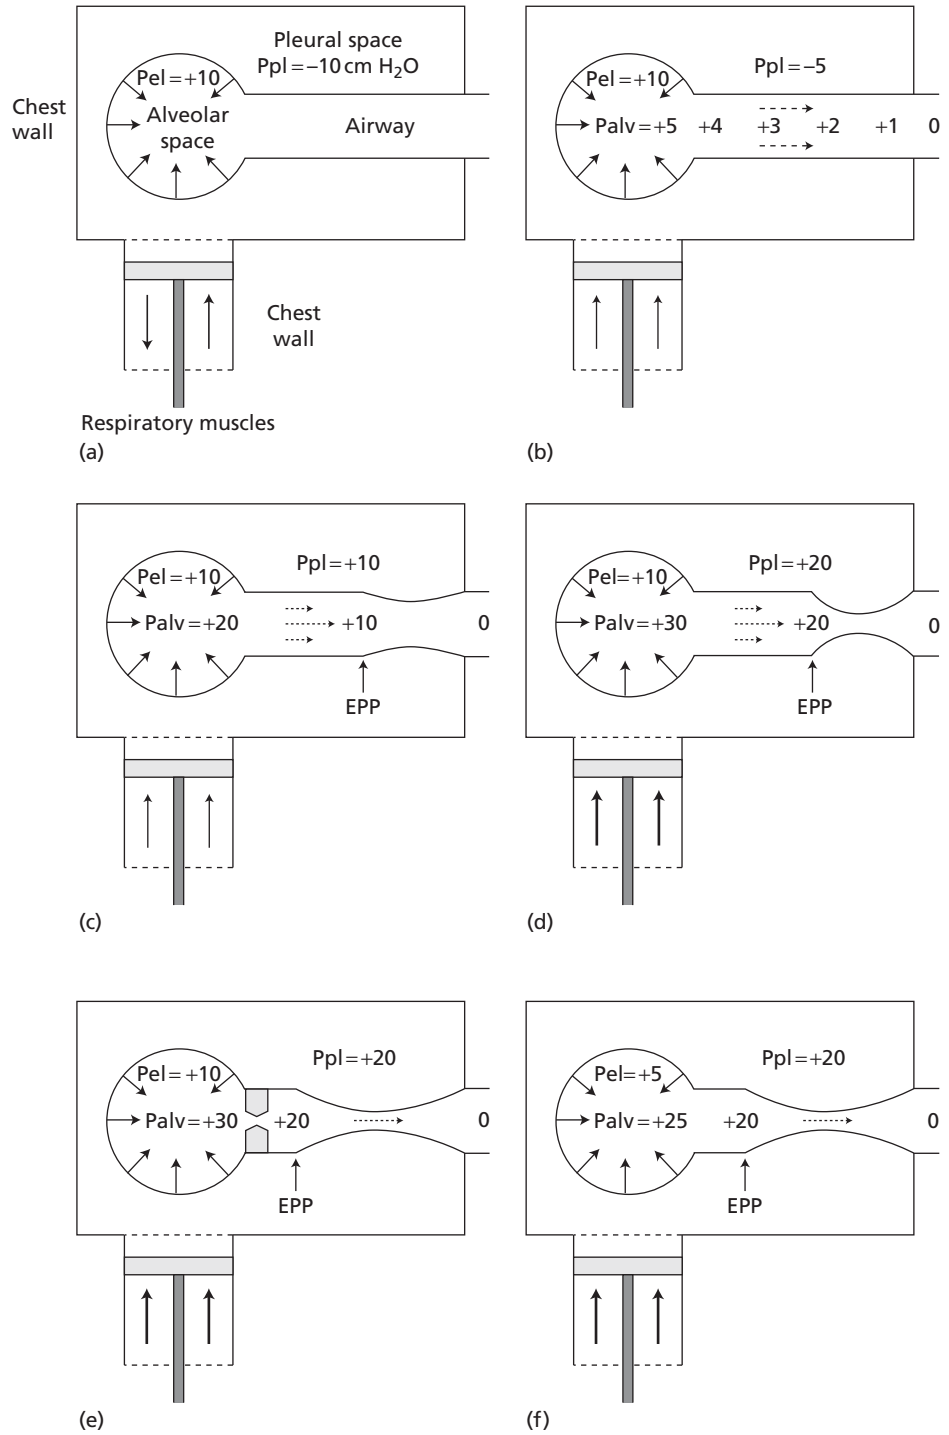

Figure 1.12 Model of expiratory flow limitation. See text for detailed explanation. (a) Description of static model. (b) Expiration during tidal breath. (c) Submaximal forced expiration. (f) Forced expiration with decreased lung elastic recoil pressure. EPP, equal-pressure point; Palv, alveolar pressure; Pel, elastic recoil pressure; Ppl, intrapleural pressure.

more proximal flow-limiting airway segment. This is illustrated in Figure 1.12(e), which depicts partial obstruction in the most distal part of the airway. Peripheral airway narrowing may occur as a consequence of pathological features such as inflammation and excess mucus. As a result of the increase in peripheral airflow resistance, a

greater portion of the driving pressure between alveolus and airway dissipates over the obstructed segment of airway. Hence, the EPP migrates distally and a longer segment of the more proximal airway is subjected to compressive pressures. Total airway resistance would increase and maximal expiratory airflow would be expected to decrease.

Loss of lung elastic recoil also has an impact on maximal expiratory airflow limitation. One mechanism relates to the effects of lung elastic recoil on the diameter of the intraparenchymal airways, which are not shown in the model. A decrease in lung elastic recoil at any specified lung volume will reduce airway calibre and increase peripheral airflow resistance. The effect on maximal expiratory airflow will be similar to that shown in Figure 1.12(e).

Another effect of elastic recoil on maximal airflow limitation is less intuitive. Note that an arbitrary value of 10 cm H₂O is assigned to P_{el} in Figure 1.12(a–e). Note also that when flow limitation becomes evident, as in Figure 1.12(d and e), the difference between P_{alv} and the intra-airway pressure at the EPP has the same magnitude as P_{el} (10 cm H₂O). Viewed in this manner, lung elastic recoil effectively keeps airways open by opposing the high compressive pressures that develop in the pleural space during forced expiration. Figure 1.12(f) illustrates the effect of decreased lung elastic recoil on flow limitation. In this example, a P_{el} of 5 cm H₂O has been assigned to an ‘emphysematous balloon’. With the same force exerted by respiratory muscles on the pleural space ($P_{pl} = 20$ cm H₂O), P_{alv} now increases to only 25 cm H₂O instead of 30 cm H₂O. There is a corresponding decrease in the intra-airway pressure that opposes airway compression. Consequently, the EPP migrates distally, the compressed segment of airway becomes longer, with a corresponding decrease in maximal expiratory airflow.

Lung hyperinflation

A second characteristic and very important physiological abnormality in COPD is hyperinflation. This is variably defined as abnormally large TLC, FRC or RV. Lung volumes can be measured either by the washin or the washout of tracer gases, such as helium, or by plethysmography. Because tracer-gas methods require long equilibration times in the presence of severe COPD, plethysmography is the more accurate method. In clinical practice the diagnosis of COPD can usually be made from clinical and spirometric findings alone, but lung volume measurements may be useful in selected patients.

Figure 1.8 illustrates both the expiratory airflow abnormalities and the hyperinflation that are typical of COPD. As the FEV_1 and the FVC decrease, RV and TLC increase. Indices of hyperinflation, particularly the RV and RV/TLC, track closely with spirometric measures of expiratory airflow obstruction across a broad range of COPD severity [33]. This suggests that the functional and structural features that relate to expiratory airflow obstruction, namely loss of lung elastic recoil and increased peripheral airway resistance, are also responsible for an abnormally large RV.

RV is sometimes termed the ‘volume of trapped air’, a description that is probably apt. As described previously,

lung volume, lung elastic recoil and peripheral airway resistance are intimately interrelated. As lung volume becomes smaller, elastic recoil decreases and the attendant loss of radial tension causes narrowing of the peripheral airways. At some point, resistance effectively becomes infinite and flow ceases. Several lines of indirect evidence suggest that peripheral airways in humans may actually close at lung volumes near RV, a phenomenon that has been directly observed in experimental animal lungs [34]. Calculations suggest that surface tension at the air–liquid interface on the epithelial surface of peripheral airways may be substantial as the lung volume nears RV, so that an intact surfactant system may be essential if the terminal bronchioles are to remain patent [35].

Structural correlates of expiratory airflow limitation

Expiratory airflow limitation is functionally related both to a loss of lung elastic recoil and to an increase in airflow resistance through the bronchial tree. Emphysema is presumed to be the morphological equivalent of abnormal lung elastic recoil, while a variety of pathological changes, particularly those in the peripheral airways, are thought to be responsible for increased airflow resistance through the bronchial tree. Consequently, there is the expectation that a detailed quantitative assessment of emphysema and airways disease in a lung from a COPD patient should allow a reasonably accurate prediction of spirometric function. Over the past several decades, numerous efforts to show such pathological and physiological correlations have yielded rather disappointing results.

Investigators have utilized several approaches when undertaking correlative structure–function studies, and each of these has certain advantages and limitations. Most commonly, investigators have compared lung tissue obtained at necropsy with function tests performed prior to death. Patients with severe disease tend to be heavily over-represented in this type of study and the interval between the last pulmonary function test and death is variable. Tissue may also be acquired from patients undergoing lung resection surgery, which is usually performed for localized carcinomas. This approach has the major advantage of allowing detailed pulmonary function testing shortly prior to the scheduled surgery. It has the disadvantage of providing only a limited amount of tissue in most patients, with attendant problems in achieving uniform inflation and fixation. Also, potential surgical candidates must have sufficiently good lung function if they are to tolerate resection, which excludes most patients with severe COPD. Lung-volume-reduction surgery provides new opportunities for obtaining resected lung tissue from patients with severe disease, but the samples are relatively small and they

may be poorly representative of the remaining lung. Correlation studies have also been carried out in post-mortem lungs. Tests of mechanical function performed in carefully selected postmortem lungs are reproducible, and forced expiratory flow rates obtained from such studies correspond quite closely with those obtained in living, age-matched adults [36]. The major disadvantage is in not knowing how severely postmortem changes might affect the results. Finally, CT imaging permits an accurate, indirect assessment of emphysema severity that can be compared against tests of function.

Efforts to show a correlation between emphysema severity and the FEV_1 have yielded inconsistent results [11,37–39]. Most published reports demonstrated either a relatively weak inverse relationship or one that was not statistically significant. Trivial degrees of emphysema may be associated with severe airflow obstruction in selected patients, while others may have normal or near-normal spirometry in the face of fairly advanced emphysema. In the largest series yet published, the Vancouver group of investigators found no statistically significant relationship between emphysema severity and the FEV_1 in 407 patients with mild-to-moderate COPD who were tested shortly before surgery for lung resection [38].

Efforts to show correlations between airflow obstruction and the severity of pathological changes in the conducting airways have fared no better. Numerous efforts to show correlations between expiratory airflow obstruction in COPD with mucous gland enlargement and other pathological features in the cartilaginous airways have been for the most part unsuccessful [40]. These results are perhaps not surprising in light of the retrograde catheter studies, which suggested that the principal pathological changes accounting for increased airflow resistance in COPD were to be found in the peripheral airways [20,27]. Those studies raised an expectation that careful assessments of peripheral airways disease, including features such as inflammation, fibrosis and smooth muscle enlargement, might show closer correlations with spirometric abnormalities. Early, small studies appeared to show such associations [10,41]. However, in the previously cited studies of 407 patients by the Vancouver group, no statistically significant relationship was found between the FEV_1 and total pathology score, or any of its components, for either the membranous or the respiratory bronchiole [38].

Thus, the largest and best available correlative studies indicate that the relationship of FEV_1 with either airway pathology or emphysema is at best tenuous. It bears emphasizing that most existing studies sampled only one part of the continuum between normal lung and severe COPD, and this provides a somewhat restricted view of the larger picture. For example, the Vancouver study included very few non-smokers and no patients with severe disease

[38]. Many other studies have been restricted to patients with severe disease [37,39]. When a broader assessment is made in age-matched groups who may be presumed to have increasing levels of ventilatory dysfunction (never smokers, smokers without known COPD, and smokers with severe COPD), emphysema severity and multiple elements of airways disease were found to progress in parallel [11]. In addition, a wealth of circumstantial evidence from human studies and more direct evidence from experimental animal studies indicate that emphysema and some elements of airways disease are important morphological determinants of expiratory airflow obstruction. These considerations notwithstanding, the ability to estimate the magnitude of ventilatory impairment in COPD from the most detailed pathological assessments is surprisingly poor. One can only speculate as to the reasons.

Ventilation distribution and gas exchange

COPD is characterized by progressive blood gas abnormalities. Mild hypoxaemia may be present in the early stages of COPD, and it usually progresses as the disease worsens. Hypercapnia may accompany more severe disease. Untreated hypoxaemia and hypercapnia can cause pulmonary hypertension and cor pulmonale, which contribute to the morbidity and mortality associated with this disease. The structural derangements and specific mechanisms responsible for gas exchange abnormalities in COPD are exceedingly complex and imperfectly understood.

Gas exchange within the lung is most efficient when the ratio of ventilation/perfusion (\dot{V}/\dot{Q}) remains close to unity within all lung regions. It is obvious that no gas exchange can occur if a ventilated zone receives no blood supply. A relative excess of ventilation is described as 'alveolar dead space', 'wasted ventilation' or a 'high \dot{V}/\dot{Q} abnormality'. Such regions behave functionally as though some portion of the lung region received normal blood flow while the remainder received none. An increase in the dead space/ tidal volume ratio (V_D/V_T) reflects lung zones with an abnormally high \dot{V}/\dot{Q} . V_D/V_T is usually 0.3–0.4 in normal subjects, but it may increase to as much as 0.7–0.8 in patients with severe COPD. In those patients the major portion of each inspired breath represents 'wasted ventilation'.

Alveolar regions that are underventilated in relation to their blood supply are described as low \dot{V}/\dot{Q} zones. The proportion of cardiac output that passes through a completely unventilated lung region is termed the shunt fraction, and the admixture of shunted blood with other pulmonary venous blood is manifest as arterial hypoxaemia. A \dot{V}/\dot{Q} region of less than 1 but greater than zero behaves as though some part of the region received normal ventilation and the remainder received none. Lung regions with low

\dot{V}/\dot{Q} abnormalities are thought to be the principal cause of hypoxaemia in COPD.

Pathological states affecting either ventilation or perfusion homogeneity might in theory cause regional \dot{V}/\dot{Q} to deviate from unity. Radioactive scanning and other techniques show that COPD is characterized by abnormal patterns involving both ventilation and perfusion. It is generally believed that pathological changes occur initially on the ventilation side and that abnormal perfusion patterns may partly result from compensatory flow regulation. Disease in the peripheral airways and alveolar spaces creates regions of both hyperventilation and hypoventilation. Hypoventilation causes localized hypoxia, which in turn stimulates a vasoconstrictor response in the neighbouring arteries. The attendant reduction in blood flow re-establishes a regional \dot{V}/\dot{Q} that is close to unity. Long periods of hypoxia may induce tissue remodelling in small pulmonary arteries, such as intimal fibrosis and smooth muscle hypertrophy, which lead to irreversible pulmonary hypertension. Because abnormalities in the pulmonary vascular bed may be regarded as secondary events, attention is directed to mechanisms by which abnormal ventilation patterns arise in COPD.

Ventilation is the process by which ambient air is transported to the alveolar spaces and resident air is removed to the environment. It is defined as the fractional turnover of inspired gas volume to resident gas volume for any given portion of the lung. Under normal resting conditions, each breath replaces approximately 10–15% of the resident gas volume. Gas is transported from the airway opening to the alveolar–capillary interface by convection and by diffusion. Transport within the proximal airways occurs by convection predominantly, whereas diffusion is more important within the alveolated gas-exchanging regions of the lung. Diffusion is not thought to be an important rate-limiting step for gas transport in the distal airways under normal conditions, but it may become so when diseases such as emphysema cause extensive anatomical rearrangements.

The compliance of a lung region and the change in transpleural pressure to which it is subjected determine ventilation. For a given change in transpleural pressure, a relatively more compliant lung region expands to a greater degree and receives more ventilation than does a less compliant region. An example is to be found in the normal human lung. As shown in Figure 1.6, the lung becomes progressively stiffer as it expands. As a result of gravity effects, a pleural pressure gradient develops from apex to base with apical pressures being more negative. Because the lung apex is subjected to a larger transpleural pressure, it is overinflated relative to the lung base. Consequently, the apex is less compliant and it receives a relatively smaller volume of each inspired breath than does the lung base. Non-homogeneous lung elastic behaviour brought about

by any pathological condition could cause uneven ventilation by a similar mechanism.

Emphysema is a prototype of diseases that cause abnormal lung elasticity. Emphysema tends to be non-uniform in its distribution, both within a single region and between regions. Large emphysema lesions may reside immediately adjacent to apparently normal lung parenchyma. Because of differences in the shape of their respective pressure–volume characteristics, an emphysematous region might be either hyperventilated or hypoventilated relative to normal adjacent lung. This occurs because the pressure–volume curve of the emphysematous lung exhibits greater concavity towards the pressure axis (see Fig. 1.6). Consequently, it is overly compliant at low lung volumes but abnormally stiff at high lung volumes. If a discrete emphysema lesion were located at the lung apex so that it were subjected to a relatively large transpleural pressures, it would overexpand and be less compliant than surrounding normal lung. Therefore, this region would receive less ventilation with each tidal breath. By a parallel argument, the same emphysematous region might be abnormally compliant and overventilated if located at the lung base.

Existing evidence suggests that most emphysematous regions may be relatively underventilated, as shown in Figure 1.13 [42]. Other variables remaining constant, this should give rise to a low \dot{V}/\dot{Q} zone. However, emphysematous regions also tend to be underperfused because a portion of the capillary bed has been lost. Thus, focal emphysematous regions could represent a broad range of \dot{V}/\dot{Q} zones, both high and low, depending upon several critical variables.

Figure 1.13 illustrates another mechanism by which emphysema might cause uneven ventilation. In this example, the destructive change of early centriacinar emphysema is associated with a substantial enlargement of the respiratory bronchiole. Distal portions of the acinus remain largely intact. Enlargement of the proximal airway effectively increases the volume of ‘dead space’ ventilation to the more distal portions of that transport pathway. At end expiration, all gas-transport pathways contain resident gas. With the next inspiration, the ‘dead-space’ must be cleared before inspired air reaches the gas-exchanging region. With a larger ‘dead space’, a given volume of inspired air penetrates less deeply into the acinus. As a result, it is expected that the proximal emphysema lesion might be relatively overventilated while the more distal acinar regions might be underventilated.

Airways disease probably also contributes to \dot{V}/\dot{Q} disturbances in the lungs of COPD patients, though little is known of specific mechanisms. Theoretical considerations suggest that at resting ventilation rates, severe airway narrowing or even complete closure would be necessary to substantially decrease ventilation to lung parenchyma

Figure 1.13 Postulated mechanisms for uneven ventilation in COPD. Dark shading indicates resident gas. Light shading represents inspired air. (a) Inspired breath is uniformly distributed in a normal lung unit. (b) Panacinar emphysema lesion is less compliant than normal lung and is less well ventilated, even though inspired air is uniformly distributed. (c) Centriacinar emphysema lesion increases ‘dead space’ so that distal portion of the unit is underventilated. (d) Obstruction of terminal bronchiole causes underventilation of distal alveolated structures.

subtended by a particular airway. Large plugs of mucus may sometimes occlude a proximal bronchus in patients with COPD, but the peripheral airways are probably more important as a cause of ventilation heterogeneity. Although never directly visualized, inflammatory exudate or excess mucus might well cause intermittent or complete obstruction of terminal bronchioles, resulting in an underventilated region (see Fig. 1.13). If the bronchiole were to remain occluded for an extended period, atelectasis might not occur because of ventilation via collateral channels.

Gas exchange is dependent on numerous other factors, including pulmonary blood flow distribution, neural control of breathing, chest wall mechanics, systemic haemodynamics, metabolic demands and respiratory muscle function. The final common expressions of disordered gas exchange in COPD, arterial hypoxaemia and hypercapnia represent a summation of multiple complex mechanisms.

Clinical and pathological subtypes of COPD

Older studies suggested that some patients with COPD could be fitted into so-called emphysematous and bronchitic

subtypes, based upon certain distinguishing clinical, pathological and physiological criteria [43]. At one time this idea enjoyed widespread currency and the subject is still presented as established fact in some standard textbooks. As implied by their names, either predominant anatomical emphysema or predominant bronchitis (airways disease) was thought to provide the morphological basis for distinguishing clinical and physiological features. The patient with the emphysematous subtype of COPD was sometimes described as ‘type A’ or ‘pink puffer’, while the terms ‘type B’ or ‘blue bloater’ depicted the bronchitic subtype.

The typical emphysematous patient was described as a cachectic elderly individual who related a long history of progressive and unrelenting breathlessness. Sputum production and recurrent chest infections were notable by their absence. The chest roentgenogram revealed a small cardiac silhouette along with the roentgenographical signs of advanced emphysema and lung hyperinflation. Arterial blood gases showed only mild hypoxaemia and hypercapnia and cor pulmonale was not a prominent clinical feature. A decrease in lung elastic recoil and a severely impaired diffusing capacity for carbon monoxide reflected the severe underlying emphysema.

The typical patient with predominant bronchitis was described as overweight, if not obese, with plethoric facies and obvious cyanosis. Chronic cough and sputum production were considered an essential feature of the bronchitic subtype. The other prominent aspects of the bronchitis patient were severe hypoxaemia, an accompanying hypercapnia, and consequent to the deranged blood gases, cor pulmonale and polycythaemia. Cor pulmonale was manifest clinically as peripheral oedema, cardiac enlargement and electrocardiographical signs of right ventricular enlargement. Reflecting the lack of severe emphysema, lung elastic recoil and diffusing capacity for carbon monoxide were normal or near normal.

The clinical features that distinguish COPD subtypes may be recognizable in selected patients, but most patients with COPD cannot be so simply categorized. It has been proposed that COPD represents a spectrum, with the emphysematous patients at one end and the bronchitic patients at the other. Because of extensive overlap between the two groups, clinical investigations have compared only those patients at the extreme ends of the spectrum. Subgroup distinctions have usually been made on clinical and physiological grounds, which have not been uniform.

Efforts to correlate lung pathology with the clinical subtype of COPD have generally been contradictory and inconclusive. Claims to the existence of the emphysematous and bronchitic subtypes of COPD rest largely on a single small study in which clinical data were compared with autopsy findings [43]. These findings could not be confirmed in subsequent similar studies by others [44,45]. Cor pulmonale is

generally considered an essential feature of the bronchitic patient but not the emphysematous patient. Consistent with this concept, small necropsy studies have shown little relationship between right ventricular weight and emphysema severity [46–48]. Similarly, the extent of emphysema as defined by CT imaging bears little relationship to the severity of blood gas or pulmonary haemodynamic abnormalities [49]. However, neither is there a strong relationship between mucous gland enlargement, long considered the essential lesion of the bronchitic subtype, and right ventricular weight [48,50,51]. Correlations of peripheral airways disease with right ventricular weight has been found by some investigators but not others [48,50].

Patients with COPD vary in their propensity for developing hypoxaemia, hypercapnia and pulmonary hypertension, so that the terms 'pink puffer' and 'blue bloater' may have some validity as clinical descriptive terms. However, very little is known as to why these differences exist. There is clearly no scientific justification for describing such patients as having either the emphysematous or bronchitic subtype of COPD.

CHAPTER 2

The physiology of breathlessness

Donald A. Mahler

Under normal conditions respiration is an unconscious activity regulated by automatic control centres in the brainstem as well as by voluntary output from the cerebral cortex. A variety of abnormalities that affect the respiratory controller, tracheobronchial tree, the alveolar–capillary membrane, and/or the muscles of respiration can contribute to a conscious awareness of breathing experienced as unpleasant or uncomfortable. A respiratory ‘sensation’ is considered to be the neural activation resulting from the stimulation of a receptor, whereas the ‘perception’ is the individual’s reaction to the sensation [1]. The individual typically describes the experience as ‘I am short of breath’ or ‘I can’t get enough air’, whereas physicians and investigators commonly identify the patient’s complaint by the word dyspnoea.

Various definitions of breathlessness, or dyspnoea (used synonymously in this chapter), have been proposed. These include: ‘difficult or laboured breathing’ [2], ‘an awareness of respiratory distress’ [3], ‘the sensation of feeling breathless or experiencing air hunger’ [4], and ‘an uncomfortable sensation of breathing’ [5]. However, in 1999 a committee of experts supported by the American Thoracic Society proposed the following definition of dyspnoea [1]: ‘A subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity’. This experience results from interactions between multiple physiological, psychological, social and environmental factors that may produce behavioural responses.

This chapter is divided into five sections. First, the neurophysiological model for our current understanding of dyspnoea is described. Secondly, I consider the possible mechanisms contributing to this perception in patients with COPD. Thirdly, the various descriptors of breathing discomfort are discussed as they represent a unique language. The different descriptors of breathlessness selected by patients with specific respiratory diseases support our understanding of the mechanisms contributing to dyspnoea. Fourthly,

I review briefly the ability of patients with COPD to perceive breathlessness in response to the addition of respiratory loads or after the acute administration of an inhaled bronchodilator. Finally, I describe how different treatment strategies might provide relief of dyspnoea in patients with COPD.

Neurophysiological model for dyspnoea

Figure 2.1 summarizes the putative pathways of the neurophysiological model for understanding dyspnoea [1,6–8]. The location and presumed stimuli of the receptors that cause dyspnoea are summarized in Table 2.1.

Receptors

There is strong evidence that dyspnoea is directly affected by inputs from chemoreceptors. Peripheral chemoreceptors are located in the carotid bodies and are stimulated predominantly by hypoxia to increase respiration. Furthermore, hypercapnia, as modulated by an increase in H^+ ions, can stimulate central chemoreceptors located in the medulla. However, chemoreceptors are not considered

Figure 2.1 A summary of the putative pathways of the neurophysiological model for understanding dyspnoea.

Table 2.1 Location and presumed or major stimuli of receptors that cause dyspnoea. (From American Thoracic Society [1] and Comroe [6] with permission.)

Location	Presumed or major stimulus
<i>Chemoreceptor</i>	
Central medulla	Hypercapnia/acidosis
Carotid body	Hypoxaemia
<i>Mechanoreceptor</i>	
Upper airway and face	Mouthpiece; lack of airflow
Lung	Lung inflation; inhalation of irritants; interstitial congestion; dynamic airway compression
<i>Chest wall</i>	
Joints	Alteration and/or distension
Tendons	Alteration and/or distension
Muscles	Alteration and/or distension

essential for the development of breathlessness. Many patients with COPD, as well as those with other respiratory diseases, experience dyspnoea despite adequate oxygen tensions and eucapnia.

Pulmonary mechanoreceptors respond to mechanical stimuli that are distributed throughout the respiratory system (airway and lung parenchyma). These receptors respond to both chemical (e.g. irritants such as dust or smoke) and mechanical stimuli that can cause broncho-constriction. Pulmonary stretch receptors in the airways respond to lung inflation. C-fibres (unmyelinated nerve endings) located in the alveolar wall and blood vessels are stimulated by interstitial congestion. The corresponding afferent pathways of these mechanoreceptors project to the brain via the vagal nerve. There is evidence that vagal information not only influences the level and pattern of breathing, but may also contribute to the sensation of dyspnoea.

Mechanoreceptors are also located in the joints, tendons and muscles of the chest wall and can play a part in respiratory sensations. Studies involving voluntary constrained breathing, constrained thoracic expansion, as well as chest wall vibration, support the concept that chest wall receptors can cause or contribute to breathlessness.

Central nervous system

The sensory inputs from the various receptors must reach the cerebral cortex in order to be experienced as 'difficult breathing'. Respiratory neurons located in the brainstem project corollary discharges to the sensory cortex; this process contributes to the sense of breathing effort [9]. In addition, there is evidence that conscious awareness of the outgoing respiratory motor command to the ventilatory

muscles is important. In fact, current evidence suggests that the pressure generated by the inspiratory muscles, as a ratio of maximal inspiratory pressure capacity, is related to the intensity of the central respiratory motor command [10,11].

Over 40 years ago Campbell and Howell [12,13] proposed 'length-tension inappropriateness' of the respiratory muscles as an explanation for dyspnoea. This theory has subsequently been expanded to include not only information arising from the ventilatory muscles, but also afferent information originating from receptors throughout the respiratory system (see Table 2.1). Our current understanding is that the perception of dyspnoea results from a dissociation or 'mismatch' between the outgoing motor command from the central nervous system and the incoming afferent information from receptors in the airways, lungs and chest wall. The afferent feedback from sensory receptors may allow the brain to assess the effectiveness of the motor commands issued to the ventilatory muscles (i.e. the appropriateness of the response in terms of flow and volume). For any change in respiratory pressures, airflow or movement of the lungs and/or chest wall that is not considered appropriate for the outgoing motor command, the individual may experience breathlessness or an increase in its intensity. This theory has been referred to as both 'efferent-afferent dissociation' [14] and 'neuroventilatory dissociation' [15]. Thus, under certain conditions, the brain 'expects' a certain pattern of breathing or level of ventilation and a corresponding afferent feedback. Any deviation may thus cause or intensify dyspnoea.

Possible mechanisms contributing to dyspnoea in COPD

Several mechanisms may contribute to the experience of breathlessness in those with COPD [16–19] (Table 2.2). Typically, patients with COPD develop dyspnoea when they perform physical activities. The activity may be as minimal as a person taking a few steps on a level surface.

Increased ventilatory demand

Any physical exertion will increase minute ventilation to a significantly greater extent in patients with COPD compared with healthy subjects of comparable age. Although an increased physiological dead space is the major reason for the increased ventilation, hypoxaemia or an early onset of lactic acidosis may also contribute to the increased ventilatory demand. In addition, weakness of the limb muscles requires an increased ventilatory response to exertion; this weakness could result from various causes including deconditioning, systemic effects of COPD or poor nutrition.

Table 2.2 Possible mechanisms contributing to dyspnoea in patients with COPD.

Increased ventilatory demand
Increased physiological dead space
Hypoxaemia
Early onset of lactic acidosis
Limb muscle weakness resulting from deconditioning, systemic effects of COPD and/or poor nutrition
Dynamic airway compression
Dynamic hyperinflation
Inspiratory threshold loading
Shortening of the vertical muscle fibres of the diaphragm (functional weakness)
Increased airway hyperreactivity
Respiratory muscle weakness

Dynamic airway compression

In patients with expiratory airflow obstruction any increase in expiratory effort above the critical transpulmonary pressure can result in dynamic airway compression of airways downstream from the flow limitation. This airway distortion and collapse may stimulate mechanoreceptors in the airway and lead to breathlessness. Evidence to support this proposed mechanism comes from laboratory studies, which applied negative expiratory pressure (NEP) via a mouthpiece in patients with COPD [20]. However, the relative contribution of dynamic airway compression to breathlessness experienced by patients with COPD during daily activities is not clear.

Hyperinflation

Some patients with very severe COPD may be hyperinflated at rest. This finding may be evident by a 'barrel chest' on physical examination as well as a depressed or 'flat' diaphragm on the lateral chest radiograph. Hyperinflation develops as a consequence of the patient's inability to exhale completely because of expiratory flow limitation. One proposed method to examine expiratory flow limitation is the application of NEP [21]. Eltayara *et al.* [22] found that flow limitation as determined by NEP was a better predictor of dyspnoea than standard spirometric measures.

Moreover, various studies have demonstrated that many patients with COPD develop *dynamic hyperinflation* during exertion because of expiratory flow limitation [23,24]. When normal healthy individuals exercise they generally decrease end-expiratory lung volume (EELV); in contrast, EELV frequently increases in patients with COPD during exertion because lung emptying is incomplete because of the expiratory airflow limitation. Although the magnitude of the increase is variable, investigators have reported a

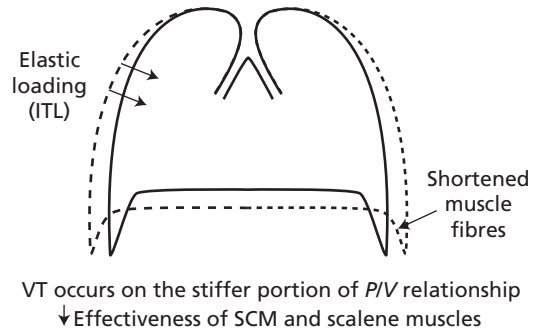

Figure 2.2 The major consequences of dynamic hyperinflation include an inspiratory threshold load (ITL) resulting from enhanced elastic recoil as well as shortening of the vertical muscle fibres of the diaphragm. P, pressure; SCM, sternocleido-mastoid; V, volume; VT, tidal volume.

change in the range of 300–600 mL for EELV during exercise in those with COPD [18]. This increase in EELV may be determined non-invasively by having the individual patient perform serial inspiratory capacity (IC) manoeuvres during exercise.

The major consequences of dynamic hyperinflation include an inspiratory threshold load because of increased elastic recoil as well as shortening of the vertical muscle fibres of the diaphragm (Fig. 2.2). The shortened muscle fibres compromise the ability of the diaphragm to generate pressure (i.e. functional weakness). The net effect of dynamic hyperinflation is a constrained tidal volume response despite vigorous inspiratory effort [18].

Airway reactivity

Many patients with COPD report that various 'triggers' cause breathlessness including exposure to cold air, inhalation of dusts and other airborne irritants, respiratory tract infections, in addition to physical exertion. In Lung Health Study I, approximately 70% of the 5887 smokers, aged 35–60 years, with spirometric evidence of early COPD exhibited a 20% decrease in forced expiratory volume in 1 second (FEV_1) at a dose of 25 mg/mL methacholine [25]. This finding suggests a high percentage of patients with at least early COPD have some degree of airway hyperreactivity.

Respiratory muscle weakness

The muscles of respiration may become weak in patients with COPD [26,27]. The causes are likely multifactorial including deconditioning, poor nutrition and possible systemic manifestations of COPD. There is evidence that inflammation, oxidative stress, etc., which occur in patients with advanced COPD, can affect both skeletal and respiratory muscle function. Certainly, weak respiratory

muscles could contribute to a 'mismatch' between the outgoing central motor command and the ventilatory response that would cause breathlessness.

In many patients with COPD a combination of the above factors may act concurrently to contribute to breathing difficulty.

Qualities of dyspnoea

Different pathophysiological processes appear to cause distinct qualitative sensations that reflect the experience of breathing discomfort in healthy individuals as well as in patients with respiratory disease [5,28–31]. For patients with COPD the following descriptors of breathlessness were selected in response to specific questionnaires:

- In the UK, 'distress' associated with breathing was identified [29].
- In the USA, three descriptors: 'My breathing requires effort' (51%); 'I feel out of breath' (49%), and 'I cannot get enough air in' (38%) were indicated [5].
- In Canada, 'increased inspiratory difficulty' and 'unsatisfied inspiratory effort' were chosen [30].

The descriptors selected by patients living in different countries with distinct cultures illustrate a common theme – those with COPD sense breathlessness as part of inspiratory muscle contraction. Further support for this concept is that patients with COPD report that breathing difficulty occurs 'when breathing in' far more frequently than 'when breathing out' [5,30].

These collective findings support the concept that inspiratory 'work/effort' associated with breathing contributes to the breathlessness experienced by patients with COPD. Although expiratory airflow obstruction is the major pathological abnormality in COPD, the consequent resting and/or dynamic hyperinflation result in an 'elastic load' as well as shortening of the vertical muscle fibres of the diaphragm, which clearly contribute to the experience of dyspnoea in COPD.

Perception of breathlessness

One method to examine respiratory perception is to ask subjects to estimate the magnitude of breathlessness while breathing through a system of resistive breathing loads. Mahler *et al.* [32] reported that patients with COPD showed similar exponents of the psychophysical power function for loads (range, 10–85 cm H₂O/L/s) compared with healthy subjects of comparable age. Thus, patients with COPD perceived breathlessness in response to the added loads in a manner similar to control subjects. However, both groups exhibited a large range of magnitude estimation responses.

In another study, Nosedá *et al.* [33] asked patients with COPD to indicate any changes in shortness of breath at rest after inhaling normal saline and then after inhaling the bronchodilator terbutaline. These investigators found that 50% (eight of 16 subjects) reported marked relief in breathlessness and were called 'high perceivers'. In contrast, the other 50% showed little or no perceptual change after inhaled normal saline and terbutaline; they were considered 'low perceivers'.

Van Schayck *et al.* [34] suggested that poor perception of dyspnoea in patients with obstructive airways disease contributed, in part, to the failure of these patients to report this symptom to their primary care physicians. Such patient behaviour could lead to underdiagnosis of airways disease in the general population.

Possible mechanisms for relief of dyspnoea with specific interventions

At the present time the relief of dyspnoea is directed at the treatment of the underlying pathophysiology of the disease. As the mechanisms causing breathlessness are multifactorial and interdependent, the primary cause(s) of dyspnoea (see Table 2.2) may be different for individual patients with COPD. Furthermore, responses to a specific therapy may vary considerably between patients. The presumed mechanisms whereby different treatments relieve dyspnoea in patients with COPD are listed in Table 2.3.

The information in Table 2.3 is based on current knowledge and understanding of how different treatments work in patients with COPD. Moreover, different mechanisms can clearly be interrelated. For example, improvement in ventilatory capacity may concomitantly reduce hyperinflation and thereby allow the vertical muscle fibres of the diaphragm to lengthen. The enhanced position of the diaphragm promotes an increase in functional strength.

Various clinical trials have demonstrated that bronchodilators can relieve breathlessness by one or more mechanism: increase ventilatory capacity; reduce dynamic airway compression; reduce resting and dynamic hyperinflation; and increase the length of the vertical muscles of the diaphragm [18,23,35,36]. Inhaled corticosteroids provide modest increases in lung function and also decrease airway reactivity [37–39]. Whether the reduction in hyperreactivity with inhaled corticosteroids attenuates dynamic airway compression is unclear.

For decades it has been recognized that oxygen therapy acts on the peripheral chemoreceptor and thereby reduces minute ventilation. However, two recent studies have shown that hyperoxia reduced hyperinflation, as measured by inspiratory capacity manoeuvres, both at rest [40] and during exercise [41]. More importantly, there were

Table 2.3 Putative mechanisms whereby specific treatments provide relief of dyspnoea.

	Ventilatory		↓ Airway compression	↓ Hyperinflation	↓ Airway hyperreactivity	↑ Respiratory muscle function
	↑ Capacity	↓ Requirement

concomitant improvements in the severity of dyspnoea with oxygen therapy in both studies, which may, in part, be related to the benefits on hyperinflation.

In addition, it is possible that some of these strategies may alter the processing and perception of breathlessness in the central nervous system. More detailed information about these specific treatments is available in the relevant chapters of this book.

CHAPTER 3

The physiology of muscle

Ghislaine Gayan-Ramirez and Marc Decramer

Chronic obstructive pulmonary disease (COPD) is a multi-organ system disease in which dyspnoea, decreased exercise capacity and impairment of quality of life are common. Importantly, the decrease in exercise performance is associated with mortality in these patients. In response to COPD, the respiratory muscles that are working against increased mechanical loads adapt to cope with this chronic load. In addition to respiratory muscle dysfunction, there is accumulating evidence that peripheral muscle dysfunction is also present in COPD patients. Adaptation of peripheral muscles in response to COPD, however, differs from the adaptation of respiratory muscles.

The aim of this chapter is to summarize the knowledge of the physiological adaptations of different respiratory and peripheral muscles in response to COPD.

Muscle dysfunction in COPD patients

Muscle activity and recruitment

Respiratory muscles

In COPD patients, both the respiratory muscle strength and the load to the respiratory muscles are altered. Indeed, the inspiratory muscles have to cope with a higher resistive load (higher airway resistance) and a higher elastic load (resulting from a decrease in the dynamic compliance). In addition, in patients with more severe COPD, the action of the inspiratory muscles is confronted by the charge due to the intrinsic positive end-expiratory pressure (PEEPi) and to the posterior movement of the rib cage at end-expiratory volume when the latter is above the relaxation volume of the rib cage. As a consequence, an imbalance between the respiratory muscle capacity and the load they have to deal with develops. Therefore, in order to maintain adequate ventilation, the central command to the respiratory mus-

cles is increased in COPD patients. Electromyographical studies [1,2] and data on discharge frequency [3] revealed that the motor command to the diaphragm is increased at rest in patients with severe COPD but the contribution of the diaphragm to tidal volume in these patients decreased [4]. Also, the discharge frequency of the parasternal intercostals is elevated in patients with severe COPD compared with controls [5]. Similarly, the discharge frequency of the scalenes and also the number of recruited motor units are enhanced in COPD patients [5]. By contrast, the sternocleidomastoids are not recruited during quiet breathing [6], but only during exercise [7]. Activation of the abdominal muscles is frequent in COPD patients. This activation mainly concerns the transversus abdominis whose recruitment is proportional to the level of airway obstruction [8]. This activation leads to an increase in abdominal pressure at the end of expiration in patients with severe COPD [4], contributing thereby to the PEEPi described in these patients [9].

Peripheral muscles

Very few data are available concerning the activity and recruitment of peripheral muscles in COPD. Actually, modification of the electrical activity of the quadriceps was demonstrated in patients with COPD compared with healthy subjects [10]. M-wave duration was increased from exercise onset but its amplitude was decreased [10]. This indicates that the muscle excitability propagation was impaired in these patients [10]. However, in another study, M-wave amplitude was shown to be unchanged post-exercise [11]. On the other hand, abnormalities in the surface electromyography of the quadriceps appeared very soon after exercise onset in COPD patients compared with healthy individuals [10]. Interestingly, 3 weeks of endurance training normalized the electrical activity abnormalities in the muscles of these patients [12].

Muscle mass

Respiratory muscles

Concerning the mass of the diaphragm, the literature is still controversial. While in one study the mass and the thickness of the diaphragm were reported to be increased in patients with COPD [13], a reduction in the volume and the thickness of the diaphragm was observed in another study [14]. According to Arora and Rochester [15], the diaphragm dimensions of COPD patients are likely to be similar to those of patients without chronic pulmonary diseases.

There are no data available concerning the mass of the respiratory muscles other than the diaphragm in COPD patients.

Peripheral muscles

The prevalence of peripheral muscle wasting in COPD patients is estimated to be 30% and this increases with disease severity. Even if body weight is well preserved, muscle mass may be low [16]. Only indirect evaluations of peripheral muscle mass are available for COPD patients. Fat-free mass is usually used as a marker for muscle mass. Using bioelectrical impedance analysis, fat-free mass has been reported to be decreased in COPD patients [17]. Interestingly, a strong correlation between mean fibre cross-sectional area of the vastus lateralis and fat-free mass was found in COPD patients [18]. Magnetic resonance imaging revealed a lower cross-sectional area of the calf muscles (−13%) in patients with COPD compared with control subjects [19]. More recently, using computed tomography, a decrease in the thigh muscle cross-sectional area (approximately 30%) has been reported in COPD patients compared with healthy age-matched controls [20]. It is important to mention that muscle mass loss in COPD patients is associated with muscle weakness [20,21] and poor exercise tolerance [22]. It is also a predictor of mortality independently of lung function [23].

Muscle fibre type and size

Based on their physiological and metabolic properties, the different fibre types of skeletal muscles are classified as type I (slow oxidative fibre), type IIa (fast oxidative and glycolytic fibre), and type IIx and IIb (fast glycolytic) fibres. The fibre profile of a muscle is a determinant of its metabolic capacity and can be assessed classically with ATPase staining or by separating the different myosin heavy-chain isoforms by electrophoresis or western blotting. Immunohistochemistry determines the presence of hybrid fibres, namely fibres co-expressing different myosin heavy-chain isoforms.

Respiratory muscles

In the diaphragm of COPD patients, the proportion of the slow myosin heavy-chain isoform (MHC-I) is increased at the expense of the fast MHC-IIa and MHC-IIb [24–27] (Fig. 3.1). A positive correlation between the proportion of the diaphragm MHC-I and total lung capacity (TLC) and functional residual capacity (FRC) has been found, while an inverse relationship is present with the forced expiratory volume in 1 second (FEV_1) [25]. More recently, Levine *et al.* [28] showed that the relationship between the proportion of pure type I fibres in the costal diaphragm of COPD patients and FEV_1 was exponential. Thus, when FEV_1 fell

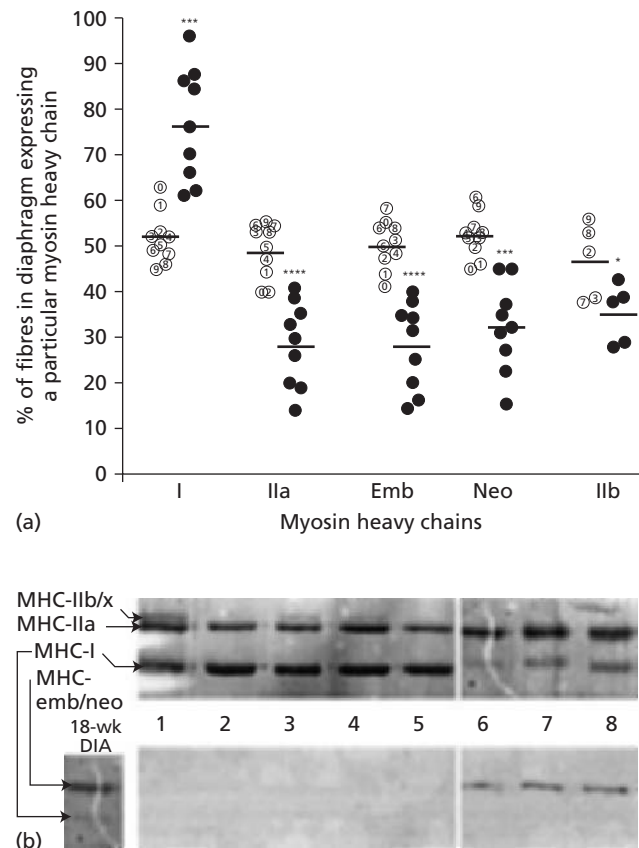

Figure 3.1 (a) Proportion of diaphragm fibre containing slow (I), type IIa, embryonic (Emb), neonatal (neo) and type IIb myosin heavy chain isoforms in control subjects (open circles) and in COPD patients (closed circles). Circles represent individual values. Number in circles indicates specific individuals. * $P < 0.05$; *** $P < 0.001$; **** $P < 0.0001$ vs controls. (b) Representative SDS-PAGE and immunoblotting of diaphragm myosin heavy-chain (MHC) isoforms from controls (lanes 1, 3, 4), COPD (lanes 2 and 5), 18-week-old fetus (lane 6) and 28-week-old fetus (lanes 7 and 8). The immunoblotting is specific for the embryonic MHC isoform. (From Nguyen *et al.* [26] with permission.)

below 60% of the predicted value, an increase in type I fibres developed in the costal diaphragm of COPD patients [28]. Like the diaphragm of healthy subjects, the diaphragm of COPD patients contains neonatal and embryonic MHC [26]. As for the MHCs, the proportion of the slow myosin light-chain (MLC) isoforms is increased in the diaphragm of COPD patients along with a decrease in the fast MLC isoforms [24]. The diaphragmatic fibre diameters are reduced in COPD patients compared with patients with normal lung function, this decreased diameter being correlated with vital capacity (VC) and FEV_1 [29]. An atrophy of type II fibres correlated with the amount of weight loss has also been reported in patients with COPD [30].

For the external and internal intercostal muscles, in contrast to the diaphragm, the proportion of type II fibres and fast MHC isoforms increased in COPD patients, the percentage of type II fibres being inversely related to the level of airway obstruction [31]. Moreover, an atrophy of type II fibres is also present in these muscles [30,32] and was shown to be correlated with weight loss [30].

Only a few data are available for the sternocleidomastoid muscle adaptation in COPD and these data are controversial. In one study, a decrease in the fibre size was described in these muscles [33], while in another no changes in dimension were reported [34]. There are no data available concerning the fibre profile of the other respiratory muscles in COPD patients.

Peripheral muscles

The changes in muscle fibre phenotype depend on disease severity. In patients with moderate COPD, the fibre proportion of the quadriceps does not change [30,35] while significant type II atrophy is observed, this atrophy consistently correlated with weight loss [30]. In advanced COPD, a decrease in type I fibre proportion together with a reciprocal increase in type II fibre proportion were reported in the vastus lateralis [35–41] (Fig. 3.2), while both fibre types atrophied [18,36]. No correlation was found between this shift in fibre proportion and exercise capacity [35,37]. An increased proportion of MHC-IIb as well as of fast MLCs was also observed in the vastus lateralis of COPD patients [35]. Positive correlations were found between VC and FEV_1 and the proportion of slow MHC [35]. A selective type IIx atrophy with a shift from type I to IIx fibre type was recently reported in the vastus lateralis biopsies obtained from weight-stable COPD patients [42]. In addition, the low oxidative capacity of the vastus lateralis was closely related to the proportion of type I fibres [41]. The adaptation of the vastus lateralis in response to COPD is thus clearly different from the adaptation occurring in the diaphragm.

For the biceps, while fibre proportions remained unchanged, the diameter of all fibre types and more particularly of the type II fibres was reduced in severe COPD

Figure 3.2 (a) Proportion of the myosin heavy-chain (MyoHC) isoforms of the vastus lateralis in normal subjects (light bars) and in COPD patients (dark bars). Values are means and SD. * $P < 0.05$ vs controls. (b) Representative SDS-PAGE of MyoHC isoforms (slow: I, type IIa and type IIx) separation from vastus lateralis of normal subjects (lanes A and B) and COPD patient (lanes C and D). (From Maltais *et al.* [37] with permission.)

compared with control subjects. Decreased diameters were correlated with the amount of weight loss and reduction in FEV_1 (percentage of predicted value; % pred) [43]. Also, a type II atrophy correlated with weight loss was reported in the latissimus dorsi of COPD patients [30].

Recent data revealed that neither the size nor the proportion of the fibres of the deltoid muscle was affected in COPD patients compared with controls [44]. However, there was a trend to increased type I fibres with increased air trapping (as represented by residual volume (RV)/TLC ratio) but this did not reach statistical significance [44].

Muscle capillarity

Respiratory muscles

In COPD patients, the number of capillaries in the diaphragm increases proportionally with disease severity. A relationship is thus present between the number of capillaries in the diaphragm and FEV_1 (% pred) [45]. This probably represents a structural adaptation of the diaphragm in response to the increased chronic load.

The number of capillaries per fibre is higher in the external intercostal muscles of patients with severe COPD and was inversely related to FEV_1 [46].

Peripheral muscles

A reduction of 53% in the number of capillaries per unit cross-sectional area was observed with electron microscopy in the vastus lateralis of patients with COPD compared with age-matched controls [47]. Similar data were reported by others using histological techniques [38]. Moreover, the capillary/mitochondria ratio was decreased in the vastus lateralis of these COPD patients as the number of mitochondria per unit surface was unchanged [47]. Data are controversial concerning the capillary/fibre ratio in the vastus lateralis of COPD patients, as this ratio was reported to be lower in one study [38] but unchanged in another [36]. The number of capillary contacts for both type I and II fibres were significantly lower in patients with COPD but, when normalized for fibre cross-sectional area, the number of capillary contacts for each fibre type was similar in COPD patients and control subjects [36]. Reduced oxygen delivery within muscle in COPD patients may be related to the lower number of capillary contacts, together with a lower myoglobin level as found in the vastus lateralis of these patients [47].

To the best of our knowledge, there are no data available concerning the number of capillary contacts in the lower limb muscles other than the vastus lateralis and in the upper limb muscles.

Metabolic enzymes

The metabolic properties of a muscle depend on its fibre composition. To evaluate the oxidative or glycolytic potential of a muscle, the content in mitochondria and the concentration of several enzymes are measured. These include the enzymes specific for the oxidative capacity (e.g. citrate synthase, succinate dehydrogenase, 3-hydroxyacyl coenzyme A dehydrogenase) and the enzymes representative of the glycolytic capacity (e.g. lactate dehydrogenase, phosphofructokinase, hexokinase).

Respiratory muscles

It seems that the oxidative capacity of the diaphragm in COPD is better preserved than the glycolytic capacity. Compared with subjects with normal lung function, the activities of hexokinase and lactate dehydrogenase were decreased in the diaphragm of patients with moderate COPD [48]. A twofold increase in succinate dehydrogenase activity in all diaphragm fibre types along with an increase in the succinate dehydrogenase to myosin/ATPase ratio was reported in severe COPD patients compared with patients with mild pulmonary impairment [27]. In severe

COPD, the phosphofructokinase activity in the diaphragm is decreased but the citrate synthase activity is unaffected [49]. The activity of the phosphofructokinase was inversely related to static lung volume and to diaphragm type II proportion [49].

The oxidative capacity as well as the hexokinase activity of the internal and external intercostal muscles are increased in COPD patients [50]. In fact, according to Pasto *et al.* [51], the oxidative capacity of the external intercostals is preserved in COPD patients and glycolytic activity increased proportionally to disease severity.

Peripheral muscles

In agreement with the changes in fibre profile, the oxidative capacity of the quadriceps is reduced in patients with COPD compared with controls [52–54]. Citrate synthase and, to a lesser extent, 3-hydroxyacyl coenzyme A dehydrogenase were lower in patients with COPD. In addition, citrate synthase activity was significantly correlated with peak $\dot{V}O_2$, and this independently of lung function [53]. No significant differences were seen in glycolytic enzyme activities in COPD patients except for phosphofructokinase, which increased significantly in one study [52] but remained unchanged in another [53]. Surprisingly, elevated activity of the cytochrome-c oxidase (a key enzyme of the electron transport chain) has been found in the quadriceps of COPD patients compared with healthy controls [55], but it is believed that the activities of all mitochondrial enzymes would respond in a similar way to a given situation.

Few data are available on metabolic enzymes in the upper limb muscles of COPD patients. It seems that the citrate synthase activity of the deltoid is preserved or increased in patients with severe COPD compared with subjects with normal lung function [44]. Interestingly, the activity of lactate dehydrogenase (a glycolytic enzyme) was significantly higher in the deltoid of these patients [44]. An inverse relationship was also found between citrate synthase or lactate dehydrogenase activity and FEV_1 (% pred) as well as with air trapping (represented by RV/TLC) [44].

Structural alterations

Respiratory muscles

Sarcomere length in the diaphragm of patients with COPD is shorter than that of subjects with normal lung function [56]. An inverse relationship was also found between diaphragm sarcomere length and TLC and RV [56]. Although sarcomere disruption was observed in normal diaphragm, the number of disrupted sarcomeres was significantly higher in the diaphragm of COPD patients [57]. An increase in the number of mitochondria was found in the diaphragm of COPD patients, the concentration of mitochondria was inversely related to the severity of

airways obstruction, while a direct relationship was found with air trapping [56]. Recently, the degree of airflow obstruction was shown to be inversely related to abnormal diaphragm [58]. Finally, the diaphragm of COPD patients showed more irregular-shaped fibres as well as more smaller fibres compared with non-COPD patients undergoing thoracotomy [59]. Increased content of β -spectrin was also present in the diaphragm of these COPD patients, indicating alterations in the spectrin–cytoskeletal complex [59].

For the other respiratory muscles, the shortening occurring in the muscle fibres when the volume moves from FRC to TLC is minimal for the parasternal intercostals, the scalenes and the sternocleidomastoids [34,60]. Therefore, the fibre length of these muscles is better preserved than in the diaphragm of patients with COPD. The fibre size of the external intercostal muscles correlated with $P_{I_{max}}$ values [61].

Peripheral muscles

Myopathological examination of the vastus lateralis revealed only the presence of a slight increase in fibrosis and fat cell replacement in COPD patients compared with age-matched controls [42]. In addition, in COPD patients with low body mass index (BMI), apoptosis in the quadriceps has been demonstrated, BMI being inversely related to apoptosis [62].

There were no structural alterations in the deltoid of patients with COPD compared with control individuals [63]. The frequency histograms of the deltoid fibre diameters, however, demonstrated a multimodal distribution with higher standard deviation values, wider range of diameters and a greater proportion of both atrophic and hypertrophic fibres [63].

Muscle strength

Respiratory muscles

At FRC, the maximal inspiratory static pressure as well as oesophageal pressure are reduced in patients with COPD compared with healthy subjects [64]. Along the same lines, the transdiaphragmatic pressure developed during electrical [64] or magnetic [65] stimulation of the phrenic nerves is lower in these patients, while the function of the expiratory muscles seems to be well preserved although the maximal expiratory static pressure is normal [66]. In contrast to healthy subjects, body position has an effect on maximal inspiratory pressure in COPD patients in whom this pressure is higher in the sitting position than the lying position, especially in advanced disease [67]. Furthermore, it was recently shown in diaphragm single fibres that maximal specific force generation of both the MHC-slow and the MHC-IIa isoforms was reduced as was the myofibrillar calcium sensitivity [68].

The decrease in diaphragm force is related to the fact that the length of the diaphragmatic fibres is shorter in COPD [69], such that the diaphragm is contracting on the ascending branch of its length–tension relationship. Animal models have shown that diaphragm adapted to chronic hyperinflation by losing sarcomeres in series such that the diaphragm force–length relationship is preserved and is shifted to shorter length [70]. Whether this phenomenon is present in the diaphragm of patients with COPD has never been demonstrated but, interestingly, at a given lung volume, these patients are able to generate maximal inspiratory pressures that are higher than those developed by healthy subjects [64].

There are no data available concerning the force of other respiratory muscles in COPD patients.

Peripheral muscles

The decreased muscle strength in patients with COPD is now well documented [20,71,72]. Quadriceps force is reduced by 30% in patients with moderate to severe COPD [20,72] and also the strength of the shoulder girdle muscles (pectoralis major: –40%; latissimus dorsi: –48%) [20] (Fig. 3.3) and of the handgrip and elbow flexion muscles [73] has been reported to be reduced. In addition to reduced strength, the cross-sectional area of the thigh, measured by computed tomography scanning, is considerably reduced in COPD patients [20] (Fig. 3.4). The reduction in strength was, however, proportional to the reduction in thigh area [20], suggesting that the loss in muscle force was entirely a result of muscle atrophy. Furthermore, quadriceps strength and muscle cross-sectional area were positively correlated with FEV_1 [20]. Quadriceps force also correlated with exercise capacity and 6-min walking distance [20,72]. Interestingly, because the contractile properties of the

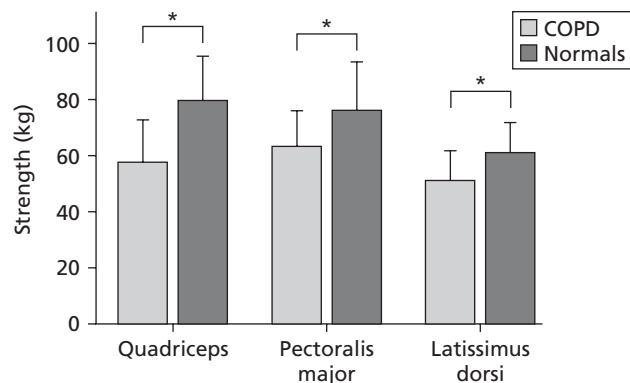

Figure 3.3 Strength of the quadriceps, the pectoralis major and the latissimus dorsi muscles obtained in normal subjects (light bars) and in COPD patients (dark bars). Values are mean and SD. * $P < 0.005$ vs controls. (From Bernard *et al.* [20] with permission.)

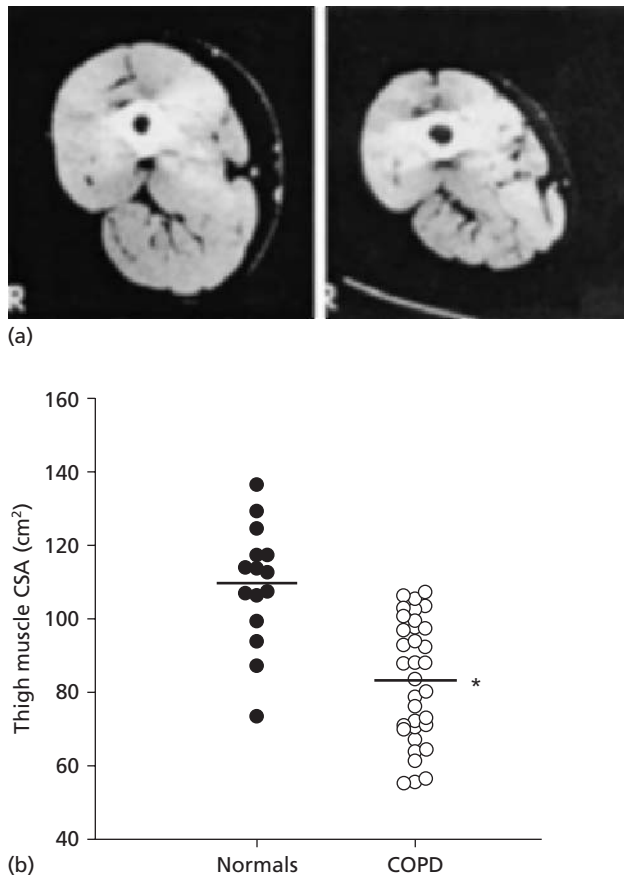

Figure 3.4 (a) Computed tomography of the thigh cross-sectional area of the vastus lateralis in a representative normal subject (*left*) and a representative patient with COPD (*right*). (b) Individual values of the thigh cross-sectional area (CSA) of the vastus lateralis obtained in normal individuals (closed circles) and in COPD patients (open circles). The horizontal lines represent the mean of each group. * $P < 0.0001$ vs controls. (From Bernard *et al.* [20] with permission.)

vastus lateralis are preserved in patients with COPD, the reduction in quadriceps strength in these patients is unlikely to be explained by an alteration of the contractile apparatus [40]. Finally, force impairment was more severe for the lower limb muscles than for the upper limb muscles, probably because of a greater reduction in activity of the lower limbs in these patients [20,72].

Muscle endurance

Respiratory muscles

Because the diaphragm of COPD patients is working against increased mechanical loads, it has been suggested that such a loading would result in chronic endurance training of the diaphragm. Thus, information on muscle endurance capacity can be derived from muscle metabolic measurements.

The diaphragm adapts to chronically increased workload induced by obstruction and hyperinflation by shifting from fast to slow fibre type, by increasing oxidative enzymes consistent with an increase in mitochondrial density. The degree of adaptation is correlated with disease severity. Also, increased efficiency of mitochondrial ATP production is present in these patients [74]. Interestingly, the increase in oxidative capacity of the diaphragm (when represented by \dot{V}_{\max} : maximal respiratory rate of the mitochondrial respiration) in COPD patients [74] was approaching values obtained for the vastus lateralis muscle after 6 weeks of endurance training [75].

Endurance data for the respiratory muscles other than the diaphragm are not yet available.

Peripheral muscles

The data available on peripheral muscle endurance in COPD patients are contradictory. Thus, while 35% [76] and 65% [77] reductions in the endurance of the vastus lateralis in COPD patients were reported by some researchers, no changes were observed in another study [78]. Discrepancies between these studies may be attributed to the fact that endurance measurement is strongly dependent on motivational factors so variability may be high. On the other hand, these discrepant data may simply reflect heterogeneity in skeletal muscle function between COPD patients. Further, it was shown that the quadriceps endurance in patients with COPD was impaired to a greater extent than the quadriceps muscle strength of these patients [79]. More recently, a decrease in quadriceps endurance was reported in COPD patients and was associated with an increase in oxidative stress in the vastus lateralis of these patients. Endurance time was correlated with lipid peroxidation and oxidized protein [80].

Data on upper limb muscles are also not clear. Endurance of the elbow flexor muscle seems to be preserved [81] while that of the adductor pollicis muscle is slightly reduced [78].

Fatigability

Respiratory muscles

An imbalance between load and capacity is present in the respiratory muscles of COPD patients. Fatigue has been induced separately in the diaphragm and the rib cage muscles in volunteers breathing against resistance [82,83]. Further, it has been hypothesized that COPD patients develop respiratory muscle fatigue during exacerbations, leading to ventilatory failure and hypercapnia. However, it was not possible to prove the presence of respiratory muscle fatigue. Actually, it is believed that rapid shallow breathing as chosen by COPD patients would represent a way to avoid respiratory muscle fatigue but at the expense of hypercapnia [84].

Peripheral muscles

A significant reduction in quadriceps twitch force (more than 15%) was found after high-intensity cycle exercise in 58% of COPD patients [11]. This was subsequently confirmed in another study where it was also shown that potentiated quadriceps twitch force was decreased in 81% of these patients after exercise [85], suggesting that potentiated twitch was a more sensitive index of contractile fatigue. Quadriceps fatigue following exercise affected patients with more severe disease ($FEV_1 < 40\%$ pred) (seven out of nine) as much as those with milder disease (10 out of 12), although exercise in severe COPD was performed at lower intensities [85]. Of interest, while quadriceps low-frequency fatigue after cycling is frequent in COPD patients, such fatigue is not observed after exhaustive walking, suggesting that symptom limitation in COPD is exercise-specific [86].

In stable COPD patients, mechanical efficiency of the upper limb muscles has been shown to be preserved during submaximal exercise [87]. Differences in muscle fibre composition as well as differences in training status between upper and lower limbs probably contributed to the observation that arm exercise tolerance is less impaired than leg exercise tolerance in COPD patients.

Muscle bioenergetics

Respiratory muscles

An increase in maximal oxidative capacity was reported in the costal diaphragm of COPD patients compared with control subjects [74]. In addition, inverse relationships were found between diaphragm maximal oxidative capacity and FEV_1 (% pred) and RV/TLC [74]. These data suggest that the improvement in oxidation and phosphorylation implies an increased efficiency of ATP production by the mitochondria. A twofold increase in succinate dehydrogenase activity, an indicator of mitochondrial oxidative capacity, of each fibre type was observed in the diaphragm biopsies of patients with severe COPD compared with age-matched controls [27]. In addition, mitochondrial oxidative capacity relative to ATP demand was higher in each of the fibre types in the diaphragm of COPD patients [27]. These data show that patients with severe COPD have an increased capacity to generate ATP through aerobic oxidative pathways [27]. ATP and creatine phosphate content is decreased in the internal and external intercostal muscles of COPD patients, these decreases being related to the level of airway obstruction [32].

Peripheral muscles

^{31}P magnetic resonance spectroscopy is a non-invasive method used to measure muscle metabolism. The ratio of intracellular phosphocreatine/inorganic phosphate is

generally measured with this technique as it is related to that of ATP/ADP. This measure seems to be representative of the mitochondrial phosphorylation potential. In patients with COPD, reduced phosphocreatine and ATP contents and a decrease in intracellular pH have been found in skeletal muscles under resting conditions while lactate and inorganic phosphate concentrations are increased [39,88–90]. In addition, during exercise, a greater decline in muscle intracellular pH and phosphocreatine/inorganic phosphate ratio is observed in these patients [19,91–93]. However, blood lactate levels increased very rapidly at low levels of exercise in patients with COPD [19,94,95]. These data show evidence of impaired oxidative phosphorylation and abnormal metabolic regulation in COPD patients.

Potential causes of muscle dysfunction in COPD patients

Alterations in muscle environment

COPD

Muscle metabolism is altered in COPD patients but the mechanisms underlying the muscle abnormalities are still unknown. However, several factors related to COPD such as hypoxia, hypercapnia, inflammation, undernutrition and oxidative stress may contribute to these alterations.

Hypoxia

Chronic hypoxia is well known to exert adverse effects on skeletal muscles. Its role in muscle deconditioning in COPD patients is probably essential as hypoxia reduces exercise performance. Reduction in maximal force and endurance has been reported in the diaphragm, the adductor pollicis and vastus lateralis of hypoxaemic COPD patients [78,96]. A positive correlation was even reported between arterial partial pressure of oxygen and percentage of type I fibres in the vastus lateralis of COPD patients [39]. Even if it remains difficult to be certain about the degree of tissue hypoxia in COPD patients, the fact that capillary/fibre ratio is reduced further impaired oxygen delivery to muscle tissue in these patients.

Hypercapnia

Acute or chronic hypercapnia frequently occurs in COPD patients with acute or chronic respiratory insufficiency. Marked reduction in ATP and phosphocreatine concentrations and intracellular acidosis were observed in the quadriceps of COPD patients with acute respiratory failure [88,89]. A decrease in maximal inspiratory muscle strength was described in COPD patients with chronic hypercapnia compared with normocapnic COPD patients [97].

Inflammation

Pro-inflammatory cytokines such as tumor necrosis factor α (TNF- α) and interleukin 6 (IL-6) can induce muscle wasting in animals [98,99]. An increase in serum levels of TNF- α and its soluble receptors has been reported in malnourished COPD patients [100–102] but also in COPD patients with normal BMI [103]. However, this increase in circulating cytokines seems not to be linked to a decrease in dietary energy intake [104]. Also, increases in IL-6 serum levels [103,105,106], or its soluble receptors [103], were observed in COPD patients where the IL-6/dehydroepiandrosterone (DEHA) ratio, a marker of the catabolic/anabolic balance, was significantly correlated with the mid-thigh muscle cross-sectional area [106]. A relationship was found between the reduced creatinine–height index (used as an index of skeletal muscle mass) and the increased circulating levels of IL-6, TNF- α and their soluble receptors [103], supporting a contributory role for systemic inflammation in muscle wasting in COPD patients. Recently, enhanced serum levels of IL-8 were reported in patients with stable COPD and in those hospitalized for acute exacerbation [107]. In these patients, the force of the quadriceps was inversely related to log IL-8, suggesting a contributory role for systemic inflammation in skeletal muscle weakness [107]. In addition, increased levels of TNF- α in the quadriceps muscle of stable COPD patients were recently reported [108]. The molecular mechanisms by which inflammation may lead to muscle atrophy are still unknown. However, there are several ways by which TNF- α may affect muscle cells. For example, TNF- α is known to activate the nuclear transcription factor NF- κ B and to induce the expression of a variety of genes including the inducible form of nitric oxidase synthase (iNOS). This is particularly interesting as activation of NF- κ B and upregulation of iNOS expression have been demonstrated in the quadriceps muscles of COPD patients with low BMI [109]. Increased oxidative stress was also shown in the quadriceps muscle of stable COPD patients in whom iNOS and nitrotyrosine protein levels were increased compared with healthy sedentary subjects [108].

Nutritional imbalance

The incidence of undernutrition in COPD patients varies between 25 and 50%, depending on disease severity. Nutritional depletion is associated with a poorer outcome in COPD patients [110,111]. Because increases in daily and resting energy expenditure are frequent in COPD patients, they may contribute to body weight and muscle mass loss especially in severe COPD patients in whom the caloric intake decreased [112,113]. Depletion of high-energy phosphate compound (ATP and phosphocreatine) and cations (magnesium and potassium) in the respiratory muscles is particularly severe in undernourished patients

with respiratory failure resulting from acute or chronic lung disease [114]. The effect of nutritional status on respiratory muscle function in COPD patients is, however, still controversial. Indeed, it remains difficult to determine the additive role of undernutrition in the observed respiratory muscle weakness, especially because nutritional support failed to increase lean body mass in these patients [115], suggesting that other factors are probably involved in muscle wasting and dysfunction in COPD patients. Even when assessing diaphragm contractility with magnetic phrenic nerve stimulation, a test that is independent of patient effort, Hamnegård *et al.* [116] did not find any differences in diaphragm strength of severe COPD patients, either undernourished or normally nourished.

Oxidative stress

The term oxidative stress refers to alterations caused by the reactive oxygen species. Under physiological conditions, the generation of reactive oxygen species is removed by the cellular antioxidant systems which include antioxidant vitamins, protein and non-protein thiols, and antioxidant enzymes. Excessive production of reactive oxygen species may lead to an imbalance between oxidant–antioxidant such that extensive cell and tissue damage may occur.

Actually, there are only a few studies reporting the level of oxidative stress in the diaphragm of COPD patients. Thus, compared with control subjects, severe COPD patients showed an increase in protein oxidation in their diaphragm [117]. This increased expression was, moreover, inversely related to disease severity. Immunohistochemistry revealed an increased level of 4-hydroxy-2-nonenal, a marker of lipid peroxidation in the diaphragm of COPD patients [59].

Total glutathione has been shown to be reduced in leg muscles of COPD patients compared with control subjects [118]. An increase in lipid peroxidation and Mn-superoxide dismutase (an enzyme involved in dismutation of superoxide anions) have been found in the quadriceps of COPD patients when compared with controls [119]. Protein oxidation and catalase were similar in the two groups as were the expressions of neuronal NOS and endothelial NOS isoforms. Interestingly, 3-nitrotyrosine levels were also significantly elevated in the quadriceps of the patients with COPD and these levels were positively correlated with the degree of airflow obstruction [119].

Comorbid conditions

Electrolyte disturbances

Although electrolyte disturbances may affect muscle function, few studies have examined these effects in COPD patients. In case electrolyte disturbances are severe, cell destruction, myopathy and rhabdomyolysis may occur especially with hypokalaemia and hypophosphataemia.

Hypokalaemia is frequently caused by diuretic therapy.

Potassium deficiency alters membrane electrical properties of the muscle cells towards hyperpolarization [120]. In addition, hypokalaemia is associated with glycogen depletion which in turn affects muscle contraction under anaerobic conditions [120]. This latter observation is particularly important for COPD patients in whom the oxidative capacity is already reduced.

Hypophosphataemia in COPD patients may be frequent and is caused by malnourishment or by renal reabsorption failure brought about by some medication (theophylline, diuretic, corticosteroids, β -agonist) [121]. Hypophosphataemia is associated with a reduction in diaphragmatic function [122,123] and serum levels of phosphate are related to transdiaphragmatic pressure [122]. Further administration of phosphate to COPD patients with hypophosphatemia improves diaphragmatic function [122,123].

Deconditioning

COPD patients are subjected to various degrees of deconditioning, ranging from reduced activity to prolonged bed rest. Deconditioning is the adaptive response of muscle to disuse. Signs of deconditioning are present in the peripheral muscles of COPD patients. These include reduced oxidative enzyme capacity, atrophy of type I fibres and reduction in type I fibre proportion. It is important to mention that physical activity in daily life is an important predictor of risk of readmission to hospital and mortality in patients with COPD [124,125]. Patients' estimation of time spent in physical activities in daily life is, in fact, not accurate when compared with objective assessment [126]. Compared with matched healthy subjects, stable COPD patients are effectively less active, walking less and lying down more than controls [127]. Inactivity is worsened during hospitalization resulting from acute exacerbation and, although recovery occurs, the levels of inactivity in these patients is still significantly reduced 1 month after discharge compared with stable COPD patients [128].

Cardiac failure

There are no data available on the effects of cor pulmonale on muscle function in COPD patients. In patients with congestive heart failure, inspiratory muscle weakness is present and is more pronounced than that observed in peripheral muscles [129–132]. In the diaphragm, the proportion of type I fibres decreased and there is also a disproportionate atrophy of type I and II fibres while the activity and the protein levels of the sarcoplasmic endoplasmic reticulum calcium ATPase (SERCA) pump diminished [24,133,134]. A downward displacement of the diaphragm occurs at the end of expiration in patients with chronic heart failure which was strongly correlated with the changes of left ventricular morphology [135].

For peripheral muscles, strength was found to be

decreased or unchanged [136–138]. Structural changes and fibre shift towards type II [139] as well as type IIB and/or type IIA atrophy were reported [140,141]. This was associated with a reduction in oxidative enzyme capacity but glycolytic enzyme function was preserved [140,141].

Ageing

It is well known that muscle force and muscle mass decrease with age because of a reduction in fibre cross-sectional area, mainly of the type II fibres [142]. Although COPD affects elderly individuals, peripheral muscle dysfunction in these patients is unlikely to be accounted for by the ageing process alone, because the muscle abnormalities seen in these patients are clearly more pronounced than those in age-matched individuals.

Anabolic hormones

Growth hormone, insulin-like growth factor I (IGF-I) and androgenic steroids are stimulators of muscle growth and development. In healthy elderly individuals, the circulating levels of IGF-I are decreased [143,144]. In COPD patients, the serum levels of IGF-I tended to be lower than aged-matched individuals [107,145,146]. A positive correlation was also found between circulating IGF-I and quadriceps peak force in COPD patients [107].

Testosterone has been shown to exert its anabolic properties by increasing the fractional synthesis rates of actin and MHC and by stimulating protein synthesis, resulting in muscle hypertrophy [147,148]. In men testosterone levels decline with age and in women testosterone levels start to decrease with the menopause. In addition, sex hormone binding globulin, to which testosterone is bound, increases with age and postmenopausally in females such that free testosterone is substantially reduced in these individuals [149,150]. In acutely ill, hospitalized COPD patients, levels of testosterone are low and are correlated with the severity of arterial hypoxaemia and hypercapnia [151]. In men with COPD, levels of testosterone are considerably lower than those of age-matched subjects [152].

CHAPTER 4

Exercise limitations and cardiopulmonary exercise testing in COPD

Norman R. Morris, Lewis Adams, Bruce D. Johnson and Idelle M. Weisman

Chronic obstructive pulmonary disease (COPD) is a progressive disorder that leads to a gradual deterioration of lung mechanics and gas exchange. Early manifestations include mild exertional dyspnoea and reduced activity levels [1,2]. As the disease progresses, with further lung tissue destruction and remodelling, there are additional losses in lung elastic recoil, altered ventilation and perfusion relationships, an increased work and cost of breathing, and dyspnoea that becomes more prominent with activity [3,4]. There may be further functional limitations imposed by progressive pulmonary hypertension and by production of cytokines and inflammatory mediators that may impair skeletal muscle function (beyond the results of inactivity) with the disease appearing a more systemic illness than previously appreciated [5–7]. The focus of this chapter is to discuss practical aspects of clinical exercise testing, to review components of exercise limitation in patients with COPD and address current therapeutic strategies in this population.

Clinical exercise testing modalities

There are several modalities of exercise testing used in clinical practice. Some provide basic information, require minimal technical expertise and are simple to perform; while others provide a more complete assessment of all the components involved in exercise and require more complex technology. The following are the most popular exercise tests used in the clinical setting in order of increasing complexity: (i) 6-minute walk test; (ii) shuttle walk test; (iii) cardiac stress test, when cardiac ischaemia needs to be ruled out; and (iv) the cardiopulmonary exercise test (CPET), which may on occasion include arterial blood gas assessment. The CPET typically includes electrocardiographic assessment along with measurements of expired gas exchange. The reader is referred to other sources for a

discussion of these different exercise testing modalities [8,9] as this review primarily focuses on the information gained from the more comprehensive but commonly used non-invasive CPET.

Indications

CPET involves the measurement of oxygen uptake ($\dot{V}O_2$), carbon dioxide output ($\dot{V}CO_2$), minute ventilation (\dot{V}_E), and other variables in addition to the monitoring of a 12-lead electrocardiogram (ECG), blood pressure, and pulse oximetry (SpO_2) during a maximal symptom-limited incremental exercise test on the cycle ergometer or on the treadmill [10]. When appropriate, the additional measurement of arterial blood gases provides important information on pulmonary gas exchange and many automated systems now allow measurement of the tidal flow–volume loop placed according to a measured inspiratory capacity (IC) within the maximal flow–volume envelope (MFVL) to help better assess the degree of mechanical constraint to breathing [11].

CPET is clinically useful in the evaluation of patients with COPD and permits:

- 1 Objective determination ($\dot{V}O_{2max}$) of functional capacity or impairment;
 - 2 Evaluation of the mechanisms of exercise limitation, such as the contribution of different organ systems involved in exercise (e.g. heart, lungs, blood and/or skeletal muscles);
 - 3 Differentiation between heart and lung disease;
 - 4 Monitoring of disease progression and response to treatment;
 - 5 Determination of the appropriate intensity needed to perform prolonged exercise (for constant load testing); and
 - 6 Exercise prescription for cardiopulmonary rehabilitation.
- Maximal exercise testing can be safely performed in the

vast majority of patients with respiratory disease with careful monitoring of the ECG and arterial oxygen saturation (Sao_2).

CPET is important in relating symptoms to exercise limitation, especially when exertional symptoms are disproportionate to resting pulmonary function tests (PFTs) and when hypoxaemia may contribute to exercise limitation and O_2 requirements need to be directly quantified. Furthermore, CPET permits the evaluation of therapeutic interventions on exercise capacity, relief of dyspnoea and improvement in exercise tolerance. The efficacy of CPET in monitoring a variety of treatment modalities (bronchodilators, exercise training, lung volume reduction surgery (LVRS), continuous positive airway pressure (CPAP) and proportional assist ventilation (PAV)) directed at improving breathing strategy and/or reducing dynamic hyperinflation, thus resulting in improved breathlessness and exercise capacity, has been demonstrated [12–17]. CPET complements other clinical and diagnostic modalities and by directly quantifying work capacity improves the diagnostic accuracy of impairment–disability evaluation.

Methodology (CPET)

Commercially available automated systems process four primary signals: air flow, O_2 , CO_2 and heart rate, which form the basis for the determination of all the measured and derived cardiopulmonary variables [18]. The current systems are technically advanced and provide online analysis of expired respiratory gas exchange using either breath-by-breath or modern mixing chamber techniques [19,20]. Both are acceptable for clinical exercise testing [18]. The more popular breath-by-breath technique is associated with a high degree of breath-to-breath variability ‘noise’ which can be minimized by 30–60-s interval averaging of the data [21]. Cardiopulmonary measurements obtained during maximal CPET in both control subjects and patients are reproducible provided that calibration and quality assurance procedures are followed [18,22].

Exercise testing can be performed using either a cycle ergometer or a treadmill. Traditionally, exercise testing in respiratory patients has used cycle ergometry. However, depending on the reasons for which CPET was requested, a treadmill might be an acceptable alternative. For clinical CPET purposes, electronically braked cycle ergometry, which maintains a given work level independent of cycling frequency, may be preferable to treadmill testing. Advantages of using cycle ergometry include: direct quantitation of work rate, less noise (artefact) on ECG, ease in collection of blood samples during exercise, expense and safety [18]. However, one important limitation using the cycle is that the $\dot{V}\text{O}_{2\text{max}}$ achieved is usually 5–11% less than

on a treadmill, which is likely because of more local fatigue and less muscle mass involved in exercise as well as the electrically propelled treadmill possibly pushing patients beyond usual comfort or motivation levels.

Protocols

There are several symptom-limited protocols that can be used with either the cycle ergometer or the treadmill (Fig. 4.1) [18,23]. These include incremental protocols in which the work intensity is increased in a square wave fashion, from 5 W every 1–3 min for debilitated patients to 25 W every 1–3 min for mild disease or healthy subjects, and the ramp protocol in which the power is increased continuously. Both should be programmed to achieve maximal aerobic capacity in 8–12 min [24]. The comparability of these protocols for metabolic and cardiopulmonary measurements is well established [20,25,26]. Subsequently, these results can be used to establish constant work (‘steady-state’) protocols (see below). CPET results are quite reproducible although, like most physiological tests, there appears to be a learning curve and most subjects will tend to perform slightly better or be willing to work slightly harder on subsequent studies [21,23].

Increasingly, constant work exercise at a standardized submaximal work load (based on an initial incremental exercise test) is being utilized to evaluate the impact of therapeutic interventions including exercise training, oxygen therapy, bronchodilators and LVRS. Recent work

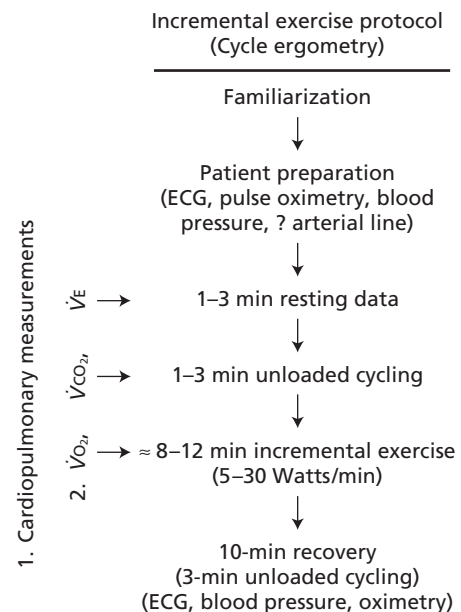

Figure 4.1 Typical incremental cycle ergometer exercise protocol used for clinical testing. ECG, electrocardiogram.

has suggested that Borg dyspnoea ratings, measurements of IC (as a reflection of dynamic hyperinflation) and endurance times during submaximal exercise are reproducible and sensitive in patients with severe COPD [27–29]. Furthermore, constant work endurance times were more sensitive than 6-minute walk test in determining therapeutic effectiveness of pharmacological intervention [29]. More recent work would suggest, however, that endurance shuttle walk tests are sufficiently sensitive to detect changes after bronchodilatation, which may reflect in part differences in quadriceps femoris muscle fatigue occurring more frequently with cycling than walking [9].

An exercise intensity of 65–80% of the maximum work rate achieved during the incremental exercise test has been used for the constant work rate test, which results in $\dot{V}_{O_{2peak}} > 90\%$ of the value obtained in the maximal exercise evaluation [14,30]. To evaluate therapeutic effectiveness of various interventions, it should be kept in mind that intensity of exercise can influence the study outcome. For example, low level activity (e.g. < 50% of peak work) in patients with moderate–severe COPD may result in patients being limited primarily by the endurance capabilities of their peripheral muscles, while exercise > 70% of peak work should result in a sufficient ventilatory stimulus so that most patients would come close to reaching the mechanical limits imposed by their airways. Thus, to examine an intervention aimed at improving maximal expiratory airflows, a higher intensity of exercise should likely be chosen [28].

Patient safety

Extensive literature documents that symptom-limited exercise testing is safe with the risk of medical complications during exercise testing related to the underlying

disease, with morbidity for patients in the range of 2–5 per 100 000 clinical exercise tests [31–35]. Advantages to performing CPET over less structured exercise tests include not only the extensive amount of physiological information gained, but also safety. Typically, trained personnel, physicians, exercise physiologists and nurses, carry out exercise testing under controlled and stable conditions for temperature and humidity, with emergency equipment and a bed available, while carefully monitoring the electrocardiogram, blood pressure, symptoms and O_2 saturation [23,36,37]. These trained individuals should be knowledgeable about the conduct and risks of testing, contraindications to testing and the criteria for terminating exercise tests.

Measurements

Computerized metabolic systems allow for an impressive number of variables to be measured or derived during exercise (Table 4.1). The number of variables actually used will vary and be a function of the reasons for exercise testing. The most commonly measured variables are listed below. Figure 4.2 shows an example of the normal cardiopulmonary responses to exercise in a healthy adult.

Oxygen consumption (\dot{V}_{O_2})

\dot{V}_{O_2} rises linearly with increases in work rate to a maximal value. The measurement of $\dot{V}_{O_{2max}}$ or $\dot{V}_{O_{2peak}}$ remains the best available index for the assessment of aerobic capacity [24]. $\dot{V}_{O_{2peak}}$ can be estimated from work rate; however, previous studies have suggested such estimates may not always be reliable [38]. $\dot{V}_{O_{2peak}}$ may be expressed in absolute values (L/min), per kilogram body weight (mL/kg/min) and as percentage of predicted. The optimal normalization for body mass remains somewhat controversial.

Table 4.1 Cardiopulmonary variables measured during exercise testing. (Modified from Zeballos and Weisman [21].)

Variables	Non-invasive	Invasive
Work	Work rate	
Metabolic	\dot{V}_{O_2} , \dot{V}_{CO_2} , R, AT (a.k.a. LT)	Lactate
Cardiovascular	HR, HRR, ECG, BP, O_2 pulse	
Respiratory	\dot{V}_E , V_T , fb, VR, PET_{O_2} , PET_{CO_2}	
Pulmonary gas exchange	Sp_{O_2} , \dot{V}_E/\dot{V}_{CO_2} , \dot{V}_E/\dot{V}_{O_2}	Sa_{O_2} , Pa_{O_2} , $P(A-a)_{O_2}$, V_D/V_T
Acid–base		pH, Pa_{CO_2} , HCO_3^- .
Symptoms	Dyspnoea, leg fatigue, chest pain	

Abnormality of a variable does not necessarily define exercise limitation in that category.
 AT, anaerobic threshold; BP, blood pressure; ECG, electrocardiogram; fb, breathing frequency; HCO_3^- , bicarbonate; HR, heart rate; HRR, heart rate reserve; O_2 , oxygen; $P(A-a)_{O_2}$, alveolar-arterial oxygen difference; Pa_{CO_2} , arterial partial pressure of carbon dioxide; Pa_{O_2} , arterial partial pressure for oxygen; PET_{CO_2} , end tidal partial pressure for carbon dioxide; PET_{O_2} , end tidal partial pressure for oxygen; R, respiratory exchange ratio; Sa_{O_2} , arterial oxygen saturation; Sp_{O_2} , oxygen saturation; \dot{V}_{CO_2} , carbon dioxide production; \dot{V}_D/\dot{V}_T , dead space to tidal volume ratio; \dot{V}_E , minute ventilation; \dot{V}_E/\dot{V}_{CO_2} , ventilatory equivalents for carbon dioxide; \dot{V}_E/\dot{V}_{O_2} , ventilatory equivalents for oxygen; \dot{V}_{O_2} , oxygen uptake; VR, ventilatory reserve; \dot{V}_T , tidal volume.

Figure 4.2 Results of a maximal, minute-by-minute, incremental, cardiopulmonary exercise test of a young, healthy, physically active person. The upper panel shows response of \dot{V}_{O_2} uptake (\dot{V}_{O_2}), \dot{V}_{CO_2} output (\dot{V}_{CO_2}), minute ventilation (\dot{V}_E) and respiratory exchange ratio (R) to the progressive increase in work rate. The middle panel shows the responses of heart rate (HR) and O_2 pulse (\dot{V}_{O_2}/HR) and the lower panel the responses of the ventilatory equivalent for O_2 (\dot{V}_E/\dot{V}_{O_2}), ventilatory equivalent for CO_2 (\dot{V}_E/\dot{V}_{CO_2}), end-tidal pressure for O_2 (PET_{O_2}) and end-tidal pressure for CO_2 (PET_{CO_2}). Also shown is the transition zone corresponding to the anaerobic threshold (AT).

In addition to the typical expression in mL/kg/min (e.g. American Heart Association, American College of Sports Medicine), others have expressed \dot{V}_{O_2} relative to body mass index (kg/m^2) or for fat-free mass (mL/kg/min) [39]. $\dot{V}_{O_{2max}}$ values have been regarded as most reliable when \dot{V}_{O_2} does not increase (plateau) despite further increase in work rate [25,40]. Such a plateau, however, especially in COPD patients, is not often observed, and the maximum \dot{V}_{O_2} achieved has been called $\dot{V}_{O_{2peak}}$ [41]. This implies that if a subject could be pushed harder, there may be a small further increase in the peak value. For practical purposes, however, $\dot{V}_{O_{2peak}}$ is likely quite close to $\dot{V}_{O_{2max}}$ and thus they are often used interchangeably.

A reduced $\dot{V}_{O_{2peak}}$ (defined by the Fick equation, $\dot{V}_{O_2} = HR \times SV \times a-\dot{V}_{O_2} \text{ diff}$) reflects problems with O_2 delivery (heart, lung, systemic and pulmonary circulation; and blood) and/or peripheral abnormalities (reduced O_2 utilization and/or muscle dysfunction) [42–44]. A reduced $\dot{V}_{O_{2peak}}$ may also reflect poor effort. $\dot{V}_{O_{2peak}}$ is modulated by physical activity and, as such, has been the gold standard for the evaluation of fitness. A number of normative studies have derived predicted equations based on age and gender [20,45]. A normal $\dot{V}_{O_{2peak}}$ reflects a normal aerobic power and exercise capacity and suggests that no significant functional abnormality exist. In some subjects, however, even though the $\dot{V}_{O_{2peak}}$ may be near normal, exercise testing may reveal other abnormalities (e.g. abnormal breathing patterns) that may be of diagnostic value [28,46,47]. A reduced $\dot{V}_{O_{2peak}}$ is usually the starting point in the evaluation of a cardiopulmonary exercise test [48].

Although $\dot{V}_{O_{2peak}}$ is most commonly reported, it may also be of interest to assess the slope of rise in \dot{V}_{O_2} relative to work. In health, this slope is approximately a rise in \dot{V}_{O_2} of 10 mL for every watt increase in work. Clinically, an abnormal slope of this relationship is most often caused by O_2 transport dysfunction (heart failure and pulmonary hypertension); less commonly O_2 utilization dysfunction may also be associated with a reduced slope of this relationship [49,50]. Obese individuals may show an increase in \dot{V}_{O_2} for a given external work rate, but the slope of the relationship is usually normal [24].

Carbon dioxide production (\dot{V}_{CO_2})

Paralleling the changes in \dot{V}_{O_2} with exercise are the changes in the volume of CO_2 expired. At low levels of exercise, the volume of CO_2 expired tends to be slightly less than the uptake of O_2 ; however, this becomes equimolar in moderate exercise and exceeds O_2 uptake with moderate to heavy exercise. The relationship of \dot{V}_{CO_2} to \dot{V}_{O_2} is known as the respiratory exchange ratio (R). Under steady-state conditions, this ratio may reflect the fuels being consumed at the muscle (similar to the respiratory quotient, RQ). However, with non-steady-state or heavy exercise this more accurately reflects transient changes in CO_2 stores and exceeds 1.0 when lactate buffering occurs and when pH falls causing a significant hyperventilation [51,52]. Anxiety-related hyperventilation will also cause a high R. As noted, \dot{V}_{CO_2} is typically assessed in combination with \dot{V}_{O_2} or with minute ventilation (\dot{V}_E).

Heart rate (HR)

The best index for the evaluation of cardiac function during exercise would be the measurement of cardiac output. However, this is not routinely performed in the clinical exercise laboratory. It is well established that increases in cardiac output are initially accomplished by increases in stroke volume and heart rate (HR), and then at higher work

rates almost exclusively by increases in HR [24]. Achievement of age-predicted values for heart rate typically reflects maximal or near maximal effort and presumably signals attainment of $\dot{V}_{O_{2max}}$ and, in turn, maximal cardiac output [53]. For interpretative purposes, it is extremely important to remember that there is considerable variability (10–20 b/min) within an age group when estimates of maximal HR are used. The difference between the age-predicted maximal HR and the maximum HR achieved during exercise is referred to as the HR reserve (HRR) [20]. Normally, at maximal exercise, there is little or no HRR. In patients with COPD, the achievement of peak heart rate during exercise may vary considerably depending on the disease severity and medications. Marked mechanical constraints to breathing may result in a submaximal HR attained during exercise.

Oxygen pulse (O_2 pulse)

The O_2 pulse is the \dot{V}_{O_2} divided by HR. This is equivalent to the product of stroke volume multiplied times the arterial–mixed venous oxygen difference (a- \dot{V}_{O_2} diff, extraction). Some studies have suggested that the O_2 pulse may be a good non-invasive estimate of stroke volume because the degree of extraction tends to reach similar levels in multiple populations [48]. The classic response is an initial linear rise with workload followed by a gradual plateauing as exercise intensity increases.

Ventilation (\dot{V}_E)

Minute ventilation (expressed in L/min) is typically determined from respiratory rate and tidal volume. Ventilation includes both alveolar and dead space ventilation and is most often expressed relative to ventilatory capacity (see Ventilatory reserve below) or metabolic demand (see Ventilatory efficiency below).

Ventilatory reserve (VR)

This concept is used to determine the degree of mechanical limitation or constraint to breathing during exercise. It is typically expressed as the maximal ventilation achieved during exercise relative to the maximal voluntary ventilation (\dot{V}_E/MVV) or some estimate of the MVV (e.g. forced expiratory in 1 s (FEV_1) multiplied times 35–40) used as an index of ventilatory capacity [45]. VR is dependent on many factors responsible for altering ventilatory capacity and ventilatory demand. Those influencing ventilatory demand include metabolic demand (fitness), body weight, mode of testing, dead space ventilation as well as neuro-regulatory and behavioural considerations. Ventilatory capacity, in turn, is influenced by multiple factors including ventilatory muscle function, genetic endowment, ageing and disease [54–57]. The ventilatory capacity may also vary during exercise depending on bronchodilatation or bronchoconstriction and the regulation of the operational lung

volume (where one breathes relative to the constraints imposed by the boundaries of the maximal flow–volume envelope (see below)) [11].

A high \dot{V}_E/MVV is one of the criteria often used to indicate encroachment on the ventilatory reserve and increasing ventilatory constraint to breathing. A reduced or absent ventilatory reserve especially when accompanied by other respiratory abnormalities (and an inability to achieve maximal HR) increases the likelihood that respiratory limitation may be a significant contributing factor to exercise limitation.

Limitations to the use of classical VR

Although widely used and practical, MVV may not always be a reliable indicator of the maximal available ventilation nor provide adequate insight into abnormalities in breathing strategy [11]. The MVV is typically a 15-s test, and patients will typically produce pulmonary pressures in excess of those produced even during maximal exercise [58]. In addition, patients have a tendency to perform the MVV at higher lung volumes than those achieved during exercise, taking advantage of the higher available maximal expiratory flows at the higher lung volumes. However, this can increase the work and cost of breathing because of the increased elastic load as one approaches total lung capacity (TLC).

A more comprehensive assessment of the degree of ventilatory constraint can be gained by comparison of the exercise tidal flow–volume loop to the maximal volitional flow–volume envelopes [11]. This display of the exercise breathing pattern provides visual insight into the degree of ventilatory constraint and the strategies used to achieve a given level of ventilation relative to that which is available. Quantification of the degree of constraint from the tidal flow and volume responses to exercise relative to the MFVL has been suggested (Fig. 4.3). In addition to a more in depth assessment of ventilatory constraint during exercise, a more precise assessment of ventilatory capacity (VECAP) can be obtained. This assessment of ventilatory capacity takes into account the tidal volume, the operational lung volume (end-expiratory lung volume, EELV) and the constraints imposed by the maximal expiratory flow–volume curve. To account for changes in ventilatory capacity during exercise (i.e. bronchodilation or constriction), comparisons can be made to an MFVL obtained during or immediately post exercise [11]. Exercise tidal flow–volume loop analysis has been applied in several clinical settings [55–57, 59–61].

Anaerobic threshold (AT)

With progressive increases in work intensity, there is a work intensity or \dot{V}_{O_2} where lactate would begin to accumulate. This was termed the lactate threshold and subsequently it was determined that non-invasive gas exchange measurements could fairly closely approximate these changes in lactate accumulation. Although the exact

Figure 4.3 Defining expiratory flow limitation. Tidal exercise flow–volume loops are aligned within maximal expiratory flow–volume envelope according to a measured end-expiratory lung volume (EELV). The percentage of the tidal breath (V_{FL}) that expiratory air flows meet or exceed the maximal expiratory flows are used as an estimate as to the degree of expiratory flow limitation. EILV, end-inspiratory lung volume [11].

mechanism for the rise remains somewhat controversial and may vary depending on disease population, the lactate rise in health most likely reflects accumulative recruitment of glycolytic fibres [54,62,63]. The lactic acid is subsequently buffered by bicarbonate and the by-product becomes CO_2 production in excess of typical metabolic CO_2 production. This results in a rise in the \dot{V}_{CO_2} and a parallel increase in minute ventilation to maintain iso-pH.

Current knowledge suggests that the AT may be affected by factors that impact both O_2 delivery and O_2 utilization processes, pattern of muscle fibre recruitment, and possibly others [64]. The AT usually occurs at 50–70% $\dot{V}_{\text{O}_{2\text{max}}}$ in sedentary individuals and higher in fit individuals [45]. There is a wide range of normal predicted values (35–70%) making its usefulness in clinical decision making somewhat limited [23,34].

Although there are several ways to determine the AT non-invasively, none appears consistently superior. Currently, the modified V-slope method (\dot{V}_{CO_2} vs \dot{V}_{O_2} plot) is most popular [65]. The AT, using the ventilatory equivalents method, is defined as the lowest (nadir) for $\dot{V}_E/\dot{V}_{\text{O}_2}$ and end tidal partial pressure for oxygen (PET_{O_2}) before beginning to consistently increase, while $\dot{V}_E/\dot{V}_{\text{CO}_2}$ and PET_{CO_2} remain unchanged, and R is approximately 1.0. An approach that combines the modified V-slope and the ventilatory

equivalents method is recommended [21]. Blood samples for standard bicarbonate or lactates help avoid false-positive non-invasive AT determinations that have been reported in COPD [66]. The AT determination is helpful as an indicator of level of fitness and to monitor the effect of physical training [67]. The AT is reduced in a wide spectrum of clinical entities (e.g. heart disease, lung disease, deconditioning, post lung and heart transplantation, muscle abnormalities (metabolic myopathy)) and therefore may be of limited discriminatory value in interpretative schemes [68].

Ventilatory efficiency ($\dot{V}_E/\dot{V}_{\text{CO}_2}$ and $\dot{V}_E/\dot{V}_{\text{O}_2}$)

Ventilatory efficiency is determined by how much ventilation is achieved for a given level of metabolic demand (i.e. $\dot{V}_E/\dot{V}_{\text{CO}_2}$ and/or $\dot{V}_E/\dot{V}_{\text{O}_2}$). Because \dot{V}_E is more closely linked to \dot{V}_{CO_2} , the relationship of \dot{V}_E to \dot{V}_{CO_2} has typically been reported [51]. In healthy subjects, it typically requires approximately 25 L of ventilation for every 1 L of carbon dioxide produced. $\dot{V}_E/\dot{V}_{\text{CO}_2}$ and $\dot{V}_E/\dot{V}_{\text{O}_2}$ are typically similar until near where the AT occurs and then $\dot{V}_E/\dot{V}_{\text{CO}_2}$ tends to stay constant while $\dot{V}_E/\dot{V}_{\text{O}_2}$ starts to rise [69]. The degree of ventilation produced is best described in the alveolar air equation where $\dot{V}_E = K \times \dot{V}_{\text{CO}_2} / (\text{Paco}_2 \times (1 - V_D/V_T))$ [54]. Thus, the relationship of $\dot{V}_E/\dot{V}_{\text{CO}_2}$ is critically influenced by dead space ventilation, and arterial CO_2 levels. A high dead space ventilation increases the $\dot{V}_E : \dot{V}_{\text{CO}_2}$ ratio as does hyperventilation (reduced Paco_2 values). An inadequate hyperventilation during exercise (high or rising Paco_2) may result in a low $\dot{V}_E : \dot{V}_{\text{CO}_2}$ particularly if the V_D/V_T is normal. Various $\dot{V}_E : \dot{V}_{\text{CO}_2}$ values have been reported, including, the lowest point in an incremental test, at or near the AT, the slope of \dot{V}_E relative to \dot{V}_{CO_2} and peak. For most purposes, the $\dot{V}_E/\dot{V}_{\text{CO}_2}$ nadir occurs near the AT where it is usually reported since during heavy exercise, it is more susceptible to variation in the degree of hyperventilation, altered breathing pattern, anxiety and the degree of acidosis [69]. Under some circumstances, the peak values may be important as when a relatively sudden increase in $\dot{V}_E/\dot{V}_{\text{CO}_2}$ with heavier exercise occurs in patients with pulmonary hypertension, likely related to the high pulmonary pressures and the shunting of blood through a patent foramen ovale [70]. Examining the PET_{CO_2} , or preferably Paco_2 (if available), is useful in distinguishing between a hyperventilation-induced increase in $\dot{V}_E/\dot{V}_{\text{CO}_2}$ versus that related to a high dead space.

Blood gases

In the clinical laboratory when more specific gas exchange information is needed, direct arterial blood gas (ABG) sampling during exercise should be considered. This may be useful in a patient with significant oxygen desaturation (< 85%) during a non-invasive cardiopulmonary exercise test or in patients with a markedly elevated $\dot{V}_E/\dot{V}_{\text{CO}_2}$. It may also be of importance in patients where it is difficult to obtain clean non-invasive gas exchange data because of

problems with the mouthpiece or non-invasive estimates of oxygen saturation.

Measurements of P_{aO_2} , P_{aCO_2} , combined with ventilatory measurements also allows the assessment of the alveolar (PA_{O_2})–arterial (P_{aO_2}) oxygen pressure difference ($AaDO_2$) and physiological dead space to tidal volume ratio (V_D/V_T) [71]. V_D/V_T determined non-invasively using PET_{CO_2} can often yield unreliable results [72]. Abnormal widening of the $AaDO_2$ with exercise, usually reflects ventilation–perfusion (V/Q) mismatching, but may also be a result of diffusion abnormalities, anatomical shunt and/or reduced O_2 saturation in mixed venous blood (thereby worsening the V/Q mismatching shunt effect) [73]. Failure of V_D/V_T to decrease normally with exercise is indicative of V/Q abnormalities caused by increases in physiological dead space (wasted ventilation).

Pulse oximetry (Sp_{O_2})

Sp_{O_2} is only an estimation of the arterial O_2 saturation with actual $Sa_{O_2} \pm 4\%$ of the pulse oximetry readings [74]. Each laboratory should validate its pulse oximeter(s) with arterial oxygen saturation. This is important because some pulse oximeters underestimate and others overestimate true arterial oxygen saturation, especially at $Sa_{O_2} < 88\%$ [75]. Caution should be exercised in the use of pulse oximetry in darker skinned subjects, because the inaccuracies reported in Caucasians appear to be exaggerated [76]. Pulse oximeters cannot be used in patients with high levels of carboxyhaemoglobin, resulting from smoking or CO exposure, as COHb is not measured. Pulse oximeters measure functional Sa_{O_2} and not fractional saturation as do CO-Oximeters. Care should be exercised in interpreting changes obtained by pulse oximetry alone. Significant desaturation, defined as change in $Sp_{O_2} > 5\%$, should be confirmed with arterial blood gases [77].

Clinical signs and symptoms

In a symptom-limited test it is important to describe and characterize signs and symptoms limiting the test (e.g. chest pain, breathlessness, leg fatigue, wheezing, diaphoresis, arrhythmia) [43]. Ratings of perceived exertion symptoms (breathlessness, fatigue, chest pain) using the Borg Scale (0–10) or other rating scores including visual analogue scales should be noted with the physiological measurements [78–81] (see section on Dyspnoea under Exercise limitations in COPD below).

Exercise limitations in COPD

As COPD progresses, there is a gradual loss of lung elastic recoil, a destruction of lung parenchyma and inhomogeneities in the compliance characteristics of the lung. This

leads to airway narrowing or collapse (airflow limitation) at higher and higher lung volumes, progressive air trapping, a maldistribution of ventilation, areas of hypoxic pulmonary vasoconstriction, pulmonary hypertension and ventilation–perfusion mismatching resulting in a high dead space ventilation and areas of effective shunt, leading to progressive hypoxaemia. In mild to moderate disease, blood gas homeostasis may be preserved, while the dominant effect is the altered lung mechanics. Given the large reserves of the pulmonary system, at rest many of these changes may not render the patient particularly symptomatic; however, with activity and the increased ventilatory demands required to maintain arterial P_{O_2} and eliminate metabolic CO_2 , patients become symptomatic. Table 4.2 summarizes factors involved in limiting exercise tolerance in patients with COPD.

Table 4.2 Factors contributing to exercise limitations in patients with COPD.

Lung mechanics

Tissue destruction (alveolar)

Loss of parenchymal elastic recoil

- Expiratory flow limitation
- Hyperinflation
- Increased inspiratory elastic load
- High work and cost of breathing

Gas exchange

Tissue destruction (alveolar–capillary)

Loss of elastic recoil

Ventilation–perfusion abnormalities

- High dead space ventilation
- Widened alveolar–arterial difference
- Hypoxaemia

Cardiovascular

Hyperinflation

Reduced intrathoracic space

Reduced venous return

- Reduced cardiac output

Hypoxaemia

Pulmonary hypertension

- Reduced cardiac output

Peripheral muscles

Deconditioning

Inflammation

Competition for blood flow

Dyspnoea

Respiratory drive

Central perception

Inspiratory muscles

Chemoreceptors

Figure 4.4 Flow–volume response to exercise in the average fit healthy young adult during incremental exercise plotted within the maximal expiratory flow–volume (MFVL). In this population, end-expiratory lung volume (EELV) progressively decreases with exercise and expiratory flow limitation is only present near EELV over a small portion of the tidal volume. Considerable room exists to increase ventilation even at peak exercise.

Lung mechanics

In health, with large pulmonary reserves, the ventilatory demands of exercise (required to maintain blood gas homeostasis) are met with a fairly efficient breathing pattern and strategy, which minimizes the work and cost of breathing [54]. The ventilatory response to exercise in young and older healthy subjects is shown in Figure 4.4. Classically tidal volume increases and EELV falls as expiratory muscles are recruited, optimizing inspiratory muscle length. As exercise intensity increases, tidal volume continues to increase up to approximately 50% of the vital capacity (VC), which is followed by predominantly a breathing frequency response. EELV may drop further (0.5–1 L) and there is some encroachment on the inspiratory reserve volume (IRV); however, the alinear portions of the pressure–volume relationship of the lungs and chest wall are avoided and, even at maximal exercise, expiratory flow rates typically only approach the maximal available flow rate near EELV. Inspiratory pleural pressures continue to become more negative and approach -20 to -30 cm H_2O and only approach a small percentage of the available capacity for producing inspiratory pressure [60]. Even with maximal exercise, the cost of breathing is estimated to only approach 5–7% of the whole body $\dot{V}O_2$ in the average fit young adult [59,82].

With healthy ageing, there is some loss in pulmonary reserves so that the typical 70-year-old male will have an approximately 25–30% decline in VC and a similar decline in maximal expiratory flow rates (FEF_{25-75}), primarily because a loss of lung elastic recoil [83]. Despite this loss

in ventilatory reserve, the healthy older adult is able to increase ventilation with exercise with minimal increments in ventilatory cost relative to the younger adult. Only with very heavy exercise and with sustained high levels of physical training (increased metabolic demands), might the older adult reach significant mechanical limitations to breathing, typically associated with a mild to moderate degree of dynamic hyperinflation and expiratory flows that approach or reach the maximal available flows over a portion of the tidal breath (typically over the later half of the tidal breath, near EELV) [55].

The aged adult would therefore develop a breathing pattern and strategy that would be similar to a younger person with mild COPD (e.g. 15–30% reduction in FEV_1). Typically, older subjects will approach expiratory flow limitation at a \dot{V}_E of approximately 50–70 L/min and will need to increase EELV slightly to produce ventilations beyond 70 L/min. With more moderate lung disease, 40–50% reductions in FEV_1 , patients will approach expiratory flow limitation over a portion of the tidal breath even at rest. Thus, with exercise, to be able to increase ventilation, they will need to dynamically hyperinflate almost immediately to take advantage of the shape of the maximal expiratory flow–volume envelope and the available flows at the higher lung volumes [84,85]. However, as EELV starts to rise, it becomes more difficult to maintain tidal volume because of a shrinking IRV. As end inspiratory lung volume approaches TLC, the elastic load begins to rise as patients move away from the linear portion of the pressure–volume characteristics of the lung and chest wall. In addition, expiratory muscles need to be heavily recruited to produce large

Figure 4.5 Patient with history of moderate COPD (forced expiratory flow at 50% of VC = 35% of predicted for age). End-expiratory lung volume (EELV) increases from the onset of exercise and expiratory flow limitation is present over > 80% of the V_T by peak exercise. Inspiratory flows approach those available over the higher lung volumes. Little room exists to increase ventilation. EILV, end-inspiratory lung volume; TLC, total lung capacity.

expiratory flows early in expiration and thus the work and cost of breathing begins to rise substantially. Previous studies have suggested that this cost of breathing may approach 15% of the whole body $\dot{V}O_2$ in older, relatively fit adults and as much as 30–50% of the whole body $\dot{V}O_2$ in patients with severe COPD at ventilations of 30–40 L/min [85]. In terms of cardiac output and blood flow distribution, this would be a large percentage of blood flow unavailable to the muscles of locomotion, as previous work in animals and humans have suggested that the respiratory muscles will preferentially recruit blood flow at the expense of the locomotor muscles [86,87]. This reflex reduction in blood flow to locomotor muscles, along with the deconditioning process, may contribute to the symptoms of leg fatigue rather than dyspnoea as a primary limiting factor during exercise. Figure 4.5 is an example of the flow–volume responses to exercise in a relatively active older patient with moderate COPD.

Gas exchange

In healthy humans, the partial pressure of oxygen in the arterial blood (P_{aO_2}) generally remains close to resting

values, even during heavy exercise [88]. Arterial CO_2 (P_{aCO_2}) also is maintained relatively close to resting values through precise ventilatory control mechanisms. Only with heavy exercise is there a compensatory increase in ventilation that is out of proportion to the CO_2 produced resulting in a fall in P_{aCO_2} [54]. The alveolar (PA_{O_2}) to arterial oxygen difference ($AaDO_2$) tends to remain constant or in some cases fall slightly with very light exercise and then increases primarily as a result of a rise in PA_{O_2} [89]. In some healthy, typically endurance trained subjects with heavier exercise, P_{aO_2} may fall despite a rising PA_{O_2} [60]. The widening of the $AaDO_2$ in these healthy subjects has been considered to be related to a lack of time for end-capillary diffusion (resulting from a high cardiac output), interregional ventilation perfusion inhomogeneities and a 1–2% shunt due to the thebesian and bronchial circulations, which becomes more prominent as the mixed venous P_{O_2} falls [89]. The ventilatory dead space to tidal volume ratio (V_D/V_T) in healthy younger adults is approximately 0.20–0.30 and falls with exercise as the tidal volume increases. With healthy ageing, there tends to be a decline in resting P_{aO_2} values likely resulting from more inhomogeneities in ventilation–perfusion relationships [83]. There is also a rise in V_D/V_T .

However, during exercise older healthy adults tend to do a relatively good job at maintaining P_{aO_2} values, although the $AaDo_2$ tends to widen at a lower intensity of exercise than in young adults [90].

COPD is associated with relatively variable blood gas responses, with some patients having a well-preserved response to exercise and others with marked declines in P_{aO_2} [91,92]. In general, however, there is a much greater widening of the $AaDo_2$ at much lower work intensities than in age- and gender-matched controls. CO_2 elimination is also variable, from a relatively normal fall in P_{aCO_2} with heavy exercise to a rise in P_{aCO_2} , likely because subjects cannot increase alveolar ventilation enough to achieve adequate CO_2 removal. V_D/V_T can be quite high in patients with COPD so that they need to attain a much higher total ventilation than in healthy subjects to achieve a similar level of alveolar ventilation. Arterial hypoxaemia during exercise is primarily a result of ventilation–perfusion mismatching, with a contribution in some subjects from a diffusion limitation as well as increased shunt [89]. The hypoxaemia not only contributes to the sensation of dyspnoea, but may also result in worsening pulmonary hypertension that in turn may influence cardiac function and contribute to a reduced exercise tolerance. Previous studies have suggested that treadmill walking may be associated with more exercise-induced hypoxaemia than cycling [93].

Dyspnoea

Clinically, dyspnoea is a term for shortness of breath that is commonly found in COPD patients. The American Thoracic Society defines dyspnoea as ‘a term used to characterize a subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity’ [94]. The experience derives from interactions among multiple physiological, psychological, social and environmental factors, and may induce secondary physiological and behavioural responses. Dyspnoea is extremely distressing for the patient and is typically described as ‘having to fight for every breath’ or ‘a sense of impending doom’.

Many patients with COPD fall into a spiral of increasing levels of dyspnoea and decreasing levels of physical activity (Fig. 4.6). As the spiral progresses, dyspnoea arises at increasingly lower levels of exertion, and patients decrease the level of physical activity in an effort to avoid the sensation of dyspnoea. This decrease in the level of activity leads to further deconditioning. Eventually, this spiral will lead to dyspnoea impacting on activities of daily living (ADL) including basic functions such as washing and dressing. As a result, patients have a significant loss of quality of life. Interventions for COPD patients focus on dyspnoea as a key outcome measure often over and above any improvement in functional capacity [95,96].

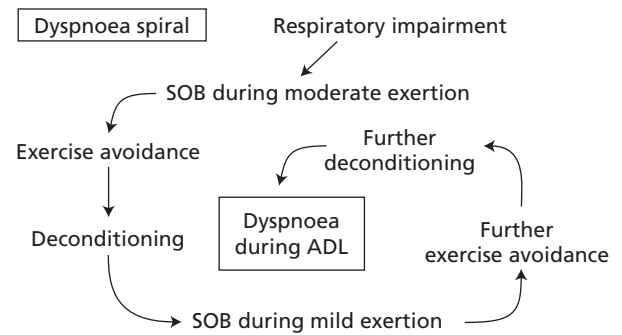

Figure 4.6 The cycle of decline associated with COPD. ADL, activity of daily living; SOB, Shortness of breath.

Pathophysiology

The recent evolution of functional brain mapping techniques of positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have provided new insights into dyspnoea perception. Using different technologies, these brain mapping techniques have suggested that the sensation of dyspnoea is associated with a pattern of activation of phylogenically ancient limbic and paralimbic cortical structures (e.g. anterior insular cortex, anterior cingulate gyrus and amygdala) [97–101].

As far as the respiratory system is concerned it seems that dyspnoea perception depends more on the degree to which the brainstem respiratory complex is stimulated than on the movement of the ventilatory apparatus. Thus, increases in ventilation associated with exercise, hypoxia, hypercapnia and metabolic acidosis are associated with dyspnoea while volitional ventilation is not [102]. Most interestingly, this is the case even in patients with severe COPD [103,104]. In addition, dyspnoea accompanies central respiratory stimulation in the absence of a ventilatory response in subjects with high spinal cord transection [105] or following experimental respiratory muscle paralysis [106,107]. For patients with COPD, one may hypothesize that exertional dyspnoea could be a manifestation of the increased central respiratory activity necessary to achieve adequate ventilation in the face of respiratory mechanical impairment. This hypothesis fits with the finding that progressive hyperinflation in COPD patients leads to increasing dyspnoea as greater respiratory muscle activity is required to ventilate at high lung volumes where compliance is low [108]. Support for this idea is provided in the study by Lahrman *et al.* [109] who showed that a decrease in dyspnoea following LVRS was accompanied by a decrease in lung hyperinflation and a reduced neural activity in the diaphragm. It also could explain the observation that exertional dyspnoea in COPD patients is lessened when non-invasive ventilatory support is provided [110].

An individual’s personality, emotional state and cognitive function seem likely to impact on their experience of dyspnoea [111]. Dyspnoea has been reported in both

hyperventilation syndrome and in those individuals prone to panic attacks [112,113]. There is evidence that patients with airflow limitation perceive dyspnoea less intensively when they become familiar with the situation that is giving rise to their dyspnoea [112].

Assessment scales that rate dyspnoea

A number of instruments are available that allow reasonably reproducible rating of the intensity of dyspnoea during exercise or in response to specific questions. Two of the most common scales used to rate dyspnoea are the visual analogue scale (VAS) and the Borg scale. VAS is a horizontal or a vertical line, usually 10 cm long, anchored at either end with words such as 'no dyspnoea' and 'maximal dyspnoea'. In response to a question (e.g. 'How short of breath are you?'), the subject marks a point along the line so that the length reflects the intensity of the sensation [114,115]. This scale was first used for rating the sensation associated with increased airway resistance and was only later adopted for the quantification of breathlessness [80,116].

The Borg scale is a 12-point category scale with extremes of 'nothing at all' and 'maximal' [79]. Unlike the VAS, the Borg scale includes verbal descriptors (e.g. 'slight', 'severe') to assist in rating the symptom. Like the VAS, the Borg scale has good reproducibility but the proximity of the terms 'slight' and 'severe' in the Borg scale may reduce its sensitivity and discourage subjects from using the whole scale as they do the VAS [114,115,117]. Although researchers have utilized the Borg and the VAS scales, clinicians often rely on a simple verbal numerical rating scale ranging from zero to 10 [118].

Importantly, there appears to be good correlation among the various rating scales, even when used in mechanically ventilated patients [119]. Moreover, it has been shown that patients can reliably use such dyspnoea ratings to reach a predetermined level of exercise and oxygen consumption [120]. Notably, there has been some development of new scales to assess dyspnoea such as the word-labelled visual analogue scale (LVAS) [121].

Exercise performance as an assessment of dyspnoea

In patients with COPD, exercise testing is used to quantify the degree of functional impairment. It has been presumed

that there is an association between functional capacity and the severity of dyspnoea, with those individuals with the poorest exercise capacity having the highest ratings of dyspnoea. However, such a presumption may be somewhat simplistic and the performance in such a test is likely to reflect a complex interaction of physiological limitations, associated symptoms and cognitive factors, especially motivation. Simple questionnaires designed to assess dyspnoea severity have required patients to assess their own exercise tolerance compared with their peers (e.g. Medical Research Council American Thoracic Society (ATS) scale) [122]. Although such scales are simple and widely used, they are insensitive, require individuals to make comparisons with others, and cannot measure changes with therapeutic interventions. The traditional test is the Baseline Dyspnoea Index, a rate-administered test, developed to rate patients with regard not only to the 'magnitude of the task' that elicits dyspnoea (e.g. hills compared with level ground) but also to the impact of dyspnoea on activities of daily living and the effort expended before dyspnoea occurs [123]. Similar and easier to use self-administered questionnaires have been developed, but these have not been widely used [124].

Peripheral muscle dysfunction

For patients with COPD, limited exercise capacity is a major cause of morbidity. While many early studies in patients with COPD focused on the central limitations to exercise capacity such as ventilation and gas exchange, the large degree of variation in exercise capacity for given level of airflow limitation and the reduced exercise tolerance following lung transplantation suggests that peripheral factors such as skeletal muscle dysfunction may also have a role (Fig. 4.7) [125]. In particular, there appears to be either impaired oxygen utilization associated with a greater reliance on glycolytic activity and/or an abnormal redistribution of blood flow to the exercising muscle in these patients [126,127].

Changes in skeletal muscle structure and function with COPD

Muscle mass and cross-sectional area

Compared with healthy age-matched controls, patients with

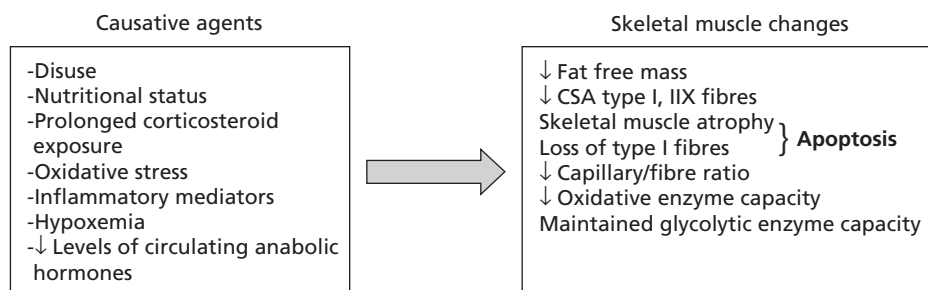

Figure 4.7 Factors contributing to skeletal muscle abnormalities in patients with COPD. CSA, cross-sectional area.

COPD have a reduced skeletal muscle fat-free mass (FFM) and cross-sectional area of type I and IIa fibres [128–131]. Using dual-energy X-ray absorptiometry (DEXA), Gosker *et al.* [132] reported a lower FFM in 15 patients with COPD (49.5 ± 8.2 kg) compared with 15 age-matched controls (58.7 ± 10.8 kg; $P = 0.03$). Moreover, COPD patients had a lower mean fibre cross-sectional area (CSA) than healthy subjects (COPD patients $3839 \mu\text{m}^2$; healthy controls $4428 \mu\text{m}^2$; $P = 0.037$).

The reduction in FFM has been cited as a strong predictor of decreased exercise capacity ($\dot{V}O_{2\text{peak}}$) and muscle strength of individuals with COPD [133]. In a group of 25 subjects with severe COPD ($FEV_1 = 32 \pm 11\%$ predicted), $\dot{V}O_{2\text{peak}}$ was significantly correlated with FFM ($r = 0.56$; $P < 0.005$) [129,132]. However, this study reported that the relationship was weaker in the COPD group than for healthy age- and gender-matched controls ($r = 0.84$; $P < 0.001$ for controls), suggesting that other factors apart from the loss of FFM are involved in the decreased exercise capacity in COPD patients.

Skeletal muscle morphology

Morphological changes in skeletal muscle have traditionally been determined using needle biopsy techniques. Recent studies of needle biopsy samples taken from the vastus lateralis muscle in COPD patients have shown significant muscle fibre atrophy [131,132,134], changes in fibre composition with a selective loss of type I fibres [132,134–137], reduced capillary to fibre ratio [131,138] and a reduction in oxidative enzyme capacity [139–141] compared with healthy controls.

In one of the original investigations of skeletal muscle dysfunction in patients with COPD, Jakobsson *et al.* [135] found atrophy and loss of type I fibres in 18 patients with COPD, eight of whom had severe COPD with chronic respiratory failure. These results were supported in a later study by Whittom *et al.* [131] who reported a selective loss of type I fibres in patients with COPD compared with controls and a decrease in the cross-sectional area of type I, IIa and IIb fibres. However this finding has not been a universal, with others reporting selective decrease in the cross sectional area of Type IIa and IIX fibres in COPD patients [132]. In addition, Whittom *et al.* [131] reported that the percentage of type IIb fibres (fast twitch glycolytic) was higher in COPD patients compared with controls and that cross-sectional area of the IIb fibres was retained. The results of these studies suggest that there is selective loss of the oxidative fibres of the vastus lateralis in patients with COPD (type I and IIa fibres) with a concomitant loss of cross-sectional area. At the same time, there appears to be an increase in the size and percentage of IIb fibres with COPD.

The change in the skeletal muscle fibre type with COPD appears consistent with the changes in activities of enzymes associated with ATP production. Several studies

have reported a decrease in the activity of mitochondrial enzymes such as citrate synthase (CS) and β -hydroxyacyl CoA-dehydrogenase (HAD) [127,137,139,141] in COPD patients. While there has been some evidence to suggest that the decrease in the activity of oxidative enzymes is associated with an increase in the activity of enzymes associated with glycolysis such as phosphofuctokinase (PFK) and lactate dehydrogenase (LDH), this finding has not been universal [137,139]. For example, Maltais *et al.* [127] reported that there was a decrease in the activity of CS and HAD in COPD patients compared with healthy controls. However, there was no reported change in the activity glycolytic enzymes such as PFK, LDH and hexokinase.

Interestingly, the functional and morphological changes in skeletal muscle with COPD appear to be confined to the lower limb. The study by Gea *et al.* [142] examined the metabolic characteristics of the deltoid muscle in the upper limb of 10 patients with COPD and nine healthy age-matched controls. While finding that exercise capacity (measured using cycle ergometry) was significantly reduced in COPD patients, these authors found that handgrip strength was essentially preserved in COPD patients when compared with healthy subjects. In addition, this study reported the activities of CS and PFK were the same in COPD and control subjects and that the activity of LDH was elevated in COPD patients compared with controls. These authors concluded that the upper limbs of patients with COPD had an essentially unchanged metabolic profile whereas (based on the findings in other studies) the lower limb had an altered metabolic profile with lower levels of oxidative enzymes.

In addition to impaired oxygen utilization of oxygen, COPD patients have altered delivery of oxygen at the level of the skeletal muscle. Jobin *et al.* [138] reported a decrease in the number of capillaries to fibre ratio in COPD subjects compared with controls (0.83 ± 0.05 COPD, 1.56 ± 0.10 controls; $P < 0.001$). Another study reported a trend for lower capillary to fibre ratio ($P = 0.15$) and a reduction in the number of capillaries in contact with skeletal muscle fibres in patients with COPD compared with healthy individuals [131]. The reduction in the number of capillaries in contact was greatest in the more oxidative fibres (type I, IIa) in the COPD patients. However, this study correctly noted that when the number of capillaries in contact was corrected for the differences in cross-sectional area the differences between the healthy and COPD patients was removed.

It is not clear what impact COPD has on the maximal vasodilatory capacity of the lower limb in COPD patients. The maximal vasodilatory capacity is an indicator of the ability to vasodilate the local vascular bed following during reactive hyperaemia. In healthy older individuals, vasodilatory capacity tends to decrease with age and is correlated with exercise capacity [143]. Moreover, vasodilatory capacity has been shown to increase with endurance training in

young and older individuals [144]. While it may be hypothesized that the decline in physical activity with COPD may in turn result in a decrease in the vasodilatory capacity, Sabapathy *et al.* [145] have recently reported no significant difference in the peak calf blood flow responses between age- and gender-matched controls and COPD patients. This may suggest that there is a time lag for the reduction in peak calf blood flow responses and while not present in patients with moderate COPD, individuals with severe COPD may well have reduced vasodilatory capacity in association with significant reductions physical activity levels.

Recent studies have suggested that COPD patients develop a greater degree of fatigue in skeletal muscle during endurance exercise when compared with healthy controls [146,147]. Endurance cycle ergometry induces quadriceps twitch muscle fatigue and a locus of symptom limitation (legs) that is different from the predominance of dyspnoea and absence of quadriceps twitch leg fatigue reported in COPD with walking which may partially explain the difference [7,9]. There appears to be some debate on the actual mechanism for greater development of fatigue in skeletal muscle in COPD. Allaire *et al.* [148] suggested that the limitation in skeletal muscle endurance in COPD patients was related to lower levels of oxidative enzymes (CS) and independent of the cross-sectional area of the skeletal muscle. Most recently, Saey *et al.* [149] have suggested that the greater contractile fatigue found in some COPD patients following constant work cycling exercise is because of the greater reliance on glycolytic (non-aerobic) metabolism during exercise.

Proposed mechanisms of skeletal muscle dysfunction in COPD

While it is now accepted that COPD is associated with an inherent skeletal muscle dysfunction, the underlying mechanism for this dysfunction has yet to be elucidated. It has been suggested that skeletal muscle dysfunction associated with COPD may be the result of several factors including deconditioning, malnutrition, skeletal muscle myopathy and low levels of circulating anabolic hormones [150–152].

Generally speaking, the changes in skeletal muscle morphology with deconditioning are similar to those seen with COPD. Following a period of bedrest, microgravity or detraining, there is a reported decrease in the number and CSA of type I fibres and a decrease in the activity of mitochondrial enzymes CS, HAD and succinate dehydrogenase (SDH) [153–155]. However, unlike COPD patients, deconditioning in healthy individuals is not typically associated with an increase in the activity of glycolytic enzymes PFK and LDH. Indeed, some studies examining the changes in enzyme activity following a period of leg immobilization reported a decrease in both CS and LDH [154,156].

Poor nutritional status is common in COPD patients, with one pulmonary rehabilitation programme reporting that 35% of patients entering the programme were nutritionally depleted [157]. This reduction in nutritional status in COPD patients has been associated with a decreased skeletal muscle strength and endurance [158].

Prolonged exposure to high-dose corticosteroids can result in significant myopathy in COPD patients [159]. While the role of prolonged hypoxia, hypercapnia and oxidative stress are less clear, there is emerging evidence that some if not all of these factors may combine to result in significant myopathic changes in skeletal muscle for patients with COPD [150].

It should be noted that not all studies have reported significant myopathic changes in COPD patients. Recently, Heijdra *et al.* [160] reported that a group ($n = 32$) of COPD subjects (FEV_1 $38 \pm 11\%$ predicted) had a similar FFM index (FFMI) as age-matched controls ($n = 36$). Moreover, these authors reported similar phase II steady-state oxygen uptake kinetics ($\tau = 72 \pm 32$ s COPD patients; $\tau = 78 \pm 37$ s controls). These authors questioned the existence of underlying skeletal muscle myopathy in COPD patients given that normal and healthy groups had similar oxygen uptake kinetics.

The role of oxidative stress as a causative factor for the myopathic changes in skeletal muscle in patients with COPD has received recent attention. Couillard *et al.* [161,162] examined whether oxidative stress was involved in the myopathy typically associated with COPD. These authors found that local muscle activity induced oxidative stress in COPD patients and that this in turn was associated with decreased muscle endurance. Local exercise-induced oxidative stress failed to raise antioxidant activity in COPD patients, in contrast to controls where an elevation of antioxidants was observed. These observations are consistent with increased oxidative stress in the myopathic changes in skeletal muscle in COPD.

There is evidence to suggest that the level of circulating anabolic hormones, such as insulin-like growth factor (IGF)-I and testosterone, are low in patients with COPD [163,164]. Recently, Debigare *et al.* [134] reported that there was a significant disturbance in catabolic–anabolic metabolism in COPD, with a distinct shift toward catabolism, which may contribute to skeletal muscle wasting in patients with COPD.

Cardiovascular abnormalities

Although the progressive loss of lung function remains the primary limitation in COPD, there is also evidence that significant cardiovascular limitations exist in this population, particularly in more severe patients [165]. A study by Montes de Oca *et al.* [166] found oxygen pulse measured

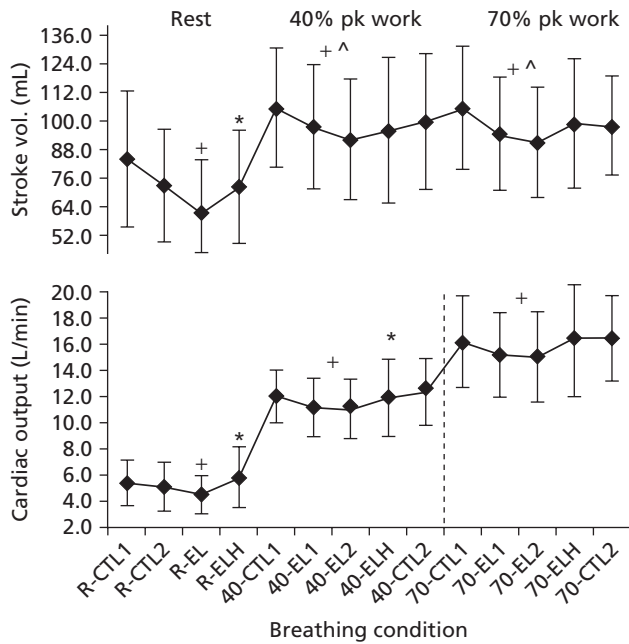

Figure 4.8 Influence of an expiratory load on stroke volume (SV) and cardiac output (CO) in healthy subjects. SV and CO are shown for each breathing condition (CTL, control; EL, expiratory loading; ELH, expiratory loading + voluntary hyperinflation) at three workloads. Vertical dotted lines indicate change in workload. Significance $P < 0.05$. (+) Average of two CTL conditions compared to EL (rest) or average EL conditions (exercise). (*) EL condition (rest) or average of EL conditions (exercise) compared with ELH condition. (#) ELH condition compared with average of two CTL conditions. (^) EL1 compared with EL2 (exercise) [169].

during exercise to be the best predictor of peak $\dot{V}O_2$ in patients with an average FEV_1 of 0.79 L. Oelberg *et al.* [167] found a blunted cardiac output during exercise in patients with COPD relative to normal subjects. During activity, patients with COPD experience increased expiratory loads as well as progressive hyperinflation as ventilatory demands increase. In the resting state, expiratory loads created by positive pressure breathing reduce cardiac output likely via an effect of increasing pleural pressure and right atrial pressure and subsequently reducing venous return [168]. We recently studied healthy subjects to determine the influence of a small expiratory load (10 cm H_2O) on cardiac function during exercise (Fig. 4.8) [169]. We found a small but consistent drop in cardiac output (15–20%) resulting from a fall in stroke volume without complete compensation in heart rate. In COPD patients during exercise, studies have suggested some subjects may produce expiratory pressures > 20 – 30 cm H_2O [170]. Thus, it would be expected that these loads may further inhibit increases in stroke volume and possibly cardiac output during exercise.

There is also the potential separate influence of a chronic hyperinflation combined with a dynamic hyperinflation during exercise on cardiac output [170]. Because the heart and lungs share a common surface area, a progressive hyperinflation with chronic disease or dynamically with exercise may increase competition for intrathoracic space and inhibit cardiac filling via a change in cardiac compliance. We previously observed a significant fall in cardiac output with chest wall restriction (40% decline in VC) in healthy subjects [171]. This level of heart and lung competition for intrathoracic space may be similar to that observed in patients with severe COPD and hyperinflation.

Other changes associated with COPD also occur that may further reduce cardiac output responses to exercise in COPD patients. This includes a progressive pulmonary hypertension and right heart failure, polycythaemia and ineffective negative intrathoracic pressure generation by the diaphragm muscles [172,173].

CPET in evaluation of therapeutic interventions

Lung volume reduction surgery

The potential utility of CPET is highlighted by its emergence as an important tool in the evaluation of patients being considered for LVRS. The range of application of CPET in this patient group includes the determination of cardiopulmonary functional status and assessment of potential operative risk prior to surgery; the determination of exercise training prescription before and after LVRS; quantification and monitoring of the clinical response to surgery; and also definition of the underlying pathophysiologic mechanisms responsible for improvements in exercise performance resulting from LVRS [16,174–177].

In several studies, exercise capacity has been shown to improve after LVRS. This has been attributed to reduced hyperinflation, improved inspiratory muscle pressure generation (reduced drive to breathe), reduced oxygen cost of breathing and/or improved blood gas homeostasis, all leading to reductions in the perception of dyspnoea [15,178]. The NETT was a large National Institutes of Health (NIH) funded trial of a total of 1218 patients with severe emphysema who underwent pulmonary rehabilitation and were randomly assigned to undergo LVRS or to receive continued medical treatment [16]. Overall in this trial, LVRS increased the chance of improved exercise capacity but did not bestow a survival advantage over medical therapy. It did yield a survival advantage for patients with both predominantly upper lobe emphysema and low baseline exercise capacity. Patients previously reported to be at high risk and those with non-upper-lobe emphysema

and high baseline exercise capacity were considered poor candidates for LVRS because of increased mortality and insignificant functional gain. A 10-W change in cycle ergometry work rate was determined as a minimally clinically significant difference in this study in determining the impact of pulmonary rehabilitation on exercise tolerance.

Exercise training

Exercise training is a recommended, integral component of comprehensive pulmonary rehabilitation in patients with COPD and other chronic lung diseases [31,152,179,180]. CPET provides valuable information prior to exercise training to determine exercise capacity, anaerobic threshold, safety (ischaemia, arrhythmias, O₂ desaturation) and training intensity [181,182], and can be repeated following training to document improvement objectively and to refine training levels.

Exercise training to relieve dyspnoea

The goal of exercise training in lung disease patients is to carry improvement in performance and dyspnoea that is achieved with one form of exercise (e.g. treadmill walking) into activities of daily living. However, only since 1989 have controlled trials of rehabilitation regularly included measures of dyspnoea [183,184]. Exercise training appears to be a critical part of pulmonary rehabilitation programmes for reduction in dyspnoea [184,185].

Importantly, exercise training may decrease dyspnoea even when it does not improve exercise performance or mechanical efficiency [186]. Although most studies have utilized treadmills or cycles, weight training is also effective. Home-based exercise training has also been shown to improve dyspnoea and exercise performance [187].

Most commonly, exercise training for COPD patients is incorporated into a pulmonary rehabilitation programme that includes an education as well as an exercise component. A programme of dyspnoea management (including relaxation, breathing retraining, pacing, self-talk and panic control) without an exercise component was compared with general health education; neither improved dyspnoea nor 6-minute walking distance [188]. One study showed that treadmill training with or without nurse coaching was equally effective in reducing dyspnoea during exercise testing and with activities of daily living [189].

Several studies have recently explored intermittent exercise training as an alternative to continuous exercise training for COPD patients [190,191]. Healthy older individuals performing intermittent or continuous exercise training at the same absolute intensity with the same total work completed resulted in similar training adaptations [192]. Intermittent exercise performed at the same intensity as continuous exercise has been associated with lower ratings

of perceived exertion and degree of dynamic hyperinflation in COPD patients [193]. It remains to be seen if intermittent exercise is a better mode of endurance exercise training in COPD patients. Two recent studies compared training adaptations with high-intensity intermittent (90 and 100% of W_{max} , respectively) with low-intensity continuous (60 and 50% of W_{peak} , respectively [190,191]). Both studies reported that both intermittent and continuous exercise training resulted in similar reductions in ratings of breathlessness during submaximal exercise.

Exercise training and skeletal muscle

Given that deconditioning of the skeletal muscle as a result of disuse is believed to be a major contributing factor to skeletal muscle dysfunction, it is no surprise that endurance exercise training is a significant component of any pulmonary rehabilitation programme. However, endurance training as a method of reversing skeletal muscle deconditioning has not always been an accepted part of pulmonary rehabilitation and has only recently become accepted practice (ATS guidelines) [31]. Indeed, in an early study of only seven COPD patients, Belman and Kendregan [194] reported that there were no significant changes in lower limb skeletal muscle enzymes following 6 weeks of endurance training (leg cycling). This led these authors to conclude that COPD patients were unable to exercise at an intensity high enough to induce a classic training response.

However, more recent studies have clearly demonstrated that endurance exercise training improves both the maximal and the submaximal exercise response in COPD patients [67,195,196]. In addition, endurance exercise training has been shown to alter both the morphological and histochemical properties of skeletal muscle [131,197]. In an important study, Maltais *et al.* [197] reported that 11 patients with severe COPD ($36 \pm 11\%$ FEV_1 % predicted) had a significant increase in the activity of CS and HAD following 12 weeks of cycle training (30 min, three times per week). The activity of other glycolytic enzymes PFK, LDH and HK did not change with endurance training.

In a similar study, Whittom *et al.* [131] examined the changes in fibre type proportions, the CSA of muscle fibres and the capillary to fibre ratio following 12 weeks of endurance training in 12 patients with COPD ($37 \pm 11\%$ FEV_1 % predicted). This study reported an 11% increase in $\dot{V}O_{2peak}$ and a significant increase in the CSA of the type I and IIa fibres. However, the proportion of type I, IIa, IIb, IIab fibres remained unchanged and there was no significant change in the number of capillaries per fibre.

Given the well-documented reductions in lower limb muscle strength with COPD, there have been few studies examining the effect of strength training in patients with COPD. In an early study, Simpson *et al.* [186] reported that 8 weeks of lower limb strength training in a group of 14

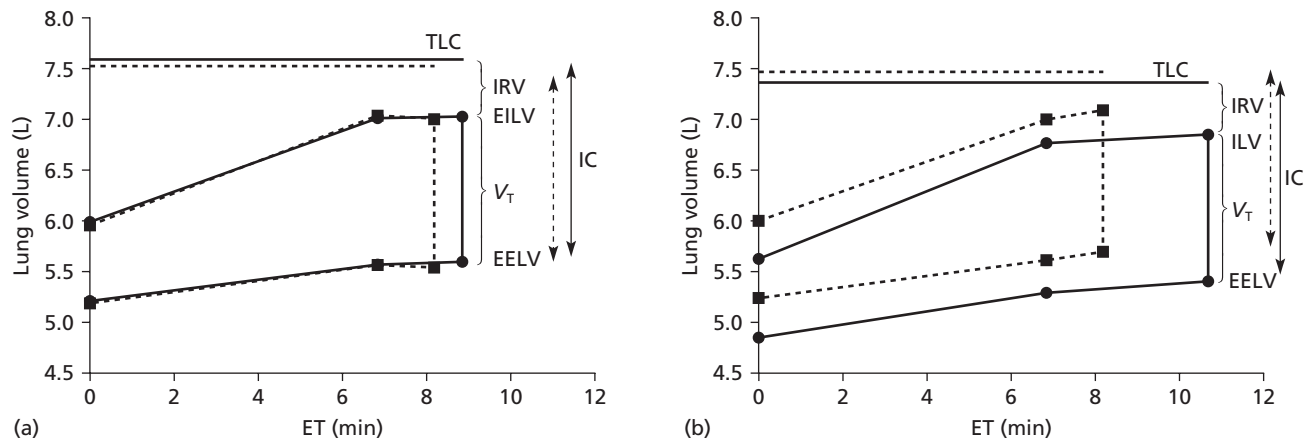

Figure 4.9 Operating lung volumes at rest and during exercise at baseline (■--) and after 42 days (●—) of treatment with placebo (a; $n = 91$) and tiotropium (b; $n = 96$). EELV, end-expiratory lung volume; EILV, end-inspiratory lung volume; IC, inspiratory capacity; IRV, inspiratory reserve volume; TLC, total lung capacity; V_T , tidal volume [14].

COPD patients resulted in a 16–44% increase in the maximal voluntary contraction (MVC). The resistance training consisted of three sets of 10 repetitions of three lower limb exercises. Subjects commenced training at 50% of one-repetition maximum (1-RM) and progressed to 85% of 1-RM in the final weeks. There were no significant changes in the MVC of 18 COPD patients who acted as a control.

Bernard *et al.* [198] compared the impact of 12 weeks of aerobic training with 12 weeks of strength and aerobic training in two groups of patients with moderate to severe COPD. Each training group completed 30 min of cycling exercise at 80% of the peak power achieved during the pretraining peak exercise test. The strength and aerobic training group completed an additional four strengthening exercises (two upper and two lower limb). While each group had a similar and significant increase in $\dot{V}_{O_{2peak}}$ and 6-minute walking distance, the aerobic plus strengthening exercise group had a greater increase in quadriceps strength and cross-sectional area compared with the aerobic training alone group. These authors noted that strength training was well tolerated and elicited less dyspnoea than aerobic training in the subjects who participated in the study. Importantly, strength training provided some diversity to the training programme and tended to maintain motivation and interest in the participants.

A recent interesting study by Casuburi *et al.* [199] examined the effect of strength training in 47 men with COPD with and without testosterone supplementation. Subjects all had low testosterone levels prior to commencing the study. Subjects completed either 10 weeks of strength training or control (no strength training) with or without testosterone supplementation. The authors reported that the testosterone injections were well tolerated by all subjects. Testosterone injections alone resulted in a 2.3-kg increase in lean body mass (as measured using DEXA) and a

17% increase in the lower limb 1-RM (leg press). On the other hand, testosterone plus strength training resulted in a significantly greater increase in lean body mass (3.3 kg) and lower limb 1-RM (26.8%).

Bronchodilators

A number of studies have used CPET as a measure of effectiveness of pharmacological treatment [12–14,28,84,200–203]. Both short- and long-acting β -agonists as well as short- and long-acting anticholinergic agents have been shown to improve exercise tolerance. This appears to be particularly true for the long-acting anticholinergic agents while the evidence for improved exercise capacity regarding the use of long-acting β_2 -mimetics is not as clear [12]. In a randomized, double-blind, placebo-controlled, parallel group study, the long-acting anticholinergic agent tiotropium was shown to reduce chronic hyperinflation, allow for greater tidal volumes during exercise, reduce dyspnoea and improve endurance time (Fig. 4.9) [14,28]. At a standardized time point (isotime), IC was also greater consistent with reduced dynamic hyperinflation, despite an increase in \dot{V}_E . A second study has confirmed these data for improvements in chronic and exercise-induced dynamic hyperinflation, dyspnoea, endurance time and IC measured at isotime as well as demonstrating a sustained effect over 8 h [203]. Improvements in lung mechanics and the ventilatory responses to exercise were also observed in a study by O'Donnell *et al.* [13] using salmeterol and are also consistent with earlier work using shorter acting agents [84].

Interestingly, tiotropium combined with classic pulmonary rehabilitation has been shown to improve and, furthermore, enabled sustained (3 months after cessation of a 25-week pulmonary rehabilitation programme) improvement

in exercise capacity (treadmill endurance time) beyond that achieved by rehabilitation by itself with usual treatment [204]. Presumably, more consistent management of airway patency attributed to longer acting anticholinergic agents appears to facilitate training by allowing higher intensity training associated with greater physiological benefit and then sustaining its effect at least in the short term after cessation of formal pulmonary rehabilitation in this challenging patient population. Future exercise training studies should evaluate the pharmacological agents providing maximal bronchodilatation combined with treatments described below in order to optimize therapeutic strategies.

Oxygen and low-density gas therapy

Oxygen therapy reduces pulmonary vascular resistance (in patients with hypoxaemia and pulmonary hypertension), reduces minute ventilation and likely reduces the peripheral chemoreceptor stimulation resulting from hypoxia [17,167,205–207]. All of these appear to lead to a substantial improvement in exercise capacity. There is also evidence that supplemental oxygen during exercise may be beneficial in non-hypoxaemic COPD patients [208,209]. This may also be because of a reduction in ventilation and dyspnoea, a blunting of respiratory drive as well as a mild bronchodilatation. By reducing \dot{V}_E demand, the degree of expiratory flow limitation and lung hyperinflation is reduced [206].

Helium gas (79%) combined with oxygen (21%, heliox), results in a gas density that is approximately one-third that of air. Flow increases, particularly at the higher lung volumes, as a result of decreased turbulence with the large airways. This leads to a general reduction in the resistive work of breathing and increases the size of the maximal flow volume envelope in most patients with COPD. Palange *et al.* [30] found that, in a group of moderate to severe COPD patients exercising at 80% of their maximum power output, heliox resulted in a twofold increase in exercise endurance capacity. This was because of an increase in \dot{V}_E and tidal volume during exercise and to a significant reduction in lung hyperinflation and dyspnoea at isotime. Other studies have combined increased inspired oxygen gases with low-density gases in an attempt to optimize benefits from both gases with beneficial results. Such a strategy used during rehabilitation may help achieve a greater skeletal muscle stimulus for training [17].

Pressure support ventilation

The application of inspiratory pressure support during exercise increases endurance, reduces dyspnoea, unloads the respiratory muscles and prolongs the development of

exercise-induced lactataemia [210,211]. Proportional assist ventilation (PAV), a mode of ventilation that matches ventilator output to patient effort, is more tolerable for patients with COPD and is as effective at prolonging exercise as conventional inspiratory pressure support [212]. Hawkins *et al.* [213] used PAV as an aid to exercise training in patients with severe COPD and found that mean training intensity was 15% higher in the group that used ventilatory assistance vs subjects training without assistance. In addition, the group with PAV had a 33% increase in exercise capacity vs the non-PAV group which had a 15% increase post training. Although the number of subjects in this study was limited and it is difficult to perform a blinded study with this type of intervention, the findings of this study and previous work on exercise capacity with pressure support breathing suggest this may (along with oxygen, pharmacological treatment and low-density gases) provide a method to help minimize the cycle of decline in patients with COPD.

Conclusions

CPET has an integral role in assessing the health status of patients with COPD. Exercise tolerance may decline rapidly, and CPET provides important prognostic information as well as practical information regarding primary sources of limitation, degree of mechanical constraint, hypoxaemia and guidelines for exercise training. It also plays an important part in evaluating response to therapy using endurance cycle and treadmill protocols; however, future clinical trials may also use endurance shuttle walk tests as an assessment tool as they are sufficiently sensitive in discerning response to bronchodilator therapy in patients with COPD. Although patients with COPD are limited by marked reductions in maximal expiratory airflows, a progressive hyperinflation, ineffective inspiratory muscles and a rising elastic load (work and cost of breathing), the illness becomes a systemic syndrome resulting in deterioration of skeletal muscle function and cardiac limitations to exercise. Pharmacological management aimed at maximally maintaining airway patency and reducing hyperinflation, exercise training as a part of a comprehensive pulmonary rehabilitation programme, oxygen therapy and, finally, surgical therapies help to improve exercise capacity in this population and limit the rapid decline in functional capacity.

CHAPTER 5

Clinical assessment of control of breathing

Joseph Milic-Emili and Antonia Koutsoukou

In this chapter no attempt is made to cover the vast literature available on the topic. Instead, this account is limited to a description of the clinically relevant advances made using a simple approach for studying the control of breathing. It is hoped that this account will provide a useful framework for more clearly perceiving, defining and explaining a range of breathing problems in patients with chronic obstructive pulmonary disease (COPD). More detailed recent reviews can be found elsewhere [1,2].

General considerations

Breathing involves the interaction of chemical, neural, muscular and mechanical processes. Considering this complexity, it is remarkable that normal individuals are able to maintain a narrowly set range of blood gas tensions during most of their daily activities, involving different metabolic demands, respiratory loads and body posture. Even more astonishing is the fact that most patients affected by various respiratory diseases also exhibit essentially normal blood gases, reflecting the substantive adaptive capacity of the control system of breathing. In some patients, however, the control system of breathing can be so disrupted that they lose the ability to maintain an adequate alveolar ventilation with a resultant impairment of blood gas tensions. Thus, an increase in resting arterial P_{CO_2} (P_{aCO_2}) beyond the normal limits indicates a breakdown or adaptation of the control system of breathing (ventilatory failure), the upper normal value of P_{aCO_2} amounting to approximately 43 mmHg [3]. This limiting value of P_{aCO_2} applies over a wide range of ages (up to 80 years) and is valid for both sitting and a supine position [3,4].

Figure 5.1 depicts the classic relationship of P_{aCO_2} to forced expiratory volume in 1 second (FEV_1) in COPD patients described in 1965 by Lane *et al.* [5]. At FEV_1 below 1.5 L, some patients exhibit hypercapnia (ventilatory fail-

Figure 5.1 Relationship between arterial P_{CO_2} (mmHg) and forced expiratory volume in 1 s (FEV_1) (litres) in 200 unselected COPD cases referred to a routine pulmonary function laboratory. Ventilatory failure is arbitrarily represented by $P_{aCO_2} > 47$ mmHg (horizontal line). (From Lane *et al.* [5] with permission.)

ure) while others maintain P_{aCO_2} within or even below normal limits. Based on the mistaken assumption that FEV_1 is a marker of the mechanical impediment to breathing, it was proposed that hypercapnic patients were ‘non-fighters’ because their poor inspiratory drive did not allow them to maintain an adequate alveolar ventilation in the face of increased respiratory load, as reflected by the low FEV_1 [6]. In contrast, the non-hypercapnic patients were defined as ‘fighters’ because they were thought to be endowed with a good inspiratory drive, which allowed maintenance of an adequate alveolar ventilation. These patients are also often referred to as ‘blue bloaters’ and ‘pink puffers’, respectively. This attractive hypothesis, however, has been disproved in studies based on measurement of mouth occlusion pressure and analysis of breathing pattern [7]. In addition,

the nature of the mechanical impediment to breathing which leads to ventilatory failure in COPD patients is now better understood, and FEV_1 is no longer considered a useful marker of respiratory loading.

Theory and methods of control of breathing

Mouth occlusion pressure

Responses to various stimuli are expressed quantitatively by the 'sensitivity' or input–output relationship of the system that controls breathing. The input can be simplified by carrying out experiments in which a single stimulus, such as P_{CO_2} or P_{O_2} , is the only important variable, but it has been more difficult to find a good measure of the output of the system. In general, however, the most commonly used output variable is pulmonary ventilation. It has long been recognized that in the presence of mechanical loading of breathing (e.g. increased elastance and flow resistance of the respiratory system), the ventilatory output reflects both how much the patient 'wants' to breathe, an issue directly involving respiratory control, and how much his or her mechanical abnormality 'allows' him or her to breathe in response to a given level of respiratory stimulation, an issue that involves control of breathing only indirectly. To circumvent this problem, responses to respiratory stimuli have been assessed in terms of oxygen consumption of the respiratory muscles, mechanical work rate of the respiratory muscles, pleural pressure swings and diaphragmatic electromyography (EMG). All of these output variables involve measurements that are technically complex and, with the exception of the O_2 cost of breathing, cause discomfort to patients, for these measurements involve the use of oesophageal balloons or electrodes. The mouth pressure generated by the inspiratory muscles against an airway occluded at end-expiration has been proposed as a useful alternative [8]. The subject is allowed to breathe through a mouthpiece with a valve arranged so that he or she breathes in through one tube and out through another. Taking care that the subject cannot see them and is unable to anticipate the manoeuvre, the operator closes off the inspiratory tube while the subject is breathing out. Unaware of this manoeuvre, the subject begins his or her next inspiration in the usual way, but now generates negative pressure in the mouthpiece instead of taking in air. After a short interval he or she realizes that the tube is blocked and makes some abnormal movement, but the pressure generated in the first 0.1 second ($P_{0.1}$) is an expression of the force generated by his or her inspiratory muscles in a more or less isometric contraction, under the same respiratory neural stimulus as the preceding unobstructed

breaths. Reduced to its essentials, the apparatus required to measure the mouth occlusion pressure consists only of a mouthpiece, valve, pressure transducer and recorder, and it can easily be brought to a patient on the ward. Unlike inspiratory work or diaphragm EMG it requires no oesophageal balloons or electrodes, and a minimum of electronic apparatus and skill. In fact, it offers no more trouble than the conventional spirometric methods.

A full account and critique of the mouth occlusion pressure technique is provided elsewhere [8,9]. Briefly, $P_{0.1}$ depends on both: (a) the neural drive to the inspiratory muscles (a summation of the chemical, reflex, higher nervous, brainstem and spinal inputs which are eventually integrated at the level of the inspiratory motor neurons in the spinal cord); and (b) the effectiveness of the inspiratory muscles as pressure generators. The latter depends on the lung volume and geometry of the respiratory system [10]. In general, with increasing lung volume, the diaphragmatic and extradiaphragmatic inspiratory muscle fibres become shorter, and hence develop less force for a given neural drive (force–length relationship). Furthermore, with increasing lung volume, the radius of curvature (r) of the diaphragm increases (flatter diaphragm) and hence, because of the Laplace relationship ($P = 2T/r$), for a given tension T (which is related to force) less pressure is developed. Thus, $P_{0.1}$ is an index of *neuromuscular inspiratory drive* representing the pressure available to produce the changes in lung volume or ventilation.

Analysis of the respiratory cycle

The breathing movements can be regarded as a mechanical event in the respiratory control mechanism, which is both an expression of 'output' and a source of 'input' to the respiratory controller. The spirogram, simple as it looks, is the result of an extremely complex process which, to some extent, can be decoded by appropriate analysis. Further, it is the manifestation of control of breathing that is most accessible to clinical observation.

The respiratory cycle consists of an ascending limb, inspiration, and a descending limb, expiration. It can be characterized schematically by the volume displaced (V_T), duration of inspiration (T_I) and duration of expiration (T_E), as well as by the mean inspiratory flow (V_T/T_I). There is ample evidence that T_I , T_E and V_T/T_I can be independently controlled by various mechanisms such as reflexes and chemoreceptor stimulation [11–16]. The interaction of these mechanisms results in a given breathing cycle. Although the nature of the interaction is not fully understood, as a first useful approximation one can regard the breathing cycle as the result of a 'driving mechanism' (inspiratory neurons firing) turned on and off by cyclic 'timing mechanisms' [14–16].

Ventilation equations

The classic equation defines ventilation (\dot{V}_E) as the product of tidal volume and respiratory frequency (f):

$$\dot{V}_E = V_T \times f \quad (5.1)$$

However, considering the breathing cycle as being the result of a 'driving' and a 'timing' mechanism, another equation to partition ventilation has been proposed [17]:

$$\dot{V}_E = (V_T/T_I) \times (T_I/T_{TOT}) \quad (5.2)$$

where T_I/T_{TOT} is the ratio of inspiratory to total breathing cycle duration and is commonly referred to as the inspiratory duty cycle.

The advantage of analysing ventilation by equation 5.2 is that it partitions ventilation into two components: one related to neuromuscular inspiratory drive (V_T/T_I) and the other (T_I/T_{TOT}) reflecting the timing mechanism. A change in pulmonary ventilation can result from a change in V_T/T_I or in T_I/T_{TOT} , or both.

Alveolar ventilation equation

Clinical evaluation of control of breathing has often been based on measurement of the ventilatory response to CO_2 [18], hypoxia [19] and muscular exercise. While these responses provide useful information, assessment of control of breathing during air breathing at rest is the fundamental first step. In fact, having defined ventilatory failure in terms of an increased $Paco_2$ during resting breathing, it seems imperative to explain how this is brought about. Clearly, this requires the study of control of breathing under the conditions prevailing at the time when the blood sample was taken to obtain the $Paco_2$.

The $Paco_2$ is given by the ratio of metabolic CO_2 production (\dot{V}_{CO_2}) to alveolar ventilation, and can be expressed in the following form:

$$Paco_2 = k \times \dot{V}_{CO_2} / \dot{V}_E (1 - V_D/V_T) \quad (5.3)$$

where k is constant, \dot{V}_E is minute ventilation, V_T is tidal volume and V_D is physiological dead space. The latter can be computed from measurements of the other variables in equation 5.3.

Inspection of equation 5.3 reveals that the breathing pattern plays an important part in determining $Paco_2$; for a given \dot{V}_E and V_D , the alveolar ventilation will decrease the smaller the V_T (and hence the higher the respiratory frequency).

Mechanical impediment to breathing

The problem in maintaining a normal $Paco_2$ in COPD is due to impaired respiratory mechanics. Implicit in the

definition of this disease, there is initially increased inspiratory and expiratory flow-resistance, but the latter reverts in time to tidal expiratory flow limitation with concurrent dynamic pulmonary hyperinflation. It is this that causes the main impediment to breathing in COPD. In this disease the abnormalities in respiratory statics are not by themselves severe, although with severe hyperinflation the compliance may be reduced because tidal breathing occurs in the flat upper portion of the static volume–pressure curve of the respiratory system. Although the inspiratory flow-resistance may be markedly increased, the resistive inspiratory work during resting breathing is relatively low because at rest the inspiratory flow is low. In COPD the main impediment to breathing is neither elastic nor resistive but is represented by an inspiratory threshold load (i.e. intrinsic positive end-expiratory pressure, PEEPi), which is brought about by dynamic hyperinflation.

Dynamic hyperinflation (DH). In normal individuals at rest, the end-expiratory lung volume (functional residual capacity, FRC) corresponds to the relaxation volume (V_r) of the respiratory system (i.e. the lung volume at which the elastic recoil pressure of the respiratory system is zero) [20]. Pulmonary hyperinflation, which is defined as an increase in FRC above the predicted normal range, may be caused by increased V_r as a result of loss of lung recoil (e.g. emphysema) and/or dynamic pulmonary hyperinflation, which is said to be present when the FRC exceeds V_r . Dynamic hyperinflation exists whenever the duration of expiration is insufficient to allow the lungs to deflate to V_r prior to the next inspiration. This may occur when expiratory flow is impeded (e.g. increased airway resistance) and/or expiratory time shortened (e.g. increased breathing frequency). Expiratory flow may also be reduced by other mechanisms, such as persistent contraction of the inspiratory muscles during expiration and expiratory narrowing of the glottic aperture. In COPD patients hyperinflation is very common, and is mainly caused by tidal expiratory flow limitation [21–23].

Expiratory flow limitation (EFL). The term expiratory flow limitation should be used only to describe a condition in which expiratory flow cannot be augmented at a given lung volume by further increasing pleural and therefore alveolar pressure. This phenomenon is exhibited by both normal subjects and patients with respiratory disorders during correctly performed maximal forced expiratory manoeuvres in which, from peak expiratory flow, expiratory flow rates cannot be increased by increasing the expiratory effort and, thus, are maximal [24,25].

While normal subjects and athletes do not exhibit EFL even during maximal exercise [26], in COPD patients tidal EFL is commonly present even at rest [21,22].

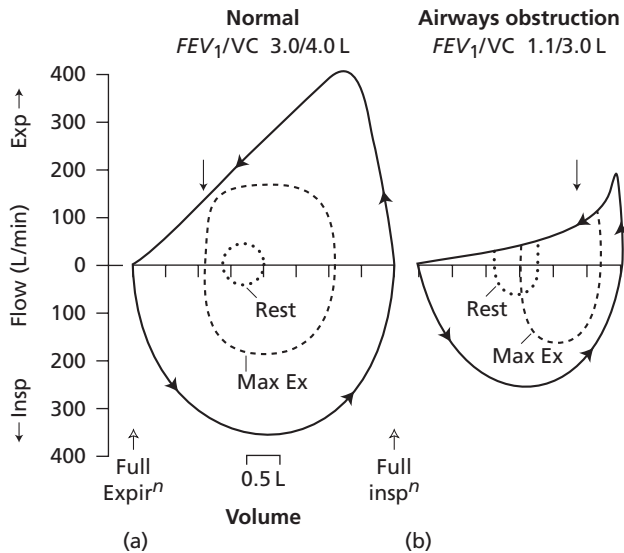

Figure 5.2 Flow–volume curves of a normal subject (a) and a patient with severe COPD (b). Tidal flow–volume loops at rest (dotted lines) and maximum exercise (Max ex, dashed lines) are compared with maximum flow–volume loops (outer solid lines). Forced expiratory volume in 1 s (FEV_1) (vertical arrows) is below the resting end-expiratory volume in the normal subject but well above in the COPD patient. $Expir^n$, expiration; $insp^n$, inspiration; VC, vital capacity. (From Leaver and Pride [27] with permission.)

Two main mechanisms promote the occurrence of tidal EFL: reduction of expiratory flow reserve and increase in ventilatory (flow) requirements. The expiratory flow reserve in the tidal volume range is given by the difference between the maximal flows available and the actual tidal flows developed during expiration. In normal individuals at rest the expiratory flow reserve is very high (Fig. 5.2a), while in patients with severe COPD there may not be any flow reserve left even at rest (Fig. 5.2b). In the latter condition, ventilation can only be increased by augmenting the operating lung volume with a concurrent increase in expiratory flow reserve, or by decreasing the duration of inspiration with a concurrent increase in time available for expiration.

Because the FRC is lower in the supine position than sitting [20], with a concomitant reduction in expiratory flow reserve, tidal EFL is an earlier manifestation in the supine position [21,22]. With ageing, there is a preferential decrease of maximal expiratory flow at low lung volume [28], which makes elderly individuals more susceptible to developing tidal EFL, particularly in the supine position.

The increased ventilatory requirements of COPD patients [7] augment the expiratory flow requirements because of greater tidal volume and faster respiratory frequency, promoting tidal EFL. In COPD patients who do not exhibit

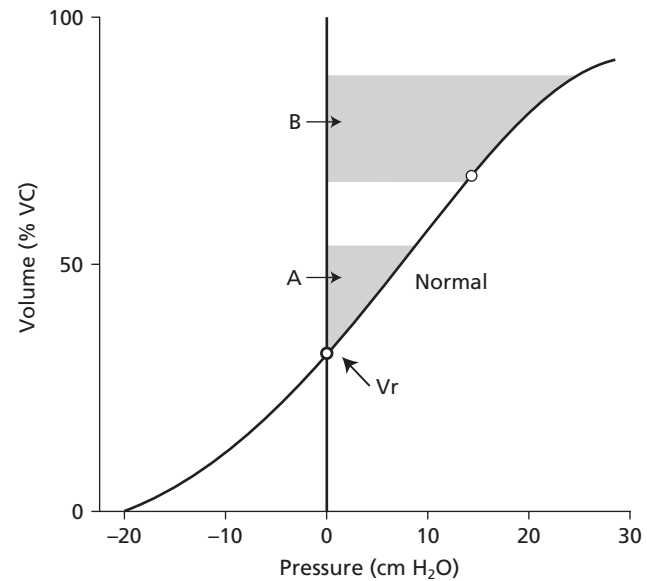

Figure 5.3 Static volume–pressure diagram of relaxed respiratory system showing the increase in work caused by dynamic hyperinflation. VC, vital capacity; Vr, relaxation volume of respiratory system. A: elastic work of breath started from relaxation volume (normal); B: work of similar breath to A but started from higher volume than Vr. In case B, the intrinsic positive end-expiratory pressure is 15 cm H₂O. See text for further information.

EFL at rest but have little expiratory flow reserve, EFL will occur at relatively low levels of exercise, while patients with larger flow reserve may achieve greater exercise levels without developing EFL [23].

Effects of dynamic hyperinflation on inspiratory work. Figure 5.3 illustrates the pressure required to overcome the static recoil of the respiratory system for the same tidal volume (20% of vital capacity, VC) inhaled from Vr (34% VC) and from an increased end-expiratory lung volume corresponding to 67% VC. As shown by the hatched areas in Figure 5.3, the static work increases approximately fivefold when the breath is inhaled from 67% VC (case B) relative to the breath taken from the Vr (case A). Clearly, dynamic hyperinflation implies an increase in static work of breathing (WOB). Furthermore, as lung volume increases, there is a decreased effectiveness of the inspiratory muscles as pressure generators because their fibres become shorter (force–length relationship) and their geometrical arrangement changes [10]. Thus, in COPD patients there is a vicious cycle: the inspiratory flow-resistive WOB is invariably increased because of airway obstruction but, more importantly, as a result of hyperinflation, there is increase in WOB resulting from PEEPi (see below) and impairment of the mechanical performance of the inspiratory muscles.

This promotes dyspnoea and exercise limitation, and eventually leads to hypercapnic ventilatory failure and inspiratory muscle fatigue [10,21,29].

Intrinsic positive end-expiratory pressure (PEEPi). Under normal conditions, the end-expiratory elastic recoil pressure of the respiratory system is zero (see Fig. 5.3, case A). In this case, the alveolar pressure becomes sub-atmospheric and gas flows into the lungs as soon as the inspiratory muscles contract. When breathing takes place at lung volumes greater than V_r , the end-expiratory elastic recoil pressure of the respiratory system is positive (15 cm H₂O in case B of Fig. 5.3). The elastic recoil pressure present at end-expiration has been termed auto- or intrinsic positive end-expiratory pressure (PEEPi) [30,31]. When PEEPi is present, onset of inspiratory muscle activity and inspiratory flow are not synchronous; inspiratory flow starts only when the pressure developed by the inspiratory muscles exceeds PEEPi and hence the alveolar pressure becomes sub-atmospheric. In this respect, PEEPi acts as an inspiratory threshold load, which increases the inspiratory effort. This places a major burden on the inspiratory muscles. In fact, the work performed by PEEPi in case B of Figure 5.3 is given by the product of PEEPi and V_T , which represents most of the hatched area. The remainder of this area is elastic work.

Because the static volume–pressure relationship of the respiratory system is approximately linear (see Fig. 5.3), PEEPi is approximated by the product of the static elastance of respiratory system (Est, r_s , the reciprocal of the slope in Fig. 5.3) and the magnitude of dynamic hyperinflation (i.e. the increase of FRC above V_r):

$$\text{PEEPi} = \text{Est}, r_s (\text{FRC} - V_r) \quad (5.4)$$

This implies that dynamic hyperinflation (FRC – V_r) and PEEPi are closely related indices. However, in actively breathing subjects it is very difficult to determine PEEPi [32], whereas the degree of dynamic hyperinflation can be readily assessed from measurements of the inspiratory capacity (see below).

Methods for assessing EFL. Comparison between maximal and tidal flow–volume loops has been widely used to detect EFL, which is assumed to be present when the tidal expiratory flow impinges on or exceeds the maximal expiratory flow–volume curve (see Fig. 5.2b) [22,24]. However, this method is not valid because of the different volume and time history between resting breathing and the FVC manoeuvre [21,22,33]. In fact, because the inflation volume and speed of inspiration during resting breathing are necessarily different from those obtained during the FVC manoeuvre, it is axiomatic that detection of flow-limitation based on comparison of tidal with maximal flow–volume curves is not valid.

Recently, the negative expiratory pressure (NEP) method has been introduced to detect EFL [22,34]. A small negative pressure is applied during tidal expiration, thus widening the pressure gradient between the alveoli and the airway opening. In the absence of EFL, with NEP there is an increase in expiratory flow compared with the preceding control breath. In contrast, in the presence of EFL the expiratory flow does not increase throughout the entire or part of the tidal expiration over that of the preceding control expiration. With the NEP method the volume and time history is not a problem because these are necessarily the same during the control and NEP test breaths.

Methods for assessing pulmonary hyperinflation. Pulmonary hyperinflation is commonly assessed through the measurement of the FRC with body plethysmography. In patients with severe airway obstruction, however, this method may overestimate the actual FRC because during the panting manoeuvre the transmission of alveolar pressure to the mouth is delayed by increased airway resistance [35]. On the other hand, measurements with the nitrogen washout or helium dilution methods may underestimate the FRC because of gas trapping in the lung. However, in patients with tidal EFL at rest the increase of FRC is accompanied by a reduction in resting inspiratory capacity (IC). In contrast to FRC, measurement of IC is simple, cheap and reliable, providing a useful tool for the indirect assessment of pulmonary hyperinflation [36]. Indeed, in COPD patients a reduction of IC implies dynamic hyperinflation.

Assessment of control of breathing in COPD

Stable patients at rest

Chronic obstructive lung disease is characterized by: (a) impaired pulmonary gas exchange; (b) changes in the mechanical properties of the ventilatory apparatus which increase the load on the respiratory muscles; and (c) decreased effectiveness of the inspiratory muscles as pressure generators as a result of thoracic overinflation. Despite these disadvantages, some patients are able to maintain adequate ventilation while others develop hypercapnia. Originally, it was suggested that patients who do not develop CO₂ retention are ‘fighters’, because they increase sufficiently the inspiratory drive to compensate for their impaired respiratory function, while the ‘non-fighters’ have defective inspiratory drive, and hence exhibit CO₂ retention [6]. If this hypothesis is correct, patients with CO₂ retention should have high $P_{0,1}$ values, while patients with CO₂ retention should exhibit $P_{0,1}$ values lower than the non-CO₂ retainers. However, Šorli *et al.* [7] showed that there

Table 5.1 Mean values (\pm SD) of pulmonary gas exchange data in 15 stable COPD patients breathing air at rest. (From Šorli *et al.* [7] with permission.)

	P_{aCO_2} (mmHg)	\dot{V}_E (L/min)	V_T (L)	V_D (L)	\dot{V}_{CO_2} (L/min)	$P_{0.1}$ (cm H ₂ O)
Group A ($n=8$)	38 ± 4	10.6 ± 1.8	0.71 ± 0.09	0.37 ± 0.07	0.26 ± 0.03	3.3 ± 0.10
Group B ($n=7$)	50 ± 9	9.4 ± 1.0	0.56 ± 0.07	0.32 ± 0.05	0.28 ± 0.05	4.3 ± 0.13

was no difference in $P_{0.1}$ between hypercapnic and non-hypercapnic patients (Table 5.1), both exhibiting higher $P_{0.1}$ values than normal individuals ($P < 0.001$). Why then do some patients retain CO_2 ? This can be answered by analysis according to equation 5.3. As shown in Table 5.1, there is no difference in \dot{V}_E , V_D and \dot{V}_{CO_2} between patients without and with CO_2 retention, although the values are higher than normal. Tidal volume, on the contrary, is significantly lower in the hypercapnic patients (group B). Thus, by use of equation 5.3, it is possible to conclude that CO_2 retention in COPD patients is closely associated with decreased V_T . A decreased V_T , however, can be caused by decreased inspiratory flow or shortened inspiratory duration, or both. As shown in Figure 5.4, the mean inspiratory flow (V_T/T_I) does not differ between patients with and without CO_2 retention; in both it is higher than normal.

That V_T is significantly smaller in hypercapnic compared with non-hypercapnic patients has been confirmed by several cross-sectional studies [37–41]. Furthermore, in a longitudinal investigation it has been shown that the increase in P_{aCO_2} is associated with a decrease in V_T , with no significant change in respiratory frequency [42]. However, some evidence suggests that in patients with severe hypercapnia ($P_{aCO_2} > 55$ mmHg) a reduction of \dot{V}_E may contribute to hypercapnia [40].

As shown in Figure 5.4, the reduction of V_T in the hypercapnic patients (group B) is caused entirely by reduced T_I , while V_T/T_I is actually higher than normal. This was

initially attributed to vagally mediated reflexes originating from the irritant and J-receptors within the lung [7]. While such mediation is not excluded, it is likely that it mainly reflects uncoupling of neuromuscular and spirometric timing resulting from the presence of DH and PEEPi [43]. As a result of PEEPi, there is a delay between the onset of inspiratory muscle activity, as reflected by negative swing in pleural pressure, and the onset of inspiratory flow, the time-lag depending on the time taken by the pressure developed by the inspiratory muscles to balance PEEPi [32,43]. Thus, spirometric T_I underestimates the neuromuscular T_I , and the opposite occurs in terms of T_E . In contrast, in the absence of DH and PEEPi, the onset of neuromuscular and spirometric inspiration are essentially synchronous, and the pressure developed by the inspiratory muscles is expended solely to overcome the elastance and resistance offered by the respiratory system. Thus, in patients with PEEPi, a large part of the inspiratory muscle effort may be wasted in overcoming PEEPi and, as a result, V_T is reduced. In fact, Haluszka *et al.* [44] found a significant correlation between P_{aCO_2} and PEEPi in stable COPD patients. In line with Šorli *et al.* [7], they also observed that V_T was significantly lower in the hypercapnic patients, and interpreted their results as follows. Increasing severity of COPD results in increased flow resistance leading eventually to tidal EFL, which in turn causes DH and PEEPi. Pulmonary hyperinflation results not only in increased work of breathing because of PEEPi but also in decreased

**Figure 5.4** Average spiromgrams at rest in non-hypercapnic (a) and hypercapnic (b) COPD patients compared with normal subjects. Bars placed at peak inspiration indicate 1 SD. Mean inspiratory flow (V_T/T_I) is represented by slope of ascending limb of schematic spiogram. V_T , tidal volume. (From Šorli *et al.* [7] with permission.)

effectiveness of the inspiratory muscles as a pressure generators [10]. When DH and PEEPi reach a critical level, an adequate V_T can no longer be maintained because of impending inspiratory muscle fatigue [45]. Thus, patients reduce tidal volume and alveolar ventilation, with a concomitant increase in P_{aCO_2} . If hypercapnic COPD patients are asked to voluntarily restore V_T to normal values, they invariably develop diaphragmatic fatigue, suggesting that shallow breathing may be an adaptive strategy used to avoid inspiratory muscle fatigue. Regional differences in PEEPi enhance maldistribution of pulmonary ventilation and impaired gas exchange, contributing to increased P_{aCO_2} and decreased P_{aO_2} [46]. In short, DH and PEEPi have a pivotal role in causing hypercapnic ventilatory failure in COPD.

In actively breathing subjects in whom assessment of PEEPi is not feasible [32], the decrease in IC is commonly used as a surrogate marker of DH and PEEPi. Because in COPD the respiratory elastance is essentially normal (~ 10 cm H_2O/L), according to equation 5.4 a decrease in IC of 1 L implies a PEEPi of approximately 10 cm H_2O .

Diaz *et al.* [47] found a significant correlation of P_{aCO_2} to IC in stable COPD patients at rest, and suggested that the difference between ‘blue bloaters’ and ‘pink puffers’ was mainly caused by the presence or absence of DH and PEEPi. This is supported by the highly significant linear correlation of P_{aCO_2} to PEEPi [44] and IC (% pred) [47] found in COPD patients. In ‘blue bloaters’, the small V_T (see Fig. 5.4) reflects the ‘tip of the iceberg’, with most of the inspiratory effort being expended against PEEPi. In contrast, in ‘pink puffers’, PEEPi is absent and hence there is no ‘iceberg’ penalty. Nevertheless, the ‘pink puffers’ also exhibit an increased $P_{0.1}$ which is not chemoreceptor-mediated because the P_{aCO_2} is normal or below normal (see Table 5.1) and the hypoxic drive is modest [7].

The premorbid response to CO_2 has been advocated as a determinant of hypercapnia in COPD. This is an attractive hypothesis, based on the wide variation of ventilatory response to CO_2 observed among normal individuals [48]. Thus, individuals with low ventilatory response to CO_2 when developing lung disease with mechanical impairment should retain CO_2 , whereas those with high ventilatory responses would avoid CO_2 retention by increasing ventilation. However, this theory does not explain why the P_{aCO_2} is either normal or below normal in the ‘pink puffers’.

Relationship between P_{aCO_2} and FEV_1 . Inspection of Figure 5.1 shows that FEV_1 is not a good marker of hypercapnia. This is further confirmed by the fact that high P_{aCO_2} values can often be found in stable patients with FEV_1 higher than 1.5 L (Fig. 5.5) [40]. Furthermore, in a longitudinal study of COPD patients it was found that the variations in P_{aCO_2} were independent of the evolution of FEV_1 and VC [42].

Figure 5.5 Relationship between arterial P_{CO_2} (P_{aCO_2}) and FEV_1 in stable hypercapnic (\circ) and non-hypercapnic (\bullet) COPD patients. (From Parot *et al.* [39] with permission.)

This is not surprising because in COPD patients the FEV_1 describes events that occur at volumes well above FRC (see Fig. 5.2b) and hence is of little or no consequence in terms of regulation of P_{aCO_2} at rest.

Assessment of severity of COPD. The severity of COPD is commonly based on the value of FEV_1 , expressed as percentage predicted. To the extent that ‘severity’ implies curtailment of exercise capacity and increased dyspnoea, the choice of FEV_1 is not appropriate in view of the very poor correlation of this parameter to both exercise capacity [49,50] and chronic dyspnoea [21]. Assessment of severity of COPD according to IC (% pred) or presence or absence of EFL at rest appears to be more appropriate [47,49,50].

Stratification of COPD patients into two severity categories – those with and those without EFL sitting at rest – appears to be clinically very useful because the EFL patients not only have severe curtailment of exercise capacity and marked chronic dyspnoea, but also exhibit increased P_{aCO_2} and decreased P_{aO_2} both at rest and during exercise [47,49]. Thus, this category of patients exhibits the altered blood gases that categorize the ‘blue bloaters’. It should also be noted that this stratification also reflects patients with and without a reduction of resting IC [47].

Orthopnoea. In stable COPD patients with tidal EFL in sitting and/or supine position at rest, there is a high prevalence of orthopnoea, which mainly results from increased inspiratory effort resulting from PEEPi in the supine position [51]. However, increased airway resistance in recumbency also contributes to orthopnoea.

Stable patients during exercise

A detailed description of exercise physiology is provided in Chapter 4 of this book. This brief account is designed to provide a coherent link between the control of breathing at rest and during exercise in COPD patients. During exercise in normal subjects, V_T increases at the expense of both the inspiratory and expiratory reserve volumes (see Fig. 5.2a), and hence the work of breathing is shared among the inspiratory and expiratory muscles. In contrast, in COPD patients in whom EFL is present at rest, the increase in V_T during exercise occurs entirely at the expense of the inspiratory reserve volume with a concurrent increase in FRC (see Fig. 5.2b). In this case all the work of breathing is sustained solely by the inspiratory muscles, whose burden is markedly increased through increased PEEPi and respiratory elastance, as patients now breathe along a flatter portion of the static volume–pressure curve (see Fig. 5.3). Furthermore, the increase in lung volume during exercise is associated with a further expansion of the thoracic cage to a point where the inspiratory muscles may operate very inefficiently [10]. More important, however, is the fact that in such patients the maximal tidal volume during exercise (V_{Tmax}) is limited by the reduced IC. This implies that exercise capacity and V_{Tmax} should be lower in COPD patients with than those without tidal EFL at rest. This was confirmed by Diaz *et al.* [47] who studied the breathing pattern and gas exchange at peak exercise in stable COPD patients with ($n = 29$) and without ($n = 23$) tidal EFL at rest. They did not measure $P_{0.1}$ because this variable is not reliable during exercise [9]. The maximal oxygen uptake ($\dot{V}O_{2max}$) was significantly lower in the EFL patients, and in all of them was below the normal limits. In contrast, 35% of the non-EFL patients had $\dot{V}O_{2max}$ within the normal limits. The lower $\dot{V}O_{2max}$ in the EFL patients was associated with lower ventilation, mainly as a result of lower V_T . In fact, there was a significant correlation of $\dot{V}O_{2max}$ to V_{Tmax} ($r = 0.7$, $P < 0.0001$). Because T_I was the same, the lower V_{Tmax} in the patients with tidal EFL at rest was caused entirely by lower V_T/T_I (Fig. 5.6). This is contrary to results obtained at rest (see Fig. 5.4), and suggests that in the EFL patients the exercise-induced increase in inspiratory load resulting from PEEPi becomes so large that an adequate V_T/T_I can no longer be achieved [47].

In the above study, the EFL patients exhibited higher $Paco_2$ and lower Pao_2 at rest than the non-EFL patients. At peak exercise, the former subjects exhibited a further significant increase in $Paco_2$ and decrease in Pao_2 , while in the non-EFL patients these variables did not change. Because V_D and $\dot{V}CO_2/\dot{V}_E$ were similar in the two groups of patients, it follows from equation (5.3) that the increase in $Paco_2$ during exercise was caused by lower V_{Tmax} .

The results of Diaz *et al.* [47] are similar to those obtained

Figure 5.6 Average spiromgrams during maximal exercise in COPD patients without (●) and with (○) tidal expiratory flow limitation at rest. V_T , tidal volume. (From Diaz *et al.* [47] with permission.)

on a smaller number of patients by Koulouris *et al.* [23], who also showed that most COPD patients who were not EFL at rest become EFL during exercise. One of the most important findings by Diaz *et al.* [47,49] was a close correlation of resting IC to V_{Tmax} ($r = 0.77$, $P < 0.0001$) and $\dot{V}O_{2max}$ ($r = 0.75$, $P < 0.001$). The latter implies that when cardiopulmonary exercise testing (CPET) is not available or is contraindicated, the exercise capacity may be predicted to a useful approximation by simple measurement of IC.

Inspiratory capacity and exercise tolerance

Because in COPD patients reduced exercise capacity shows a weak link to FEV_1 and forced vital capacity (FVC) [47,49,50], it has been suggested that factors other than lung function impairment (e.g. deconditioning and peripheral muscle dysfunction) are the predominant contributors to reduced exercise tolerance [52–54]. Recent studies based on assessment of IC and FEV_1/FVC ratio, however, indicate that lung function impairment is the major contributor to reduced exercise tolerance in COPD [47,49,55]. In fact, because the IC and FEV_1/FVC ratio together account for 72% of the variance in $\dot{V}O_{2max}$ [49], only 28% of the variance can be ascribed to other factors such as deconditioning and peripheral muscle dysfunction, or decreased cardiac output as a result of PEEPi [47]. These considerations pertain to average values; in individual patients the contribution of these factors may be different.

Figure 5.7 illustrates the relationship between $\dot{V}O_{2max}$ during incremental, symptom-limited exercise on a cycle ergometer and IC in ambulatory COPD patients [47]. The patients were stratified according to the presence or

Figure 5.7 Relationship of maximal oxygen uptake during exercise ($\dot{V}O_{2\max}$) to resting inspiratory capacity (IC) in 52 COPD patients with (○) and without (●) tidal expiratory flow limitation at rest. (From Diaz *et al.* [49] with permission.)

absence of EFL during resting breathing in a sitting position. In the absence of EFL the IC was within normal limits and, with two exceptions, the $\dot{V}O_{2\max}$ was either normal or the reduction was mild to moderate ($\dot{V}O_{2\max}$ between 77 and 56% pred) [56]. In contrast, in all EFL patients IC was below the normal limits and the reduction in $\dot{V}O_{2\max}$ was severe to very severe. Figure 5.7 also shows that in EFL subjects the $\dot{V}O_{2\max}$ decreases approximately linearly with increasing severity of dynamic hyperinflation, as reflected by decreased IC. There were no patients with IC below 40% pred because such patients require domiciliary oxygen therapy, as a result of markedly reduced P_{aO_2} at rest or exercise. Supplemental oxygen elicits an increase in IC, with concurrent improvement of dyspnoea, through a reduction of ventilation and bronchodilation caused by removal of hypoxia [57,58]. An increase of IC can also be obtained with bronchodilators [cf. 2,59]. Eventually, however, dynamic hyperinflation may become so severe that patients require mechanical ventilation [32; see Chapter 48 of this book].

Finally, it should be stressed that in other forms of chronic airways obstruction, such as bronchiectasis [60] and asthma [61], the control of breathing differs from COPD, the main difference being in that tidal EFL is less common.

Dyspnoea

Together with decreased exercise tolerance, dyspnoea is the predominant complaint of patients with COPD. Because it correlates poorly with FEV_1 and FVC , it has been suggested

that dyspnoea and lung function should be considered as separate factors, which independently characterize the severity of COPD [62]. In reality, however, the poor correlation is caused by the fact that FEV_1 and FVC are poor predictors of dynamic hyperinflation, which is the major cause of dyspnoea [21]. There is a good correlation between chronic dyspnoea measured with the modified Medical Research Council (MRC) scale to various indices of dynamic hyperinflation [21], including IC [59].

A close correlation ($r = 0.86$) has recently been found between maximal exercise power and MRC dyspnoea score in stable patients with COPD [63] and bronchiectasis [60]. This suggests that the MRC dyspnoea scale is designed to assess exercise capacity rather than severity of dyspnoea per se. Further studies are required to confirm these observations, which implies that when CPET is not available or contraindicated, the maximum exercise capacity may be predicted to a good approximation by using the MRC dyspnoea questionnaire.

Mechanisms contributing to shallow breathing

The mechanisms leading to alterations in respiratory timing and consequently to shallow breathing in stable COPD patients have not yet been clearly defined. The fact that most hypercapnic COPD patients can achieve normocapnia by voluntarily increasing their ventilation [6] and that stable COPD patients, by voluntarily deep breathing, can bring the inspiratory muscles near fatigue in a few minutes [64], has led to the speculation that hypercapnic COPD patients choose 'wisely' to hypoventilate to avoid inspiratory muscle fatigue.

Because under conditions of increased load and/or reduced efficiency, the strain on the diaphragm that is required to maintain an adequate alveolar ventilation has been shown to lead to myofibril membrane damage and sarcomere disruption [65,66], it is likely that a protective mechanism might exist in order to protect the respiratory muscles from such damage. The functional elements of this protective mechanism (i.e. the way in which peripheral and mechanical stimuli are transmitted and modify the breathing pattern) have not been fully elucidated.

Small myelinated and non-myelinated phrenic afferent fibres (types III and IV, respectively) have been found to influence the central inspiratory neural activity in anesthetized cats, in which it was shown that selective stimulation of these fibres results in changes in the respiratory rhythm (altering the T_I/T_{TOT}) and, hence, in the central inspiratory activity [67]. Under states of severe respiratory stress (muscle tension, local ischaemia, accumulation of toxic metabolites) afferents from the respiratory muscles may have a predominant role in the genesis of shallow breathing [67,68].

A direct link between stimulation of group III and IV afferents and the central processing of endogenous opioids has been postulated [69], given that in anesthetized dogs respiratory depression persisted even after withdrawal of afferent fibre stimulation, whereas the magnitude of the respiratory depression was significantly reduced by naloxone. Other investigators have confirmed these results in cats and demonstrated that the phenomenon involved a supraspinal mechanism [70], which could be prevented by pretreatment with naloxone [71]. This strongly suggests involvement of endogenous opioid pathways. The fact that in COPD patients with absent respiratory response to flow-resistive loading the response could be acutely restored by administration of naloxone [72], suggests that in these patients the chronic increase in airway resistance may generate endogenous opioids to lessen the stress of prolonged dyspnoea.

The source of endogenous opioids during strenuous inspiratory resistive breathing remains elusive, and both central sites such as the hypothalamic–pituitary–adrenal (HPA) axis, and peripheral sites such as the spinal cord and peripheral nerves have been implicated [73].

Recently, it has been shown that in normal humans strenuous resistive breathing leads to a significant rise in the levels of proinflammatory cytokines (interleukins IL-1b, IL-6), adenocorticotrophic hormone (ACTH) and β -endorphin [74]. The strong correlation between the rise in the β -endorphin and ACTH and the preceding increase in circulating IL-6 allowed the authors to conclude that proinflammatory cytokines are responsible for the activation of the HPA axis, leading eventually to an increase in plasma β -endorphin and ACTH. It is tempting to suggest that the mechanism accounting for the increase of β -endorphin and ACTH could be the stimulation of small afferent nerve fibres by the cytokines that are produced during resistive breathing, given that global depletion of small afferent fibres inhibits the plasma ACTH response to intravenous IL-1b [75].

Although the stimuli for the production of the cytokines are not known, reactive oxygen species produced during fatiguing resistive breathing [76,77] could be responsible. Even though the time profile (brief) and intensity (much greater) of the increased loading of breathing in the above mentioned models are different from those in patients with chronic CO₂ retention, given that strenuous breathing causes diaphragm muscle fibre injury one could speculate that strenuous resistive breathing through reactive oxygen species induces plasma cytokine production, which in turn modulates the respiratory controllers either directly through the blood or more likely the small afferents, or via the HPA axis. The ensuing production of β -endorphins, by altering the breathing pattern, results in reduced load and alleviation of fatigue, thus protecting the ventilatory pump

from exhaustion [78]. In the last analysis, however, PEEPi and its ‘tip of the iceberg’ effect are probably the main reasons for the reduced V_T and dyspnoea exhibited by COPD patients with CO₂ retention at rest and during exercise.

Acknowledgement

The authors thank Ms Karyn Mitchell for typing the manuscript.

CHAPTER 6

Physiology and pathobiology of the lung circulation

Norbert F. Voelkel

How normal lung circulation works

Design

The lung circulation is designed as a low-pressure low-resistance system, whereas the bronchial circulation is systemic and under high pressure. The blood flow through the lung had been thought to be controlled by gravitational forces and therefore, according to West [1], apical–basal zonal patterns. However, more recent studies by Glenny *et al.* [2] indicate that lung blood flow is fractal and largely determined by the design of the vascular tree [2]. Thus, the branching pattern (branching angle and variation of branch lumen diameter of segments of the same generation) appears to determine how the blood flows through the lung circulation. ‘At the end of the day, the lung is designed as an efficient gas exchanger, and it needs to stay dry’ (John T. Reeves, personal communication).

Wagner *et al.* [3] have studied recruitment of unperfused lung vessels, which is likely maximal with maximal exercise. This opening and perfusion of a large number of ‘reserve capillaries’ likely explains why the lung circulation can accommodate fold increases in cardiac output without a substantial increase in pulmonary artery pressure [4].

Ventilation–perfusion matching

As the primary function of the lung organ is that of an efficient gas exchanger, mechanisms are needed – and exist – to match ventilation–air flow with blood flow. Hypoxic vasoconstriction – originally termed alveolar – capillary ‘reflex’ by von Euler and Liljestrand [5] – is perhaps the most recognized and best-studied aspect of ventilation–perfusion (V/Q) matching. The principle is, simply stated: what is not ventilated must not be perfused. Studies designed and performed several decades ago showed con-

vincingly that vasodilator drugs decrease the P_{aO_2} significantly by allowing perfusion of non-ventilated areas of the lung [6]. Regional hypoxia results in regional pulmonary vasoconstriction, limiting blood flow to under- or unventilated areas. Hypoxic vasoconstriction is nearly instantaneous after the occurrence of alveolar hypoxia [7], hence the original term ‘reflex’.

Hypoxic vasoconstriction may be the most important mechanism of V/Q matching, but there may be other mechanisms. These are likely endogenous vasoconstriction and vasodilator agents, which modulate pulmonary vascular tone hypoxia independently. For example, Walker *et al.* [8] showed that a cyclo-oxygenase inhibitor (meclofenamate) increased pulmonary artery pressure in trained awake dogs, indicating that a cyclo-oxygenase product was involved in the normal control of the lung circulation.

Interestingly, Naeiji *et al.* [9] treated COPD patients with supplemental oxygen to ‘remove’ hypoxic vasoconstriction and then documented a fall in the pulmonary artery pressure after prostaglandin E_2 infusion – indicating that these patients had an element of hypoxia-independent vasoconstriction – which presumably contributed to V/Q matching.

Lung circulation in COPD/emphysema

Most of the traditional lung function studies assess variables of airway disease, flow–volume, airway resistance–reactivity or trapped air–hyperinflation. The high-resolution chest computed tomography (CT) scan can assess thickened airway walls and the degree of lung tissue, and also vessel loss in emphysematous areas. Pulmonary angiography, still occasionally performed to rule out pulmonary embolism, can show the pruning of the subpleural vessels, the diffusion capacity and, when corrected for alveolar volume, can provide information regarding the loss of alveolar capillaries.

Histology of the lung vessels in COPD/emphysema

In recent years, several groups have acknowledged that the microscopically fine pulmonary arterioles are abnormal in COPD patients [10–14]. The vessel walls appear to be highly muscularized (thickened) – there may also be a thickening of the intima [14] – but usually the vessels are patent and not obliterated and there may be perivascular clusters of lymphocytes (see Plate 6.1; colour plate section falls between pp. 354 and 355). Astonishingly, little immunohistochemical interrogation of the lung vessels in COPD has been performed. A decrease or loss of expression of vascular endothelial growth factor (VEGF) and VEGF receptor proteins has been reported [15] as has loss of staining for the enzyme prostacyclin synthase, the protein critically important for prostacyclin production [16]. Because chronic hypoxia causes pulmonary vasoconstriction and is associated, in most species, with generation of muscularized arteries in the lung, most investigators have concluded that the muscularized arteries in the lungs of COPD patients are the result of chronic hypoxic pulmonary vasoconstriction. This ‘we know it when we see it’ conclusion may, however, be wrong, or perhaps only partially correct. First, chronic hypoxia does more to the lung than cause constriction of the resistance vessels. Hypoxia alters the expression of many genes in many types of lung cells [17] and stimulates production and release of cytokines and growth factors – most notably the production of VEGF [18]. Thus, there is overlap between hypoxia–hypoxemia and inflammation, and perhaps there also exists a local immune response to hypoxia. Secondly, studies performed by the group of COPD investigators in Barcelona [13] call the hypoxia-dependent mechanism of pulmonary vascular ‘remodelling’ in COPD into question. These investigators studied the vessels in the lungs of smokers with minimal lung function impairment (i.e. of patients without hypoxia, pulmonary hypertension or significant emphysema) and found vascular abnormalities [14]. If not hypoxia, what then causes the vessel walls to thicken in these patients? A hypothesis to address this question is that products of inflammation do double duty as growth factors for vessel wall cells, mostly for smooth-muscle cells [19]. These factors may be the same factors that are responsible for the ‘airway remodelling’ (Fig. 6.1). These factors may have nothing to do with the maintenance of alveolar septal capillaries, because capillary numbers are reduced in severe COPD/emphysema – hence, the decreased DLCO – or the trophic (growth) factors are being released only in the immediate vicinity of the arterioles and bronchioles.

Thus, there are two types of vascular abnormality in the lungs of patients with COPD:

1 thickening (in principle by muscularization) of arterioles, which is perhaps not caused by hypoxic vasoconstriction; and

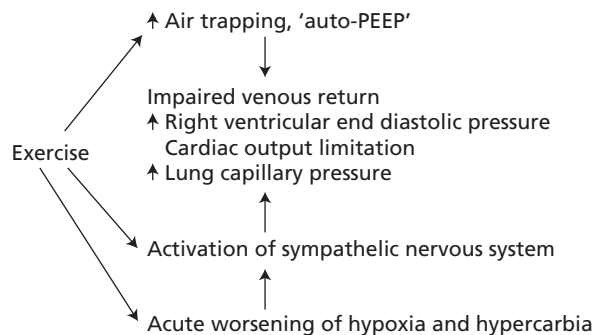

Figure 6.1 This schematic attempts to tie together the important factors that determine the haemodynamic response to exercise in patients with severe airflow limitation and symptom-limited low exercise capacity. auto-PEEP, auto-positive end-expiratory pressure. (From Voelkel & Cool [26], with permission.)

2 capillary loss by endothelial cell apoptosis [15].

Independent studies by two groups provided *ex vivo* evidence for endothelial cell dysfunction by testing for the acetylcholine-dependent vasodilatation of small diameter arteries from the lungs of COPD patients [20,21].

Taken together, the histological and functional data indicate that the vessels in the lungs of COPD patients are abnormal – likely during stages where the airway physiology is relatively preserved. Does chronic inhalation of cigarette smoke cause endothelial cell dysfunction and perhaps death of microvascular endothelial cells? If so, does cigarette smoke act directly or indirectly? How does cigarette smoke affect lung vessels?

Pulmonary hypertension in COPD

Burrows *et al.* [22] were likely the first to study the haemodynamics of patients with COPD systematically and thoroughly (i.e. they included exercise testing and the response to oxygen) (Fig. 6.2). Their data have been largely confirmed by more recent studies by Weitzenblum *et al.* [23–25]. Both studies show a large variability between patients in their baseline [22,23], as well as exercise-induced pulmonary hypertension. In addition, Burrows *et al.*'s data showed that the exercise-induced Pa pressure increase was significantly blunted when the patients were treated with supplemental oxygen; however, this was not true for all cases. The lesson to be learned from these early studies is that there is a wide spectrum of pulmonary artery pressures, from patients with little pulmonary hypertension at baseline – even with exercise, patients who show an impressive increase in the Pa pressure with exercise, to a

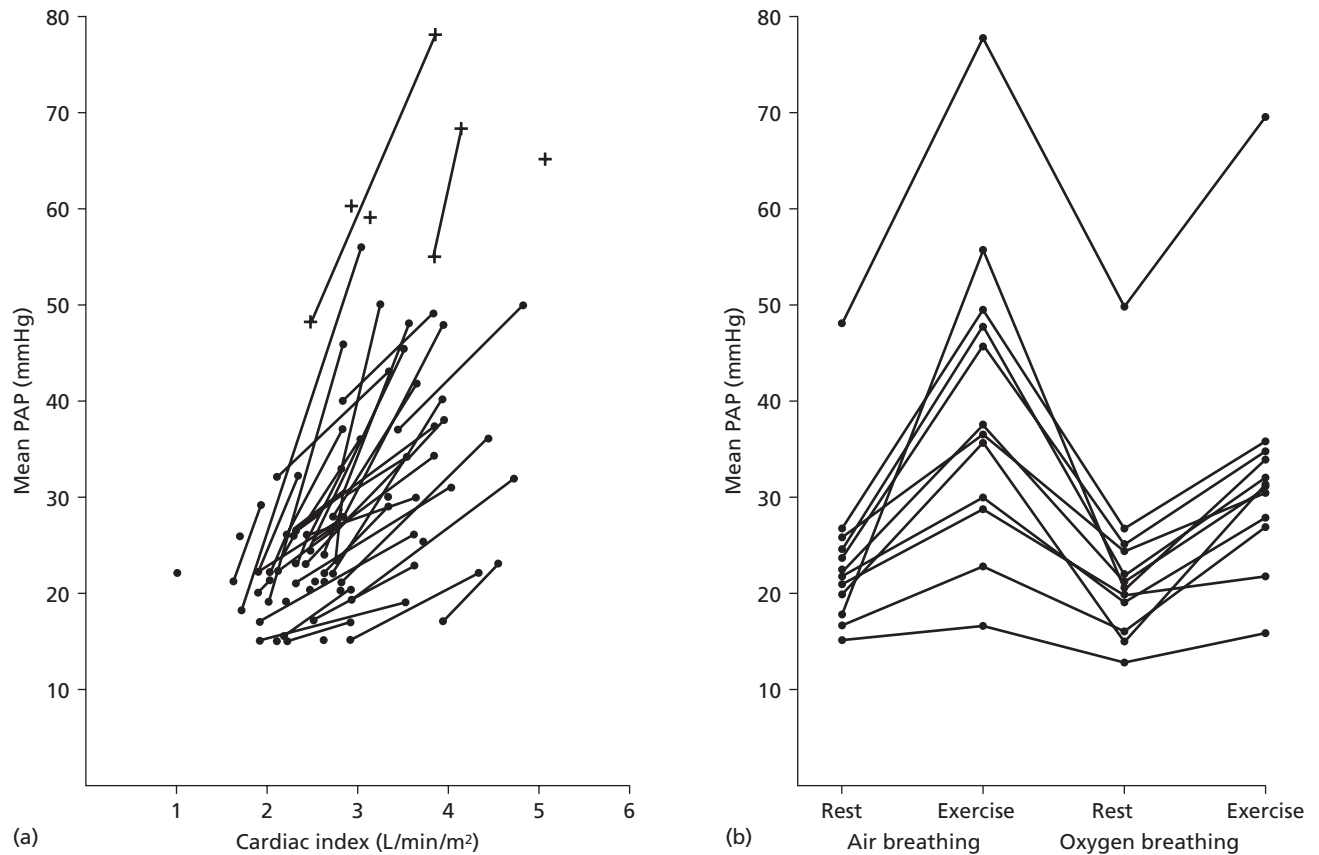

Figure 6.2 Relationship of mean pulmonary artery pressure (PAP) and cardiac index. The solid lines connect resting and exercise data. (a) The variability in the magnitude of the exercise-induced pulmonary hypertension between patients is remarkable. (b) The exercise-induced pulmonary hypertension is diminished in many of the patients. (From Burrows *et al.* [22], with permission.)

few patients where the resting pressure can be as high as seen in patients with primary pulmonary hypertension, with unusually high resting Pa pressures. Figure 6.2 attempts to provide a mechanistic concept for the exercise-induced pulmonary hypertension in COPD patients, but provides no sound explanation for the large interpatient variability. It is of interest that, to date, no study examines *all* of the variables that need to be considered for a complete understanding of resting and exercise-induced pulmonary hypertension in COPD patients – these would include the hypoxic ventilatory response, degree of hypoxic vasoconstriction, DLCO, lung volumes, auto-positive end-expiratory pressure (PEEP), cardiac output and pulmonary capillary wedge pressure. The cardiovascular–pulmonary interactions are indeed complex (see Fig. 6.2). Both the hypoxic ventilation and pulmonary vasoconstriction response are likely genetically controlled. Right and left ventricular performance are affected by auto-PEEP, polycythaemia increases pulmonary hypertension [26] and so does *in situ* thrombosis, which can occur in patients with emphysema [27]. Lastly, sleep apnoea can be the cause

of intermittent severe nocturnal hypoxaemia and intermittent hypoxic vasoconstriction, contributing to the muscularization of precapillary pulmonary arteries [28–30].

Should the pulmonary hypertension in COPD patients be treated? This remains a controversial and unresolved question. A pragmatic, but not really validated, approach would be to:

- 1 treat hypoxaemic patients with supplemental oxygen. After all, Burrows *et al.*'s [22] studies demonstrate a diminished pulmonary artery pressure rise with exercise;
- 2 treat sleep apnoea in COPD patients;
- 3 develop strategies to prevent COPD exacerbations.

Long-acting bronchodilators may have a lasting effect in COPD patients, increasing forced vital capacity (FVC) and reducing the amount of trapped air (residual volume, RV) [31,32]. If so, a significant reduction of the RV could improve cardiac performance during exercise. Several companies are developing phosphodiesterase inhibitors (PDE) for treatment of COPD, and they could have a direct effect on pulmonary artery pressure – whether these drugs impair V/Q matching remains to be seen.

Conclusions

There can be no doubt that COPD is also a pulmonary vascular disease [33] and skeletal muscle vessels may also be impaired [34]. Immune mechanisms likely involved in the pathogenesis of COPD/emphysema need to be vigorously explored to better understand the so-called pulmonary vascular remodelling of the precapillary arterioles and the disappearance of lung capillaries. The factors that control the development of pulmonary hypertension in COPD remain complex.

CHAPTER 7

Sleep in patients with COPD

Mark W. Elliott

During sleep there are profound physiological changes. This is particularly true of breathing, and in a number of conditions this has important implications. The sleep apnoea hypopnoea syndrome (SAHS) is increasingly recognized and in this condition the symptoms and other adverse health consequences (e.g. hypertension) are a result of what happens when the individual is asleep. In other conditions, changes happening during sleep exacerbate daytime function; in patients with heart failure and Cheyne–Stokes breathing, the abnormality of respiration during sleep contributes to daytime symptoms of tiredness and fatigue and is associated with a worse prognosis [1]. In patients with chest wall deformity and neuromuscular disease, nocturnal hypoventilation is important in the pathogenesis of daytime symptoms, respiratory failure and cor pulmonale [2]. Repeated episodes of hypoxaemia and hypercapnia during sleep lead, in time, to the development of daytime respiratory failure, pulmonary hypertension, right heart failure and death [3].

Breathing alters according to the state of consciousness. In healthy subjects, ventilation falls with the onset of sleep and is reduced during all phases of sleep compared with waking levels [4]. Alterations in the pattern of breathing occur, including periodic breathing, apnoea and hypopnoea, particularly with the onset of sleep and during stages I and II. Upper airway resistance may increase [5]. The changes are generally more marked during rapid eye movement (REM) sleep than non-rapid eye movement (NREM) sleep.

NREM sleep is associated with a decrease in respiratory frequency and a small increase in tidal volume. A reduction in central drive during sleep has been postulated to explain these differences. However, ventilation has been shown to fall despite an increase in occlusion pressure [6]. In awake supine humans, movements of the ribcage and abdomen account for 40 and 60% of the tidal volume, respectively. In NREM sleep, ribcage movement accounts for 65% of the tidal volume, suggesting increased intercostal activity [7].

In cats, expiratory intercostal muscle activity increases throughout NREM sleep and although its significance is not known, this increase indicates that at least some of the NREM changes are not simply a reduction of central drive compared with that during waking. By contrast to NREM sleep, during REM sleep respiratory frequency is often greater and tidal volume lower than during wakefulness and atonia of the intercostal muscles reduces or eliminates costal breathing. Ventilatory responses to chemical stimuli and other respiratory reflexes are also impaired during phasic REM sleep [8,9]. During NREM sleep the decrease in alveolar ventilation is relatively small, but this may be much more marked during REM sleep, particularly during bursts of eye movement [10], when alveolar ventilation may fall by as much as 40% of waking levels (Fig. 7.1). In healthy subjects, an increment in CO₂ tension of up to 6 mmHg above waking levels is normal [11], but this degree of hypoventilation is insufficient to cause any appreciable degree of oxygen desaturation. However, in patients with little respiratory reserve, more marked hypercapnia can occur together with significant oxygen desaturation.

Sleep in patients with COPD

Polysomnographic studies have shown that oxygen desaturation may occur in patients with COPD, and that this is particularly marked during REM sleep [12,13] (Fig. 7.2). Carbon dioxide tensions may rise; in one recent study, 47% of COPD patients had an increment in transcutaneous Pco₂ greater than 1.33 kPa (10 mmHg) above waking levels (see Fig. 7.2). This was correlated with diurnal P_aco₂, body mass index and percentage of time spent in REM sleep [14]. Alveolar hypoventilation is the dominant mechanism, with ventilation falling in one study by 18%, compared with wakefulness, during NREM sleep and 35% during REM sleep [15]. The effects of sleep on breathing in normal

Figure 7.1 This shows a 30-s epoch from an overnight polysomnogram of a patient with severe COPD. There is a period of apnoea associated with reduced chest and abdominal wall motion leading to marked oxygen desaturation. Note the phasic movements in the electro-oculograms (EOR and EOL). (C4, EEG; EMG, submental electromyogram; So_2 , oxygen saturation; AFL, oronasal airflow; CMV and AMV, chest and abdominal wall motion, respectively.)

Figure 7.2 Overnight monitoring of oxygen saturation (SaO_2) and transcutaneous carbon dioxide tension ($PtCO_2$). Note the reduction in SaO_2 at sleep onset and the episodes of marked worsening over a period of 15–20 min. These correspond to episodes of REM sleep. $PtCO_2$ also rises with sleep onset and is much more marked during the episodes of REM sleep. Over the course of the night it can be seen that the $PtCO_2$ gradually rises.

subjects discussed above, are much more marked in COPD. Patients with COPD have a higher physiological dead space than normal subjects and therefore the rapid shallow breathing that occurs in REM sleep will produce an even greater decrease in alveolar ventilation [16]. In addition, hyperinflated patients with COPD, like scoliotic patients, are more dependent upon intercostal and accessory muscle activity than normal subjects and during REM sleep, the diaphragm alone is unable to maintain ventilation [17]. In addition, contraction of the low flat diaphragm against a flaccid lower chest wall will result in costal indrawing, and a possible further reduction in ventilation. Lower respiratory system resistance rises during sleep, independent of sleep stage, because of an increase in cholinergic tone [18] and this may compromise effective ventilation still further. A reduction in functional residual capacity (FRC), because of reduced muscle tone, occurs in normal subjects and

probably in patients with COPD. The effect of this will be to increase airway closure, elevate closing capacity above FRC with consequent changes in ventilation/perfusion (\dot{V}/\dot{Q}) relationships, but this remains to be proved [19]. Many investigators [13,20,21] have stated that \dot{V}/\dot{Q} imbalance is a major cause of REM-related hypoxaemia in patients with COPD. However, the argument that because PaO_2 falls more than $Paco_2$ rises, changes in \dot{V}/\dot{Q} must be important, cannot be sustained because this is exactly what happens during transient hypoventilation because the body has the capacity to store relatively large amounts of CO_2 [22]. Nevertheless, it is likely that changes in \dot{V}/\dot{Q} do play some part. Increased upper airway resistance [23], or frank obstruction, or the change in the ventilatory response to increased upper airway resistance [24] may impact upon gas exchange during sleep and affect diurnal arterial blood gas tensions.

In a study comparing patients with airflow obstruction of similar severity, the presence of upper airway dysfunction together with increased alcohol consumption was more likely to be associated with daytime hypercapnia [25]. In another study of patients with severe SAHS and COPD, those with hypercapnia while awake were heavier, had smaller upper airway dimensions on CT scanning and a greater alcohol intake than those who were normocapnic. There was no difference in the severity of SAHS on the basis of the apnoea hypopnoea index (AHI) [26]. However, the 35% reduction in ventilation during REM sleep described above [15] occurred despite 4 cm H₂O continuous positive airway pressure (CPAP), suggesting that upper airway obstruction is not a major factor, although 4 cm H₂O CPAP may not have been sufficient to completely abolish this.

Changes in oxygen consumption, carbon dioxide production [27] and in cardiac output may also contribute to worsening of arterial blood gas tensions during sleep. Abnormal ventilatory control during wakefulness has also been implicated in the sleep hypoxaemia of COPD. Various workers have shown correlations between reduced ventilatory and occlusion pressure responses to hypoxia and hypercapnia and sleep-related oxygen desaturation [28–31]. However, it is also possible that changes in daytime ventilatory control occur as a consequence of the changes at night. Nocturnal hypoventilation causes P_{aCO_2} to rise with renal retention of bicarbonate ions to compensate for the resulting respiratory acidosis. The effect of an elevated bicarbonate is to buffer the pH changes associated with an acute rise in P_{aCO_2} and reduce the ventilatory response to CO₂ [32]. Secondly, sleep disruption reduces the daytime ventilatory response to both hypercapnia and hypoxia [33].

Patients with COPD may also complain of night-time cough. There is no correlation between apnoea or hypoxaemia and cough, which seldom occurs during sleep and only rarely awakens patients [34].

Effects of sleep-disordered breathing in COPD

It is clear that significant abnormalities of arterial blood gas tensions occur during sleep in patients with COPD and that, regardless of the exact mechanism, alveolar hypoventilation is a major contributor. However, the affect of these derangements during sleep upon survival and daytime function is not well known. Impaired sleep quality is well recognized in COPD compared with age-matched controls [35], and experience from SAHS suggests that sleep disruption is associated with impaired neuropsychiatric functioning and reduced quality of life [36]. However, there is no

evidence as yet that poor sleep in patients with COPD causes excessive daytime sleepiness [37].

Nocturnal hypoxaemia has been postulated to be important in the genesis of pulmonary hypertension during the day in COPD [38]. REM-related falls in oxygen saturation may be associated with rises in pulmonary artery pressure (PAP) of up to 20 mmHg [39]. However, the effect of transient rises in PAP during sleep is not clear. Higher mean PAP and red cell mass were found in 36 patients with COPD and mild to moderate oxygen desaturation (desaturation to at least 85% and at least 5 min spent with S_{aO_2} less than 90%) than in 30 patients who did not desaturate. However, there were also significant differences in their awake oxygenation [40]. The effect of the interaction between hypoxia and hypercapnia upon the human pulmonary circulation is not well known. However, in isolated animal preparations hypercapnia, in the presence of hypoxia, leads to a variety of different responses in the pulmonary circulation: vasoconstriction (dogs), vasodilatation (rats) or a biphasic response (cats) [41]. In humans, acidosis is a potent vasoconstrictor and therefore transient rises in CO₂ during sleep may exacerbate the vasoconstrictor response to hypoxia.

COPD and sleep apnoea hypopnoea syndrome (SAHS)

These are common conditions and available data suggest that they coexist in approximately 10% of patients [42]. Patients with COPD and impaired respiratory drive and those who have the normal risk factors for SAHS, particularly obesity, are more likely to have both conditions. The added load on the respiratory muscle pump of an increase in upper airway resistance during sleep produces acute CO₂ retention [43]. Acute derangement of gas exchange, which occurs in a patient with SAHS but normal lungs, would usually correct rapidly with termination of the apnoea and the hyperventilation that follows. However, in a patient with airflow limitation this may not be the case and, as a consequence, CO₂ retention occurs which may persist into wakefulness. Patients with both COPD and SAHS typically develop more severe hypoxia during sleep and as a result they are more prone to complications such as fluid retention and polycythaemia with less severely impaired lung function than would normally be the case [42]. Patients with SAHS and COPD and hypercapnia were found to be heavier than those who were normocapnic [44]. COPD patients without SAHS but who were hypercapnic had a smaller upper airway size, more snoring and a higher long-term alcohol consumption than those who were normocapnic [45]. These studies taken together suggest that upper airway changes during sleep are one factor contributing to diurnal respiratory failure in patients with COPD.

Table 7.1 Sleep studies in patients with COPD.

Suspected sleep apnoea syndrome
Excessive daytime sleepiness on a background of heavy snoring
Oedema or polycythaemia that are unexpected for the degree of airflow obstruction
Respiratory variable only study usually sufficient
Monitoring of transcutaneous carbon dioxide tensions maybe useful, particularly if patient is receiving supplemental oxygen

Who needs a sleep study? (Table 7.1)

Sleep studies are not routinely indicated in patients with COPD. The awake blood gas tensions provide a good indicator of likely sleep-related disturbances of gas exchange [46]. Overnight monitoring should be performed if there is the clinical suspicion of coexistent sleep apnoea syndrome or there is fluid retention or polycythaemia that are unexpected for the severity of airflow obstruction. In most cases, a limited respiratory variable only study will suffice and full polysomnography is seldom, if ever, necessary.

Treatment of sleep-disordered breathing and nocturnal hypoxia**Oxygen therapy during sleep**

Long-term oxygen therapy (LTOT) has been shown to prolong life in patients with sustained daytime hypoxia [47,48]. The question of whether patients with mild to moderate daytime hypoxaemia (arterial oxygen tension [P_{aO_2}] in the range 7.4–9.2 kPa [56–69 mmHg]) and sleep-related oxygen desaturation should be given oxygen was addressed in a study of nocturnal oxygen therapy (NOT) alone [49]. Seventy-six patients with COPD and no polysomnographical evidence of SAHS were randomized to NOT ($n = 41$) adjusted to achieve an arterial oxygen saturation of $> 90\%$ throughout the night, or to no supplemental oxygen ($n = 35$). The mean daytime P_{aO_2} was 8.4 ± 0.4 kPa at baseline. There were no differences between the groups in need for LTOT, evolution of pulmonary artery pressure or survival although the study was not adequately powered to exclude an effect of NOT. Twenty-two patients (12 in the NOT group and 10 in the control group, $P = 0.98$) required LTOT during an average follow-up of 3 years. Sixteen patients died, nine in the NOT group and seven in the control group ($P = 0.84$). After 2 years, pulmonary haemodynamics were reassessed in a subgroup of patients. In the

control group ($n = 22$), mean resting pulmonary artery pressure increased from 19.8 ± 5.6 to 20.5 ± 6.5 mmHg, which was not different from the change in mean pulmonary artery pressure in the NOT group ($n = 24$) from 18.3 ± 4.7 to 19.5 ± 5.3 mmHg ($P = 0.79$). These results suggest that the prescription of NOT to improve survival is not justified in patients with COPD.

The effect of oxygen on sleep quality is contentious, with some investigators showing an improvement [50] and others no benefit [51]. In neither of these studies was CO_2 tension measured and although severe hypoxia ($SaO_2 < 70\%$) may not cause arousal in humans [52], acute hypercapnia, with a rise in P_{aCO_2} of 6–15 mmHg, has been shown to be a reliable and powerful arousal stimulus [53]. The arousal response to hypercapnia varies between REM and NREM sleep, with arousal occurring at a much lower level of P_{aCO_2} during REM than NREM sleep [54]. A rise in P_{aCO_2} appears therefore to be more important in disrupting sleep than hypoxaemia.

Drugs

Drugs have been used in patients with COPD, targeted upon improving gas exchange and sleep quality. The rationale behind the use of protriptyline is specifically its effect upon sleep architecture. Ten to 20 mg of protriptyline taken at bed time has been shown to reduce the proportion of the night spent in REM sleep, when the most severe derangements of blood gas tensions occur, from 22 to 12% in eight patients with restrictive chest wall disorders [55]. The total amount of sleep time spent with a SaO_2 less than 80% decreased and there was a reduction in the maximum CO_2 tension reached during the night. The magnitude of the reduction in oxygen desaturation was correlated with the decrease in REM. The P_{aO_2} during the day increased by approximately 1 kPa but the changes in P_{aCO_2} and base excess failed to reach statistical significance. Similar results have been reported in COPD [56,57]. Series *et al.* [56] studied 14 patients with stable COPD in an open study. Patients took 20 mg protriptyline each night and were studied before starting treatment and after 2 and 10 weeks. There was a reduction in the percentage of sleep spent in REM from 11.1 to 4.2% but there were no other changes in sleep time or architecture. While taking protriptyline, the lowest sleep SaO_2 increased from mean 64.5% to mean 77.4% and the amount of time with SaO_2 below a given level of saturation was significantly decreased for all values greater than 65%. Arterial blood gas tensions by day showed an increase in P_{aO_2} from 57 to 66 mmHg and a non-significant fall in P_{aCO_2} from 52 to 48 mmHg. There were no changes in arterial pH or bicarbonate ion concentration. Clinical state and treatment were unchanged for 4 weeks before the start of the study and, although no control group

was studied, the benefits seen probably reflect the action of protriptyline.

Carroll *et al.* [57] recruited 18 patients with severe stable COPD to a randomized double-blind cross-over study of 10 mg protriptyline and placebo. Each limb of the study lasted 6 weeks, with assessments made before starting and after 6 and 12 weeks' treatment. Each polysomnographic study was preceded by an acclimatization night and the percentage of total sleep time (TST) spent in REM sleep was 16% on entry, 15% during the placebo phase and 8.8% while taking protriptyline ($P < 0.001$). The percentage of TST spent with SaO_2 less than 90%, 80% and 70% were all improved but only the change in %TST with $SaO_2 < 90\%$ reached statistical significance. The maximum increase in transcutaneous carbon dioxide tension (Pt_{CO_2}) was similar during both phases of the trial; however, as REM time was reduced during the protriptyline limb, the total time with Pt_{CO_2} greater than awake baseline was reduced. $Paco_2$ during spontaneous breathing fell from 6.4 kPa (5.2–8.5 kPa) to 5.8 kPa (5–8.1 kPa), $P < 0.01$ and PaO_2 increased from 6.9 kPa (4.8–10.1 kPa) to 7.8 kPa (5.1–10 kPa), $P = NS$. There were statistically significant increases in 6 minute walking distance and maximal inspiratory mouth pressures.

The beneficial effects of protriptyline upon daytime arterial blood gas tensions and function were attributed to the reduction in arterial oxygen desaturation. However, abolition of nocturnal oxygen desaturation by supplemental oxygen does not improve daytime arterial blood gas tensions. Simonds *et al.* [55] found a significant reduction in maximum Pt_{CO_2} in a group of patients with extrapulmonary restrictive disorders and Carroll *et al.* [57], in patients with COPD, noted a reduction in the time spent with Pt_{CO_2} above baseline levels, both suggesting that nocturnal hypoventilation was reduced. This may have contributed to the improved daytime arterial blood gas tensions by allowing renal excretion of bicarbonate, thereby restoring central ventilatory drive. However, the ventilatory response to carbon dioxide was not measured and a direct effect of protriptyline upon ventilatory response cannot be excluded. The anticholinergic side-effects of protriptyline were a major problem in all the studies. In the study by Carroll *et al.* [57], five of 12 male patients expressed reluctance to take protriptyline on a long-term basis, primarily because of urinary difficulties. With the advent of newer antidepressants, protriptyline has largely been withdrawn from the market and although a potent REM-suppressing and beneficial effect on sleep-disordered breathing has been demonstrated with the selective serotonin uptake inhibitor fluoxetine in obese patients [58] its use in patients with COPD has not been evaluated.

There are few studies of the effects of either oral or inhaled long-acting bronchodilators during sleep in patients with COPD. The studies are small and the results variable.

In a cross-over study of 20 patients with COPD, evening administration of theophylline resulted in less time with $SaO_2 < 90\%$ than QDS salbutamol and there was subjectively less nocturnal wheeze but no changes in sleep quality [59]. In another study, higher concentrations of theophylline resulted in a greater improvement in spirometric variables at 7 a.m. but no difference in oxygen saturation or sleep quality [60]. Mulloy and McNicholas [61] found that theophylline increased oxygen saturation and decreased transcutaneous CO_2 overnight but at the expense of impaired sleep quality in 10 stable patients. They also found beneficial effects upon exercise and a reduction in hyperinflation. Worse sleep quality was seen in another study without beneficial effects on gas exchange [62]. In patients with asthma, salmeterol but not theophylline has been shown to improve the patient's perception of sleep [63–65] but the differences are small. To date there have been no similar studies in patients with COPD. Tiotropium, a once-a-day long-acting anticholinergic agent, improves nocturnal FEV_1 compared with placebo [66] and increases nadir oxygen saturation without compromising sleep quality.

Respiratory stimulants such as medroxyprogesterone acetate, acetazolamide and almitrine have been shown to improve arterial blood gas tensions during wakefulness and sleep in some studies [67–69] but the results are not consistent [68,70] and side-effects have precluded widespread use.

Assisted ventilation during sleep

A number of studies have shown that non-invasive positive pressure ventilation (NPPV) is feasible at home during sleep in patients with COPD [71–77] and that abnormal physiology can be corrected using NPPV. However, there have been few controlled trials and most of these had small numbers of patients followed over a short period of time [78–81]. They have generally been characterized by no significant advantage from NPPV [78–80], poor tolerance [78] and worse sleep efficiency [80]. However, Meecham Jones *et al.* [79] showed improvements in daytime arterial blood gas tensions, sleep quality and quality of life during the pressure support (PSV) limb of a cross-over study comparing PSV and oxygen with oxygen alone. This was the only study in which the overnight control of nocturnal hypoventilation was confirmed and the improvement in daytime $Paco_2$ correlated with a reduction in overnight transcutaneous CO_2 . Sleep quality was shown to improve in another uncontrolled study in which an overnight reduction in transcutaneous CO_2 tension was confirmed [72]. The reason for improved sleep quality is not clear. It is likely to be multifactorial and may include better oxygenation, the reduction in CO_2 , but also offloading of

the respiratory muscles. In patients with SAHS, it is the increased effort of breathing against an occluded airway that is a major stimulus causing arousal [82], and the reduction in respiratory muscle effort [83,84], which can be achieved with non-invasive ventilation, may be important in improving sleep quality.

In a 1-year controlled trial, Casanova *et al.* [85] randomized 52 patients with severe stable COPD to either NPPV plus 'standard care' or to standard care alone. The adequacy of ventilation was determined by close observation of the patient, during the day and night, but was not confirmed objectively. The level of support was modest, with a mean inspiratory positive airway pressure (IPAP) of 12 ± 2 cm H₂O. One-year survival was similar in both groups (78%) as was the number of acute exacerbations. The number of hospital admissions was less at 3 months in the NPPV group (5 vs 15%, $P < 0.05$), but this difference was not seen at 6 months (18 vs 19%, respectively). There was either no or little difference between the groups in dyspnoea scales, gas exchange, haematocrit, pulmonary function, cardiac function and neuropsychological performance. However, the number of patients was too small to avoid a type II error and the period of follow-up too short to evaluate the effect upon outcome fully.

Clini *et al.* [86] reported a prospective randomized controlled trial of NPPV during sleep in chronic stable COPD patients, with a significant number of patients followed for a reasonable period of time. One hundred and twenty-two patients with stable chronic hypercapnia who had been on LTOT for at least 6 months were considered and 90 randomized to continuing LTOT or LTOT and NPPV. Compliance with LTOT was excellent and amongst NPPV patients the mean night-time use of 9 h compares very favourably with reported use in other studies. There were small improvements in the NPPV group in resting Paco₂ and dyspnoea and health-related quality of life, but no improvement in survival or hospital stay, although there was a trend towards a lesser time in hospital in the NPPV group compared with an increase in the LTOT group when compared with the period before the study. ICU stay was reduced in both groups, but more in the NPPV than in the LTOT group. The effect of NPPV upon sleep quality and quantity was not evaluated. In common with most other studies, there was inadequate confirmation that effective ventilation had been delivered. NPPV was deemed to be adequate when the Paco₂ was reduced by 5% during wakefulness; this reduction in CO₂ during NPPV when awake is very modest. The changes in diurnal Paco₂, which was the primary endpoint that informed the power calculation, were small and it remains to be seen whether more aggressive ventilation would have resulted in a bigger change in this and other endpoints. The average IPAP was 14 ± 3 and expiratory positive airway pressure (EPAP) 2 ± 1 cm H₂O,

suggesting that there was room to increase the pressures, at least to levels closer to those seen in the study of Meecham Jones *et al.* [79]. The fact that the effectiveness of ventilation during sleep was not confirmed is an important limitation of the study and it is possible that there was in fact no change in Paco₂ overnight, given that the pressures used were comparable with those used in the study of Lin [80] in which no effect of NPPV was seen upon nocturnal hypoventilation. If this is correct, the question arises as to why patients reported less dyspnoea and an improved quality of life. First, this could have been a placebo effect, as was seen in the study of Gay *et al.* [81]. A significant placebo effect has been seen with sham CPAP [87] and the placebo effect of a 'breathing machine' should not be underestimated. Secondly, exacerbations have been shown to have a detrimental effect upon quality of life [88] in patients with COPD. NPPV offloads the respiratory muscles [89] and reduces the sensation of dyspnoea [90,91] associated with an acute exacerbation at ventilator settings similar to those used in this study. It is possible that NPPV therefore reduced the impact of exacerbations upon the patient; this may also have contributed to the trend towards reduced hospitalization. Compliance was considered to be acceptable if NPPV use was greater than 5 h/day on average; in fact the mean daily use in those who achieved this minimum usage was much higher at 9 ± 2 h/day. This suggests that at least some patients were using the ventilator during wakefulness, which lends some support to this hypothesis. Thirdly, no data are given about input from health-care workers, which may impact upon quality of life and dyspnoea [92]. It is possible that patients receiving NPPV, which requires considerable staff input at least initially, had greater contact with medical and paramedical staff than those on LTOT alone.

Most studies suggest that it is the patients with more severe hypercapnia who are likely to benefit and there is no place for nocturnal NPPV, at present, in those without sustained daytime hypercapnia. On the basis of current knowledge, a trial of NPPV can only be justified in patients with COPD who have symptoms of nocturnal hypoventilation (morning headaches, daytime sleepiness, etc.) despite maximal bronchodilator therapy or who cannot tolerate LTOT, even with careful administration using Venturi masks or a low flow meter. It should also be considered in patients with repeated episodes of hospitalization with hypercapnic ventilatory failure requiring acute NPPV [93]. Adequate control of nocturnal hypoventilation should be confirmed as this has been a feature of the studies in which benefit has been seen [72,79].

However, NPPV does not have to be delivered during sleep to improve both daytime and sleep parameters. In a carefully designed study of patients with extrapulmonary lung restriction, NPPV was delivered either during sleep or

during the day for a 1-month period [94]. In the latter group, patients were prevented from sleeping by having to respond to intermittent prompts by pressing a button when a light came on. There were no differences between the two groups, with each showing improved diurnal blood gas tensions, increased respiratory muscle strength and a slight reduction in the occlusion pressure 100 ms after the onset of inspiratory flow (pressure generated in the first 0.1 s, $P_{0.1}$), a measure of central drive. Overnight SaO_2 and transcutaneous CO_2 tensions were also improved in both groups at the end of the study during spontaneous breathing overnight. Sleep quality was also shown to improve in a small subgroup who underwent full polysomnography. Diaz *et al.* [95] also showed significant increases in daytime Pao_2 (mean increase 1.14 kPa) and $Paco_2$ (mean decrease -1.12 kPa) when patients with COPD were ventilated for 2 h/day 5 days/week for 3 weeks. Although the effect upon sleep was not evaluated, they found that the improvement in $Paco_2$ correlated with changes in dynamic hyperinflation, intrinsic positive end-expiratory pressure (PEEP), inspiratory lung impedance, tidal volume and functional residual capacity. There was no demonstrable effect upon tests of respiratory muscle function. They concluded that the primary effect of NPPV was upon respiratory system load. Daytime ventilation may be an option in patients who cannot tolerate NPPV during sleep, but again this warrants much more detailed evaluation before this strategy becomes widespread.

The use of CPAP overnight in patients with COPD has also been evaluated and while no effect upon gas exchange or sleep quality has been demonstrated, an improvement in inspiratory muscle strength and endurance as well as walking distance has been demonstrated [96], presumably a consequence of reducing the work of breathing [97]. In patients with a combination of SAHS and COPD, CPAP improves blood gas tensions and FEV_1 [98,99] and reduces the need for hospitalization [98]. The benefit seemed to be greatest in patients with hypercapnia [99].

Conclusions

Significant changes in respiratory function take place during sleep in normal subjects. These do not usually impact upon daytime function. However, in the patient with COPD the effect may be sufficient to worsen ventilation to the point at which diurnal ventilatory failure occurs. In patients with combined SAHS and COPD, more severe derangements of daytime blood gas tensions are seen than would be expected for the degree of airflow limitation. Whether other effects such as minor degrees of sleep disruption are clinically important remains to be seen. With the increasing recognition of patients with SAHS, abnormalities

occurring solely during sleep are increasingly recognized and their implications and hence management requires further study.

CHAPTER 8

The physiology of cough

Marian Kollarik and Bradley J. Udem

The problem of cough is often underestimated when considering life-threatening diseases such as COPD. Yet chronic and non-relenting cough can substantially diminish the quality of life of those suffering from this disease [1]. In patients with COPD, cough is often a natural consequence of the mucus hypersecretion and airway obstruction that typify their disease. In some patients with inflammatory airways disease, however, the neurophysiology of the cough reflex may be pathologically altered, leading to an exaggerated sensitivity of the reflex pathways. An inappropriately sensitized cough reflex may lead to persistent 'urge to cough' sensations which result in cough in excess of functional requirements. In this review we discuss the basic physiological concepts of the cough reflex. Emphasis is placed on the nature of the afferent (sensory) neural pathways involved in the initiation of the cough response, and the potential mechanisms by which these pathways can become altered in inflammatory airways diseases such as COPD.

The cough reflex

The basic function of cough is to remove excessive or irritant material from the airways. This is achieved by the interaction of the airflow with the mucus lining the airway wall. The physical characteristics of the airflow and mucus are critical determinants of cough efficacy. A key factor underlying the clearing effect of cough is the extraordinary high linear velocity of the airflow that acts to remove irritants and mucus from the airways. The linear velocity of the airflow equals the airflow rate divided by the airway cross-sectional area (linear velocity = airflow rate/cross-sectional area). The effectors of the cough reflex (i.e. respiratory and laryngeal muscles) are activated in a highly coordinated and stereotypic pattern to generate high intrapleural pressure, which is responsible for both high airflow rate and the reduction in airway cross-sectional area.

Cough can be described in three separate phases: 'inspiratory', 'compressive' and 'expulsive' [2]. The inspiratory phase denotes the rapid inspiration of a variable tidal volume, usually larger than the eupnoeic tidal volume. This phase depends on the proper action of inspiratory muscles. Larger end-inspiratory volume inhaled during the inspiratory phase improves contractility of the expiratory muscles by improving their length-tension relationships (the length-tension relationship is optimal at higher lung volumes). Thus, larger end-inspiratory volume helps to generate the intrapleural pressure required during the subsequent phases. Cough can also occur in the absence of the inspiratory phase. This type of cough is often referred to as an 'expiration reflex'. An initial expiration reflex is often followed by bouts of more traditional coughing [2].

During the compressive phase of the cough, expiratory muscles are activated and the glottis closes (for ~0.2 s). The glottis closure allows for a great rise of intrapleural pressure (reported up to 300 mmHg ~ 40 kPa) (Fig. 8.1). The onset of the expulsive phase is marked by the opening of the glottis. When the glottis opens, the high pressure gradient between atmospheric pressure and the pressure in the airways results in a rapid expiratory airflow. The pressure gradient between intrapleural pressure and the pressure in the airways causes substantial dynamic compression of the airways as the pressure in the airways drops. The high values of the intrapleural pressure are important to achieve substantial dynamic compression of the airways. The dynamic compression is initiated early in the expulsive phase in the trachea and extends to the more peripheral airways as air is expelled. The cross-sectional area of the trachea can be reduced as much as fivefold, which leads to the fivefold increase in the linear velocity of the airflow (reported up to 25 m/s) [3]. Because the kinetic energy of a gas increases with the square of the linear velocity of the airflow, the fivefold increase in the linear velocity results in a 25-fold increase in the kinetic energy of expelled

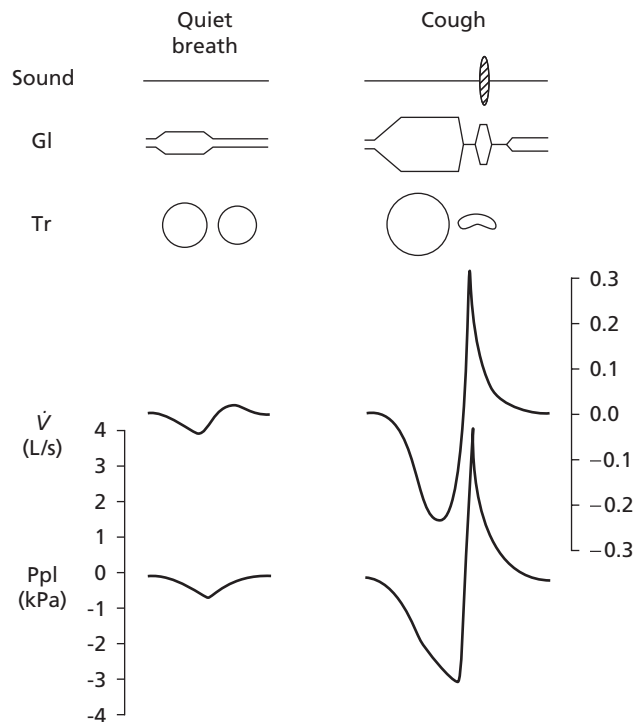

Figure 8.1 The acoustic, geometric and mechanical events in quiet breath and cough. Changes in cough sound, glottal (Gl) and tracheal (Tr) cross-sectional areas, airflow (\dot{V} ; scale on the right) and intrathoracic pressure (Ppl; scale on the left). Note dramatic reduction in the tracheal cross-sectional area in cough as a result of dynamic compression. The traces were obtained from an anesthetized cat. (Modified from Korpas and Tomori [2].)

gas which is available to interact with the mucus on the airway wall.

The expulsive phase of cough may be interrupted by the repeated glottis closures into the series of short expiratory efforts, each having compressive and expulsive components. It has been speculated that this interruptive pattern of coughing enhances clearance of the smaller airways [4]. Although all three phases are typically described, cough can be effective without complete glottis closure. Effective coughing was also reported in intubated patients and in patients with tracheostomies, who cannot achieve extreme values of intrathoracic pressure because of the functional absence of the glottis [5].

Cough is effective in clearing the mucus from the central airways but not the more peripheral airways. Theoretical estimates suggest that coughing is only effective to the 7th or 12th generation of the airways [6]. Thus, mucus from the more peripheral airways must be removed by mucociliary transport in order to be 'coughed up'.

Although the high linear velocity of the airflow is an

essential prerequisite for effective coughing, the quantity and quality of mucus are also critical factors of the cough efficacy. At high linear velocities of the airflow, mucus is torn from the airway wall and the droplets are aerosolized into the airway lumen (described as a misty flow). This phenomenon is greatly affected by the physical properties of mucus. Increased thickness of the mucus layer promotes the formation of misty flow while increased cohesiveness and adhesiveness of the mucus have the opposite effect [7]. The effect of cough on airway clearance is typically measured by the clearance of inhaled radioactive particles. This technique showed that cough improves airway clearance in COPD patients with increased mucus production [8–10]. In contrast, most studies agree that cough has little effect on airway clearance in subjects, including COPD patients, without mucus hypersecretion (unproductive cough) [8,11]. A modest benefit from cough without clinically detectable mucus secretion has occasionally been reported [12].

Other physical factors may also contribute to effective coughing. Airways are not rigid tubes and probably vibrate during the expulsive phase of the cough reflex. Cough often occurs as a succession of interrupted expirations instead of a single forced expiration. Airway wall vibration and rapid pressure swings acting on the airway wall during coughing may help to loosen the mucus from the airway wall [4]. Many stimuli that evoke cough also induce bronchoconstriction. It has been speculated that the airway smooth muscle contraction may prevent the collapse of the small diameter airways and thus facilitate the clearing of the more distal airways [13].

Neurophysiology of cough

The cough reflex is a *polysynaptic* reflex consisting of the primary afferent pathways, integration in the central nervous system, and the efferent motor pathways. Much of the current knowledge of the cough reflex neurophysiology is derived from animal models. Studies on humans are limited to morphological (bronchial biopsies in patients with cough), functional and pharmacological studies (mostly the inhalation aerosol challenges) from which only indirect inferences can be made about the cough reflex neural circuits. Additional information indicating involvement of certain neural pathways in the cough reflex in humans comes from studies in heart–lung transplant patients. The neurophysiology of cough has been more directly studied using various animal models including dogs, cats, rabbits and guinea pigs. In general terms, stimuli that provoke cough in humans also cause cough in these animals, and drugs that inhibit cough in humans also show efficacy in the various animal models.

Primary afferent (sensory) nerves

Primary afferent neurons have their cell bodies situated in sensory ganglia outside the central nervous system (CNS). The axon leaves the cell body and after a short distance bifurcates with one end innervating the peripheral target (e.g. airways, lungs) and the other end projecting centrally where it forms a synapse with secondary sensory neurons in the CNS. Information in the form of action potentials is transmitted from the periphery to the CNS along the axon. There is overwhelming experimental evidence that the afferent pathways involved in the initiation of cough are contained in the vagi nerves [14]. In humans, the relevant structures supplied by the vagi nerves include the lower part of the oropharynx, the larynx, the lower respiratory tract and the lung parenchyma. The cell bodies of the vagal afferent neurons are located in the superior (jugular) and inferior (nodose) vagal ganglia. These ganglia can be visualized as swellings along cervical portions of the vagi nerves.

Sensory nerves are subclassified based on the velocity at which they conduct action potentials along their axons. Myelinated fibres conduct action potentials at relatively high velocities (4–60 m/s). These fibres are referred to as 'A-fibres'. The other subset of vagal afferent nerve fibres are non-myelinated and conduct action potentials at a slow rate (< 2 m/s). The slow conducting fibres are referred to as sensory 'C-fibres'. It has been estimated that approximately 80% of the vagal afferent nerves innervating the respiratory system are C-fibres [15]. Most A-fibres in the respiratory system are low-threshold mechanosensors. In contrast, C-fibres are relatively insensitive to mechanical perturbation (i.e. high-threshold mechanosensors), but are readily stimulated by noxious stimuli and inflammatory mediators [16–18]. The C-fibres are therefore often referred to as 'nociceptive' or nociceptive-like C-fibres, inasmuch as they respond to noxious stimuli.

Regardless of the fibre type, in order to evoke activation, the stimuli interact with receptors or ion channels on the peripheral terminals of the afferent fibre causing a membrane depolarization. This membrane depolarization

(generator potential) spreads along the nerve fibre to an active zone where, if of sufficient magnitude, it leads to production of action potentials that travel in an all or none fashion to the central terminals of the nerve.

Vagal afferent A-fibres

With few exceptions, myelinated A-fibres innervating the respiratory system are sensitive to mechanical distortion of their receptive fields [19,20]. Many of the A-fibres in the intrapulmonary airways are sufficiently sensitive to mechanical distension of the surrounding tissue that they are activated by the cyclic changes in stretch occurring during eupnoeic breathing. These fibres are therefore characterized as 'pulmonary stretch receptors' and are found within the lungs of all mammals studied to date.

The pulmonary A-fibre stretch receptors are subclassified based on their ability to adapt to a prolonged suprathreshold stretch stimulus (Fig. 8.2) [21]. Some stretch receptors respond to the sustained lung inflation with a burst of action potential discharge which adapts rapidly (within seconds). These fibres are referred to as rapidly adapting stretch receptors (RARs). At the other end of the spectrum are stretch receptors that respond continuously through a prolonged suprathreshold lung inflation. These are referred to as slowly adapting stretch receptors (SARs). There are also subsets of A-fibres that are difficult to categorize as stretch receptors (either RAR or SAR). A significant proportion of the pulmonary stretch receptors are activated by bronchospasm resulting from the airway smooth-muscle contraction [14]. The activity of some RARs is inversely related to lung compliance [22]. In addition, some RARs can be activated by changes in the pulmonary extravascular space produced by mild elevations of left atrial pressure [23]. Lung deflation and certain inhaled irritants including cigarette smoke and ammonia also activate RARs [19,20,24,25].

Activation of SARs is thought to lead to the Hering-Breuer reflex and to inhibition of parasympathetic outflow [20]. By contrast, RAR activation can evoke tachypnoeic responses and increases in parasympathetic outflow [19].

Figure 8.2 Representative traces of tracheal pressure (Pt) and single unit recording of action potential discharge of a rapidly adapting stretch receptor (RAR), slowly adapting stretch receptor (SAR), and C-fibre in the anaesthetized rat. Note that the C-fibre does not respond to the lung distension during tidal breathing, or even when the lungs are overinflated (this fibre responded vigorously to capsaicin, not shown). The RAR and SAR both responded to the lung distention caused by tidal breathing; the difference in adaptation is obvious when the lung is overinflated for 10 s. (Modified from Ho *et al.* [90].)

Both types of stretch receptors may contribute to the cough reflex.

Vagal afferent A-fibres with characteristics similar to the pulmonary stretch receptors are less often encountered in the extrapulmonary airways [26,27]. In the dog and guinea pig, a subset of A-fibres situated in the extrapulmonary airways is exquisitely sensitive to a focal mechanical stimulus, but responds poorly to stretch or to changes in airway luminal pressure (see Plate 8.1; colour plate section falls between pp. 354 and 355) [26–28]. These extrapulmonary A-fibre mechanosensors do not fit into the classically defined categories of stretch receptors. Particularly relevant to the present discussion is the observation that activation of these extrapulmonary A-fibre mechanosensors effectively evokes coughing (see below) [27]. These low threshold A-fibre mechanosensors are relatively unimodal in their activation profile, with few other stimuli effective in evoking action potential discharge from their nerve endings [18,29]. Hypertonic saline solutions are poor activators of the extrapulmonary A-fibre mechanosensors in the guinea pig trachea; however, hypotonic solutions are effective stimuli (perhaps through mechanical means). At least a proportion of the extrapulmonary A-fibre mechanosensors can be directly activated by a modest reduction in pH (and this activation evokes cough in experimental animals) [27,30,31]. The molecular mechanism of acid-evoked activation of these A-fibres has not been elucidated, but mechanistic studies suggest that this activation may be mediated by certain acid-sensing ion channels (ASICs) [30]. The mechanisms by which the mechanical stimulus is translated into a generator potential in the nerve terminals is not yet understood. A large and growing number of mechanically sensitive ion channels have been identified [32], but the role of these channels in vagal bronchopulmonary afferent mechanotransduction is yet to be explored.

Vagal afferent C-fibres

The majority of afferent nerves innervating the respiratory system are unmyelinated slow conducting C-fibres [15,16]. C-fibres innervate the airways from the nose to the terminal bronchi. In addition, C-fibres are thought to innervate structures associated with the alveolus (juxta-capillary receptors, or J-receptors) [33]. The C-fibres innervating the conducting airways are referred to as bronchial C-fibres, whereas those deeper in the lung tissue are referred to as pulmonary C-fibres [16]. In either case, the C-fibres are poorly responsive to mechanical perturbation (i.e. they are high-threshold mechanosensors) and are quiet during normal respiration. Unlike A-fibres with their structurally more defined nerve terminals, C-fibres, at least in the conducting airways, form a lattice-like plexus within and just beneath the epithelium [34]. An example of the difference between the morphology of nociceptive-like C-fibres and

mechanosensitive A-fibres in the guinea pig trachea can be seen in Plate 8.1 (colour plate section falls between pp. 354 and 355).

Virtually all vagal bronchopulmonary C-fibres can be activated by capsaicin. In addition, C-fibres are responsive to many chemicals and autacoids associated with inflammation, with bradykinin, adenosine triphosphate (ATP), serotonin (5-HT) and acids being the most commonly studied [16,35]. Activation of C-fibres can lead to reflex responses that include increases in parasympathetic outflow (and consequent bronchoconstriction and mucus secretion), apnoea, bradycardia and, as discussed below, cough [36].

Afferent fibres that trigger cough

Based on the rather simplified categorization scheme of respiratory afferent nerves (A-fibre subtypes, C-fibres), it would seem a trivial task to label one or the other afferent nerve type as the 'cough receptor'. Despite several decades of laboratory investigation, however, the fibre type(s) involved in initiation of the cough reflex has remained difficult to pin down. The reason for the difficulty comes from a confluence of variables that confuse the issue. The variables that confound the identification of the subtype of afferent nerves initiating the cough reflex include the nature of the tussigenic stimulus, the location from which the cough is initiated, the state of consciousness, the role of competing or facilitating reflexes, and the degree of integration by the CNS of the information arising from each fibre subtype.

Subconscious cough

Experimentally, the most straightforward cough reflex to study with respect to afferent nerve pathways is that evoked in an anaesthetized animal by punctate mechanical stimulation. Mechanically probing of the larynx, trachea, carina or large bronchi leads to a cough reflex in most mammals studied (humans, monkeys, dogs, cats, rabbits, guinea pigs). There would appear to be no exception to the conclusion that the afferent fibre type responsible for cough under these conditions is a mechanically sensitive (by definition) vagal A-fibre. Cooling the vagus nerve to a temperature that blocks conduction of all A-fibres but leaves unimpeded the conduction of C-fibres, abolishes this type of cough reflex [31,37].

Vagal A-fibre mechanosensors comprise stretch receptors (pulmonary RAR and SAR), as well as extrapulmonary A-fibre mechanosensors. Several studies indicate that SARs do not directly trigger cough reflex [14]. Moreover, in a species such as the guinea pig, there are few A-fibres with the characteristics consistent with SARs in the regions of the airways that lead to cough upon mechanical

stimulation (larynx, trachea, carina, main bronchi) [18]. Studies in dogs and cats have led to the conclusion that the cough evoked by mechanical perturbation of the trachea is secondary to RARs [14,37]. In the guinea pig, the extrapulmonary cough-evoking A-fibres that are exquisitely sensitive to a punctate mechanical stimulus can also be activated by tussigenic concentrations of hypotonic and acidic solutions [18,30]. The focal mechanical stimulus-induced action potential discharge in these fibres adapts rapidly (see Plate 8.1; colour plate section falls between pp. 354 and 355) and thus one might be tempted to classify these A-fibres as a subtype of RARs. In so doing, however, one quickly gets into a nomenclature thicket. In the guinea pig and dog, there are relatively few fibres in the larynx, trachea, carina or mainstem bronchus that have characteristics of RARs (i.e. exquisite sensitivity to tissue distention) [26,38]. Moreover, although the cough-evoking fibres in the guinea pig are myelinated A-fibres, they conduct action potentials relatively slowly, only at approximately 3–6 m/s compared with 15–20 m/s for guinea pig pulmonary stretch receptors (RARs and SARs) [27]. There are also intrinsic differences in the pharmacological properties between the cough-evoking extrapulmonary A-fibre mechanosensors and the intrapulmonary stretch receptors [27]. Rather than confusing the issue with subtypes of RARs, these fibres are perhaps better left diffusely characterized as extrapulmonary A-fibre mechanosensors. In the guinea pig, these cough-provoking fibres are not found within the epithelium, but rather are situated just beneath the basement membrane [39]. Extrapulmonary A-fibre mechanosensors appear to be limited to the larynx, trachea and large bronchi, and not appreciably found in the peripheral airways or lung parenchyma [27].

In contrast to the extrapulmonary A-fibre mechanosensors, activation of extrapulmonary or intrapulmonary C-fibres is relatively ineffective in evoking cough reflexes in anaesthetized animals. Bradykinin and capsaicin are potent C-fibre activators and evoke bursts of action potentials in tracheobronchial C-fibres, but rather than cough, this is followed by apnoeic reflexes and increases in parasympathetic tone [27]. In fact, the propensity of C-fibres in the extrapulmonary airways to evoke apnoeic reflexes may inhibit the cough reflex in the anaesthetized animals. In humans under light anaesthesia, applying water to the airway mucosa leads to cough, respiratory irregularity and apnoea [40]. As the anaesthesia is deepened, the cough reflex is blocked but the apnoeic response persists [40].

Based on data from experimental animals as well as clinical studies in humans, one can conclude that cough evoked by mechanical perturbation of the extrapulmonary airways of anaesthetized animals is brought about by a single class of mechanically sensitive vagal A-fibres. A study in conscious volunteers, where a nebulized solution of tartaric

acid pulsed onto the larynx triggered a cough (expiration) reflex within 20 ms of application also directly indicates A-fibre involvement [41]. Inasmuch as the cough evoked by activation of this fibre type can be obtained in deeply anaesthetized animals as well as in anaesthetized humans and comatose patients, this is unlikely to be a reflex that can be voluntarily controlled [42]. This type of immediate cough reflex likely underlies the vigorous cough response to aspiration and possibly to mechanical effects of mucus abutting the epithelium of large airways.

Conscious cough

A 'productive' cough is evoked upon aspiration or increased mucus secretions abutting mechanosensors. This cough is termed productive because it serves the purpose of removing the provocative substance from the airways. However, some airway pathologies are associated with so-called non-productive cough. In this case, afferent nerves are signalling urge to cough sensations, despite nothing in the airways to 'cough up'. Non-productive cough is a common experience. An irritating, itchy sensation in the throat builds up until relief by a cough is demanded. The temporary relief caused by the cough is only to be followed by the return of the building itch sensations and another cough, and so on. This type of cough often follows upper respiratory tract viral infections or other airway inflammatory conditions. In some patients these irritating sensations can occur chronically for extended periods of time. The resultant chronic coughing can have deleterious effects both physically and emotionally. The afferent neurophysiology of this type of cough is poorly understood, but it is intuitively obvious that this reflex is qualitatively different from the violent cough observed within milliseconds of aspiration. The evidence to date implicates activation of C-fibres as contributors to this type of cough.

Inhalation of C-fibre stimulants such as capsaicin and bradykinin evokes cough in most awake mammals including humans [43,44]. In human studies, intravenous injection of the nicotinic receptor agonist, lobeline (a C-fibre stimulant) leads to strong 'need to cough' sensations which are absent in lung transplant subjects [45]. With the assumption that lobeline, bradykinin and capsaicin are selective for activating C-fibres, these data indicate that bronchopulmonary vagal C-fibre activation can lead to urge to cough sensations in humans.

The location of C-fibres responsible for non-productive cough is difficult to address experimentally. Monitoring the respiratory deposition of particles released from different nebulizers revealed that prostaglandin E₂ (a C-fibre stimulant) was relatively ineffective in evoking cough when the particles were deposited primarily in the more peripheral airways [46]. By contrast, cough was effectively evoked

with larger particles that were deposited mainly in the more central airways. Lung transplant patients failed to cough with inhaled capsaicin, yet their upper trachea and larynx were innervated and cough could be evoked from these regions by direct stimulation with water [47,48]. These types of studies hint that the relevant C-fibres are those found primarily innervating the conducting airways (i.e. bronchial C-fibres).

CNS integration of primary afferent input and central sensitization

We have discussed the potential roles of A-fibres and C-fibres in initiating the cough reflex. It must be kept in mind, however, that the afferent fibres comprise a sensory nervous system. The bronchopulmonary afferent fibres are never acting alone, and their activity must be interpreted within the context of an integrated nervous system. The question as to the specific type of afferent nerve that alone can lead to cough may be less relevant than questions pertaining to the nature of the integrated input to the CNS that lead to cough.

The central terminals of primary vagal airway afferent nerves synapse with secondary neurons situated in the brainstem within the nucleus tractus solitarius (NTS) [49]. The RARs as well as low threshold extrapulmonary A-fibre mechanosensors use the excitatory amino acid glutamate as their central neurotransmitter. Pharmacologically blocking the glutamate receptors in the brainstem blocks cough and profoundly disrupts normal respiration [49,50]. Bronchopulmonary C-fibres use certain sensory neuropeptides such as neurokinins and calcitonin gene-related peptide (CGRP) as central transmitters. The synaptic input of one vagal fibre type may enhance or inhibit the input from another type. In the field of pain research, for example, much attention

has been given to the ability of nociceptive C-fibre input to enhance (sensitize) the input from fast-conducting mechanosensitive A-fibres [51]. One mechanism involved in the C-fibre-induced increase in synaptic transmission occurs as a result of neurokinins released from the central terminals of C-fibres. Neurokinins stimulate receptors on secondary neurons in the CNS leading to long-lasting increases in their neuronal excitability and a consequent increase in synaptic efficacy. This sensitizing process of converging inputs may involve many other distinct mechanisms, but regardless of mechanism, has been termed 'central sensitization'. It is likely that central sensitizing processes contribute to the excessive coughing in COPD patients.

Central sensitization has helped provide mechanistic insights into states of both hyperalgesia (states of a decreased threshold for pain), as well as allodynia. Allodynia is a pain syndrome where a normally painless stimulus (e.g. brushing your hair) becomes inappropriately painful. These conditions may provide useful analogies when it comes to understanding the hypertussiveness seen in many COPD patients. In some cases a subject may be simply more sensitive to a cough stimulus (i.e. a leftward shift in an inhaled capsaicin–cough response curve, Fig. 8.3), but in others an 'urge to cough' sensation may occur to a stimulus that is ordinarily not a cough stimulus, resulting in non-productive cough (by analogy 'an allotussive state'). Airway inflammation leads to accumulation of mediators that are known to be capable of activating bronchopulmonary C-fibres. One might speculate by analogy from the somatosensory research that this activation could lead to central sensitization of the constant synaptic input from pulmonary stretch receptors (e.g. certain RARs) resulting in a poorly defined irritating itch sensation.

By considering the processes of central sensitization, one is less inclined to conclude that cough associated with

Figure 8.3 Cumulative concentration–response curve for capsaicin inhalation-induced cough in subjects with COPD compared with healthy volunteers. The cumulative percentage of subjects who coughed is expressed as a function of capsaicin concentration. These data support the hypothesis that subjects with COPD have a heightened cough reflex sensitivity to the C-fibre stimulant capsaicin. (Modified from Doherty *et al.* [68].)

airway inflammation is specifically a C-fibre or A-fibre phenomenon, but rather an integrated process. Experimental studies support the hypothesis that different types of bronchopulmonary afferent nerves functionally converge in the NTS [52,52]. For example, the C-fibres from the larynx, which alone have little effect on airway parasympathetic tone, substantially enhance the parasympathetic drive that is increased secondary to pulmonary RAR activation [52]. In the studies of cough in anaesthetized animals, stimulation of bronchopulmonary C-fibres fails to evoke cough; however, their activation quite impressively decreases the amount of the extrapulmonary A-fibre input to the NTS required to evoke the cough reflex [54]. This occurs whether the C-fibre activation occurs in the trachea or within the lungs. Indeed, activation of C-fibres within the oesophagus can sensitize the extrapulmonary A-fibre mechanosensor initiated cough reflex via central sensitizing mechanisms (B.J. Canning, personal observation). Likewise, indirect studies support the hypothesis that SARs alone do not evoke cough, but may enhance the cough reflex [55]. The extensive integration of afferent inputs at the level of the CNS may contribute to the difficulty in precisely localizing the cough stimulus within the lungs. Kinasevitz *et al.* [56] used a fiberoptic bronchoscope to deliver a unilateral mechanical tussive stimulus. All subjects coughed, but most were unable to determine which side of the lungs the tussigenic stimulus was applied.

In addition to the secondary neurons in the NTS, the cough reflex involves many complex neural pathways within the CNS. These include premotor inspiratory and expiratory neurons in the medulla, and a group of neural pathways referred to as the cough-pattern generator system. An overview of the central neural pathways involved in this 'cough centre' can be found elsewhere [50,57]. Functionally, the cough pattern generator is made up of a network of the multifunctional respiratory-related neurons in the medulla oblongata. Cortical inhibitory inputs into the cough centre are also important as evidenced by the powerful effect of placebo in controlling certain types of cough [58]. These inputs have yet to be critically defined.

Motor pathways

Although many different types of stimuli, and afferent nerve types, may initiate cough reflexes, the final efferent pathway seems to be, for the most part, common to all cough. The efferent pathways of the cough reflexes are well defined and reviewed in more detail elsewhere [13]. These pathways include the motor neurons to the respiratory muscles originating in cervical spinal cord for the phrenic nerve and thoracic segment for other respiratory muscles and the motor neurons to larynx originating in the nucleus ambiguus.

Cough in the COPD patient

Triggers of the cough reflex in COPD

The two major types of stimuli that initiate cough reflexes are mechanical perturbations and stimuli that activate nociceptive-like C-fibres. It is likely that both mechanisms are involved in initiating the excessive coughing in COPD.

Low-threshold mechanosensor activation

Mechanical probing of mucosal surface of the larynx, trachea and large bronchi evokes cough. The nerve fibres involved are myelinated low-threshold mechanosensitive A-fibres. It is likely that mucus traversing along the large airways serves as a mechanical stimulus needed to activate this mechanosensor-evoked cough. The mechanosensors are also likely activated by aspiration of foreign substances in the airways. In addition, tracheal mechanosensors can be stimulated by rapid decreases in pH, but whether the changes in local concentrations of endogenous protons are sufficient to activate afferent nerves in the inflamed airway is unknown. Finally, pulmonary RARs are activated by cigarette smoke, an observation particularly relevant to COPD [24].

C-fibre activators

Unlike the low-threshold mechanosensors that have a rather limited activation profile, C-fibres in the lungs can be activated by many types of stimuli. For this reason they are referred to as 'polymodal' nerve fibres. The stimuli may even include mechanical distortion, which is normally ineffective in activating C-fibres, because the excitability of C-fibres at sites of inflammation can be enhanced enough to respond to physiologically relevant mechanical stretch.

Capsaicin, the active ingredient in hot peppers, is a chemical used to define nociceptive C-fibres. Nearly all bronchopulmonary C-fibres in experimental animals respond vigorously to capsaicin application. Capsaicin evokes a generator potential by binding to the vanilloid receptor TRPV1 (formerly VR1). The vanilloid receptor TRPV1 is not only gated by vanilloids such as capsaicin but, importantly, can also be activated by endogenous stimuli within the lungs. These stimuli include lipoxygenase products of arachidonic acid, anandamide and hydrogen ions (pH threshold ~5.0) [59]. Moreover, there is some indication that G-protein coupled receptors such as the bradykinin B₂ receptor may lead to TRPV1 activation via various second messenger systems [60,61].

Serotonin (5-HT) can activate C-fibres in the airways via interaction with 5-HT₃ receptors [62,63]. Extracellular ATP is an effective activator of many C-fibres, and this occurs through interaction with purinergic receptors of the

P2X subtype [64,65]. Both 5-HT₃ and P2X receptors, like TRPV1, are non-selective cation channels that depolarize the nerve terminals by allowing the influx of sodium and calcium across the nerve membrane.

Bronchopulmonary C-fibres are also stimulated by mediators that act on 7 transmembrane G-protein linked receptors. Examples here include certain prostanoids, bradykinin acting through the B₂ receptor, and adenosine acting through adenosine A receptors [16,35]. The mechanisms by which activation of the G-protein linked receptor is transduced into a depolarizing generator potential has not yet been elucidated.

Mechanisms of enhanced cough in COPD

Increases in afferent activators

In most patients with COPD, the amount of coughing falls well outside the normal range. This may simply be because of more primary afferent stimulators in the COPD lung than in the healthy lung. In the first instance, the increased mucus secretion may lead to mechanically evoked cough. The physical characteristics of the mucus, combined with weakened respiratory muscles, may decrease the effectiveness of cough, leading to increased bouts of coughing.

Changes in pulmonary vascular pressure as well as the altered mechanics of breathing in the COPD patient may contribute to excessive coughing. In experimental animals both SAR and RAR type pulmonary stretch receptors may contribute to central sensitization and increased coughing, especially in the presence of inflammation and C-fibre activation. The activity of RARs may be enhanced as a consequence of increases in pulmonary vascular pressure [23]. By breathing at higher lung volumes and higher rates, both RAR and SAR activity may be enhanced in COPD patients. In clinical studies, bronchodilators have been shown to reduce cough reflexes [66]. Thus, the decreased airway calibre in COPD may indirectly contribute to excessive coughing. One can envision certain positive feedback loops operating in COPD. For example, the increase in afferent activity coming from the lungs of the COPD patient may increase reflex parasympathetic tone, and consequently increase airway smooth-muscle contractions and mucus secretion that in turn could increase need to cough sensations.

Many airway mechanosensors are imbedded in the airway wall. The stress-strain properties of the tissue will influence the efficacy of mechanical transduction in the nerve terminal. It is possible that the remodelling of the airways seen in COPD may affect the efficacy of mechanical activation of some types of bronchopulmonary afferent nerve fibres. This could indirectly increase or decrease the cough sensation arising from the lungs of the COPD patient. It should be kept in mind that these issues are extremely

difficult to address experimentally, and thus remain mere speculation.

The C-fibres lining the airways of COPD patients are likely to contribute to the excessive coughing, especially during acute exacerbations of the disease. Various inflammatory mediators may be constantly evoking action potential discharge in bronchopulmonary C-fibres leading to increases in need to cough sensations. In addition, a decrease in the pH at the site of inflammation may also contribute to bronchopulmonary C-fibre activation [30,67].

Plasticity and enhanced afferent excitability

There is sound reason to suppose that part of the excessive coughing in COPD patients can be explained by the increased amount of primary afferent nerve activators that are present within the inflamed respiratory system. In addition to this, however, the afferent nerves may be *hyper-sensitive* to a given amount of stimuli. That is, the amount of afferent activation required to trigger cough (cough threshold) may be decreased. This can occur through changes in excitability and plasticity of the afferent nerves. This concept finds experimental support in clinical studies of cough evoked by inhalation of defined concentrations of tussigenic stimuli. Cough reflex sensitivity to both capsaicin and citric acid is increased in patients with COPD (see Fig. 8.3) [68,69]. This increase cannot be explained by the sensitizing effect of cigarette smoke in smokers with COPD because cough hypersensitivity has not been found in smokers with normal lung function [70].

Electrical excitability

An increase in electrical excitability of the afferent nerve membrane will increase the amplitude of the depolarizing receptor potential, or increase the ability of the depolarization to lead to regenerative action potentials (i.e. lower action potential threshold). In addition, changes in electrical excitability can alter the frequency of action potential discharge by modulating the relative refractory period of the nerve fibre. The manifold mechanisms underlying changes in electrical excitability involve changes in the function of various ion channels situated within the afferent nerve membrane [71].

Many inflammatory mediators can act on receptors through various second messengers to modulate ion channel function. Classic second messenger pathways such as cyclic AMP-dependent kinases, phospholipase C and activation of various isoforms of protein kinase C can all lead to phosphorylation of ion channels and consequent alterations in their function [51]. This often leads to an overall increase in excitability of the afferent nerve. This has been repeatedly observed in experimental animals where, for example, certain inflammatory mediators increase the excitability of high-threshold C-fibres to the extent that

they may become activated by the mechanical forces that occur during eupnoeic breathing [35]. The increase in electrical excitability of an afferent nerve is often non-selective in that it results in enhanced activation regardless of whether the stimulus is mechanical or chemical. There are more examples published on the increases by inflammatory mediators of electrical excitability seen among C-fibre afferents than A-fibre afferent nerves; nevertheless, the mechanical threshold of extrapulmonary A-fibre mechanosensors in the guinea pig trachea (those that directly lead to cough) can be substantially reduced in the presence of allergic inflammation [72]. Many inflammatory mediators acting in concert may participate in increasing afferent nerve excitability [73]. Clinical pharmacological studies have suggested that inhibition of thromboxanes or cysteinyl leukotriene receptors can inhibit increased cough sensitivity in some subjects [74]. However, because multiple inflammatory mediators are increased in the airways of patients with chronic cough, it is unlikely that inhibition of a single mediator would normalize cough sensitivity in all COPD patients [75].

Afferent nerve plasticity

The changes in electrical excitability caused by inflammatory mediators and various second messenger systems are often short-lived, lasting only as long as the presence of the causative agent. In chronic disease, there may be more persistent 'plastic' changes that occur in the nervous system [76]. There is much attention given to the role of airway wall remodelling in the pathophysiology of airways inflammatory disease. In the same way, the nervous system within the airways may be qualitatively 'remodelled'. In this case, chemical and mechanical interactions within the bronchopulmonary nerve endings are transduced into changes in gene expression within the cell nucleus situated in the distant vagal ganglia. This can lead to changes in the afferent nerve sprouting and density, as well as to changes in the expression of neurotransmitters, receptors, ion channels and other molecules.

There have been no published studies that have rigorously addressed the hypothesis that increased afferent nerve density is related to increased cough specifically in COPD. However, studies have been carried out that have quantified nerve density in subjects with chronic cough. In one study bronchial biopsies were obtained from subjects with idiopathic persistent non-productive cough and from healthy volunteers [77]. The subjects with persistent coughing were more sensitive to inhaled capsaicin than control subjects. The overall density of nerves in the bronchial epithelium was similar between the two groups. However, there were more neuropeptide (CGRP) containing nerves in the coughing subjects compared with controls. In another study bronchial biopsies were obtained from healthy volunteers, typical asthmatic patients, and subjects

with cough variant asthma [78]. Nerve densities were not assessed, but again significantly more neuropeptide (substance P) containing nerves were noted in the epithelium of the cough variant asthma subjects than in either of the two other groups. These types of studies focus on the epithelial nerve plexus, and thus likely pertain only to the C-fibre population of nerves. A change in nerve density of the low-threshold A-fibres would be also relevant, if found in the cough region of the respiratory tract. These fibres are likely found beneath the mucosa.

The studies that evaluated nerves in the epithelium of subjects with persistent cough noted changes in the amount of neuropeptides within airway nerves, without a change in nerve density per se. Inflammation in the upper or lower airways of animal models has been noted to increase the expression of neuropeptide synthesizing genes (e.g. preprotachykinin A) in vagal sensory neurons [79–82]. The increased amount of neuropeptides in the central terminals of bronchopulmonary afferent nerves can lead to central sensitization by increasing synaptic efficacy in the brainstem and consequently increasing cough reflexes [49]. The question arises as to how inflammation in the lungs can lead to changes in gene expression in the nerve cell bodies situated in the distant sensory ganglia? The neurotrophins, exemplified by nerve growth factor (NGF), are a family of molecules adept at regulating neural gene expression by interactions with specific neurotrophin receptors located at the distant nerve terminals [83]. In this light it is worth noting that several neurotrophins including NGF are increased in the lungs during inflammatory airways disease [84,85].

A chronic change in the quantity and quality of afferent input into the CNS may also lead to plastic changes within the brainstem. This has been noted in the somatosensory system where inflammation can lead to long-lasting changes in spinal cord neurophysiology [86]. Consistent with this idea, persistent airway inflammation evoked by ozone inhalation in infant primates caused neuroplastic changes in the synaptic physiology within the nucleus of the solitary tract [87].

Treatment of cough in COPD

Therapeutic strategies aimed at inhibiting excessive coughing in COPD are generally based on the premise that cough is the natural consequence of the underlying inflammation and airway obstruction. Treatment of cough is thus appropriately integrated within the treatment of the inflammation and obstruction. While it is true that the coughing will decrease with overall improvement of the disease, in some cases it may be informative to consider the pathophysiology of cough per se as part of the pathophysiological process in the COPD. If the neurophysiology of the cough reflex is deranged by the chronic inflammatory condition such that

the cough is persistent and non-productive, it would be useful to have selective antitussive therapies available that target the hypersensitive component of the cough reflex. Regrettably, such therapies are not yet available [88].

The antitussive drugs currently available for use in the clinic have not changed appreciably over the past couple of decades [88]. Codeine is perhaps the most effective antitussive agent available, although its utility is limited by the bothersome and sometimes serious unintended consequences of central opiate action. Codeine inhibits cough mainly through interaction with μ -opioid receptors in the CNS [89]. Both δ - and κ -opioid receptor agonists are also effective in inhibiting cough in experimental animals [89]. Dextromethorphan is the most commonly used antitussive drug in use today, and is thought to work either through activation of subsets of central glutamate receptors, or opiate-like σ -receptors [89]. Dextromethorphan has fewer side-effects than codeine, but is also less efficacious in inhibiting cough than codeine and related opioids. In addition to these antitussive compounds, mucolytic agents have been used with variable success in the treatment of chronic cough.

The availability of novel effective antitussive treatments is limited, but not for lack of interest by the pharmaceutical industry. Within the pharmaceutical 'pipeline' are many interesting compounds aimed at strategically decreasing the afferent nerve excitability and cough hypersensitivity that accompany various airway inflammatory diseases. As promising as some of these compounds appear in pre-clinical studies, the propensity for novel therapies to be shipwrecked on the shoals of evidence-based medicine makes a discussion of their potential use in cough therapy premature and unproductive. Suffice it to say, it is hoped that this section on cough therapy in COPD will be first in the present textbook to be outdated.

Conclusions

In summary, cough is a complex reflex that is initiated by activation of primary vagal afferent nerves within the respiratory tract. Both low-threshold mechanosensitive A-fibres and nociceptive-like C-fibres can contribute to the initiation of cough reflexes. A consideration of the convergence of these types of afferent inputs within the CNS may help explain the cough in excess of functional demand that is commonly associated with COPD and other airways inflammatory diseases.

When the coughing becomes non-relenting and non-productive, it can have a deleterious effect on quality of life, and potentially the health of the individual. Coughing in patients with COPD occurs because at any given time they are more apt to have excessive mechanical and chemical tussigenic stimuli within their respiratory systems. In

addition, the indirect evidence indicates that many subjects with COPD suffer from an increased sensitivity to a given amount of a tussive stimulus. Although difficult to prove experimentally, evidence from various animal models indicate that an increase in cough sensitivity likely stems from increases in electrical excitability of the sensory nerve terminals, plastic changes in the cough reflex afferent pathways, and sensitizing events occurring at synapses within the CNS. These effects are likely a consequence of certain aspects of the inflammatory processes occurring in the lungs, but relatively little is yet known about the specific mechanisms involved.

CHAPTER 9

The physiology of gas exchange

**Robert Rodriguez-Roisin, Andrés Echazarreta, Federico P. Gómez
and Joan Albert Barberà**

The major goal of the respiratory system is to exchange physiological (respiratory) blood gases, namely oxygen (O_2) and carbon dioxide (CO_2), to cope with the metabolic needs of the body. To exchange these two respiratory gases adequately, alveolar ventilation and pulmonary blood flow must be properly balanced and matched within the lung, such that alveolar ventilation to pulmonary blood flow (\dot{V}_a/\dot{Q}) mismatching emerges as the most influential mechanism determining abnormal arterial blood gases in chronic obstructive pulmonary disease (COPD), both in stable and acute (exacerbation) conditions. In contrast, the role of the other two intrapulmonary determinants of physiological respiratory gases (alveolar to end-capillary diffusion impairment to oxygen and increased intrapulmonary shunt) (i.e. zero \dot{V}_a/\dot{Q} ratios), are almost negligible. Indeed, there is no diffusion limitation to oxygen in COPD and intrapulmonary shunt is only present marginally during exacerbations, even in the most life-threatening critical conditions. By contrast, the influence of the major extrapulmonary factors modulating respiratory gases, namely the inspired fraction of oxygen, overall ventilation, cardiac output and oxygen consumption (uptake), are the major determinants during exacerbations [1]. The inspired fraction of oxygen in particular has a major influence on the value of P_{aO_2} , cardiac output and oxygen consumption interact mutually via the arterial–mixed venous oxygen content difference (i.e. Fick principle), and overall ventilation governs CO_2 by means of the alveolar gas equation for carbon dioxide.

The two most characteristic pathological features of COPD, obstructive airway changes and pulmonary emphysema, in addition to varying degrees of pulmonary vascular structural abnormalities, in particular vascular wall remodelling, contribute to the development of \dot{V}_a/\dot{Q} mismatching even in the earliest stages of the disease. Alveolar hypoventilation also contributes to the development of hypercapnia in these patients [2,3].

This chapter reviews the physiological frontiers of pulmonary gas exchange abnormalities in COPD, mainly through the research carried out over the last 25 years with the multiple inert gas exchange technique (MIGET). This approach, originally designed by Wagner *et al.* [4,5], extended and complemented the relatively simple tools conventionally devoted in respiratory medicine to the assessment of the \dot{V}_a/\dot{Q} relationship, becoming central to understanding the complexity of the interplay between and within the intrapulmonary and extrapulmonary determinants of pulmonary gas exchange in acute and chronic pulmonary diseases. Moreover, the extent of \dot{V}_a/\dot{Q} inequalities detected by MIGET is better than that derived from topographical measurements with radioactive particles using scans and computed tomograms, or positron emission tomography (PET). This is especially true when used in patients with COPD [6], as imaging techniques underestimate the intraregional \dot{V}_a/\dot{Q} abnormalities and have limited spatial resolution.

Gas exchange approach

The advantages and limitations of MIGET have been extensively addressed over recent years and will not be discussed here [4,7,8]. Complete technical details of MIGET have been reported at length elsewhere [1–4,8,9] and will only be briefly explained here. The arterial, mixed venous and mixed expired concentrations of six infused inert gases, determined by gas chromatography, are used to calculate the ratio of arterial to mixed venous pressures (retention) and the ratio of mixed expired or alveolar to mixed venous pressure (excretion). Retention and excretion are then used to compute multicompartmental \dot{V}_a/\dot{Q} distributions. The six gases used include a wide variety of solubilities, from the more insoluble gas (sulphur hexafluoride) to the most soluble (acetone) through those

Figure 9.1 Representative ventilation–perfusion distributions, using the multiple inert gas methodology, in a healthy individual (see text for further explanation).

of intermediate solubility (ethane, cyclopropane, enflurane or halothane and ether). The use of these inert gases overcomes the common limitations derived from a non-linear dissociation curve on gas exchange observed for respiratory gases. Moreover, the large range of solubilities facilitates a better assessment of \dot{V}_a/\dot{Q} relationships as it is known that the gas exchange in the presence of \dot{V}_a/\dot{Q} abnormalities, is a function of its solubility [8–10]. Figure 9.1 illustrates a classic distribution of \dot{V}_a/\dot{Q} ratios in a young healthy non-smoker at rest, in a semi-recumbent position, breathing room air. The sum (distributions) of alveolar ventilation and of pulmonary perfusion (ordinate) is plotted against a broad range of 50 \dot{V}_a/\dot{Q} (from 0 to infinity) on a logarithmic scale (abscissa). Each data point indicates a specific amount of alveolar ventilation or pulmonary blood flow while the lines have been drawn to facilitate visual interpretation. Total blood flow or total alveolar ventilation corresponds to the sum of all data points for their respective distributions.

The use of logarithmic rather than linear axis of \dot{V}_a/\dot{Q} ratios is based on conventional practice in the field of pulmonary gas exchange. A logarithmic normal distribution of ventilation and blood flow is one of the simplest distributions and allows the spread to be defined by a simple variable that is the standard deviation (SD) on a logarithmic scale. Both distributions are unimodal with three major common findings: symmetry, location around an ‘ideal’ mean \dot{V}_a/\dot{Q} ratio of 1.0, and a narrow dispersion (between 0.1 and 10.0). Therefore, in young healthy individuals

there is no blood flow spread left to a zone of low \dot{V}_a/\dot{Q} ratios (poorly ventilated lung units) nor ventilation distributed to the right to a zone of high \dot{V}_a/\dot{Q} ratios (incompletely perfused, but still finite, lung units). Intrapulmonary shunt (detected by MIGET) is identified as areas with zero \dot{V}_a/\dot{Q} (in practice < 0.005) ratio (0% of cardiac output). The normal value of inert physiological dead space with infinite (in practice > 100) \dot{V}_a/\dot{Q} ratio (approximately 30% of alveolar ventilation) is also less than that computed with the traditional Bohr equation, because the inert gas approach represents only the dead space-like effects of those alveoli whose \dot{V}_a/\dot{Q} ratios are > 100 . The second moment (or dispersion) of each distribution (log SD) is the common way to assess the degree of \dot{V}_a/\dot{Q} disturbances and corresponds precisely to the square root of the pulmonary blood flow (log $SD\dot{Q}$) and that of alveolar ventilation (log $SD\dot{V}$) distributions, reflecting the variance (standard deviation) of \dot{V}_a/\dot{Q} ratios about the mean. In an ideal, perfectly homogeneous lung, both log $SD\dot{Q}$ and log $SD\dot{V}$ should be zero; in practice, in a normal healthy individual they are in the range 0.30–0.60 in young individuals and 0.70–0.75 in older people [10]. West [11] demonstrated that log $SD\dot{Q}$ or log $SD\dot{V}$ values of 1.0 and 1.5 entail moderate and severe degrees of \dot{V}_a/\dot{Q} mismatch, respectively. The degree of \dot{V}_a/\dot{Q} inequality can also be expressed as the total percentage of ventilation–perfusion in distinct regions of the \dot{V}_a/\dot{Q} range, such that the percentage of blood flow distributed in areas of \dot{V}_a/\dot{Q} ratios < 0.1 and > 0.005 and, consequently, excluding intrapulmonary shunt, is conventionally named ‘low \dot{V}_a/\dot{Q} mode’ while the amount of ventilation diverted to the region of \dot{V}_a/\dot{Q} ratios located between 10.0 and 100 (and, therefore, excluding dead space) is viewed as a ‘high \dot{V}_a/\dot{Q} mode’ [1,8]. Arterial–alveolar difference averaged for the whole range of inert gases also can be calculated and employed to give indirect estimates of the level of \dot{V}_a/\dot{Q} abnormalities, such as an overall index of \dot{V}_a/\dot{Q} heterogeneity (DISP R-E*), which includes all inert gas retention and excretion differences except the excretion of acetone [12].

In summary, using MIGET, \dot{V}_a/\dot{Q} imbalance has been shown to explain the measured P_{aO_2} and P_{aCO_2} comprehensively through the influence of the intrapulmonary factors of pulmonary gas exchange while unravelling the hierarchy with the vital extrapulmonary determinants in respiratory medicine [12].

Stable conditions

Types and severities of \dot{V}_a/\dot{Q} imbalance found in patients with COPD differ between patients and change with time in accordance with the natural history of the disease and the clinical state of the individual patient.

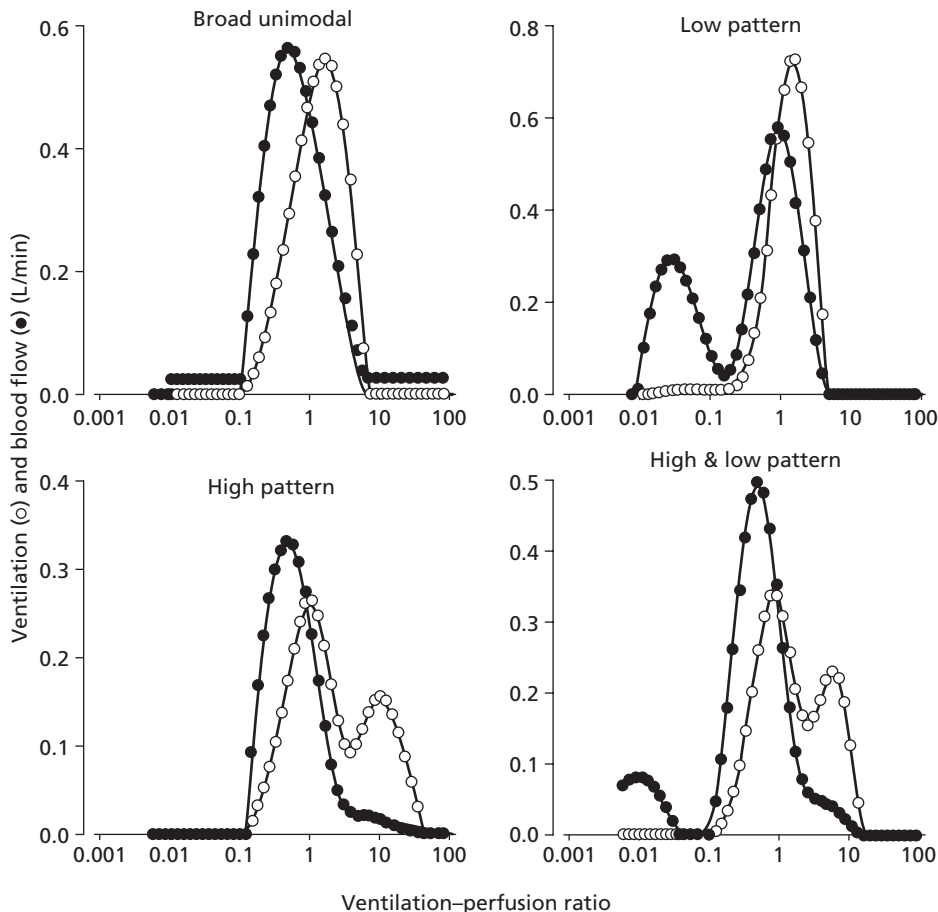

Figure 9.2 Typical profiles of ventilation–perfusion inequality shown in patients with stable COPD.

Severe stages

In the late 1970s, stable patients with advanced COPD (forced expiratory pressure in 1 s, $FEV_1 < 60\%$ predicted; GOLD stage II) with mild to severe hypoxaemia and hypercapnia representing the two classic clinical phenotypes (types A and B) were studied [13]. In these patients, distributions of \dot{V}_a/\dot{Q} ratios were extremely abnormal, and exhibited three different \dot{V}_a/\dot{Q} patterns (Fig. 9.2). The first \dot{V}_a/\dot{Q} profile showed the presence of lung units with very high \dot{V}_a/\dot{Q} ratios or a ‘high \dot{V}_a/\dot{Q} mode’ (type H), a pattern in which most of the ventilation was diverted to the zone of higher \dot{V}_a/\dot{Q} ratios. The second pattern was characterized by a large proportion of blood flow perfusing alveolar units with low \dot{V}_a/\dot{Q} ratio, named ‘low \dot{V}_a/\dot{Q} mode’ (type L). The third pattern was a mixed ‘high/low \dot{V}_a/\dot{Q} mode’ (type H-L), including additional modes above and below the main \dot{V}_a/\dot{Q} distribution. In general, the distributions of blood flow or ventilation, or both, showed moderate to severe increases. These findings suggested that type A COPD patients were more likely to have high \dot{V}_a/\dot{Q} areas and were unlikely to have low \dot{V}_a/\dot{Q} areas, unless they also had clinical evidence of type B COPD. The belief was that

the type H of the \dot{V}_a/\dot{Q} profile was caused by constant ventilation of zones with reduced blood flow, possibly corresponding to emphysematous areas with alveolar wall destruction and pulmonary capillary network loss. In contrast, COPD patients of the type B subset usually had distinct either low or high \dot{V}_a/\dot{Q} areas, or both, even though there was more variability within this patient population. Accordingly, the investigators suggested that type L likely reflected airways occluded by inspissated mucus secretions and luminal plugging, smooth muscle hypertrophy, wall oedema, bronchospasm, distortion, or some mixture of these abnormalities. The lack of increased intrapulmonary shunt was ascribed to the vigorous efficiency of both collateral ventilation and hypoxic pulmonary vasoconstriction such that airways obstruction was never complete, and the coexistence of mild to moderate increased dead space were two conspicuous complementary \dot{V}_a/\dot{Q} features.

Several studies [14–29] including more than 100 patients with stable severe or very severe airflow obstruction (mean FEV_1 approximately 36% predicted; GOLD stages III–IV), many of them hypoxaemic, with or without chronic hypercapnia, have reported abnormal \dot{V}_a/\dot{Q} patterns similar to those documented in the study above [13]. However, the

association shown with the clinical COPD types could not be established as clearly. Similarly, the levels of blood flow or ventilation diverted to regions with low or high \dot{V}_a/\dot{Q} ratios, respectively, were modest (range $\leq 10\%$ of cardiac output) in almost all the reports.

Of note is the potential modulation of an increased CO_2 output on Paco_2 and its relationship with nutritional status, a clinical phenotype in COPD with poor prognosis [30]. Under physiological conditions, the amount of CO_2 produced per unit of time is a function of the metabolic rate and the substrate used for fuel. In healthy individuals, the absorption and metabolism of carbohydrate induces an increase in CO_2 production (up to 70–100% of the oxygen uptake) because the entire body fuel utilization is transformed from predominantly fat to essentially carbohydrate in addition to the thermogenic effects of food. Malnutrition, currently considered to be one of the most characteristic features of systemic involvement in COPD patients, has been associated with poor prognosis and contributes to complications and increased mortality [30]. Other non-pulmonary (systemic) complications, including increased resting and total energy expenditure, systemic inflammatory response, cardiovascular involvement, cachexia and anorexia, have been proposed to explain malnutrition in COPD. Body weight and body composition are important in assessment of COPD patients, because loss of fat-free mass is not limited to underweight COPD patients, but also occurs in some 'normal weight' COPD patients [31]. Nutritional support has been recommended to improve clinical state and/or exercise capacity in stable COPD. However, it often fails, especially in those patients with a considerable systemic involvement. The potential pulmonary functional implications of nutritional regimens with high percentage of fat in hospitalized COPD patients are uncertain. Total caloric intake is probably a more important determinant of the magnitude of added CO_2 production than the single proportion of carbohydrate [32].

Mild to moderate stages

Over 24 patients with mild COPD (mean FEV_1 approximately 75% predicted) have been studied (see below) [17]. In general, the distribution of ventilation and blood flow were mildly abnormal ($\log \text{SDQ} < 1.0$ each), although intrapulmonary shunt was absent and dead space was within the normal range. Blood flow distributions were mostly unimodal in two-thirds of patients and discretely bimodal in the remaining one-third. By contrast, the ventilation distribution patterns were never bimodal, with no regions of high \dot{V}_a/\dot{Q} ratios.

There is only one preliminary study in patients with small airways disease [33]. A few patients (GOLD stage 0) with functional criteria compatible with small airways

disease ($FEV_1 > 80\%$ predicted with abnormal maximal expiratory flow rates and single breath nitrogen test) were compared with healthy individuals with normal lung function and also with COPD patients with $FEV_1 < 80\%$ predicted. Patients with small airways disease had normal Pao_2 and showed a mild but significant increase in the alveolar–arterial Po_2 difference with little \dot{V}_a/\dot{Q} mismatch, as expressed by small increases in the dispersions of both blood flow and ventilation, compared with controls. Yet, there were no differences in these functional outcomes between these patients with mild airways dysfunction and those with early COPD and established airflow obstruction. The contention was that functional abnormalities in peripheral small airways can induce maldistribution of ventilation and \dot{V}_a/\dot{Q} mismatching in the face of a normal Pao_2 .

A retrospective analysis of almost 90 patients in a stable condition studied at our centre, including all clinical phenotypes of COPD, showed four different patterns of \dot{V}_a/\dot{Q} distribution [34]: a broad unimodal distributions of both blood flow and ventilation (45% of the patients); a bimodal blood flow distribution, with both normal and low \dot{V}_a/\dot{Q} areas (type L) (23% of patients); a bimodal distribution of ventilation, with normal and high \dot{V}_a/\dot{Q} areas (type H) (18% of patients); and both bimodal blood flow and ventilation distribution patterns (type H-L) (14% of patients). This wide variety of patterns of \dot{V}_a/\dot{Q} distributions is interpreted as a reflection of the heterogeneity of the underlying pulmonary pathological derangement and the efficiency of compensatory mechanisms, essentially collateral ventilation and hypoxic vasoconstriction. Although the correlations between the abnormalities in the two most representative descriptors of \dot{V}_a/\dot{Q} inequality in stable COPD ($\log \text{SDQ}$ and $\log \text{SDV}$) and the degree of abnormal FEV_1 are present, the levels of significance are usually modest [2].

Exacerbations

Exacerbations of COPD provoke further \dot{V}_a/\dot{Q} imbalance, which can improve significantly after 4–6 weeks of an effective and appropriate treatment [35], indicating that an important component of the \dot{V}_a/\dot{Q} mismatching under these critical conditions is a result of partially reversible airway narrowing, such as mucus impaction, bronchial wall oedema, bronchoconstriction, lung hyperinflation and air trapping. Different studies have shown more severe, but qualitatively similar, patterns of \dot{V}_a/\dot{Q} imbalance in COPD patients needing mechanical ventilation than in those breathing spontaneously (Fig. 9.3) [35–38]. By contrast, the presence of an increased intrapulmonary shunt (4–10% of cardiac output), more evident in the more life-threatening conditions, indicates that some airways are completely occluded by inspissated secretions. It is

Figure 9.3 Most common patterns of ventilation/perfusion mismatching observed in patients with COPD during exacerbations.

plausible, however, that the efficiency of collateral ventilation and that of hypoxic vasoconstriction along with the influence of breathing hyperoxic mixtures on critical inspired \dot{V}_a/\dot{Q} ratios interact together, contributing to this disrupted gas exchange state.

It has been shown that, in COPD patients during exacerbations while breathing spontaneously, the main determinants of hypoxaemia are the levels of \dot{V}_a/\dot{Q} mismatching (approximately 50%), increased oxygen consumption (approximately 25%), likely related to an increased work of breathing, an overuse of short-acting β -agonists, and an amplifying deleterious effect of a decreased mixed venous P_{O_2} on \dot{V}_a/\dot{Q} imbalance (approximately 25%), not sufficiently offset by the simultaneous increased cardiac output. Interestingly, the role of overall ventilation was negligible. During COPD exacerbations, the extrapulmonary factors in addition to \dot{V}_a/\dot{Q} imbalance are modulating the endpoint of pulmonary gas exchange state [35], unlike in stable COPD patients. Similarly, in COPD patients requiring mechanical ventilatory support, either invasively [36,37] or non-invasively [38], the principal determinants of gas exchange in conjunction with \dot{V}_a/\dot{Q} inequality (cardiac output, overall ventilation and oxygen uptake) also have a vital role.

Non-invasive ventilation

This is particularly evident while using non-invasive ventilation in which the detrimental effects of a rapid and shallow breathing on P_{aCO_2} and acid–base status are replaced by a more physiological pattern, such that both CO_2 and pH decrease while P_{aO_2} increases (Fig. 9.4a) [35]. Interestingly, the simultaneous decrease in cardiac output, induced by the increased intrathoracic pressure, is not sufficient to limit the significant improvement of P_{aO_2} . It is also of note that,

during the application of non-invasive ventilation, \dot{V}_a/\dot{Q} imbalance remains essentially unchanged. This highlights the key influence of extrapulmonary factors, essentially represented by the efficiency of the ventilatory pattern, while the role of cardiac output is here less relevant (Fig. 9.4b).

Recently, the combined use of long-term oxygen therapy and nocturnal non-invasive mechanical ventilation in advanced COPD patients with hypercapnic respiratory failure for a period of 6 months improved both hypoxaemia and hypercapnia [39]. Moreover, the descriptors of \dot{V}_a/\dot{Q} mismatch improved remarkably towards normal. The relevance of this preliminary data is unique in that it is highly likely that \dot{V}_a/\dot{Q} abnormalities ameliorated because of an efficacious structural–functional remodelling in the airways and the pulmonary vessels under some special controlled circumstances of both nocturnal long-term oxygen therapy and non-invasive ventilation. However, this noticeable \dot{V}_a/\dot{Q} improvement in this trial in a few patients with stable advanced hypercapnic COPD remains intriguing, raising several hypotheses.

Invasive ventilation

During conventional ventilation, the abnormal \dot{V}_a/\dot{Q} patterns do not differ from those shown while breathing spontaneously and therefore do not share any special features, even in the face of the current diversity of ventilatory modalities [40]. This clinical scenario needs to be differentiated, however, from that of non-invasive ventilation, more specifically during weaning where \dot{V}_a/\dot{Q} patterns are not normal [37]. When mechanical support is discontinued, the abrupt increase in venous return because of the reduction in intrathoracic pressure provokes a significant increase in cardiac output without changes in total ventilation, although both the reduction in tidal volume and the

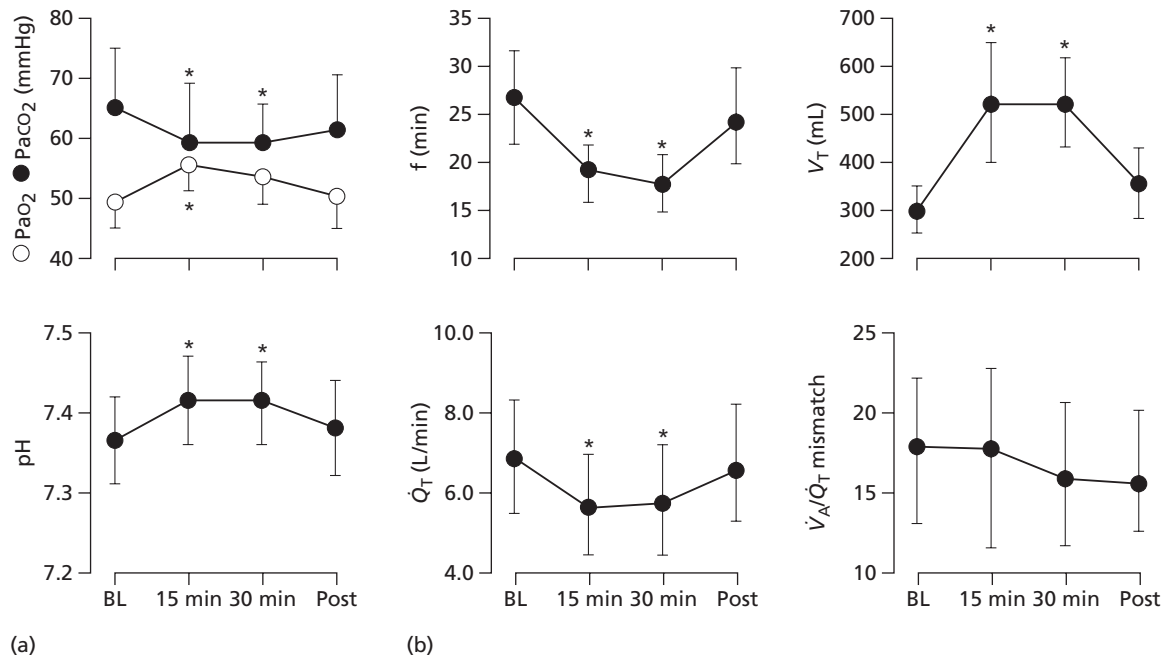

Figure 9.4 (a) Changes in P_{aO_2} , P_{aCO_2} and pH before, during a 30-min period, and then 30 min after the application of non-invasive ventilation in patients with COPD exacerbations. (b) Changes in the ventilatory pattern (top) and in cardiac output and an overall index of ventilation/perfusion heterogeneity (bottom) following the same time-course and identical non-invasive ventilatory support.

increase in respiratory frequency become less efficient. As a result, both the dispersion of alveolar ventilation and the overall \dot{V}_A/\dot{Q} heterogeneity increase, resulting in more \dot{V}_A/\dot{Q} inequalities (Fig. 9.5).

An intriguing finding was that there was only a small increase in intrapulmonary shunt from mechanical ventilation to spontaneous breathing, despite the substantial increases in cardiac output and mixed venous P_{O_2} . This was at variance with the poorly understood, strong linear relationship between increase in pulmonary blood flow and shunt fraction commonly observed in patients with acute lung injury [41]. The use of inert gas and radionuclide data showed that the critical alteration in ventilation during ventilator weaning resulted in the development of very low \dot{V}_A/\dot{Q} ratios in the basal lung regions [42]. Another striking observation during weaning was that respiratory blood gases were unchanged despite increases in mixed venous P_{O_2} and oxygen delivery. In other words, the potentially beneficial effect of the increased cardiac output on P_{aO_2} , through its positive impact on mixed venous P_{O_2} , was offset by the detrimental influence of the change in ventilatory pattern on P_{aO_2} . Despite these problems, weaning in these patients was successful. When patients were removed from the ventilator in this study, oxygen consumption did not change. Other investigators [43] have also stressed the role of cardiac output variations and other haemodynamic changes together with an increase in oxygen uptake as cause of

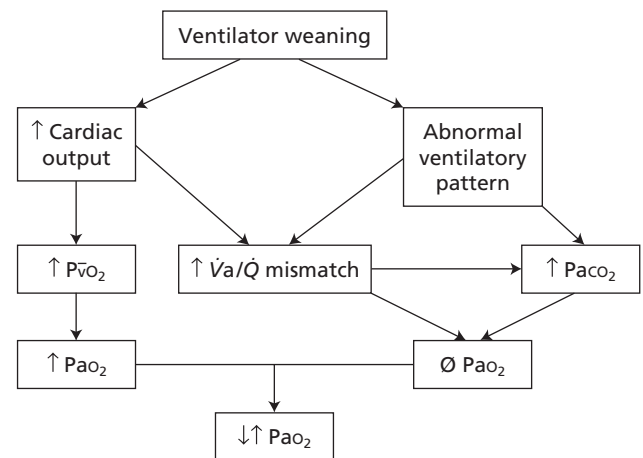

Figure 9.5 Interplay between increased cardiac output and deteriorated ventilatory pattern (extrapulmonary factors) and further ventilation-perfusion imbalance (intrapulmonary factor) during weaning in a COPD patient after 7 days of conventional invasive ventilation. The endpoint P_{aO_2} remains unchanged. ($P\bar{v}O_2$, mixed venous P_{O_2} .)

unsuccessful weaning. In patients with severe COPD with coexisting myocardial infarction and left ventricular dysfunction, oxygen consumption usually increases during weaning, which would tend to induce a decrease in P_{aO_2} .

We have also investigated the effects of positive end-expiratory pressure (PEEP) and those of intrinsic (auto) PEEP (PEEPi) on \dot{V}_a/\dot{Q} mismatching in mechanically ventilated COPD patients, with the contention that a low PEEP can improve rather than impair lung mechanics as PEEP can replace PEEPi [37]. It was shown that PEEP levels approximately 50% of the initial PEEPi improved the gas exchange state without affecting lung mechanics or haemodynamics adversely. Furthermore, the application of 'controlled hypoventilation' along with low PEEPi levels considerably reduced intrathoracic pressure, while increasing cardiac output and systemic oxygen delivery, a practice that could be recommended during exacerbations.

Taken together, these findings indicate that arterial hypoxaemia and hypercapnia during exacerbations are the integrative endpoint of \dot{V}_a/\dot{Q} abnormalities in conjunction with the active interplay of extrapulmonary indices of gas exchange, namely overall ventilation, cardiac output and oxygen uptake.

Bronchodilators

Both short-acting and long-acting β_2 -agonists are mainstays in the therapeutic strategy of COPD [44]. Yet, it is conventionally known that they may induce a decrease in arterial oxygenation, generally rapidly offset by short-term oxygen therapy. Moreover, these mild to moderate deleterious oxygenation defects, of the order of 5 mmHg in most of the studies, are well tolerated.

Intravenous terbutaline in patients with advanced COPD and mild chronic respiratory failure increased cardiac output [26], mixed venous P_{O_2} and oxygen delivery, while P_{aO_2} , systemic blood pressure and pulmonary vascular resistance decreased in the face of an improved FEV_1 . In parallel, there was further \dot{V}_a/\dot{Q} worsening (the perfusion to regions of low \dot{V}_a/\dot{Q} units increased) and this was not counterbalanced by hyperventilation and/or the potential of an active reduction in pulmonary vascular tone (Fig. 9.6). In contrast, in most severe COPD, with more airflow obstruction, hypoxaemia, hypercapnia and more pronounced pulmonary hypertension, cardiac output increased without pulmonary vascular changes. Furthermore, ventilation increased modestly but without improving airflow limitation; however, P_{aO_2} and the underlying \dot{V}_a/\dot{Q} mismatching remained stable. Gas exchange state during agent administration was not disturbed in these patients, conceivably because hypoxic pulmonary vasoconstriction was less active or even absent because of more intense structural pulmonary vascular remodelling. This would be in keeping with the concept that the progressive increase of pulmonary vascular resistance seen in advanced COPD is not only caused by irreversible structural vascular

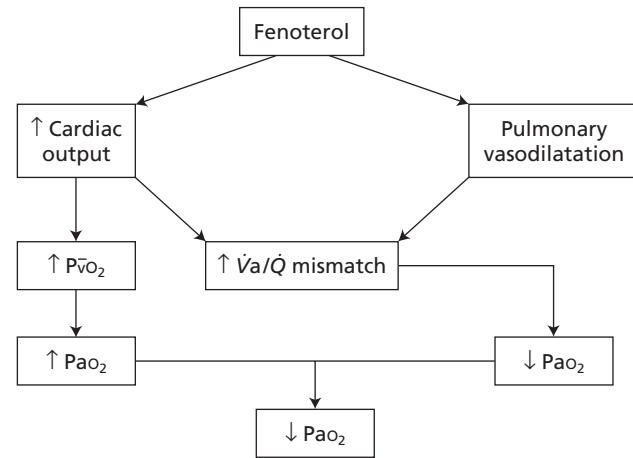

Figure 9.6 Interaction between increased cardiac output and further pulmonary vasodilation (extrapulmonary factor) and ventilation–perfusion deterioration (intrapulmonary factor) during the infusion of terbutaline in stable advanced COPD with reactive pulmonary vasculature. The endpoint P_{aO_2} ultimately decreased. (P_{vO_2} , mixed venous P_{O_2} .)

lesions, but also by a reversible component [45]. In more severe advanced COPD, the pulmonary vascular tone seems to be more altered, more rigid and fixed, and therefore less liable to be dilated by selective β -agonists.

The short-term effect on gas exchange of nebulized fenoterol, a non-selective short-acting bronchodilator [29], in stable COPD patients demonstrated only a slight reduction in P_{aO_2} caused by further \dot{V}_a/\dot{Q} deterioration. After ipratropium, gas exchange was unaltered, hence indicating that the pulmonary vascular tone was disturbed following inhaled fenoterol resulting in further \dot{V}_a/\dot{Q} imbalance. The impact of intravenous aminophylline on \dot{V}_a/\dot{Q} mismatching has been also assessed in COPD patients recovering from a severe exacerbation [15]. Aminophylline improved spirometry but did not adversely affect arterial blood gases or the underlying \dot{V}_a/\dot{Q} disturbances. Although therapeutic doses of aminophylline can increase \dot{V}_a/\dot{Q} mismatching in some patients, the overall effect is in general modest and of little clinical significance in patients with advanced COPD. No inert gas studies are available using long-acting β -agonist and anticholinergic bronchodilators. A preliminary analysis of an ongoing study in COPD during the first days of hospitalization for exacerbations in our centre highlights no deterioration of \dot{V}_a/\dot{Q} imbalance in the face of a simultaneous moderate increased cardiac output (approximately 15%), with marginal changes in the other extrapulmonary factors governing gas exchange. In contrast, when these patients become stable, \dot{V}_a/\dot{Q} mismatching further deteriorated and P_{aO_2} significantly decreased, suggesting active release of hypoxic pulmonary vasoconstriction.

Structure and gas exchange

COPD encompasses an abnormal inflammatory response of the lungs that involves alveolar spaces (emphysema), small and large airways (bronchiolitis) and pulmonary vessels (remodelling) [44]. This widespread structural derangement will ultimately result in alveolar ventilation to pulmonary blood flow imbalance, particularly in severe and very severe stages of the disease. A recent study in a cohort of more than 600 COPD patients, 37% with severe to very severe disease, showed that 61% died from respiratory failure [46].

Alveoli

The influence of pulmonary emphysema and small airway disarrangement on \dot{V}_a/\dot{Q} mismatching has been investigated extensively in patients with mild to moderate COPD [17]. It has been shown that emphysema was positively correlated with the alveolar–arterial oxygen partial pressure difference (AaPo₂) but negatively for Pao₂. Moreover, the levels of emphysema severity showed a positive correlation with the dispersion of blood flow (log SDQ) and that of alveolar ventilation (log SDV). In essence, the more severe the degree of emphysema, the more abnormal the \dot{V}_a/\dot{Q} mismatch. The degree of abnormality in the log SDQ suggests the preferential development of regions with lower than normal \dot{V}_a/\dot{Q} ratios. These findings indicate therefore that poorly ventilated lung units associated with emphysema could be one of the structural determinants of abnormal Pao₂ in these patients. Thus, arterial hypoxaemia may be related to the loss of alveolar attachments of bronchiolar walls shown in emphysema, resulting in both distortion and narrowing of the lumen of bronchioles. This leads to impairment of alveolar ventilation in many regions of the lung and, consequently, to the presence of low \dot{V}_a/\dot{Q} ratios (Fig. 9.7; see also Plate 9.1; colour plate section falls between pp. 354 and 355) [47]. Similarly, it has been observed that areas of centrilobular emphysema have a greater residual volume (air trapping) and lower compliance, resulting in a reduction of ventilation/volume ratio. Accordingly, this could be an additional mechanism of reduction of effective ventilation in peripheral alveolar units. There is also a close correlation between the degree of emphysema and the abnormalities in the dispersion of alveolar ventilation (log SDV). This may be caused, at least in part, by wasted ventilation related to the dysfunction and/or loss of pulmonary capillary network of emphysematous spaces. This in turn induces the development of regions with lung units with high \dot{V}_a/\dot{Q} ratios, hence increasing the dispersion of ventilation. In this regard, the bimodal \dot{V}_a/\dot{Q} pattern of the ventilation distribution alluded to above, with a major amount

of ventilation to high \dot{V}_a/\dot{Q} ratios (type H) observed in patients with advanced type A COPD, would be an extension of this finding, likely reflecting large areas of destroyed parenchyma.

Airways

Bronchiolar lesions were found to be related to \dot{V}_a/\dot{Q} imbalance as shown by the correlation between the airway inflammation score and the dispersion of ventilation (log SDV̇). This finding reflects a heterogeneous distribution of inspired air to alveolar spaces caused by airway obstruction secondary to bronchiolar damage, thereby inducing the increase in the dispersion of ventilation (see Fig. 9.7; see also Plate 9.1; colour plate section falls between pp. 354 and 355). In contrast, there was no correlation between these chronic alterations in peripheral small airways and arterial blood gases, an observation akin to the deficient relationship between these structural changes and the dispersion of blood flow (log SDQ). Notwithstanding, the lack of correlation between small airways abnormalities and both the dispersion of blood flow and the percentage of perfusion to regions with low \dot{V}_a/\dot{Q} ratios cannot be extrapolated to the typical \dot{V}_a/\dot{Q} findings in patients with highly developed COPD, principally during exacerbations [35–38]. In severe to very severe stages of COPD, a bimodal blood flow \dot{V}_a/\dot{Q} profile may be more common and can be attributed to an acute superimposition of abrupt, potentially reversible airway changes (such as bronchial wall oedema or inspissated mucus plugging) on the chronic airways abnormalities.

In summary, these data suggest that there is a wide variety of \dot{V}_a/\dot{Q} abnormalities in patients with COPD. At one end of the spectrum are those patients with mild to moderate COPD and mild arterial blood gas abnormalities, with modest \dot{V}_a/\dot{Q} inequality, mainly characterized by broadly unimodal \dot{V}_a/\dot{Q} patterns of the dispersions of blood flow and alveolar ventilation. At the other end of the spectrum are those patients with severe advanced COPD and abnormal arterial blood gases who show dramatic \dot{V}_a/\dot{Q} imbalance, with bimodal \dot{V}_a/\dot{Q} patterns of either pulmonary blood flow or alveolar ventilation distributions, or both, depending on clinical conditions and reflecting different levels of COPD progression. Ultimately, historical type B COPD patients with regions of high \dot{V}_a/\dot{Q} ratios share emphysema as well as chronic bronchitis areas, whereas type A COPD patients with regions with low \dot{V}_a/\dot{Q} ratios are seldom detected. The latter patients usually have increased dead space and sporadically modest levels of increased intrapulmonary shunt, in particular during exacerbations. In between these two extremes there are many patients with different degrees of \dot{V}_a/\dot{Q} imbalance, depending on progression, clinical status and therapy.

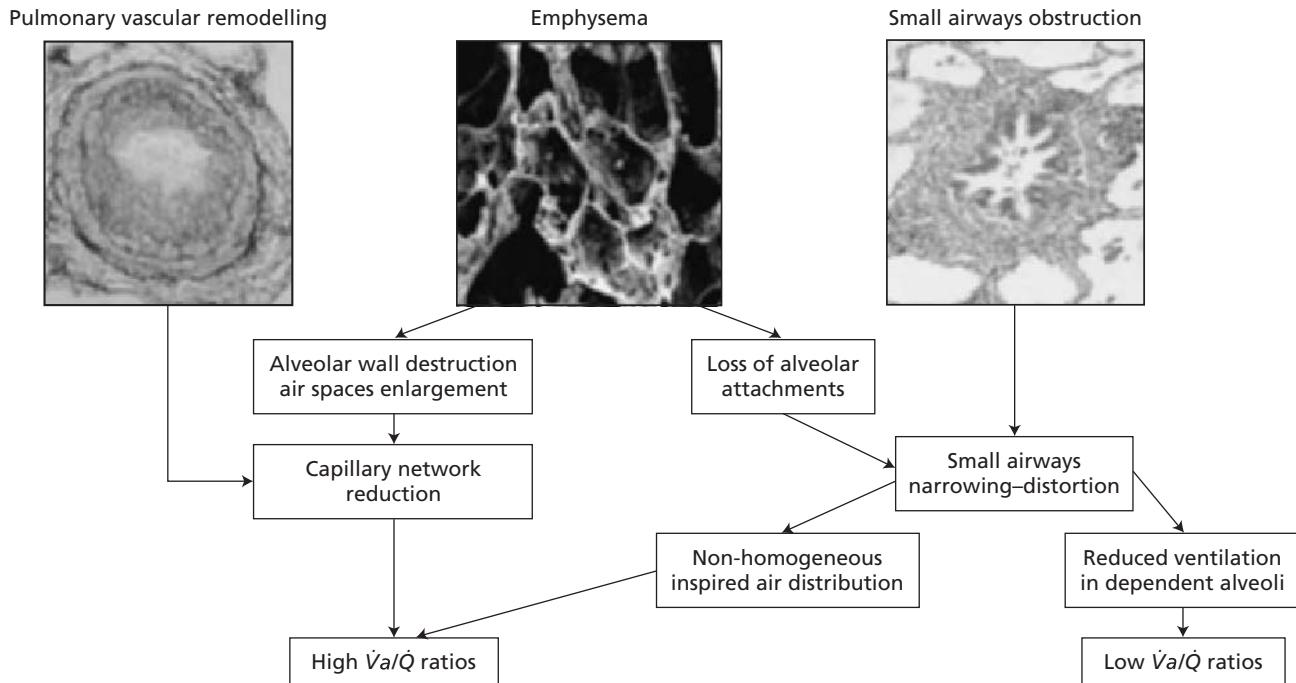

Figure 9.7 Schematic diagram of the correlations between key pathological features of COPD (small airways obstruction, pulmonary emphysema and vascular remodelling) and pulmonary gas exchange state (ventilation–perfusion imbalance) in stable advanced COPD. See also Plate 9.1; colour plate section falls between pp. 354 and 355.

Vessels

The relationship between the pulmonary vascular abnormalities and the \dot{V}_a/\dot{Q} relationships in COPD patients has been investigated [48]. It has been shown that the lower the degree of response to 100% oxygen (a relatively simple tool to assess the state of pulmonary vascular reactivity), the greater the thickness of the intimal layer of the pulmonary muscular arteries. Furthermore, the width of the intima was correlated with some gas exchange abnormalities, namely P_{aO_2} and the amount of \dot{V}_a/\dot{Q} mismatch, as expressed by both the dispersion of alveolar ventilation and an overall descriptor of \dot{V}_a/\dot{Q} imbalance. It was also correlated with the underlying degree of bronchiolar inflammation, a finding that can be considered central to the development of further abnormal \dot{V}_a/\dot{Q} progression (see Fig. 9.7; see also Plate 9.1; colour plate section falls between pp. 354 and 355). Moreover, in patients with mild COPD, the intimal enlargement in pulmonary arteries coexists with a superior \dot{V}_a/\dot{Q} impairment and this arterial wall thickness in small vessels may minimize the response of pulmonary vascular reactivity to the breathing of different oxygen concentrations.

Using a multivariate analysis, it has been shown that two of the best independent predictors of hospitalization for exacerbations in patients with moderate to severe COPD

were pulmonary artery pressure value > 18 mmHg and $P_{aCO_2} > 44$ mmHg [49]. Thus, pulmonary vascular pressures could represent an outcome of the deleterious effects of alveolar hypoxia on the pulmonary vessels, indicating the individual's vulnerability to arterial hypoxaemia. It is well established that both anatomical and functional pulmonary vascular derangements that result in pulmonary hypertension are characteristic features of the natural progression of COPD. Plausible mechanisms of the development of pulmonary hypertension in COPD include remodelling of pulmonary vessels, hypoxic pulmonary vasoconstriction, polycythaemia and emphysematous damage of the capillary network. Pulmonary vascular remodelling appears to be one of the central causative factors of pulmonary hypertension in COPD, as suggested by its failure to resolve after arterial hypoxaemia correction during acute or continuous oxygen administration.

Patients with severe emphysema with air trapping had a mean pulmonary artery pressure > 20 mmHg and a normal cardiac index [50]. Nevertheless, the pulmonary artery pressure correlated negatively with P_{aO_2} and with the severity of emphysema, and a subsequent multiple stepwise regression analysis demonstrated that P_{aO_2} was not an independent predictor of elevated pulmonary artery pressure. This finding led to the conclusion that in patients with severe emphysema, the commonly increased pulmonary

artery pressure is not related to hypoxaemia or impaired systemic oxygen transport.

Altogether these data point to the central role of pulmonary vascular remodelling as part of the repair response to acute and/or chronic injury. This remodelling appears to be one of the key pathobiological determinants of pulmonary hypertension development in COPD, being manifested throughout the spectrum of disease severity. Moreover, structural changes of pulmonary vasculature in COPD preferentially affect the pulmonary muscular arteries as well as the pre-capillary vessels. In patients with end-stage COPD, the media is commonly normal or atrophic while the intimal coat is thickened by deposition of longitudinal muscle, fibrosis and elastosis in pulmonary muscular arteries resulting in cor pulmonale [51]. At the pre-capillary level, the formation of a medial coat of circular smooth muscle is surrounded by a new internal elastic lamina, and occasionally the lumen is subdivided into parallel tubes.

In a seminal study on the pulmonary vascular state in cystic fibrosis patients undergoing lung transplantation [52], it was observed that endothelial pulmonary vascular dysfunction correlated linearly to pre-transplantation Pao_2 . This suggested that chronic hypoxaemia may have a detrimental influence on endothelial cell metabolism and possibly the synthesis of endogenous nitric oxide (NO) production, probably having a crucial role in the pulmonary vascular remodelling process in COPD. Although chronic hypoxaemia may explain the impairment of endothelial dysfunction in advanced COPD, the mechanisms operating in mild COPD without coexisting hypoxaemia remain unknown. It has been shown that endothelial dysfunction of pulmonary arteries is already active in early mild COPD [45]. These patients exhibit a significantly reduced vascular dilation in response to increasing concentrations of acetylcholine (ACh) and adenosine diphosphate (ADP) early in the natural history of COPD. The maximal pulmonary vascular dilation correlated significantly with the FEV_1/FVC ratio, indicating that endothelial dysfunction may be enhanced by COPD progression. These data are similar to the findings observed in end-stage cystic fibrosis [52], except for the fact that mild COPD patients do not have associated arterial hypoxaemia. Interestingly, both patients with COPD and smokers with normal lung function demonstrated the same severity of intimal thickening in pulmonary arteries. These findings suggest that structural vascular changes might be initiated well before the impairment of pulmonary vascular reactivity or lung function, and that cigarette smoking may coexist with structural abnormalities of the pulmonary vasculature related to the remodelling process, even in the absence of reduced airflow. The presence of gas exchange abnormalities in some patients with mild to moderate COPD out of proportion to the severity of airflow

obstruction may be explained by the finding that the severity of intimal thickening in the pulmonary arteries in these patients correlates with the severity of the inflammatory infiltrate in small airways, suggesting a common inflammatory process [48].

It was also shown in both mild COPD patients and smokers with normal lung function that the number of inflammatory cells in the adventitia of pulmonary muscular arteries is increased [53]. This inflammatory infiltrate is mainly composed of activated T lymphocytes, driven by a higher proportion of the $CD8^+$ subset, resulting in a reduced $CD4^+/CD8^+$ ratio, similar to that shown in large and peripheral airways and in the alveolar septa [54,55]. The severity of the inflammatory pulmonary vascular wall reaction correlated with the FEV_1/FVC ratio, the severity of endothelium dysfunction and also with the extent of the intimal thickness of the pulmonary vessels.

It has been suggested that the reduction in NO synthesis or release by the pulmonary endothelium may contribute to the structural and functional abnormalities of the pulmonary vasculature shown in the early stages of COPD. Patients with mild COPD, compared with non-smokers, expressed less endothelial NO synthase (eNOS) in their pulmonary arteries and this finding was correlated with endothelial dysfunction and enlargement of the intimal coat of pulmonary arteries [56]. It is of note that in smokers with normal lung function the expression of eNOS adopted an intermediate position between non-smokers and COPD patients, suggesting that inhibition of eNOS by the components of cigarette smoking in the pulmonary vasculature may precede the development of an established COPD phenotype. In contrast, no differences were observed in endothelin-1 (ET-1). Similar data on eNOS have been recently confirmed in lung tissue specimens excised by lung volume reduction surgery (LVRS) [57].

In addition, the smooth muscle cell proliferation and extracellular matrix deposition shown in the intimal layer of pulmonary muscular arteries in moderate COPD [58] may be linked to an enhanced expression of vascular endothelial growth factor (VEGF) associated with arterial wall enlargement in early mild COPD [59]. In severe emphysema the immunohistochemical expression of VEGF in pulmonary arteries and its protein content in lung tissue tend to be down-regulated despite intense vascular remodelling [57]. This is consistent with the reduction of VEGF expression in the lungs from emphysematous patients [60]. At an early COPD stage, VEGF might be a key signalling molecule linking changes in endothelial function with vascular remodelling. In COPD patients with advanced disease including emphysema, the vascular expression of VEGF is reduced, consistent with the anatomical changes that take place in the underlying lung parenchyma.

These findings suggest that cigarette smoke can be expli-

citly implicated very early in the pathogenesis of pulmonary vascular abnormalities in COPD. It can be hypothesized therefore that a chronic CD8⁺ T-cell inflammatory process, CD8⁺ accompanied by the release of a cascade of inflammatory mediators (including interleukin 8 [IL-8], leukotriene B₄ and tumour necrosis factor α [TNF- α]) is influentially involved in the development of the structural and functional disturbances of the pulmonary vasculature in mild COPD. Recently, a negative correlation has been demonstrated between the levels of Pao₂ and TNF- α *in vivo* [61]. This suggests that TNF- α contributes to weight loss and the systemic effects. Likewise, a direct effect of cigarette smoke might induce the thickening of the intimal coat through cell proliferation, resulting in pulmonary vascular remodelling which ultimately leads to pulmonary hypertension. As disease progresses, the coexistence of chronic severe hypoxaemia in more advanced COPD may further amplify and/or enhance this pulmonary vascular effect.

Future prospects

The study of human lung tissue is a critical research area in COPD [62]. One of the most appropriate sources of tissue for study is surgically explanted specimens from patients undergoing lung transplantation, although it only reflects accelerated end-stage COPD. Mild pulmonary hypertension is a common complication in COPD. However, characterization of the inflammatory pulmonary vascular process by advanced cellular, molecular and histopathological tools has received relatively little attention to date. Pulmonary hypertension is associated with shorter survival rates and is a predictive factor of worse clinical condition in COPD. The actual incidence of pulmonary hypertension in COPD is insufficiently known but varies from 20 to 91% in advanced emphysematous phenotypes [63]. Unfortunately, the therapeutic options available to patients with COPD are limited, and no pharmacological therapy is available as yet to slow down the progressive decline in FEV₁. Domiciliary long-term oxygen therapy appears to be the only medical therapy to improve survival in advanced COPD with chronic respiratory failure.

Given the relative ineffectiveness of current therapeutic modalities, substantial progress in COPD treatment will require novel therapies. Recent advances in the understanding of the pathophysiological processes underlying COPD, as discussed in this chapter, may help to identify potential therapeutic approaches in the future. One example [64] could be based on the finding that treatment of rats with a VEGF blocker causes emphysema associated with endothelial cell apoptosis and with enhanced oxidative stress but is not accompanied by inflammation. Oxidative stress decreases VEGF, and the expression of both VEGF

and its receptor are decreased in emphysema [60]. A reduction in VEGF might be implicated in the apoptotic changes that take place in the alveolar septa of emphysematous lungs. As a result, pharmacological inhibition of apoptosis might prevent loss of alveoli. Similarly, it is conceivable that agents that modulate the vasoconstrictor–dilator balance could be beneficial in COPD patients with pulmonary vascular involvement. Pulmonary gas exchange pathobiology in COPD encompasses a multidimensional process involving large and small airways, alveolar walls and pulmonary arteries, resulting in a wide spectrum of \dot{V}_a/\dot{Q} imbalance in accordance with the underlying degree of airflow obstruction. Ultimately, the structural and functional correlations may help to foster new and specific therapeutic targets.

SECTION 2

**COPD and allied
conditions**

CHAPTER 10

The natural history of COPD

Jørgen Vestbo

Our knowledge about the natural history of COPD comes mainly from large epidemiological studies over the last four decades describing aspects of the natural history of chronic respiratory symptoms and of obstructive lung function impairment. This has mainly been a result of the development of standardized questionnaires and the application of spirometry in large-scale studies. Although no single study has followed its participants with lung function measurements from birth to old age, it is possible to put the information from studies covering different parts of life together and present a relatively clear picture of the natural history of forced expiratory volume in 1 s (FEV_1), and other lung function measures [1].

The natural history of COPD should include two distinctly different time periods:

1 Growth of lung function, from pre-birth to the values reached at age 20–25 years

2 Decline in lung function in adult life.

This is illustrated in Figure 10.1 and implies that reduced lung function may be caused by inadequate growth of the lungs during childhood (or even *in utero*) and adolescence, premature start of decline in FEV_1 in early adulthood, accelerated decline after the age of 30 years throughout middle and old age, or even a combination of all these factors [2].

Previously, growth of lung function was generally ignored when considering COPD. However, it has become apparent that the maximally attained FEV_1 prior to the normal decline from adulthood is important [3]. Even a normal decline in FEV_1 may result in reduced lung function in old age if the starting point at age 25 years is very low. As with other chronic diseases, such as ischaemic heart disease, genetic and non-genetic prenatal factors as well as perinatal factors may be of importance. Our knowledge of genetic determinants of a low maximally attained lung function is poor and in COPD genetic determinants mainly point to genetic products that may affect the individual's susceptibility to smoking and presumably other environmental

Figure 10.1 Growth of forced expiratory volume in 1 s (FEV_1), the plateau phase and the decline with age in a normal individual.

factors. Both family and twin studies have confirmed a significant genetic contribution to the variance in pulmonary function [4–7] but, other than α_1 -antitrypsin, few strong specific genetic factors are known.

In some studies low birth weight has been shown to predict low lung function in adult life, consistent with the theory connecting pre- and perinatal events with many chronic diseases proposed by Barker *et al.* [8,9]. However, it can be difficult to separate the effects of perinatal events from those of other strong risk factors, especially socioeconomic status [10,11], maternal smoking status [12,13] and subsequent smoking habits [14]. In the study by Barker *et al.* [8], the effect of birth weight was not limited to lung function in adult life, but was also related to subsequent death from COPD. Le Souëf [15] has pointed out that a disease such as COPD, which is generally considered a disease secondary to adult smoking, in fact has its roots in childhood. Smoking during pregnancy affects both growth

in general and lung growth *in utero* and leads to decreased lung function at birth [12,13,16]. An altered growth of lung function, resulting from genetics, perinatal factors or exposures during childhood and adolescence, such as recurrent infections [17,18] or smoking [14], will result in a suboptimal level of lung function in early adulthood. Evidence of mild airway obstruction and slowed growth of lung function was found in smoking American adolescents [14] and this is in accordance with a previous study showing a slowing of growth of FEV_1 in smoking adolescents with respiratory symptoms [19]. Depending on subsequent lifestyle, this may increase the risk of developing COPD. Likewise, a recent study showed effects of air pollution on lung function, including FEV_1 , in school children in California [20]. An effect on growth of lung function resulting from exposures such as smoking and air pollution is likely to be larger in subjects from lower socioeconomic strata. This could potentially explain why the effects of socioeconomic status on lung function are obvious even in early adult life [10].

The growth phase of FEV_1 continues until approximately the age of 20–25 years, when the maximum values are reached. Thereafter follows a phase of quite stable lung function, the so-called ‘plateau phase’, which may last until approximately 35 years of age. Subsequently, as part of the ageing process, the FEV_1 starts to decline in an accelerating fashion. This is the most well-described part of the lung function curve and the decline in FEV_1 is often reported in millilitres per year rather than as percentage change of FEV_1 by year. The mean values of FEV_1 decline in healthy men and women approximately 30 mL/year and 25 mL/year, respectively [1]. This means that an average reduction in FEV_1 for a healthy non-smoking man is approximately 1.2 L from the 40th to the 80th year of life. An interesting observation from longitudinal studies is the phenomenon of tracking, which means that a measurement of FEV_1 before the age of 10 years is a strong predictor of the level of FEV_1 in early adulthood and probably even in old age, a finding similar to the course of body height throughout life.

The lung function impairment that usually characterizes COPD is generally believed to be the result of changes over decades. The most important and also best investigated deviation from the normal course of changes in lung function is the accelerated decline of FEV_1 in the middle-aged or elderly smoker. Adult smokers experience on average an FEV_1 decline of 40–50 mL/year, an excess of the normal annual decline of 15–20 mL/year. Yet, the FEV_1 of some smokers may decline by 80–100 mL/year. Thus, although the rate of decline in FEV_1 shows considerable interindividual variation in the literature, the notion of rapid decliners seems justified. The smokers who are most susceptible to the deleterious effects of tobacco may lose 3–4 L of FEV_1 during four decades, a process with devastating clinical

consequences. Most studies link COPD to cigarette smoking, mainly because cigarettes are smoked much more often than cigars, cheroots or pipes. From studies including all types of smokers it seems that the type of tobacco smoked has a minor role, if any [21]. The crucial factor seems to be the amount smoked and the extent of inhalation [22]. Filter cigarettes do not differ significantly from non-filter cigarettes, presumably because the substances causing lung function impairment originate from the volatile part of cigarettes which is not reduced by filters.

The role of environmental tobacco smoking (ETS) has been more difficult to comprehend. In a recent review on the effect of passive smoking on children [23], it was concluded that maternal smoking is associated with small but statistically significant deficits in FEV_1 and other spirometric indices and that the association was almost certainly causal. In adults, the role of ETS is less clear. The effect of ETS on lung function and COPD seems to depend strongly on the setting in which it is studied and in particular in which country ETS is studied. Even if studies from China, which show the largest effects, are excluded, a possible effect of ETS seems to be present [24].

Smoking cessation has in several surveys been shown to reduce both the prevalence of respiratory symptoms and the decline in FEV_1 [22,25–28]. The first change in lung function seen after smoking cessation is a small increase, usually in the region of 30–50 mL for FEV_1 . This is presumably because of the disappearance of the acute inflammatory oedema in the smoker’s airways. The favourable change in subsequent decline in lung function is seen in younger subjects and in those without apparent COPD, whereas the beneficial changes are less apparent in older subjects with overt COPD [22,26]. In young and middle-aged subjects, it is a matter of debate whether the decline in FEV_1 after smoking cessation normalizes completely. At present it seems that in general quitters continue to have an FEV_1 decline that is slightly larger than that seen in those who have never smoked [23,26,27]. Whether this is because a small number of the quitters have continuous respiratory symptoms indicating an ongoing inflammation in the airways remains to be seen.

Besides smoking other exposures may accelerate FEV_1 decline. The association between occupational exposures and excess decline in lung function has previously been the topic of heated debate, but presumably weaknesses in early study designs have led to an underestimation of the role of occupational exposures in COPD [29]. An important milestone in demonstrating the role of occupational exposures was the study of Paris area workers, in which working men with exposure to gases, dust or heat had an accelerated decline in FEV_1 [30]. In this study, the effect of different exposures on FEV_1 decline was examined and on average the exposed men had 5–15 mL/year excess decline in FEV_1

resulting from the exposure. These and other findings from both occupational cohorts and general population samples have led to a general acceptance of a causal relationship between occupational exposure to dust and development of COPD [31–36].

Chronic mucus hypersecretion and recurrent lower respiratory tract infections have also been proposed as events accelerating FEV_1 decline. This point is discussed in more detail in the last part of this chapter.

Asthma is generally regarded as distinctly different from COPD. Longitudinal population studies have, however, shown that asthmatics may have a more rapid decline in FEV_1 than non-asthmatics [37–39]. This is likely to be seen in only a proportion of asthmatics but indeed demonstrates a group with presumed increased susceptibility to exposures leading to loss of lung function. Asthma patients also have an increased mortality risk, primarily because of an increased COPD mortality [40]. It has been argued that features usually associated with asthma – such as airway hyperresponsiveness – determines susceptibility to extrinsic exposures leading to COPD and thus are central in the natural history of COPD. This is usually referred to as the ‘Dutch hypothesis’ and is dealt with separately later.

Once airway obstruction has developed the further course of disease is characterized by accelerated decline of lung function and the development of dyspnoea. In addition, patients with chronic mucus hypersecretion are particularly prone to recurrent lower airways infections, resulting in acute exacerbations with a frequency up to several exacerbations each year. At this stage it is now generally accepted that many patients show signs of systemic disease, reflected in measurable systemic inflammation, loss of body mass and changes in other organs such as skeletal muscle [41–43]. Along with the progressive decline of FEV_1 , and especially recurrent exacerbations, patients experience the gradual loss of health status or health-related quality of life [44,45]. Late in the course of the disease disability is present as a result of the severely reduced lung function. The progressive loss of FEV_1 may be accompanied by a decrease in the volume adjusted diffusion capacity (diffusion constant) brought about by emphysema.

With more decreased lung function, hypoxaemia develops and, secondary to this, elevation of the pulmonary arterial pressure. In severe COPD, the mean pulmonary artery pressure increases approximately 0.5–3 mmHg/year. As a consequence of the high pressure in the pulmonary vascular bed, right ventricular hypertrophy, ‘cor pulmonale’, develops. Because severe COPD is the disease of current and former elderly smokers, comorbidities caused by other smoking-related diseases such as ischaemic heart disease, general atherosclerosis and cancer are important features of COPD [46]. Although many COPD patients may die from

cardiovascular diseases, the risk of dying from respiratory failure or respiratory infections is high, especially in patients with chronic hypoxaemia [47,48].

Reduced FEV_1 is a strong predictor of morbidity and mortality in established COPD. Survival is more closely related to postbronchodilator FEV_1 than to the prebronchodilator value [49], whereas it is unclear whether bronchodilator reversibility as such is a significant predictor of prognosis [50]. COPD patients with peripheral oedema resulting from cor pulmonale have a 5-year survival of 30–40% [51]. Other predictors of mortality in established COPD include smoking, low body weight for height, dyspnoea, chronic mucus hypersecretion, signs of ischaemic heart disease and male gender. Low body weight, expressed as low body mass index (BMI), is an indicator of malnutrition and probably systemic disease in patients with COPD. Low BMI ($< 20 \text{ kg/m}^2$) interacts with the level of FEV_1 with regard to mortality, being a much stronger predictor of death in severe COPD than in mild or moderate disease [52]. Recently, an index combining lung function, dyspnoea, body mass and exercise tolerance has been shown to be a better prognostic indicator than staging of COPD based on lung function alone [53].

The British and Dutch hypotheses in COPD

So far, attempts to understand the natural history of COPD have been influenced by the prevalent description of anatomy and physiology as well as the clinical description of the disease. In addition, the heterogeneity of COPD, covering a spectrum from a disease of the airways resembling asthma to a disease of the pulmonary parenchyma, has made it difficult to provide a single hypothesis describing the development and progression of the disease.

Initially, COPD was not defined but described as ‘obstructive bronchitis’ in contrast to ‘simple bronchitis’. This was the basis for the ‘British hypothesis’, which claimed that chronic mucus hypersecretion (CMH), by setting the stage for recurrent airway infection, was causative in the development of airway obstruction. In the 1960s, Fletcher *et al.* performed a 7-year longitudinal study of a working population consisting of 30–60-year-old men, mostly heavy smokers and all of whom lived in London in a period of heavy air pollution. The seminal work by Fletcher *et al.* [54] rejected the ‘British hypothesis’ by showing that in middle-aged men CMH and progressive airway obstruction were two separate entities, although often occurring concomitantly because of a common risk factor – smoking. Whereas the progressive airway obstruction was the most important disease process resulting in progressive disability in COPD patients, the presence of mucus hypersecretion clearly

predisposed to recurrent bronchopulmonary infections causing increased morbidity and absence from work.

However, it is likely that these findings have been over-interpreted. Fletcher *et al.* [55] clearly state that 'In the preclinical stages of these disorders, which we have studied, we find no causal relationship between them, for neither mucus hypersecretion nor clinical chest illnesses cause accelerated loss of FEV₁'. Whereas it seems likely that the progressive loss of lung function is not initiated by recurrent lower respiratory tract infections, the study by Fletcher *et al.* cannot describe the role of infection in later stages of COPD. Also, the fact that the London study, and other studies with similar findings, was conducted in selected occupational cohorts may have skewed the picture.

Within the last 15 years several studies have shown CMH and lower respiratory tract infections (LRTIs) to be less innocent. Mortality studies have all shown an association between CMH and overall mortality [56,57] as well as COPD mortality [58,59]. In the latter study, the excess risk of mortality associated with CMH was caused by an increased risk of death associated with infection [60]. Regarding an association between CMH and development of COPD, fewer studies have confirmed an association between CMH and FEV₁. Sherman *et al.* [61] reported an excess FEV₁ decline in men with CMH in the US Six Cities Study but the association was weak. In the Copenhagen City Heart Study, Vestbo *et al.* [62] showed that CMH was associated with an excess FEV₁ decline: 22.8 mL/year in men; 12.6 mL/year in women. CMH was also associated with an increased risk of subsequent hospitalization resulting from COPD. This raised the possibility that CMH accelerates progression of disease. However, the association may only be present in established COPD as the same group has shown that CMH in subjects with normal lung function does not seem to predispose to airflow obstruction [63]. The effect of CMH on COPD morbidity is also present in the elderly [64]. The mechanism in established COPD is still not entirely clear but it is most likely the increased risk of exacerbations or LRTIs associated with CMH that may lead to an excess decline in FEV₁ in this random population sample. Support for this comes from 5-year data from the US Lung Health Study. Kanner *et al.* [65] showed that LRTIs, which in this study were associated with CMH, were linked with lung function decline in patients with mild COPD: every 1 LRTI/year in smokers was associated with a decrease in FEV₁ of approximately 7 mL. This decrease may seem small but in a patient with 2–3 exacerbations per year the excess decline would be approximately 20 mL/year. These findings were further supported by a smaller 4-year UK study of patients with moderate to severe COPD [66]. In this study, patients with frequent exacerbations (median 4.2/year) showed a more rapid decline in FEV₁ (difference 8 mL/year) than infrequent exacerbators (median 1.9/year).

In terms of the percentage decline, FEV₁ fell by 4.2%/year in frequent exacerbators compared with 3.6%/year in infrequent exacerbators.

Thus, the pendulum seems to have swung regarding our view on CMH, exacerbations and progression of COPD [67]. CMH and LRTIs may not have a role in initiating changes leading to fixed airflow obstruction. In established COPD, however, CMH increases the risk of exacerbations and the most recent data seem to show that this impacts on the natural history of COPD.

With the initial rejection of the 'British hypothesis' a new approach to the understanding of factors related to the development of chronic bronchitis and emphysema was possible. In 1961 a group of Dutch investigators put forward the hypothesis that various forms of airways obstruction such as asthma, chronic bronchitis and even emphysema should be considered as different expressions of the same underlying abnormality and introduced the term 'chronic non-specific lung disease'. They suggested that host factors, airway hyperresponsiveness and allergy define susceptibility to the development of airways obstruction by interacting with environmental factors such as smoking and air pollution. This was subsequently named the 'Dutch hypothesis' [68–70]. Although the idea of combining asthma with bronchitis and emphysema into a single disease category has not gained wide acceptance outside the Netherlands, several prospective studies have until now shown that airway hyperresponsiveness is a significant predictor of FEV₁ decline, development of respiratory symptoms and even mortality from COPD [71–77]. One of the problems of interpreting the role of airway hyperresponsiveness as a host susceptibility factor for the development of COPD is the fact that airway hyperresponsiveness may develop secondary to development of airways obstruction resulting from changes in airway geometry. Yet it seems that airway hyperresponsiveness is a significant predictor of both the preclinical and clinical course of COPD and asthma, even after some adjustment for the impact of airway geometry. With regard to allergy, which in epidemiological studies is usually measured as skin prick test positivity or elevated levels of IgE, it has been shown that these allergy markers may interact with smoking in predicting FEV₁ decline and survival. Based on the analyses of survival and the course of lung function of the participants in the longitudinal Tucson respiratory study, Burrows *et al.* [78] suggested that the 'Dutch hypothesis' is valid for the subgroup of COPD patients with obstructive lung function impairment mainly caused by airways disease: patients who clinically share some common characteristics with asthma and that the term asthmatic bronchitis is a relevant description of this group. On the other hand, the 'Dutch hypothesis' is probably less relevant to COPD patients with a more 'malignant type of disease', where emphysema is

the main cause of airways obstruction. An important consequence of the 'Dutch hypothesis' is that asthma could be regarded as a risk factor for COPD. As long-standing asthma does not result in emphysema in the absence of smoking, it may well be that the risk factors of the emphysematous type of COPD are different and in general much more research is needed regarding the natural history of different subtypes of COPD [79]. However, this may prove to be difficult to disentangle as most patients cannot be clearly subtyped into bronchitic or emphysematous, most patients in fact have features of both, and small airways disease. Postma and Boezen [70] have suggested that mapping of genes in asthma and COPD may eventually show if the 'Dutch hypothesis' is a suitable explanation for the pathogenesis of COPD.

In conclusion, we have quite detailed knowledge on the natural history of COPD although the majority of studies to date have used FEV_1 as a proxy for COPD. The future challenge will be to disentangle the different phenotypes of COPD and gain more knowledge on the factors differentiating these phenotypes.

CHAPTER 11

Cystic fibrosis

Marcus P. Kennedy and Michael R. Knowles

Cystic fibrosis (CF) is an autosomal recessive, multisystem disorder with predominant morbidity and mortality resulting from pulmonary disease [1,2]. CF lung disease is characterized by chronic airways obstruction and bacterial infection which leads to bronchiectasis, respiratory failure and early death with a median age of survival of 32 years. The identification of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene in 1989 [3] was a major step towards understanding the pathophysiology of CF. The *CFTR* gene product functions as a cyclic adenosine monophosphate (cAMP) regulated chloride (Cl⁻) channel, and as a regulator of other ion channels in the airways [4–7]. *CFTR* is expressed in the epithelium that lines tubular structures in the lung and other organs, including the sweat duct, pancreas, liver, vas deferens and portions of the gut. Defective *CFTR* function in the lungs leads to thickened airway mucus, ineffective mucociliary and cough clearance, and chronic bacterial infection [8]. Nearly 40% of CF patients in the USA are now adults, requiring that pulmonologists have an up-to-date knowledge of the pathogenesis, diagnosis and treatment of the lung disease [9]. Other manifestations of CF include pancreatic exocrine insufficiency with malabsorption and malnutrition, CF-related diabetes, male infertility, sinusitis and osteopenia.

In the USA, there are approximately 120 specialized CF clinical centres sponsored by the Cystic Fibrosis Foundation (CFF). These centres offer high-quality clinical care and also coordinate clinical research on various aspects of the disease. A number of comprehensive consensus statements have been published as a combined effort between the CFF and physicians at CF centres, which outline recommended diagnostic and treatment protocols for various aspects of the disease, of which some are cited here [10–17]. The CFF foundation website (<http://www.cff.org/>) also contains information on all aspects of the disease with links to related websites.

Epidemiology and genetics

CF is a recessive genetic disorder, reflecting mutations in the *CFTR* gene. CF occurs in 1 in 3000 live births in Caucasian populations, but is much less common in African and Asian Americans. Approximately 5% of Caucasians are carriers, and it has been suggested that the preponderance of heterozygotes (carriers) reflects protection from chloride-secreting diarrhoeal infection in the distant past [18,19].

The *CFTR* gene is located on the long arm of human chromosome 7. It consists of 250 kB of genomic DNA containing 27 exons. *CFTR* is a 1480 amino acid membrane protein with 12 membrane-spanning regions. Heterozygote carriers of a *CFTR* mutation are asymptomatic, without evidence of disease. This suggests that 50% of the normal level of functional *CFTR* is enough to prevent the CF phenotype. More than 1000 distinct mutations have been described in the CF gene. The most common mutation is the $\Delta F508$ mutation, which reflects deletion of three bases and leads to a loss of a single phenylalanine. This results in misfolding and cellular degradation of the protein, and absence of functional *CFTR* on the apical membrane of airway epithelia. The $\Delta F508$ mutation accounts for 70% of the CF alleles, and 50% of CF patients are homozygous for the $\Delta F508$ mutation [1]. Depending on the molecular abnormality in *CFTR*, there is a spectrum of consequences from ‘severe’ loss of function mutations to ‘mild’ mutations with partial and/or residual function.

This heterogeneity of molecular defects leads to a spectrum of clinical disease. At one end of the spectrum, ‘severe’ mutations resulting in absence of functional *CFTR* correlate strongly with pancreatic exocrine insufficiency, but less strongly with severity of lung disease. ‘Mild’ mutations with residual function of *CFTR* are associated with pancreatic

Classic cystic fibrosis (no functional CFTR protein)	Non-classic cystic fibrosis (some functional CFTR protein, providing survival advantage)
<p>Chronic sinusitis</p> <p>Severe chronic bacterial infection of airways</p> <p>Severe hepatobiliary disease (5–10% of cases)</p> <p>Pancreatic exocrine insufficiency</p> <p>Meconium ileus at birth (15–20% of cases)</p> <p>Sweat chloride value usually 90–110 mmol/L; sometimes 60–90 mmol/L</p> <p>Obstructive azoospermia</p>	<p>Chronic sinusitis</p> <p>Chronic bacterial infection of airways (later onset, but variable)</p> <p>Adequate pancreatic exocrine function (usually); pancreatitis (5–20% of cases)</p> <p>Sweat chloride value usually 60–90 mmol/L; sometimes normal (< 40 mmol/L)</p> <p>Obstructive azoospermia</p>

Figure 11.1 Classic (left-side) and non-classic (right-side) cystic fibrosis. Non-classic cystic fibrosis patients usually have better overall survival with later onset and more slowly progressive lung disease, and better nutritional status.

exocrine sufficiency and milder pulmonary disease. From these observations, ‘classic’ CF is associated with two loss-of-function mutations, and ‘non-classic’ CF patients have at least one copy of a mutant gene that confers partial function of CFTR. Figure 11.1 compares the classic and non-classic phenotypes [20]. There are also ‘mono-organ’ forms of disease associated with mild mutations in *CFTR*, including congenital bilateral absence of the vas deferens [21], and idiopathic chronic pancreatitis [22,23]. Screening for 25 of the more common mutations is recommended for all pregnant women or women planning pregnancy by the National Institutes of Health [24].

The variability in clinical phenotype extends beyond the type of mutation in *CFTR* and reflects environmental and non-*CFTR* genetic influences (modifier genes). An initial report investigated the influence of variants in 10 genes other than *CFTR* on the severity of pulmonary disease in a large population of CF patients and identified that genetic variation in transforming growth factor $\beta 1$ (*TGF $\beta 1$*) modified disease severity in cystic fibrosis [25,26]. Investigation of other genes is in progress.

Pulmonary disease

Pulmonary disease is the chief cause of morbidity and mortality in CF. In this section, an overview of the key aspects of pulmonary disease is described, including a discussion of normal airway epithelial ion transport, defective ion transport in CF, cellular and organ-level pathophysiology, clinical features, microbiology and complications.

Normal airway epithelial ion transport

Airway surface liquid (ASL) plays a key part in mucociliary clearance, which is an important airway host defence mechanism. In normal airway epithelia, the ASL is comprised of a periciliary layer (PCL) and a mucus layer, and tight regulation of the volume and composition of ASL is required for optimal function [5,6,8,27]. The low-viscosity PCL layer allows effective ciliary movement and mucociliary clearance. As the volume of surface liquid is moved by mucociliary clearance from the large surface area of

Figure 11.2 Airway epithelial ion transport: cell models display the location of key ion transport proteins. (a) In normal airway epithelia, Na⁺ enters the cell through apical amiloride-sensitive Na⁺ channels (ENaC) and is extruded across the basolateral membrane by Na⁺-ATPase; Cl⁻ follows through the paracellular pathway to maintain electrical neutrality. The 'alternative' calcium activated channel (Cl_a⁻) is closed under basal circumstances. (b) In cystic fibrosis, the apical membrane Na⁺ conductance is large, because of the loss of the tonic inhibitory effect of *CFTR*, leading to increased net Na⁺ (and Cl⁻) absorption. PD, transepithelial potential difference.

the distal airways to the much smaller surface area of the proximal airways, isotonic volume absorption occurs via active ion transport. The lung is often depicted as an inverted funnel, reflecting the relative surface area of the distal versus proximal airways.

Sodium (Na⁺) absorption is the dominant ion transport pathway in the airway surface epithelium of adult humans [28]. Figure 11.2(a) depicts basal ion transport across the proximal airway epithelium in a normal lung. Active Na⁺ absorption, dependent on apical membrane Na⁺ channels (EnaC) and the Na⁺-K⁺-ATPase pump, mediates ASL volume absorption under basal conditions. This Na⁺ absorption is inhibited by luminal amiloride, acting on amiloride-sensitive epithelial channels (EnaC). Chloride (Cl⁻) ion follows through the paracellular pathway to maintain electrical neutrality. Under some circumstances, normal airway epithelia can slow Na⁺ absorption and induce Cl⁻ secretion via apical Cl⁻ channels, with Cl⁻ entry from the basolateral Na⁺-K⁺-2Cl⁻ transporter. Water permeability of airway epithelium appears to be high relative to other barrier epithelia, and water follows the movement of salt by osmosis; thus, there is net volume absorption under basal conditions [29–31].

Defective ion transport in cystic fibrosis

Ion transport in CF is abnormal. A loss of functional *CFTR* affects both the Na⁺ and Cl⁻ ion transport pathways. CF airway epithelia have an accelerated basal rate of Na⁺ (and volume) absorption that reflects the absence of the tonic inhibitory effect of *CFTR* on epithelial Na⁺ channel (EnaC) activity [4,8]. Figure 11.2(b) highlights the abnormal basal ion transport in cystic fibrosis airways, with unabated

Na⁺ (and volume) absorption via an increase in the apical membrane Na⁺ conductance, and increased basolateral Na⁺-K⁺-ATPase pump activity. This acceleration of Na⁺ (and volume absorption) results in depletion of the ASL. In the face of ASL volume depletion, CF airway epithelia are also missing the capacity to add liquid back to airway surfaces, because of the absence of *CFTR* functioning as a 'secretory' Cl⁻ channel. Nasal epithelial potential difference (PD) is one tool to assess normal and defective *CFTR* function. In normal epithelia, perfusion of the luminal surface with a Cl⁻-free (containing amiloride) solution results in a hyperpolarization of transepithelial PD (resulting from a Cl⁻ diffusion potential). This hyperpolarization ('secretion of Cl⁻') is further augmented via addition of a β -agonist (isoproterenol) to increase cellular cAMP and thereby increase *CFTR* activity. In CF epithelia, the basal PD is raised (accelerated Na⁺ transport) and there is no hyperpolarization in response to luminal Cl⁻-free solution and isoproterenol [32]. Thus, the predominant defect from loss of *CFTR* function is hyperabsorption of salt (and liquid) from the luminal surface of airways, coupled to an inability to secrete Cl⁻ and liquid.

Pathophysiology at microcellular level

Figure 11.3 highlights the consequences of loss of *CFTR* function in the airways. Excessive volume absorption, loss of PCL and continuous build-up of mucus allows gel-forming mucins (MUC5AC and MUC5B) in the mucus layer to adhere to luminal surface glycoproteins, including tethered epithelial surface mucins (MUC1 and MUC4). Despite the fact that mucus plugs are a major component of CF-related lung disease, there have been no defined

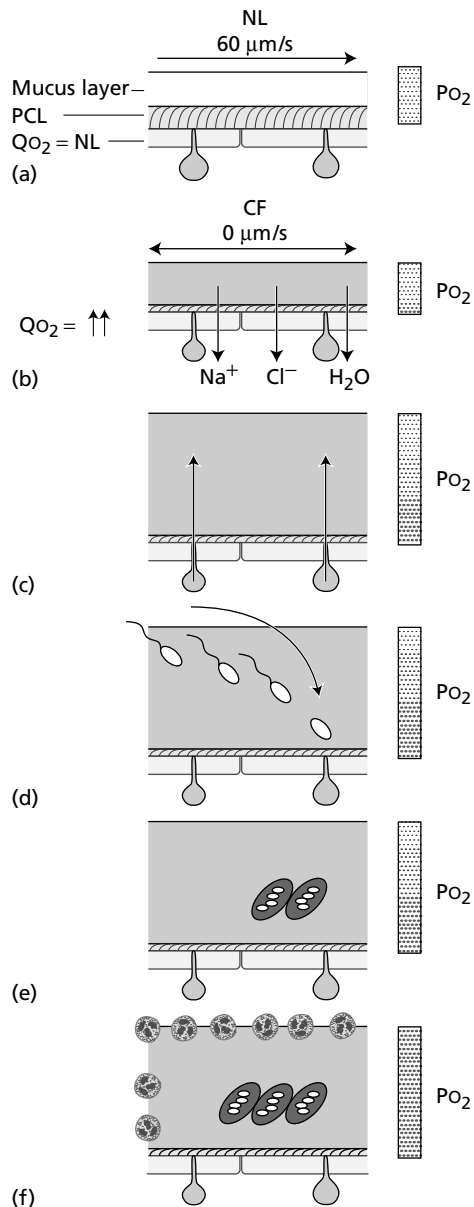

Figure 11.3 Schematic model of the pathogenesis of chronic *Pseudomonas aeruginosa* infection in cystic fibrosis (CF) patients. (a) Normal airway epithelia, a thin mucus layer (clear) resides atop the periciliary layer (PCL) (tinted stripes). Efficient mucociliary clearance, denoted by the vector is facilitated by the presence of low viscosity PCL. A normal rate of epithelia O_2 consumption (Q_{O_2} ; left) produces no O_2 gradients within this thin ASL (denoted by light spotted bar). (b–f) CF airway epithelia. (b) Excessive CF volume depletion (denoted by vertical arrows) removes the PCL, mucus becomes adherent to epithelial surfaces and mucus transport slows or stops (bidirectional vector). Raised O_2 consumption occurs. (c) Persistent mucus secretion (denoted as mucus secretory gland/goblet cell units; dark grey) with time increases the height of the luminal mucus masses/plugs. Raised epithelial Q_{O_2} generates steep hypoxic gradients (dark spotted in bar) in

primary genetic abnormalities in mucus [33,34]. There may be some secondary changes in glycosylation, sulfation or other post-translational modifications of mucins secondary to abnormal *CFTR* function [35]. ‘Abnormal mucus’ is primarily a function of excessive concentration of macromolecules in the mucus layer, reflecting defective ion (and liquid) transport [8]. Taken together, these effects lead to loss of both mucociliary and cough clearance. Furthermore, this viscous mucus is a nidus for early bacterial infection.

Initial pathogenic organisms include *Staphylococcus aureus* and *Haemophilus influenzae*, with eventual chronic infection with Gram-negative organisms, including *Pseudomonas aeruginosa* and *Burkholderia cepacia*. Figure 11.3 highlights mechanistic steps in the progression of *P. aeruginosa* infection. Raised oxygen consumption in stagnant mucus on the respiratory cell surface is an ideal niche for *P. aeruginosa*, which can use nitrogen-based compounds as an alternative energy source [36,37]. Macrocolonies develop, and have increased alginate production in this hypoxic environment [36], with resistance to secondary defences, including a slowing of the influx of neutrophils [38]. Formation of macrocolonies down-regulates many bacterial cell functions in an energy-conserving fashion, including loss of ‘O’ side-chains [39], flagellum and pili [40] and down-regulation of the production of toxins [41]. As described in Figure 11.3, a host inflammatory response occurs in an attempt to counteract infection with a massive recruitment of neutrophils, release of oxidase products and proteases, and upon cellular decomposition, DNA. Airway macrophages are also involved with release of tumour necrosis factor (TNF), interleukin 1 (IL-1) and IL-8, which contribute to the overall chemotactic and neutrophil-activating activity in the CF lung [42]. The presence of an increasing macrocolony density and infiltration of neutrophils adds to the hypoxia of the airway surface mucus layer.

Pathophysiology at macro-organ level

Compromise of *CFTR* function leads to a number of complications depending on the organ system involved. Loss of *CFTR* function has its most severe consequences in the lungs. CF neonates have normal lungs at birth, but radiological evidence of abnormalities in the distal conducting

thickened mucus masses. (d) *P. aeruginosa* bacteria penetrate into hypoxic zones within the mucus masses. (e) *P. aeruginosa* adapts to hypoxic niches within mucus masses with increased alginate formation and the creation of macrocolonies. (f) Macrocolonies resist secondary defences, including neutrophils, setting the stage for chronic infection. The presence of increased macrocolony density and, to a lesser extent, neutrophils render the mucopurulent mass hypoxic (dark spotted bar).

airways occurs early in life [43,44]. Obstruction of the conducting airways occurs, secondary to a gradual build-up of thickened mucus, and secondary bacterial infection. The inflammatory response, secondary to neutrophil infiltration, leads to protease and elastase release with tissue breakdown. Remodelling is associated with fibrosis and ectasia of the airways (bronchiectasis).

Pulmonary function testing is compatible with disease in the conducting airways [45]. There is obstruction to airflow and air trapping. Reduction in the maximal mid-expiratory flow (MMEF) occurs first, then in the forced expiratory volume (*FEV*), and finally in the forced vital capacity (*FVC*), with increased residual volume and forced residual capacity. The alveolar space is relatively preserved, as is the diffusing capacity (DLCO). As disease progresses, pulmonary function worsens, with a variable pattern of loss of lung function, which can be linear or stepwise, slow or rapid. Acute reductions in *FEV*₁ and *FVC* often herald pulmonary exacerbations, which require intensified treatment.

Chronic infection with an associated chronic inflammatory response leads to gradual loss of lung function, bronchiectasis and, eventually, end-stage disease with respiratory failure.

Clinical manifestations

Chronic suppurative airway disease is present in more than 98% of adults who have CF, and over 90% of deaths are related to progressive pulmonary insufficiency. Respiratory symptoms start with a recurrent cough and sputum production, which is sometimes associated with wheezing. The cough eventually occurs on a daily basis, becoming productive of mucopurulent secretions. Damage to the conducting airways via the inflammatory response occurs, and hyperinflation and the clinical findings of a barrel-shaped chest are similar to COPD patients. Airway reactivity is a common finding, with one study highlighting wheezing in 50% of young children with CF [46]. The chest X-ray may appear normal initially, or may show subtle changes of hyperinflation. Eventually, hyperinflation with interstitial markings develops. With progression of disease, peribronchial cuffing, 'tram tracks' and rounded shadows of saccular bronchiectasis occur, eventually leading to changes consistent with bronchiectasis, cyst formation and fibrosis. Abnormalities tend to be more prominent in the upper lobes. Chest computed tomography (CT) allows greater detail and assessment of bronchiectasis and recent studies demonstrate that bronchiectasis commonly begins before the age of 5 years [43].

Ultimately, there is progressive decline in lung function with frequent exacerbations, which are heralded by clinical features including increased sputum production, loss of appetite and worsening in pulmonary function. Signifi-

cantly, fever is relatively uncommon. Progression leads to loss of function of the conducting airways with bronchiectasis, and eventually hypoxia (initially, with or without hypercarbia) and respiratory failure.

Microbiology

Bacteriology

Mortality in CF is predominantly a function of chronic airway infection and tissue damage from the host inflammatory response. *S. aureus* and *P. aeruginosa* are the primary aetiological agents of pulmonary infection in adults with CF. Before effective antistaphylococcal therapy became available, *S. aureus*-related pulmonary infection was the leading cause of death. With effective therapy, morbidity is reduced. However, the emergence of methicillin-resistant *S. aureus* (MRSA) has led to 10–20% of adults being infected with this agent, and necessitating the use of intravenous therapy with exacerbations. The effect of MRSA infection in one case–control study was more frequent antibiotic treatment, although there was not worsening in lung function [47].

Chronic bacterial infection of the airways with *P. aeruginosa* occurs in more than 80% of adults and adolescents with CF [35]. Although the burden of *P. aeruginosa* is high (10^8 per millilitre of airway secretions), sepsis associated with *Pseudomonas* infection is rare in CF. The development of chronic *Pseudomonas* infection has been described in the pathophysiology section and is illustrated in Figure 11.3. The potential risk for emergence of drug-resistant organisms is high in patients with *P. aeruginosa* infection, because eradication of the organism from adults is impossible. The adaptation of bacteria to a heterogeneous and changing environment promotes the selection of hypermutable strains, as evident in isolates from CF versus non-CF patients. These strains contribute to the emergence of antibiotic-resistant organisms [48].

Other bacteria, such as *H. influenza*, *Moraxella catarrhalis*, *Stenotrophomonas maltophilia*, *Alcaligenes xylosoxidans* and Enterobacteriaceae are being recovered with increased frequency as life expectancy increases. Multidrug-resistance patterns to these organisms are developing. *B. cepacia* is found in approximately 10% of CF adults. It can be divided into nine different genomovars by molecular analysis, with *B. multivorans* and *B. cenocepacia* comprising 90% of the isolates in CF [49]. Infection is associated with an accelerated decline in lung function and shortened survival in a subset of patients. *B. cenocepacia* is associated with poor outcomes post lung transplant and is considered a contraindication to transplant in some centres [50,51]. *B. cepacia* also causes the 'cepacia syndrome', with rapid deterioration in lung function, bacteraemia and death within 6 months occurring in adolescent and young adult CF patients [52].

Mycobacteriology

In a recent multicentre trial, non-tuberculous mycobacteria (NTM) have been found in sputum of 13% of 1000 CF patients older than 10 years, with 72% being *Mycobacterium avium* complex (MAC) and 18% having *Mycobacterium abscessus* [53]. Diagnosis of NTM is challenging, because infection can mimic worsening of CF seen in chronic *Pseudomonas* infection. Improvement in culture techniques [54,55], repeating cultures and CT scanning [56] has helped this diagnostic challenge. The clinical course of CF is often minimally affected by MAC [53], and treatment has become more feasible. For *M. abscessus*, the clinical course is usually worse, and eradication is difficult to achieve and requires prolonged intravenous therapy.

Treatment of NTM in CF can also be difficult because of altered drug absorption and metabolism [57]. Follow-up of CT findings and acid-fast bacilli (AFB) cultures are recommended for a single NTM isolate from sputum in the absence of a decline in clinical course or if CT findings are not suggestive of infection [53,58].

Aspergillus

Approximately 50% of CF adults will periodically culture *Aspergillus fumigatus*, but only a small subgroup develops allergic bronchopulmonary aspergillosis (ABPA). ABPA should be suspected in any patient with pulmonary infiltration or deterioration not responding to conventional therapy. Testing of immunoglobulin E (IgE) and IgG specific for *Aspergillus* is useful; routine screening for ABPA in CF with total IgE level has been recommended with specific *Aspergillus* serology obtained only if the total IgE level exceeds 500 IU/mL [10,59,60]. Systemic steroid therapy is often sufficient to treat APBA, but side-effects occur; some advocate itraconazole treatment in addition, which may reduce the average daily oral steroid dose and occurrence of acute exacerbations [10,59]. Invasive aspergillosis is very uncommon in CF patients, although it may occur in the immunocompromised post-transplant population [13]. Some advocate anti-aspergillus treatment prior to lung transplant in patients with evidence of *Aspergillus* colonization [61,62].

Complications

The major pulmonary complications [14,63] include respiratory failure, pneumothorax and haemoptysis (Table 11.1).

Respiratory failure

This complication leads to death in more than 90% of CF patients. The slowly progressive airways disease and bronchiectasis lead to both hypoxic and hypercapnic respiratory failure. Airway obstruction from mucosal oedema, thickened airway secretions and bronchoconstriction leads

Table 11.1 Clinical disease in cystic fibrosis.

Complication	Life time prevalence (%)
<i>Pulmonary</i>	
Respiratory failure	100

Distal intestinal obstructive syndrome (DIOS)	20
Cholelithiasis	12
Clinical cirrhosis	5
Cystic fibrosis arthropathy	5

to ventilation/perfusion mismatch and hypoxaemic respiratory failure, with secondary pulmonary hypertension. Adequate supplemental oxygen is usually sufficient to prevent fluid retention, and limit adverse effects of pulmonary hypertension. Hypercapnia occurs late in the disease. Alveolar hypoventilation occurs secondary to air trapping, increased dead space and reduced vital capacity, as well as muscle weakness and fatigue. Acute respiratory failure can occur during exacerbations of bronchiectatic infection and some patients with respiratory failure resulting from reversible causes benefit from mechanical ventilation, but aggressive management (including intensive airway clearance) is necessary to wean as rapidly as possible [64]. Individuals with progressive respiratory failure, despite appropriate ongoing treatment, do not usually respond to mechanical ventilation [63]. Non-invasive ventilation devices have been used with some success, avoiding intubation in some patients, although close monitoring by trained staff is required [65,66]. For patients with end-stage disease, daily/nocturnal non-invasive ventilation (BIPAP) is frequently useful to bridge to transplantation [65].

Haemoptysis

Massive haemoptysis, defined as bleeding of more than 240 mL blood in a 24-hour period, occurs in 1.8% of CF adults per year [17] and previously had a high mortality rate before bronchial artery embolization (BAE) was available [67,68]. Haemoptysis can be successfully managed in most CF patients with BAE [68], but a recent review in a specialized CF centre revealed a mortality of 9% during

23 ICU admissions for massive haemoptysis [64]. Recurrent episodes of moderate haemoptysis (three or more bouts of 100 mL/day blood within a week) are also considered a major bleeding event and require admission and consideration for urgent therapy and haemorrhage control [63,68]. The source of this bleeding is usually enlarged tortuous bronchial arteries secondary to chronic inflammation. Initial treatment measures include a brief period of bed rest and cough suppression, along with intravenous antibiotics. BAE has proven to be effective for most episodes of major haemoptysis, and surgical intervention is rarely indicated [68].

Pneumothorax

The incidence of spontaneous pneumothorax in adults is 1.4% per year [17]. A high incidence of subpleural air cysts has been found. Caution is taken with CF patients with pneumothorax and most are admitted for observation. Although the rate of recurrence approaches 50%, most authors recommend a conservative initial approach to treatment: observation, aspiration or chest tube drainage depending on size [69]. Pleurodesis is recommended only for persistent air leak or recurrence [63]. Pleurodesis is not an absolute contraindication to lung transplantation, although surgical pleurodesis is preferred to chemical methods [69].

Diagnosis

Diagnosis is based on a combination of pertinent clinical findings, plus biochemical evidence (CFTR dysfunction; abnormal sweat test) or genetic testing. Abnormal CFTR function can be documented by elevated sweat chloride concentrations or abnormal nasal potential difference (NPD). Where sweat chloride tests are normal or borderline, and two mutations are not identified, abnormal nasal potential difference measurements can be used as evidence of CFTR dysfunction [12,32].

Sweat chloride

This is the gold standard test in experienced hands. Sweat is collected by iontophoresis and the chloride concentration is determined. A value of greater than 60 meq/L is consistent with CF and distinguishes CF from normal controls in adults. A lower cut-off point (< 40 meq/L) is necessary for diagnosis in children. Accuracy is greatly increased when experienced technicians in specialized CF centres perform the test under stringent conditions [70,71]. A false-negative rate occurs in only 1% of subjects in experienced laboratories. Patients are frequently referred to CF centres with a misdiagnosis of CF based upon an elevation in sweat

chloride level that reflects faulty technique. A number of other conditions are associated with a false-positive sweat chloride test, including hypothyroidism and adrenal insufficiency [12].

Nasal potential difference

The nasal transepithelial potential difference can also identify abnormal CFTR function. This test needs to be performed in specialized centres, as standardization of measurements is critical. Nasal potential difference measurements (including responses to amiloride, chloride-free solution and isoproterenol) may demonstrate abnormal CFTR function even when sweat Cl⁻ values are normal [72,73].

Genetic/molecular diagnosis

Genetic testing for common mutations is effective at documenting CF mutations on both alleles in the vast majority of CF patients [1,2]. Most laboratories in the USA screen for 20–30 of the most common mutations, which identifies the causative mutations in 90% of CF patients [1,74]. Ethnic differences in mutations should be considered in every patient. In patients with clinical features of CF with but only one CFTR mutation defined by screening, intensive genetic testing is likely to identify a second CFTR mutation or polymorphism [75].

Treatment of lung disease

The goals of therapy are to slow the progression of pulmonary disease by removing viscous, infected mucus, treating infection and improving nutritional status [17,76]. Other aspects of care include treatment of sinus disease, diagnosis and treatment of diabetes mellitus and addressing psychosocial issues.

A multidisciplinary approach coordinated by a specialized centre is recognized as the most effective method. There are over 100 specialized centres throughout the USA that are standardized and monitored by the CFF. This team approach involves physicians, nurses, dietitians, social workers and physical and respiratory therapists with overlapping responsibilities. It has been demonstrated that patients attending specialized centres have better outcomes [77].

Airway clearance

Although large randomized control trials are unavailable, physiotherapy is considered a cornerstone of therapy in CF [78]. A meta-analysis from 1995 compared modalities available at that time and concluded that no method of

physiotherapy was beneficial over other methods, but all were better than no physiotherapy [79].

A variety of traditional techniques are used, including postural drainage, percussion, vibration techniques, breathing exercises and directed cough. Newer techniques include the forced expiration technique and autogenic drainage. Recently, devices have become available to help mucus clearance, including positive expiratory pressure (PEP) masks, flutter devices and external percussive vests. Physical exercise has a central role in the management of patients with CF [80,81].

Inhaled hypertonic saline

One approach that targets the basic pathophysiology (Figs 11.2 and 11.3) is aerosolized hypertonic saline, which hydrates the mucosal surface and improves mucus clearance [82]. A recent long-term placebo controlled trial of 7% hypertonic saline in CF identified that it is an inexpensive, safe, and effective additional therapy with reduction in exacerbations and decline in lung function over 48 week period [83].

Nutrition

Chronic malnutrition with significant weight retardation and linear growth failure has been recognized as a general problem among CF patients [15,84]. Malnutrition results from increased caloric expenditure associated with chronic respiratory disease, decreased caloric intake and malabsorption of ingested nutrients because of pancreatic exocrine insufficiency.

Abnormal liver function and vitamin deficiencies secondary to pancreatic insufficiency are contributing components. To maintain their ideal body weight, patients are encouraged to eat a diet that provides 120–150% of the recommended energy intake of normal age- and sex-matched controls [85]. Nocturnal enteral feeding is considered if weight falls below 85% of the ideal body weight [15]. Gastrostomy feeding is much preferred to long-term parenteral feeding, and has been demonstrated to result in sustained weight gain and a slowing in decline of respiratory function [86]. Prevention of malnutrition from the time of diagnosis is associated with better lung function and improved survival [87]. No single strategy of treatment works for all patients and it is essential that an experienced dietitian gives individually tailored nutritional advice to each patient [88].

Antibiotic therapy

The frequent and targeted use of antibiotics improves survival in CF [1,89]. Antibiotic management in CF targets

signs of pulmonary exacerbations, which include increased production of sputum, cough, dyspnoea and sometimes a low-grade fever. Antibiotic guidance is based on sputum cultures and sensitivities and clinical response [76,90]. Mild exacerbations are often treated with an oral agent with or without an inhaled agent for 14–21 days. Intravenous antibiotics are used if the patient fails oral therapy, culture reveals an organism resistant to available oral therapies or the exacerbation is severe. Double antibiotic coverage is used against Gram-negative organisms because of a synergistic effect and to reduce the development of drug resistance, which occurs more frequently with monotherapy. A usual combination against *P. aeruginosa* is an aminoglycoside, plus a cephalosporin or broad-spectrum penicillin derivative. In more advanced disease, courses of up to 3 weeks may be required. An important development in parenteral antibiotic therapy is improved delivery systems and availability of home health services, transferring the administration of intravenous antibiotics from an inpatient to an outpatient setting and reducing inpatient stay and cost.

An important aspect of antibiotic therapy in CF patients is pharmacokinetics, because there is increased plasma clearance of almost all hydrophilic antibiotics (aminoglycosides, penicillins and cephalosporins) in CF patients [91,92]. This rapid elimination dictates the use of larger (and sometimes more frequent) doses of antimicrobials. Renal clearance of aminoglycosides is accelerated for unclear reasons, and CF patients require at least 6 mg/kg/day in divided doses. Patients are at risk of renal and ototoxicity from aminoglycosides, and monitoring of serum aminoglycoside levels is required.

Infection with *B. cepacia* is difficult to treat because of intrinsic resistance to aminoglycosides and polymyxins. Initial isolates can be sensitive to antipseudomonal β -lactams and co-trimoxazole, but resistance develops rapidly, with eventual resistance to all available antimicrobials.

Aerosolized antibiotics are being now used both as treatment and prophylaxis. Tobramycin prophylaxis has been shown to reduce hospital admissions by 25% after 10 weeks of therapy [93]. Colistin is another available nebulized antibiotic; resistance is uncommon, and it is rarely used as an intravenous agent because of side-effects [94–96].

Macrolide therapy

Chronic macrolide therapy appears to improve lung function [97–99] and reduce exacerbations in both adults and children with chronic *P. aeruginosa*. The standard dose for adults is 500 mg azithromycin three times per week. It is unclear whether the improvement is related to an anti-inflammatory or antimicrobial effect, or both. Cultures for AFB need to be checked prior to commencement of macrolide

Table 11.2 Predictors of worse outcome in cystic fibrosis after lung transplantation [101].

Adverse prognostic factors	
Female gender	Older age
Diabetes mellitus	Pancreatic insufficiency
Low weight-for-age score	<i>Burkholderia cepacia</i> infection
Frequency of pulmonary exacerbations	Low FEV_1

FEV_1 , forced expiratory volume in 1 s.

therapy, to prevent development of infection with non-tuberculous mycobacteria that is macrolide resistant.

Aerosolized DNAase

The endonuclease DNAase I cleaves denatured DNA in mucus and improves the clearance of airway secretions. Chronic use of DNAase improves FEV_1 and reduces the frequency of exacerbations [100]. DNAase is not useful in patients with severe lung disease [101].

Bronchodilator therapy

A subgroup of CF patients has bronchoconstriction secondary to airway hyperreactivity, and these patients often respond to inhaled bronchodilator therapy [1,2]. Large trials testing the long-term effects of inhaled bronchodilator on the progression of disease are not available for either short- or long-acting β -agonists. Clinical practice is to continue usage required for symptomatic relief.

Anti-inflammatory therapy

Controlling the magnitude of the inflammatory response in the airways is likely to be useful in CF. Early studies showed that prednisone slowed the loss of lung function in CF children, but side-effects (including diabetes, growth failure and cataract development) were unacceptable [102,103]. Studies of inhaled corticosteroid have been underpowered, therefore it is not clear whether they benefit CF lung disease or not. Like bronchodilators, they are used for symptomatic benefit. Ibuprofen (high dose) is beneficial in slowing the decline of lung function of children less than 13 years of age, but there is no evidence of benefit in adults [104].

Vaccinations

Annual influenza vaccinations are recommended, but pneumococcal vaccine is not routinely indicated because

of the relative absence of *Streptococcus pneumoniae* as an infectious organism in CF adults.

Lung transplantation

Approximately one-third of all double lung transplants in adults are performed for CF [13]. Overall, the 5-year survival post-transplant is approximately 50% but there are several predictors of mortality in lung transplantation (Table 11.2). An $FEV_1 < 30\%$ is used as a threshold for referral for transplantation [13,105].

Extrapulmonary manifestations

Impaired *CFTR* function leads to abnormal secretory function and associated clinical disease in other organ systems. Table 11.1 highlights common clinical features of CF.

Pancreatic disease

The pancreas in CF patients is destroyed by autodigestion *in utero*, reflecting a defect in Cl^- (liquid) secretion to flush digestive enzymes from the pancreatic ducts into the intestinal lumen. The lack of pancreatic enzyme secretion into the gastrointestinal tract leads to malabsorption of protein and fat with steatorrhea. This leads to failure to thrive in children, deficiencies in fat-soluble vitamins (A, D, E and K) and malabsorption and malnutrition. Management of pancreatic exocrine deficiency involves enteral replacement of enzymes (lipase, protease and amylase). The dosage depends on patients' weight and dietary fat intake [15,84].

Damage to the endocrine function of the pancreas also occurs and CF-related diabetes occurs in up to 35% of adults at age 25 [16,106]. CF-related diabetes is usually treated with insulin replacement. Glucose intolerance often worsens with exacerbations in pulmonary disease and with steroid therapy. Long-term survival is worse for patients with CF-related diabetes mellitus [16].

Interestingly, 'non-classic' CF patients with mild mutations usually have residual pancreatic exocrine function and can suffer from pancreatitis, whereas 'classic' (e.g. homozygous $\Delta F508$) patients have complete loss of pancreatic function and never have pancreatitis [20,22].

Gastrointestinal disease

Meconium ileus (MI) is the neonatal presentation of CF in approximately 15–20% of patients. An equivalent called 'distal intestinal obstructive syndrome' (DIOS) occurs in approximately 20% of adults [107]. DIOS involves impaction of inspissated intestinal contents in the terminal ileum, caecum and proximal colon. It can present as colicky abdominal pain, intestinal obstruction, abdominal distension

or bilious vomiting, with various clinical signs that can mimic appendicitis, colonic strictures and volvulus. If appropriate medical management is initiated (including nasogastric tube, treating electrolyte imbalance, fluid replacement and enemas), surgical intervention is rarely required [108].

Hepatobiliary disease includes cholelithiasis and cirrhosis, which reflects obstruction of biliary flow secondary to abnormal *CFTR*. Management includes optimization of nutrition status, replacement of fat-soluble vitamins and cholecystectomy if necessary. Liver transplantation may be needed in end-stage disease, which occurs in 2–5% of patients [11].

Gastroesophageal reflux disease occurs more frequently in CF patients [109], which can be also a cause of chronic cough.

Sinus disease

Panopacification of the paranasal sinuses occur in > 90% of patients at 8 months of age, with nasal polyposis in 10–30% of patients [110]. Despite this, the frequency of symptoms is lower than expected in adults (24%) [111]. Surgery is reserved for severe disease and symptomatic nasal polyposis.

Reproductive system

Reduced fertility occurs in females (approximately 20% are infertile), which is often a consequence of secondary amenorrhoea from chronic systemic illness, although cervical mucus abnormalities are also involved [112]. An FEV_1 of greater than 50% predicts better maternal and fetal outcome in pregnancy [113]. Males are usually infertile as a result of complete absence of the vas deferens, although men with a splice mutation have been reported to father children [73,114].

Osteoporosis

There is a high risk of osteopenia-associated bone fractures in CF adults, which reflects multifactorial causes related to delayed puberty, malabsorption, reduced vitamin D, glucocorticoid treatment and chronic lung infection [115,116].

Musculoskeletal system

Clubbing of both fingers and toes is common in patients with CF. Some develop hypertrophic osteoarthropathy. CF-associated arthropathy occurs in 2–9% of patients [117].

Cystic fibrosis in comparison with COPD

End-stage lung disease occurs in CF and COPD, but the time course and most clinical features are different (Table 11.3).

CF is a genetic disease of the conducting airways with morbidity usually commencing early in life. Smoke-induced COPD progresses over decades, and the alveolar destruction of emphysema contrasts with the airways disease and bronchiectasis of CF. Chronic bronchitis (CB) leads to an obstructive lung disease with some similarities to CF. Specifically, both CF and CB have 'abnormal mucus' in the airways with recurrent cough, sputum production and exacerbations of bacterial infection of the airways. For CF, the abnormal mucus reflects defective ion transport rather than primary (genetic) abnormalities in mucus [8,33,34], but the aetiology of abnormal mucus in CB is not well understood. It may reflect complex genetic and/or environmental interactions that lead to changes in the species or glycoforms of mucins produced in response to the irritant stimuli. Recent studies in an animal (mouse) model of accelerated Na^+ transport [118] resemble aspects of CB, raising the possibility that the inflammatory stimulus of cytokines associated with CB may secondarily modify ion transport in an adverse fashion and contribute to the pathophysiology of CB.

Despite the differences in clinical phenotype between CF and COPD, there are likely some common genetic and pathophysiological links between the airways disease in these two disorders. As summarized in Chapter 37 by Hersh and Silverman, there are many candidate genes that have been associated with several pathways in COPD, including proteases–antiproteases, oxidant–antioxidants, inflammatory cytokines, and the β_2 -adrenergic receptor. Many of these genes have been implicated as genetic modifiers of the lung disease in CF [119–121], but the only proven genetic risk factor for COPD (severe α_1 -antitrypsin deficiency) [122,123] has been shown to have no association with worse lung disease in CF [124–127]. Nonetheless, we predict that ongoing studies in large populations of COPD and CF patients are likely to identify some common genetic variants (e.g. glutathione S-transferases, matrix metalloproteinases and inflammatory cytokines), which have an adverse role in the airways disease of both disorders. In fact, recent studies have suggested that genetic variants in *TGF β 1* may influence phenotypic severity in both CF and COPD [25,26,128].

Prospects for the future

CF life expectancy has improved considerably over recent decades, with a current median survival age of 32 years. Lung transplantation programmes are achieving 5-year survival of 50%. The effect of early-targeted therapy to prevent and treat infection and inflammation is being assessed and will likely bear fruit over the next decade. Developments in antimicrobial and anti-inflammatory therapy are occurring at a rapid pace. Therapies targeting

Table 11.3 Comparison of cystic fibrosis and chronic obstructive pulmonary disease. **Similarities are in bold type.**

	Cystic fibrosis	COPD
Age of onset	Childhood	Adulthood

ABPA, allergic bronchopulmonary aspergillosis; NTM, non-tuberculous mycobacteria.

altered ion transport and abnormal mucus clearance are being investigated.

Successful transfer of the *CFTR* gene to *CFTR*-deficient cultured cells with production of effective chloride channels has been performed [129], but progress in gene transfer *in vivo* has been less successful [130]. Improvement in duration of expression, vector delivery and production and reduction in inflammatory responses are needed to progress this ultimate cure of CF.

CHAPTER 12

Bronchiectasis and COPD

Robert Wilson

Patients with bronchiectasis usually complain of a chronic productive cough and recurrent lower respiratory tract infections. They often become breathless with exertion and wheeze, without much variability. Chest discomfort is common and they may also have sharper pains or aching over the sites of bronchiectasis. These symptoms are easily confused with the chronic bronchitic end of the COPD spectrum. However, in more severe cases, the volume of sputum produced and the presence of chronic bronchial suppuration resulting from bacterial infection makes it unlikely that the two conditions will be confused. Haemoptysis, which nowadays is seldom severe, is more common in bronchiectasis, as is chronic rhinosinusitis. Tiredness is a symptom common to both conditions, but in poorly controlled bronchiectasis it is much more severe, and patients are unable to function normally later in the day [1].

Most patients diagnosed with bronchiectasis are non-smokers. This may be influenced by current medical practice, in that an opinion is more likely to be sought and investigations performed in non-smoking patients who have a productive cough. Patients often have symptoms from an early age, which are very different from COPD, and make it less likely that patients will begin smoking. A history of wheezy bronchitis in childhood may be present, and in some patients bronchiectasis (and the consequent symptoms) occurs following a childhood pneumonia. Similarly, hereditary causes of bronchiectasis such as cystic fibrosis and primary ciliary dyskinesia have symptoms from birth or soon after.

Other features of the two conditions are similar. Symptoms of anxiety or depression may be present as in any chronic illness. We have found that in bronchiectasis depression correlates with severity of disease, but the level of anxiety may be much higher than is appropriate [2]. Exercise tolerance, the frequency of exacerbations, requirement for hospital admission, the presence or absence of

Pseudomonas aeruginosa infection, and raised systemic markers of inflammation in the stable state are the best predictors of quality of life in bronchiectasis [3–5], which is not dissimilar to studies of this type in COPD [6].

The prevalence of severe cystic bronchiectasis has decreased since the introduction of vaccination against childhood infections, improved socioeconomic conditions and the availability of antibiotics, but in parts of the world where social conditions are poor and health care less available, bronchiectasis remains a much more common cause of morbidity and mortality. The availability of high-resolution computed tomography (CT) has increased the recognition of milder forms of disease. This cylindrical or tubular form has been termed ‘modern’ bronchiectasis [7]. The disease is usually bilateral and may be widespread, although the lower lobes are usually worst affected. Progression of disease may be bimodal, with most patients stable or declining slowly, whereas a smaller number progress more rapidly for reasons that are not clear at present.

The findings on examination are similar to COPD. Coarse inspiratory crackles are sometimes heard over the site of bronchiectasis but quite often, particularly in milder cases, there are no signs in the lung to suggest the diagnosis. Wheezes and squeaks may be heard as a result of obstructed airways, and patients may have signs of hyperinflation. Clubbing is quite unusual, because it only occurs in severe cases with cystic bronchiectasis, which are less prevalent than in the past.

Pathology

Bronchiectasis results from loss of structural proteins such as elastin from the bronchial wall, and the muscle and cartilage layers also show signs of damage. These changes lead to abnormal chronic dilation of the affected bronchi. Copious secretions may be produced by increased numbers of goblet

cells and hypertrophic submucosal glands, and these are poorly cleared and hence partially obstruct the airway lumen. Mucociliary clearance is delayed for several reasons: there is pooling of excess secretions in abnormal dilated airways; ciliated cells are lost when the epithelium is damaged and they are replaced by goblet cells; purulent mucus is less elastic and more viscous, making it difficult to clear by both ciliary beat and coughing. Side branches of the tortuous airways are frequently obliterated, and there may be complete fibrosis of small airways. There may be peribronchial pneumonic changes with evidence of parenchymal damage.

Lymphocytes predominate in the bronchial wall, which contains lymphoid follicles and nodes, whereas neutrophils are abundant in the lumen. As well as B lymphocytes, plasma cells and CD4⁺ T lymphocytes in the follicles, there is a well-developed cell-mediated immune response, with increased numbers of activated T lymphocytes, mainly of the suppressor/cytotoxic CD8⁺ phenotype, antigen-processing cells and mature macrophages [8].

Pathogenesis

We remain ignorant of the cause of bronchiectasis in up to half of cases. The more important causes that have been identified are listed in Table 12.1. Broadly speaking, the host defences are usually impaired in some way, and this may either be a systemic problem or one that is local in the lung, and it may be hereditary or acquired. Whatever the cause, inhaled bacteria that are normally cleared are able to persist and multiply in the airway lumen. Neutrophils are then attracted to this site by products of bacteria themselves, and also by mediators released from host cells (e.g. interleukin 8 [IL-8], C5a and LTB₄). Serum levels of the adhesion molecules E-selectin, ICAM-1 and VCAM-1 are elevated, suggesting that endothelial activation occurs, probably within the lung [9]. Many patients with bronchiectasis have chronic bacterial infection of the airway, and the failure of the inflammation to eradicate the infection is partly caused by the impaired defences, but also by the number of bacteria present and their pathogenic determinants [10].

Chronic neutrophilic inflammation has the potential to cause tissue damage via spillage of proteolytic enzymes such as elastase and reactive oxygen species, which overwhelm the lung's ability to neutralize them. Immune complexes, which are formed between bacterial antigens and antibodies (produced locally and by protein transudation), trigger other inflammatory cascades. Infection and inflammation may spread to involve adjacent areas of normal bystander lung. The lung's defences are further weakened by damage to both the surface epithelium and deeper structures of the bronchial wall, leading to the accumulation

Table 12.1 Causes of bronchiectasis.

<i>Congenital</i> e.g. defective bronchial wall (Mounier–Kuhn syndrome and others), pulmonary sequestration
<i>Postinfective</i> e.g. tuberculosis, whooping cough, non-tuberculous mycobacteria especially <i>Mycobacterium avium complex</i> and adenoviruses
<i>Mechanical obstruction/bronchial stenosis</i> e.g. within lumen (tumour) or external compression (lymph node)
<i>Deficient immune response</i> e.g. common variable immunodeficiency, HIV, acute or chronic lymphocytic leukaemia
<i>Inflammatory pneumonitis</i> e.g. aspiration of gastric contents, inhalation of toxic gases
<i>Excessive immune response</i> e.g. allergic bronchopulmonary aspergillosis, lung transplant rejection, chronic graft-versus-host disease
<i>Abnormal mucociliary clearance</i> e.g. primary ciliary dyskinesia, cystic fibrosis, Young's syndrome
<i>Fibrosis traction</i> e.g. cryptogenic fibrosing alveolitis, sarcoidosis, radiation pneumonitis
<i>Associated with inflammatory bowel disease</i> Especially ulcerative colitis, also Crohn's disease and coeliac disease
<i>Associated with connective tissue disorders</i> Especially rheumatoid arthritis, also Sjögren's syndrome and SLE
<i>Others</i> e.g. diffuse panbronchiolitis, yellow nail syndrome, associated with α_1 -antitrypsin deficiency
HIV, human immunodeficiency virus; SLE, systemic lupus erythematosus.

of mucus-containing bacteria in the lumen. These changes in turn promote continued infection and this perpetuates chronic inflammation. Epithelial cells, lymphocytes and macrophages release mediators that orchestrate this sequence of events (Fig. 12.1), which has been called a 'vicious circle' [7]. Bacterial numbers are higher during an exacerbation, either because a new strain is not constrained by the immune defences, or the defences are further impaired (e.g. because of a viral infection), and this leads to an increase in the amount of inflammation.

In COPD, tobacco smoke is the predominant cause of

A vicious circle of infection and inflammation

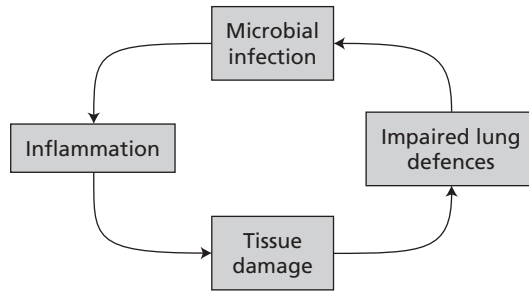

Figure 12.1 A 'vicious circle' of bacteria-stimulated host-mediated lung damage, which may occur with chronic bacterial infection of the airways or with frequent bacterial infective exacerbations.

lung damage and impaired airway defences against inhaled matter including bacteria. Bacteria are isolated in half or more of exacerbations [11], and isolation of a new bacterial strain makes the chances of an exacerbation twice as likely as when this is not the case [12]. Evidence is accumulating that exacerbations contribute to disease progression when they are frequent, and that lower airway bacterial colonization (LABC) in the stable state, which is present more often in patients with frequent exacerbations, stimulates chronic inflammation [13–16]. An animal model of chronic exposure of the lung to bacterial lipopolysaccharide has shown changes characteristic, in some ways, of those seen in both COPD and bronchiectasis in terms of inflammatory cells, cytokine expression and pathological changes in both airways and alveoli [17]. Therefore, bacterial infections and LABC in stable state COPD patients have been linked to airway inflammation in a way similar to bronchiectasis, and one study has shown a more rapid decline in forced expiratory volume in 1 s (FEV_1) in patients with LABC [18]. Bacterial numbers isolated when LABC is present correlate with markers of inflammation, including the important neutrophil chemoattractant IL-8 [15, 18, 19].

A 'vicious circle' similar to that proposed in bronchiectasis might therefore operate in some patients with COPD [20], particularly those patients with frequent exacerbations and LABC. If this were the case one would expect high-resolution CT scans to reveal evidence of bronchiectasis, although the predominant pattern might still be of COPD. In these circumstances, sputum bacteriology might reflect this shift in disease pattern. Several recent studies have shown that Gram-negative species (e.g. *P. aeruginosa*), more commonly associated with bronchiectasis and cystic fibrosis, are isolated in COPD patients [21–23]. The risk factors for isolation of *P. aeruginosa* include severe airflow obstruction and frequent prior courses of antibiotics. *P. aeruginosa* isolation in bronchiectasis is similarly associated with more severe disease and airflow obstruction [24].

Investigations

Suspicion of the presence of bronchiectasis should lead to investigation of possible causes, and an assessment of the extent of disease and functional impairment, before a management plan is constructed. This advice is unchanged if significant bronchiectasis is found in a COPD patient, because cigarette smoking does not cause this type of airway disease. The protocol of investigations performed in our unit is given in Table 12.2. Using a similar protocol, Pasteur *et al.* [25] found a cause that influenced management in approximately one-third of cases.

A chest radiograph is an insensitive test for bronchiectasis. In one study, less than 50% of patients who subsequently had positive bronchography were detected [26]. Therefore, to investigate the prevalence of bronchiectasis in COPD would require high-resolution thin section (1–2 mm) CT scans, and this would not be justifiable as a screening method because of radiation exposure. However, CT is now regarded as the 'gold' standard for establishing the diagnosis and extent of disease, and bronchography is

Table 12.2 Investigation of bronchiectasis.

All patients

Chest radiograph (PA and lateral)
Sinus radiographs
High-resolution thin-section computed tomography scan
Respiratory function tests
Blood investigations*
Sputum microscopy including eosinophils
Sputum culture and sensitivities
Sputum smear and culture for acid-fast bacilli
Skin tests (atopy, *Aspergillus*)
Sweat test (nasal potential difference, genotyping)
Nasal mucociliary clearance and nasal nitric oxide and proceed to cilia studies if these tests are abnormal

Selected patients

Fibreoptic bronchoscopy
Barium swallow (video fluoroscopy)
Respiratory muscle function
Semen analysis for ciliary function
Tests for associated conditions
Blood tests for rarer immune deficiencies

* To include: differential white cell count; erythrocyte sedimentation rate and C-reactive protein; total immunoglobulin (Ig) levels of IgG, IgM, IgA, and IgE; specific antibodies to bacterial polysaccharide and protein antigens, e.g. pneumococcal and tetanus antibodies, repeat after vaccination if low; *Aspergillus* radioallergosorbent RAST test and precipitins; autoantibodies including rheumatoid factor; α_1 -antitrypsinase.

Figure 12.2 High-resolution computed tomography of lung of patient with COPD, rheumatoid arthritis and *Pseudomonas aeruginosa* infection showing bronchiectasis (arrow).

almost never undertaken. CT scans are performed with a fast scan time (1 s or less) to reduce artefacts from respiratory motion and cardiac pulsation. The whole of the lung should be examined with 10-mm intersection spacing. The characteristic features are lack of bronchial tapering as the airways progress to the outside of the lung. The easiest method of ascertaining whether a bronchus is dilated is to compare it with the adjacent pulmonary artery. Dilated bronchi that are perpendicular to the scanning plane have a circular appearance, and then the smaller pulmonary artery gives a 'signet ring' appearance. Mucus-filled bronchi appear as branching tubules or nodules, and there may be a 'tree-in-bud' appearance indicating exudative bronchiolitis. End-expiratory scans identify increased transradiency in areas where air-trapping has occurred because of obstruction of small airways. Because the gas trapping is usually patchy, this gives a pattern of mosaic perfusion.

An example of bronchiectasis in a COPD patient with a long smoking history is shown in Figure 12.2. However, this patient also had rheumatoid arthritis (see Table 12.1), which may have influenced his lung disease. Although certain features on CT may suggest a cause of bronchiectasis (e.g. cystic fibrosis, upper lobe disease), allergic bronchopulmonary aspergillosis (proximal disease), non-tuberculous mycobacteria (diffuse mild disease with peripheral nodules that might be cavitating) or diffuse panbronchiolitis (widespread small nodules), they do not usually allow a confident diagnosis [27]. Several new volumetric techniques have improved accuracy in the assessment of bronchiectasis, but all have required increased doses of radiation which is unlikely to be justifiable [28].

Lung function tests provide a measure of functional impairment and an assessment of change with time. Airflow obstruction, which is largely fixed, and gas trapping

are very common as in COPD. However, unlike COPD, where there is often a component of emphysema, gas transfer values that have been adjusted for alveolar volume are usually well persevered unless the disease is severe. We also include a measure of exercise capacity in our assessment, because this has a strong correlation with quality of life scores [3].

Variable immune (antibody) deficiency is a relatively common cause of bronchiectasis. Immunoglobulin G (IgG) subclass deficiency by itself is not a cause of susceptibility to infection. Specific antibody levels should be measured, and if these are low the ability to respond appropriately to vaccination with polysaccharide (pneumococcal and *Haemophilus influenzae* type b) and protein (tetanus) antigens should be tested. All cases of immune deficiency may be secondary to malignancy, particularly of the lymphoreticular system, so a high index of suspicion must be maintained [1].

Sputum should be examined by microscopy as well as culture for respiratory pathogens including fungi and mycobacteria, because eosinophils can cause mild purulence, and their presence would indicate asthma or allergic bronchopulmonary aspergillosis. *H. influenzae*, *H. parainfluenzae* and *P. aeruginosa* are the species identified most frequently, but *Streptococcus pneumoniae* and *Moraxella catarrhalis* are also common isolates, so the microbiology of COPD and bronchiectasis is similar. In a CT study, the extent and severity of bronchiectasis, the severity of bronchial wall thickening and the extent of decreased attenuation were strikingly greater in the patients who cultured *P. aeruginosa* [24], but it is not clear whether isolation of this bacterium is simply a marker of disease severity, as it seems to be in COPD [21–23]. *Staphylococcus aureus* is less commonly isolated in both diseases, and we found regular isolation of this pathogen in bronchiectasis to predict allergic bronchopulmonary aspergillosis or atypical cystic fibrosis [29].

Prevalence of bronchiectasis in COPD

The prevalence of bronchiectasis in the community is unknown and will remain so until a cheap and safe screening tool is developed. Magnetic resonance scans would be ideal, but have not to date proved useful, although new approaches might hold some promise [30]. Possibly, low-dose CT could screen for the 'signet ring' appearance of bronchiectatic airways, in the same way as nodules are screened for in a smoking population. Empirically one would expect the pick-up rate of bronchiectasis to be increased by targeting patients with daily sputum production of significant volumes. Munro *et al.* [31] investigated 27 patients with such a history, 11 of whom were ex-smokers and 10 had an $FEV_1 \leq 80\%$. Bronchiectasis was

identified in 15. Chronic mucus hypersecretion in COPD has been associated with more frequent exacerbations, excess decline in FEV_1 and mortality resulting from an infectious cause [32–34], and it is likely that such patients have a high prevalence of bronchiectasis.

However, in the largest CT study of the prevalence of bronchiectasis in COPD performed so far, this expected association with sputum production was not found in milder cases of cylindrical bronchiectasis. O'Brien *et al.* [35] studied 110 patients aged 40–80 years old who had been diagnosed as having COPD by their primary care physician. Patients were in a stable condition at the time of the study, and had a high-resolution CT scan and full lung function tests. The finding of a wide variation in the severity of airflow obstruction was to be expected, as was the finding of emphysema in 51% of CT scans. Bronchiectasis was found in 29%, a much higher proportion than expected. In 23 patients this was tubular bronchiectasis, but in five it was cystic and in four varicose (i.e. more severe forms of disease). Six of the patients with tubular bronchiectasis had no history of sputum production. This result suggests that in the future when designing studies on the role of bacterial infection in COPD consideration will have to be given to performing CT scans on all patients to ensure that comparisons are made of like with like.

The East London Group have published many studies of their hospital clinic-based COPD population. An overt history of bronchiectasis is one of the exclusion factors for participation in their studies. Despite this, they have recently reported the results of high-resolution CT scans in 54 subjects from this population of older patients (mean age 69 years) with severe COPD (mean FEV_1 0.96 L, 38.1% predicted). Bronchiectasis was present in 72.2%, usually mild tubular disease in the lower lobes. Interestingly, these patients with bronchiectasis had more severe exacerbations, with greater rise in symptom scores and slower rates of recovery of peak flow [36]. Our own anecdotal experience at the Royal Brompton Hospital, London, is similar to this, bronchiectasis by CT scan criteria is common in COPD patients selected because of recurrent bacterial chest infections confirmed by sputum culture and particularly isolation of *P. aeruginosa*.

More studies are required before the prevalence of bronchiectasis in COPD is determined, particularly studies of unselected patients from primary care. The results of the studies performed so far suggest that bronchiectasis by CT scan criteria will be quite commonly found. This is not surprising given evidence of the role of neutrophilic inflammation during exacerbations and in the stable state. A more difficult question is the clinical relevance of this finding. The study of the East London Group showing that these patients have more severe exacerbations, suggest that the presence of bronchiectasis may influence management.

Two recent studies have shown a prolonged infection-free interval following treatment of an infective exacerbation with quinolone antibiotics which also achieved superior bacteriological eradication compared with comparator antibiotics [37,38]. Therefore, antibiotic treatment could influence exacerbation frequency, and in this way slow decline in FEV_1 [16,39]. The presence of bronchiectasis might identify patients in whom bacterial infection has an important role in provoking heightened airway inflammation and frequent exacerbations [19,40]. It is our practice to carry out a high-resolution CT scan in patients with documented frequent (more than four per year) bacterial infective exacerbations of COPD if this does not respond to appropriate antibiotic management and optimization of other aspects of treatment, particularly if *P. aeruginosa* is isolated. Other causes of increased susceptibility to infection should be screened for in such patients.

We have studied serial change in lung function and CT scans in bronchiectasis over time [41], and overall most patients show little change. FEV_1 correlated best with mosaic attenuation (small airways disease) in the CT scans, and this feature rarely regressed. When change did occur in FEV_1 , it correlated with changes in mucus plugging (small and large airways) seen on CT. Finally, when patients' disease progressed, an increased bronchiectasis score went hand in hand with increased mucus plugging and bronchial wall thickening, which is thought to reflect airway inflammation. Therefore, knowledge that a COPD patient has bronchiectasis should focus attention on efforts to improve mucus clearance and reduce airway inflammation by controlling bacterial infection.

Non-antibiotic management of bronchiectasis and its applications to COPD

Poor clearance of mucus from bronchiectatic airways is probably the fundamental reason that patients become colonized. Therefore, physiotherapy exercises to clear secretions are a critical aspect of management. Patients are advised to perform postural drainage at least once daily, and increase the frequency to twice or three times daily if they suffer an exacerbation. Patients know from experience their most productive time of day to perform the exercises. They should be taught by a trained physiotherapist to adopt the correct position to drain an affected area identified by CT scan, and clear mucus by controlled breathing techniques (e.g. active cycle of breathing and huffing), sometimes assisted by chest clapping from the patient themselves or a partner. Approximately 10 min in any one productive position is required so, understandably, compliance with physiotherapy is poor because of the nature of the process

and the time involved. Evidence of benefit from physiotherapy is largely anecdotal, but the importance of mucus clearance is emphasized by patients with primary ciliary dyskinesia who have widespread bronchiectasis, and by a group of patients in whom cough suppression had an adverse effect on their clinical condition [42]. Medical staff should regularly remind patients of the importance of physiotherapy. Controlled breathing techniques to clear mucus may be performed more conveniently in a sitting position, and physical exercise is also an effective way of encouraging mucus clearance. These latter methods should be encouraged in COPD patients with daily mucus production.

Any asthmatic component of bronchiectasis should be treated in the usual way. Systemic corticosteroids have unacceptable side-effects when used long term to try to reduce airway inflammation, although they are used for short periods during severe exacerbations. Inhaled corticosteroids are commonly prescribed to bronchiectasis patients in an attempt to reduce airway inflammation and relieve airflow obstruction [43], but unlike COPD there is no evidence that they reduce exacerbation frequency, nor that they influence disease progression. If they are used, an objective assessment of symptoms and lung function tests should be made several months after their introduction to justify continuation. Treatment of allergic bronchopulmonary aspergillosis with high-dose inhaled corticosteroids may prevent exacerbations and airway wall damage, but in some patients systemic corticosteroids are required. The antifungal antibiotic itraconazole may be used as a steroid-sparing agent [44]. Acid reflux and rhinosinusitis should be treated if present and influenza (annual) and pneumococcal vaccinations should be encouraged. Nebulized saline may be given in an attempt to promote cough clearance by liquefying secretions in some patients, although mucolytic agents have no proven benefit. This includes nebulized recombinant DNase which improves lung function and may decrease exacerbation frequency in cystic fibrosis, but not in other forms of bronchiectasis [45].

The only curative treatment of bronchiectasis is surgical resection. 'Modern' cylindrical bronchiectasis is usually bilateral and surgery is rarely considered for this reason and because it is a less problematic type to the patient. Palliative resection may be considered if a localized area of severe bronchiectasis defies medical management and acts as a sump for infection, even if less severe disease is present elsewhere. Nasal intermittent positive pressure ventilation is often surprisingly well tolerated despite sinusitis and excess bronchial secretions, and is used in patients with respiratory failure and bronchiectasis [46]. Lung transplantation is used to treat end-stage respiratory failure resulting from bronchiectasis. This is usually bilateral or heart-lung transplantation, otherwise infection in the remaining lung may spread to the new organ.

Antibiotic management of bronchiectasis and its application to COPD

When bronchiectasis is mild to moderate, antibiotic treatment reduces the bacterial numbers in the airway to low levels and can even achieve sterility, leading to resolution of the bronchial inflammation and symptoms. The next exacerbation occurs either with a new bacterial infection, or if residual bacterial numbers increase for some reason (e.g. a reduction in the host defences with a concomitant viral infection, or a change in the bacterial strain allowing it to escape the host defences). When bronchiectasis is more severe, the airways are usually chronically colonized and the symptoms of an exacerbation may recur soon after stopping the antibiotic. In these different circumstances, antibiotics may be needed only during an infective exacerbation when there is a change in sputum production, breathlessness or malaise, or at the other end of the spectrum continuously if relapse is rapid following treatment.

LABC in bronchiectasis and COPD probably represents a balance in which the impaired host defences are able to limit the number of bacteria, such that they do not stimulate an overt inflammatory response sufficient to generate symptoms of an exacerbation [47–49]. LABC is a dynamic process, multiple strains may be present and changes may occur in both their genotype and phenotype over time; strains may be carried for variable periods of time before being lost and replaced by others [50]. Acquisition of a new strain, which is not constrained by the immune system, may lead to an exacerbation associated with an increase in bacterial numbers [12]. The total bacterial load in the bronchial tree is a very important parameter in determining the level of inflammation [19], but other factors such as the species involved may be influential, and even different strains in the same species vary in their ability to elicit an inflammatory response [51]. Some patients with COPD behave in a similar fashion to those with bronchiectasis, having LABC and repeated chest infections. Their antibiotic management can therefore be planned in a similar way. These patients are probably best recognized clinically by frequent (more than four in 12 months) exacerbations associated with purulent sputum production.

The choice of antibiotic is influenced by the high frequency of β -lactamase production by strains of *H. influenzae* and *M. catarrhalis* in patients who have taken frequent antibiotic courses in the past, and the presence or absence of *P. aeruginosa* that is resistant to oral antibiotics other than ciprofloxacin [52]. Co-amoxiclav and ciprofloxacin are our first-line choices. Dosage is usually at the higher end of the options available, to ensure good concentrations are achieved in bronchial secretions, and the length of the course should be determined by resolution of symptoms

(particularly sputum purulence) rather than fixed at a certain number of days. Although initial antibiotic choice may be empirical, sputum culture should always be performed in cases of treatment failure.

If patients are severely unwell at presentation or infected by resistant strains, intravenous antibiotics are necessary. These should be commenced in hospital where supportive treatment such as physiotherapy can also be given, but increasingly patients are being taught to administer their own injections, so that when their condition is improving their hospital stay can be shortened by finishing the course at home. Ceftriaxone (non-*P. aeruginosa* patients) and cef-tazidime plus an aminoglycoside (*P. aeruginosa* patients) are our first-line antibiotics with piperacillin-tazobactam and meropenem second-line.

Patients with frequent exacerbations who relapse quickly following antibiotic treatment may be considered for long-term prophylactic antibiotics, in some cases restricted to the winter months when infective exacerbations are more frequent. This approach should only be taken after careful consideration, and only after other aspects of management have been optimized. There are several concerns about antibiotic prophylaxis: development of resistance in the strains already present; promotion of infection by more antibiotic-resistant species (e.g. *P. aeruginosa*); and antibiotic-induced side-effects (e.g. *Clostridium difficile* infection). Three different approaches to antibiotic prophylaxis have been used: oral antibiotics, which can either be with a single antibiotic, or a rotation of several antibiotics from different classes [53]; inhaled antibiotics given as an isotonic solution via a nebulizer [54]; and regular pulsed courses of intravenous antibiotics [55]. The first two approaches have been shown to reduce exacerbation frequency, although doubts have been expressed about the third [56]. Other benefits have also been shown in various aspects of patient well-being. In broad terms, we use oral prophylaxis in patients not infected with *P. aeruginosa*, nebulized antibiotics for patients with chronic *P. aeruginosa* infection, and pulsed intravenous antibiotics for patients with most severe disease in whom other forms of prophylaxis have failed.

Continuous treatment with macrolide antibiotics has been used effectively to treat diffuse panbronchiolitis, even when there is chronic infection with *P. aeruginosa*. This condition was first described in Japan [57], where it seems to be much more common. There are unique radiological and histological features, but clinically many features are similar to idiopathic bronchiectasis. The benefit of macrolides seem certain to be more than simple antibacterial effect, although azithromycin is active against *P. aeruginosa* with prolonged courses. Macrolides also affect *P. aeruginosa* virulence determinants including biofilm made of growth. However, it is more likely that the anti-inflammatory properties of the macrolide class are responsible [58]. A recent

study has shown promising results in cystic fibrosis, and further studies in bronchiectasis and COPD are planned [59,60].

CHAPTER 13

Obliterative bronchiolitis

Hélène Levrey Hadden and Marshall I. Hertz

The term 'obliterative bronchiolitis' refers to a specific histopathological pattern resulting from fibroproliferation in the walls and lumen of bronchioles; and to the clinical syndrome which results from these abnormalities. In general, obliterative bronchiolitis results from airway epithelial injury, leading to a lymphocytic and/or neutrophilic inflammatory reaction, with subsequent fibroproliferation around and within affected airways. Obliterative bronchiolitis is a distinct entity from bronchiolitis obliterans organizing pneumonia ('BOOP') and several other clinicopathological entities characterized by inflammation of small airways. The clinical, histological, radiographical and therapeutic aspects of obliterative bronchiolitis are reviewed in this chapter.

Aetiology and clinical associations

Obliterative bronchiolitis can result from direct airway injury from external agents, including viral infections and toxic inhalations, and from autoimmune and alloimmune reactions taking place within airway structures.

Postinfectious obliterative bronchiolitis

Airway infections frequently result in airway epithelial inflammation and injury. However, given the very high frequency of these infections in normal populations, evolution into obliterative bronchiolitis is uncommon. In children, obliterative bronchiolitis can follow acute bronchiolitis caused by adenovirus, but it is a very unusual complication, occurring in less than 1% of cases. Adenovirus serotypes 3, 7 and 21 have been particularly associated with the development of obliterative bronchiolitis [1–3]. Influenza virus, parainfluenza virus, measles, pertussis and *Mycoplasma pneumoniae* alone or in combination with an adenovirus have also been reported as preludes to the disease [2,4–6].

Although respiratory syncytial virus (RSV) is the most common cause of acute bronchiolitis in infancy, and may be followed by recurrent wheezing and airflow obstruction, little information is available to directly link RSV to the later development of obliterative bronchiolitis [5,7].

Adults with postinfectious obliterative bronchiolitis have usually been reported as isolated cases with a diversity of agents, including adenovirus, parainfluenza virus, cytomegalovirus and *Mycoplasma pneumoniae* [8]. Occasionally, adult patients present with a clinical syndrome suggesting lower respiratory infection, followed by progressive dyspnoea and irreversible progressive airflow obstruction; airway infections are frequently implicated as causative of this syndrome based on clinical suspicion, despite negative cultures and serological studies.

Toxin inhalation

Inhalation of chemical fumes may lead to bronchiolar epithelial injury and inflammation, followed by airway fibroproliferation. The prototype of this mechanism of injury is the syndrome of silo filler's lung, in which inhalation of silo gas containing high concentrations of nitrogen dioxide leads to respiratory illness [9,10]. Depending on the severity of the exposure, the clinical syndrome may range from mild to severe, and from slowly progressive to fulminant. In severe cases, lung injury usually overshadows the bronchiolar abnormalities, and may lead to respiratory failure and death. After milder exposures, cough and dyspnoea are often accompanied by nausea, vomiting, headache and other non-specific symptoms. After recovery from the acute illness, progressive dyspnoea and decreased pulmonary function tests signal bronchiolar inflammation and obliteration. Corticosteroids are generally recommended for patients with significant exposures to inhaled nitrogen dioxide; they should be started as soon after exposure as possible and the duration of therapy is usually at least 8 weeks.

Anhydrous ammonia and sulphur dioxide are much more water-soluble than nitrogen dioxide; therefore, they usually dissolve in secretions on the mucus membranes of the upper airways and bronchial tree and may cause intense irritation. Eye irritation, laryngitis, cough, wheezing and airflow obstruction often follow exposure, and obliterative bronchiolitis may ensue [11,12].

An outbreak of obliterative bronchiolitis has been reported in patients who had all worked at a microwave popcorn production plant. This was believed to have been caused by the inhalation of diacetyl, a volatile artificial butter flavouring agent [13].

Toxin ingestion

Obliterative bronchiolitis resulting from ingested toxins is rare. Several cases have been reported from Taiwan and China which were associated with consumption of the plant *Sauropus androgynous* [14]. Although the syndrome is hypothesized to result from the papaverine contained in the plant, papaverine has not been shown to lead to obliterative bronchiolitis in experimental animals. This injury has proven to be quite resistant to therapy, and several affected patients have undergone lung transplantation [15].

Connective tissue disease

Obliterative bronchiolitis is one of many pulmonary problems that occur in patients with connective tissue disease [16,17]. This problem complicates rheumatoid arthritis in a small proportion of patients [18] and systemic lupus erythematosus even more infrequently. Although bronchial inflammation may occur in Sjögren syndrome, progressive systemic sclerosis and other connective tissue syndromes, obliterative bronchiolitis is rarely observed. Treatment with penicillamine may contribute to the development of obliterative bronchiolitis, although the literature is not clear as to whether the penicillamine or the underlying connective tissue disease is the causative factor [19]. Evidence against penicillamine as a causative agent is the failure to observe obliterative bronchiolitis in patients treated with penicillamine for Wilson disease.

Alloimmune reactions

Lung transplant recipients now constitute the largest population of patients with obliterative bronchiolitis, with a cumulative incidence of approximately 50% during the first 5–8 years after transplantation [20]. The exact pathogenesis of this problem is not clear, although an alloimmune-mediated mechanism is almost certainly involved [21,22]. The occurrence of acute lung rejection,

especially when episodes are recurrent or severe, is a major statistical risk factor for the subsequent development of obliterative bronchiolitis [23]. Infections, including cytomegalovirus, and the community respiratory viruses respiratory syncytial virus, parainfluenza virus and influenza may also contribute in some patients [24]. Gastroesophageal reflux has recently been identified as a risk factor for obliterative bronchiolitis after lung transplantation; it has been suggested, but not yet conclusively proven, that antireflux surgery may reduce the incidence of this problem in selected patients [25,26].

Obliterative bronchiolitis may also complicate allogeneic and autologous bone marrow transplantation [27]. Although this occurs much less frequently than in lung transplant patients, the incidence of this problem may be higher than previously appreciated [28]. The disease is usually seen in the setting of chronic graft-versus-host disease, but it is less common than other clinical manifestations of graft-versus-host disease, including skin and gastrointestinal manifestations.

Histopathology

Histopathological findings of obliterative bronchiolitis mirror the clinical manifestations, with anatomical obstruction of bronchioles resulting from fibroproliferation in the airway walls and lumen [29] (Fig. 13.1). The lesions primarily affect terminal bronchioles. A spectrum of histopathological abnormalities is seen, ranging from inflammation and fibrosis of the bronchial wall, sometimes referred to as 'constrictive bronchiolitis', to fibroproliferation within of the lumen, referred to as 'proliferative bronchiolitis'. Although these histopathological patterns may coexist, one or the other tends to predominate within the lungs of an affected individual. In many cases, the process is spatially inhomogeneous, with diseased and apparently normal bronchioles appearing in the same anatomical area. The airway epithelium is often disrupted and abnormalities ranging from none, to squamous metaplasia, to complete absence of epithelium are seen. Eventually, affected bronchioles are replaced by a small nubbin of a scar, which may be quite inapparent on lung biopsy. In postinfectious obliterative bronchiolitis, fibroblasts, leucocytes and fibrin partially or fully obstruct the airway lumen, and signs of active inflammation may still be present several years after the initial illness [30]. In many cases, abnormalities of the large airways coexist with bronchiolitis, resulting in bronchiectasis and a chronic bronchitis-like clinical picture. Inflammation of the alveolar ducts and alveoli is not a primary manifestation of obliterative bronchiolitis, but may occur if bronchopneumonia results from obstruction of more proximal airways.

(a)

(b)

Figure 13.1 Histology of bronchiolitis obliterans. (a) ‘Constrictive’ obliterative bronchiolitis. Peribronchiolar lymphocytic inflammation is accompanied by an increase in the number of mesenchymal cells and their connective tissue products in the lamina propria (arrow), compromising the airway lumen in an eccentric, constrictive fashion. An inflammatory infiltrate comprised of small round cells can be appreciated in the bronchial epithelium, and in the advancing fibrous tissue. (b) ‘Proliferative’ obliterative bronchiolitis, in which granulation tissue comprised of mesenchymal cells and capillary loops virtually fill the lumen (L, airway lumen; S, airway smooth muscle).

Clinical presentation

Progressive dyspnoea on exertion is the hallmark symptom of obliterative bronchiolitis. Cough, which may be productive at first, is often the presenting complaint. Wheezing may be present and the condition is often initially diagnosed as asthma. In cases associated with known causes, such as infections and toxic gas inhalation, the clinical symptoms generally appear within weeks of the initial insult. In general, systemic complaints and fever are absent unless secondary infections supervene.

The clinical course and progression of the disease are variable. In children with postinfectious obliterative bronchiolitis and patients with toxic gas inhalations, the clinical and radiographical features of the disease may wax and wane for several weeks or months, sometimes with recurrent episodes of atelectasis, pneumonia and wheezing. Some patients recover completely [30,31], while others display permanent obstructive airways disease that is only partially reversible [4]. In some cases patients die of progressive respiratory failure [30]. This variability in the clinical course presumably reflects a variable balance between reversible inflammation and irreversible fibroproliferation in the lower airways.

In patients with obliterative bronchiolitis resulting from alloimmune or autoimmune reactions, the course of the disease tends to be more relentlessly downhill. Periods of relative quiescence may be punctuated by bouts resembling acute exacerbations of COPD, often resulting in further irreversible loss of lung function. Although stabilization of

pulmonary function may occur, significant recovery of lost lung function is unusual.

Differential diagnosis

It is important to differentiate bronchiolitis obliterans from many other entities with similar names, physiological findings and histopathology. Other forms of COPD, including chronic bronchitis, emphysema and chronic asthma, generally evolve over a much longer time than does obliterative bronchiolitis. Obliterative bronchiolitis is not associated with cigarette smoking, and demonstrates minimal, if any, response to bronchodilator medications. Often, a history of infection or exposure to another known causative agent is present in patients with obliterative bronchiolitis.

Respiratory bronchiolitis with interstitial lung disease (RBILD) primarily affects alveolar ducts and respiratory bronchioles [32]. An increased number of alveolar macrophages is a characteristic biopsy finding. This syndrome is most often associated with cigarette smoking, and usually improves or resolves with smoking cessation. Pulmonary function tests reflect a restrictive ventilatory abnormality. High-resolution computed tomography (HRCT) scans can be very helpful in differentiating these entities, because RBILD may be characterized by extensive ground glass opacities, which are not typical of obliterative bronchiolitis.

Bronchiolitis obliterans organizing pneumonia (BOOP) is a distinct entity characterized by polyps of loose connective tissue in alveolar ducts, in association with alveolar inflammation [33]. Although BOOP and obliterative

bronchiolitis share associations with many causative agents and conditions, they are distinct clinically, radiographically, histologically and in their response to treatment. It is not clear whether these differences result from the location and severity of the initial insult, or differential healing responses between individuals. The histological lesions of BOOP may be seen in association with almost any insult known to cause obliterative bronchiolitis. However, an underlying aetiology is often not apparent, and the illness is called 'idiopathic BOOP' or 'cryptogenic organizing pneumonia'. Idiopathic BOOP is often accompanied by signs of systemic illness, including fever, malaise and weight loss. The chest radiographical findings are quite variable, but a normal radiograph is unusual. In BOOP, pulmonary function testing generally demonstrates a restrictive ventilatory abnormality with decreased diffusing capacity. In some patients with only segmental involvement, pulmonary function is normal [4].

Diffuse panbronchiolitis is a relatively common condition in Japan, China and Korea, but rare in other parts of the world [34,35]. It is most often associated with chronic sinusitis and productive cough, features that are not characteristic of obliterative bronchiolitis. Pulmonary function tests usually show airflow obstruction and a reduction in diffusing capacity. Radiographically, the disease is characterized by small nodular opacities and peripheral linear densities. Because this syndrome is quite unusual outside of Asia, it rarely confuses the diagnosis of obliterative bronchiolitis in Western countries.

Swyer-James, or MacLeod, syndrome is a variant of postinfectious bronchiolitis. It usually develops as a sequela of pulmonary infection in infancy or early childhood and leads to alveolar destruction and obliterative bronchiolitis. This may prevent the normal development of the affected lung, resulting in decreased lung volumes and blood flow, which is characterized radiographically by a unilateral hyperlucent lung with normal or reduced lung volume during inspiration and air trapping during expiration.

Diagnostic testing

Physical examination

On physical examination, affected patients may appear normal, or may display varying degrees of dyspnoea and decreased oxygen saturation, depending on the severity of their disease. Percussion of the chest may demonstrate hyperresonance, but not usually to the degree observed in patients with emphysema. Auscultation usually shows decreased inspiratory breath sounds, and end-inspiratory squeaks and crackles may be heard. Expiratory wheezes may be present, but are often absent, even in advanced disease. Clubbing is generally absent.

Pulmonary function

Pulmonary function tests typically show airflow obstruction with decreased forced expiratory volume in 1 s (FEV_1), $FEV_1 : FVC$ (forced vital capacity) ratio and mid-expiratory flow rates. There is characteristically minimal response to inhaled bronchodilators. Lung volumes are usually normal or increased, although in some cases total lung capacity (TLC) is reduced. The diffusing capacity for carbon monoxide is normal or mildly reduced. Some patients with obliterative bronchiolitis demonstrate a restrictive pattern of pulmonary function abnormalities with reduced FEV_1 , FVC and TLC; presumably the anatomical lesions in these individuals are primarily of the proliferative type, with complete obstruction of bronchiolar lumina.

Chest radiography

The plain chest radiograph is the most common non-invasive diagnostic test in obliterative bronchiolitis. Typically, pulmonary parenchymal opacities are absent, unless pneumonia complicates the picture. Hyperinflation may be apparent, and bronchial markings may be accentuated.

In children with postinfectious bronchiolitis, five radiographical patterns have been recognized [4]:

- 1 bilateral hyperlucent lungs;
- 2 unilateral hyperlucency and expansion of all or part of a lung;
- 3 unilateral hyperlucency of a small to normal-sized lung with air trapping on expiration (Swyer-James or MacLeod syndrome);
- 4 persistent complete collapse of the affected lobe; and
- 5 a mixed pattern of persistent collapse, hyperlucency and peribronchial thickening.

High-resolution computed tomography

The advent of HRCT has markedly improved the accuracy of non-diagnostic testing. Patients with obliterative bronchiolitis may show mosaic perfusion, with variable opacity in different lung zones reflecting hypoperfusion of some anatomical regions. Comparing inspiratory and expiratory HRCT scans can be very useful when inhomogeneous emptying of alveolar structures is seen, reflecting patchy air trapping. Finally, HRCT images may show peripheral branching structures that are thought to represent collapsed or fluid-filled small airways distal to obstructed bronchioles [36,37].

The use of ultrafast HRCT scans is feasible in children too young or too sick to hold their breath and allows early detection and accurate characterization of the lung process [38,39]. HRCT findings include varying degrees of bronchial wall thickening and bronchial dilatation, pulmonary vascular attenuation and areas of collapse, hyperlucency and air trapping on expiration.

Treatment

Obliterative bronchiolitis is generally poorly responsive to treatment with bronchodilators, corticosteroids and other medical therapeutics. Clearly, when a treatable infection is identified, it should be treated; however, even when the aetiology of obliterative bronchiolitis is known, specific therapy is difficult because the lesion evolves long after the initial insult. For example, there may be a hiatus of several weeks between toxic fume inhalation or respiratory viral infection and the development of progressive airflow limitation.

Bronchodilator therapies are relatively ineffective because the lesions are the result of fibroproliferation with anatomical obstruction, rather than of bronchoconstriction resulting from smooth muscle contraction. Corticosteroids are often administered, with variable results; undoubtedly they are more helpful in the early stages of the disease when anti-inflammatory therapy might be expected to be of benefit. As the disease progresses, corticosteroids are less effective. Corticosteroids are administered routinely in patients with silo filler's lung and other non-infectious inhalational airway injuries. They are also used frequently in obliterative bronchiolitis associated with connective tissue syndromes.

Erythromycin and other macrolide antibiotics have anti-neutrophil properties, and are used routinely in patients with diffuse panbronchiolitis. They have also been reported to benefit some patients with lung transplant-associated obliterative bronchiolitis [40].

Immune modulatory therapies are the mainstay of treatment for obliterative bronchiolitis resulting from alloimmune reactions. Immunosuppressive medications employed include ciclosporin, tacrolimus, mycophenolate mofetil, methotrexate and cyclophosphamide. There is evidence in the lung transplant literature that each of these agents is effective in stopping the progression of the disease in some patients, although reversal of established airflow obstruction is unusual [21]. Photochemotherapy (photopheresis) has also been shown to be beneficial in slowing disease progression in some patients [41,42].

Because the end lesion of obliterative bronchiolitis results from fibroproliferation, one would expect that antiproliferative therapies might be useful. Thalidomide has been used in some cases of chronic graft-versus-host disease after bone marrow transplantation, but its efficacy in treating obliterative bronchiolitis in that setting has not been established [43–45]. Rapamycin, a relatively new medication with immunosuppressive and antiproliferative properties, is also promising on theoretical grounds [46]. However, its clinical efficacy for obliterative bronchiolitis is also unknown at this point.

The treatment of postinfectious obliterative bronchiolitis in children is mostly supportive, consisting of oxygen therapy, bronchodilators, antibiotics for secondary infections and regular chest physiotherapy, especially if bronchiectasis is present. Despite the persisting inflammatory lesions still present at a late stage, the use of corticosteroids remains controversial, and no clinical trials in children are available. Treatment with non-steroidal anti-inflammatory therapies has been reported, as has intravenous gammaglobulin infusion.

Lung transplantation is a therapeutic option for obliterative bronchiolitis patients with severe airflow obstruction not responsive to medical therapy. The Registry of the International Society for Heart and Lung Transplantation indicates that 263 single or bilateral lung transplants were performed between January 1995 and June 2004 for patients with obliterative bronchiolitis; this represents approximately 2% of all lung transplants during that time interval [20]. Of these, approximately half were retransplant procedures for patients with obliterative bronchiolitis after lung transplantation. Recurrent obliterative bronchiolitis after repeat lung transplantation does not appear to occur with increased frequency relative to that seen in patients undergoing repeat lung transplantation for other indications [47].

CHAPTER 14

Asthma

Diana C. Grootendorst and Klaus F. Rabe

A major differential diagnosis in patients with COPD is asthma (Fig. 14.1) [1]. Although these diseases are clearly different, in some patients with chronic asthma a clear distinction from COPD is not possible [2], even when history, physical examination, physiology testing and imaging are used. A minority of patients with asthma develop irreversible airflow obstruction and other features of COPD over time [3]. Asthma is assumed to coexist with COPD in these patients and management is highly similar in severe forms of the disease(s) [1]. This chapter presents an overview of the current knowledge on aetiology, pathology, pathogenesis, pathophysiology and treatment of asthma, and discusses the possible (dis)similar pathways underlying asthma and COPD.

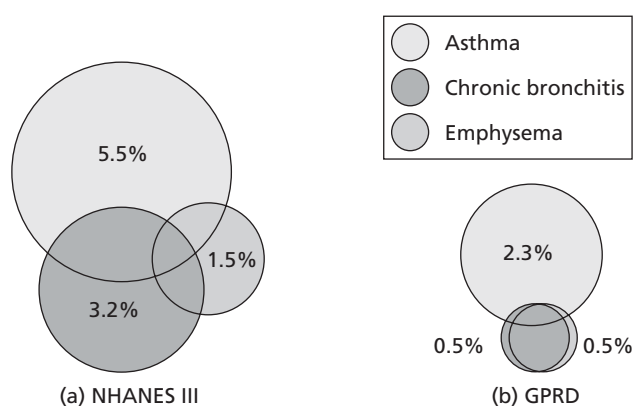

Figure 14.1 Proportional Venn diagram of obstructive lung disease (asthma, chronic bronchitis and emphysema) (a) in the USA (National Health and Nutrition Examination Survey [NHANES] III surveys from 1988 to 1994) and (b) in the UK (UK General Practices Research Database [GPRD] in 1998) for all ages. Definition

Asthma is a chronic inflammatory disease of the airways, characterized by variable airflow obstruction and bronchial hyperresponsiveness to a variety of stimuli. Symptoms of asthma include episodes of wheeze, breathlessness, chest tightness and cough, particularly at night and/or in the early morning [4]. Usually, the airflow limitation observed in asthma is (at least partly) reversible either spontaneously or following treatment [4].

Diagnosis

The clinical diagnosis of asthma is usually prompted by symptoms such as episodic breathlessness, wheezing, chest tightness and cough. These are often more pronounced at night and in the early hours of the morning [4]. Although the diagnosis of asthma can be made on the basis of symptoms alone, the accuracy is improved when objectified by lung function measurements, including the assessment of airflow limitation together with the reversibility and variability of airflow limitation.

Measurement of the forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) by flow–volume curves is used for the assessment of airflow limitation [5]. FEV_1 and FVC values below 80% of the reference value are usually considered as abnormal [5]. In addition, when FEV_1 normalized for FVC ($FEV_1 : FVC$) is below 75%, this is indicative of airflow limitation or airways obstruction.

Variability in airflow limitation is most frequently tested by measuring the response of FEV_1 to an inhaled bronchodilator such as the β_2 -agonist salbutamol [5]. An improvement in FEV_1 and/or FVC following the administration of a bronchodilator by more than 12% predicted and 200 mL or in peak expiratory flow rate by more than

60 L/min is considered an unambiguous bronchodilator response [5], fitting in with the diagnosis of asthma. Even in the absence of a bronchodilator response, the airflow limitation can be reversible after a short course of prednisolone [4]. In addition to reversibility testing, daily recording of the peak expiratory flow rate can be used to assess (daily) variability in lung function. Daily variability in peak expiratory flow rate > 20% is usually considered as a sign of unstable asthma, requiring a change in treatment [4].

Variable airways obstruction can be mimicked in the lung function laboratory by challenge tests with bronchoconstrictive stimuli such as histamine or methacholine [6]. In subjects with airways hyperresponsiveness, an exaggerated response to the bronchoconstrictor can be observed. The response to a bronchoconstrictor is usually expressed as the provocative dose or concentration of bronchoconstrictor causing a fall in FEV_1 of > 20% from baseline (PD_{20} or PC_{20}). In normal subjects, the PC_{20} is > 8 mg/mL (PD_{20} > 7.8 μ mol) of histamine or methacholine.

Having a bronchodilator response or airways hyperresponsiveness is considered to be indicative for asthma. However, absence of these features does not exclude the possibility of asthma. Furthermore, each of these features can also be present in patients with COPD [7]. Other patient characteristics, such as the presence of atopy or a positive smoking status or history, are helpful to increase or decrease the diagnostic probability for asthma instead of COPD.

Epidemiology

Bronchial asthma is one of the most common chronic diseases in high-income countries, affecting over 100 million people [4]. Reported prevalence rates for asthma show a wide variation. In adults, the prevalence of symptoms of wheeze varies from 4.1 to 32.0%, whereas the prevalence of diagnosis of current asthma varies between 2.0 and 11.9% [8]. The international patterns in asthma prevalence show that prevalences are highest among English-speaking countries (UK, New Zealand, Australia, USA and Canada) and Western Europe, and much lower in Eastern and Southern Europe [9]. During the last decades, not only the prevalence and but also the severity of asthma has increased [10,11]. Recent studies, however, show trends for a plateau in the prevalence of asthma [12].

Aetiology

Several risk factors for the development of asthma have been described. The strongest predisposing factor associated with the development of asthma, and in particular

childhood-onset asthma, is atopy [4]. Approximately 50% of asthma cases are attributable to atopic sensitization [13].

Atopic sensitization

Up to 90% of children with asthma are sensitized to common airborne allergens such as domestic mites, furred animals, fungi and pollens [14]. In particular, sensitization to house dust mite [15], *Alternaria* [16] and cockroach [17] has been shown to be associated with an increased risk for asthma in children. The relation between *level* of exposure and *development* of asthma is far from clear and seems rather controversial. In one study, the risk for the development of asthma in house dust mite sensitized children doubled with every doubling of indoor house dust mite level [18], although this dose-response relation was not confirmed in another large study [19]. Furthermore, being allergic to cat dander is a risk factor for the development of asthma, but having a cat in the house may be protective for the development of asthma [20]. Several studies have also suggested a relation between *level* of exposure to allergens and *severity* of asthma. First, patients with severe asthma are exposed to higher levels of domestic allergens to which they are sensitized, compared with patients with mild asthma [21,22]. In addition, sensitization to the moulds *Alternaria alternata* and *Cladosporium herbarum* occurs more frequently in patients with severe asthma, while this is not the case for sensitization to grass and tree pollens [23]. Secondly, seasonal variation in, for instance, house dust mites is associated with changes in peak expiratory flow rates [24] and airways hyperresponsiveness [25]. Taken together, these studies show that allergic sensitization is not only an important precursor of developing asthma, but also is associated with severity of the disease.

Genetic predisposition

In addition to atopic sensitization, asthma, which develops during childhood, has a clear genetic component [4]. Children from allergic and/or asthmatic parents have an increased risk for asthma [26,27]. Several gene loci have been linked to atopy and asthma, including chromosome 5q31 (IgE), chromosome 5q31-33 (multiple genes modulating atopic responses: IL-4, IL-13, IL-5, CD14 and GM-CSF), major histocompatibility complex region on chromosome 6, several genes on chromosome 7 (atopy, asthma and eosinophilia), chromosome 11q13 (atopy, high affinity receptor for IgE), chromosome 13q (atopy), chromosome 14, chromosome 16 [28] and the ADAM33 gene on chromosome 20p13 [29]. Genetic background and environment may interact in the development of asthma: high levels of cat allergen in the house are associated with a reduced risk of wheezing in childhood in children from

mothers with no history of asthma, whereas this is related to an increased risk for wheezing in children from mothers with a history of asthma [30].

Socioeconomic status

Another important determinant of childhood asthma may be socioeconomic status. Recently, it has been shown that the increase in incidence of asthma is driven by factors associated with improved social circumstances (higher income and education of parents, less unemployment, welfare and overcrowding), whereas severity of asthma is related to factors associated with poverty [31].

Late-onset asthma

In asthma that starts later in life, the role of atopy is less clear. The prevalence of being non-atopic is higher in adult-onset asthma than in childhood-onset asthma, and prevalences of atopy ranging from 25–30% [32] to more than 60% [33] have been described in adult-onset asthmatics. Non-atopic adult-onset asthma is known to have a more severe clinical presentation and to be less responsive to standard therapy [34]. This type of asthma may also be associated with the rapid development of persistent airflow limitation [35], indicating a worse prognosis when compared with childhood asthma. As such, late-onset asthma may be more difficult to distinguish from COPD. Factors implicated in causing adult-onset asthma include aspirin sensitivity [36], rhinitis and chronic sinusitis [37], occupational exposure to chemicals [38], exposure to fungi on the skin and nails [39], and persistent infection with respiratory pathogens [40].

Pathology

The pathology underlying the clinical presentation of both asthma and COPD is chronic inflammation of the airways [41,42]. However, even in patients with comparable fixed airflow obstruction, patients with a history of asthma have distinct pathological characteristics compared with those with COPD (see Plate 14.1; colour plate section falls between pp. 354 and 355) [2].

In general, the inflammatory infiltrate in the airway wall mucosa of patients with asthma (mainly) consists of eosinophils, mast cells and lymphocytes [43]. These features can even be found in subjects with newly diagnosed asthma [44]. Interestingly, lymphocytic and mast cell inflammation seems to be associated specifically with childhood-onset asthma, and not with late-onset asthma [45].

In patients with severe asthma, increased neutrophil numbers have been found in the lamina propria [46].

Moreover, an increase in neutrophils in the submucosa has also been implicated in sudden-onset, fatal attacks of asthma [47]. Other pathological changes of the airways that have been described in association with asthma include loss of epithelial integrity [48], smooth muscle hypertrophy and hyperplasia [49], changes in the vasculature including neovascularization, dilation and leakage [50], and thickening of the reticular layer beneath the basement membrane [48]. In patients with late-onset asthma without eosinophilia in the airways, however, subepithelial basement membrane thickening is not present, suggesting a different pathological process in these patients [45].

In addition to inflammation in airway tissue, changes in cellular infiltrate in the airway lumen are present in patients with asthma. As in bronchial biopsies, an increase in eosinophils and mast cells characterizes the inflammatory infiltrate in both bronchoalveolar lavage fluid [51,52] and induced sputum [53], with an additional increase in sputum neutrophil numbers in patients with severe asthma [54]. Furthermore, an increase in a variety of cytokines, chemokines and markers of microvascular leakage can be found in the sputum of patients with asthma, including eosinophil cationic protein (ECP), fibrinogen, albumin and interleukin 8 (IL-8) [55,56].

Pathogenesis

How do each of these factors interact and contribute to clinical asthma? It is clear that the presence of both host and environmental factors are needed for the transition from sensitization alone to allergic asthma. According to current concepts, these include dysregulation of immunological control mechanisms within the airway mucosa, and a series of environmental factors [57,58].

Initial priming of T helper (Th) cells against environmental allergens occurs *in utero*, presumably by means of transplacental transport of allergens to which the mother is exposed during pregnancy [59]. Cord blood mononuclear cells of all infants produce high levels of the Th2 cytokines IL-4 and IL-5, and low levels of γ -interferon (IFN- γ), upon stimulation of cells by house dust mite allergen. During the first year of life of non-atopic children, there is rapid suppression of these Th2 responses, with skewing towards the Th1 phenotype (high expression of IFN- γ and low expression of IL-4 and IL-5) [60]. However, in potentially atopic children, Th2 responses are consolidated, which appears to be associated with a defective neonatal IFN- γ response [60]. During this postnatal period, environmental exposures appear to be important. Exposure to high levels of microbial products reduces the risk for atopy and asthma [61]. Furthermore, exposure to dietary allergens in early childhood leads to negative regulation of Th responses via

T-cell anergy and/or deletion [57]. In contrast, postnatal exposure to inhalant allergens results in redirection towards the Th1 profile in non-atopics or in further boosting of the fetally primed Th2 response in potential atopic children [57].

Still, only a subset of subjects who are sensitized during childhood develop severe long-term sequelae [62]. An important feature appears to be the (dysregulation of) Th1–Th2 cell balance [63]. Recently, it has been shown that atopic asthmatic patients with severe persistent disease have a reduced allergen-induced Th1 response, whereas those subjects with resolved asthma do not. On the other hand, subjects with a history of asthma have increased house dust mite induced Th2 cytokine responses, irrespective of the presence or absence of ongoing asthma. These observations suggest that impaired house dust mite induced IFN- γ production might be an important factor contributing to ongoing severe asthma, whereas increased IL-5 and IL-13 production by Th2 cells upon allergen stimulation reflects the presence of the atopic state per se rather than being specifically linked to ongoing asthma [63]. In other words, this may imply that an exaggerated Th2 response induces atopy, whereas impairment in the Th1 response contributes to the severity of the disease.

Once high levels of Th2-mediated inflammation are manifest, airway remodelling may occur [57,58]. In atopic asthmatic subjects, the ‘inappropriate’ Th2 response may cause pulmonary inflammation, airway eosinophilia, mucus hypersecretion and airways hyperresponsiveness to a variety of specific and non-specific stimuli, and together result in the symptoms of asthma [64]. Notably, when considering those patients with early-onset asthma, the earlier in life sensitization develops, the more likely they are to have persistent wheeze at an adult age [65], and the more severe are the long-term consequences including wheeze [66,67] and bronchial hyperresponsiveness [67]. Nevertheless, overall, patients with late-onset asthma have more severe asthma than those with early-onset disease.

A central part in the transition from atopy to allergic asthma appears to be played by the airway epithelium, which is in a key position to translate gene–environment interactions [68]. It has been postulated that, in asthma, the airway epithelium has enhanced susceptibility to injury or an inadequate repair response, or a combination of both. As a consequence, the epithelium maintains a ‘repair phenotype’, which is responsible for increased production of pro-inflammatory mediators and pro-fibrinogenic growth factors [68]. For instance, activated epithelium releases transforming growth factor β 2 (TGF- β 2), which activates myofibroblasts under the epithelium to secrete matrix proteins, and smooth muscle and vascular mitogens [69]. Together, these processes may result in the airway remodelling that is characteristic in asthma and involves epithelial

shedding, sub-basement membrane thickening, smooth muscle hyperplasia and an increase in nerves and blood vessels [70].

Pathophysiology

What are the consequences of inflammation and airway remodelling on airway physiology? The two predominant manifestations of disordered lung function in asthma are airways hyperresponsiveness and airflow limitation [4].

Subjects with asthma can have an exaggerated bronchoconstrictor response to a wide variety of stimuli such as allergen, exercise, cold air, fumes and chemicals [4]. Typically, in subjects with asthma, the dose–response curve to bronchoconstrictor stimuli is characterized by increased sensitivity, reactivity and maximal response plateau [71]. Several factors may contribute to the development and/or worsening of hyperresponsiveness. As such, reduced airway calibre, increased smooth muscle contractility, dysfunctional neural regulation, altered permeability of the bronchial mucosa, pro-inflammatory humoral and cellular mediators, and cytokines including granulocyte–macrophage colony-stimulating factor (GM-CSF) and tumour necrosis factor α (TNF- α) have been discussed as critical for bronchial hyperresponsiveness [70].

Many factors contribute to airway narrowing in asthma, including contraction of airway smooth muscle, swelling of the airways as a result of oedema, mucus plug formation and airway wall remodelling [4]. In most subjects with asthma, these features appear to be variable, as reflected in day-to-day variation in lung function which is reversible either spontaneously or upon treatment with bronchodilators and/or anti-inflammatory agents [4,70]. In some subjects, the airflow limitation is not reversible, which seems more prominent in patients with severe asthma [72].

In addition to hyperresponsiveness and airflow limitation, it has been hypothesized that destruction and subsequent remodelling of the airways in asthma is also associated with an accelerated decline in lung function. Accelerated decline in lung function is an important feature of COPD, again underlining the parallels between the two diseases. Interestingly, in patients with persistent asthma followed prospectively, the number of CD8⁺ T lymphocytes in the lamina propria of bronchial biopsies is associated with the subsequent decline in FEV_1 [73]. This is of interest because CD8⁺ T lymphocytes were thought to be important, particularly in COPD patients. Furthermore, it has been demonstrated that subjects with self-reported asthma have a greater decline in FEV_1 over time than those without asthma [74]. Risk factors that further seem to worsen the yearly decline in FEV_1 are airflow limitation [75], bronchial hyperresponsiveness [74,76] and adult-onset asthma [77].

It should not be forgotten that in patients with asthma, smoking is a risk factor for an increased decline in lung function [74], as is the case in COPD. The influence of atopy on the rate of decline in FEV_1 is unclear, as some studies have shown no effect of atopic status [75,76], while others report a steeper decline in atopics [78], or a steeper decline in non-atopic asthmatics [77,79].

A new concept in the understanding of airway narrowing and bronchial hyperresponsiveness is perturbed myosin binding within airway smooth muscle [80,81]. According to this concept, the binding of myosin to actin, within the smooth muscle cell, is perturbed with each breath in healthy individuals. As a consequence, the number of bridges between actin and myosin are low, and the rate of turnover of actin–myosin bridges is high. In subjects with asthma, the cytokine-driven thickening of the airway wall that is associated with remodelling is thought to uncouple the load fluctuations of each breath from the muscle [82]. This allows an unperturbed binding equilibrium of myosin to actin. In this state, there are many links between myosin and actin that cycle very slowly, resulting in a static condition of the smooth muscle, also called latch [80,81]. The unperturbed myosin-binding concept can be used to explain the airways obstruction, excessive airway narrowing and bronchial hyperresponsiveness as is seen in clinical asthma.

Relations between airway inflammation and severity of asthma

It is evident that airways inflammation has a central role in asthma. Several studies have demonstrated that the severity of asthma is related to the degree of airways inflammation. Eosinophil and neutrophil numbers in sputum increase significantly over the spectrum from intermittent to severe persistent asthma [54,83,84]. Fibroblast accumulation and airway smooth muscle hypertrophy are specific characteristics of severe asthma, as opposed to mild asthma [85]. In particular, airways hyperresponsiveness is associated with the cellular infiltrate; with mast cells, CD8⁺ T lymphocytes and eosinophils within the lamina propria [86], but also eosinophil numbers in sputum [87,88] showing an inverse correlation with PC_{20} . Furthermore, increased sputum eosinophils are also associated with more pronounced exercise-induced bronchoconstriction [89] and lower lung function [87]. In patients with persistent asthma, the level of airflow limitation is inversely related to the number of eosinophils [35] and neutrophils in induced sputum [90]. Finally, exacerbations of asthma are associated with a further increase in eosinophils [91] and/or neutrophils in sputum [92] and sputum eosinophils can even be predictive of an exacerbation [93–95].

The associations between degree of inflammation and severity of asthma are usually weak and show a large variation. Nevertheless, these associations indicate that patients with more severe or unstable asthma, as characterized by increased bronchial hyperresponsiveness to various stimuli, airflow limitation and/or exacerbations, have more pronounced airway inflammation.

Different phenotypes of asthma

Clearly, asthma is a heterogeneous disease and different phenotypes within this disease have been recognized. Important and distinct phenotypes of asthma that may have an important role in the differential diagnosis of COPD include non-allergic asthma and/or late-onset or adult-onset asthma. These two phenotypes of asthma have an important overlap because the majority of patients with late-onset asthma are non-atopic [33].

Non-allergic patients with asthma have a negative skin prick test and score negative for allergen-specific IgEs in a radioallergen sorbent test (RAST). Asthma in non-atopic individuals has been associated with risk factors such as older age, female sex, sinonasal polyposis, late onset of asthma, FEV_1 below 80% predicted, lower socioeconomic class, smoking, urban location [96–98] and with a polymorphism in the RANTES gene promoter region [99].

In non-allergic subjects with asthma, a steeper decline in FEV_1 has been described [77,100], which seems associated with a (history of a) high degree of reversibility in FEV_1 [100]. As such, non-atopic asthma seems distinctly different from atopic asthma, because in atopics not reversibility in FEV_1 but rather the degree of airways obstruction (FEV_1 : FVC) together with need for treatment with oral corticosteroids are associated with a more pronounced and progressive decline in FEV_1 [100]. Again, these studies underline that those patients with non-allergic asthma are the most difficult to distinguish from COPD.

In addition to this, the pathology in the airways is different between allergic and non-allergic asthmatics: eosinophil and mast cell numbers in the lamina propria of bronchial biopsies are increased both in atopic and non-atopic asthmatics, although eosinophil numbers are significantly more increased in atopic asthmatics. Furthermore, neutrophil numbers are increased in non-atopic asthmatics whereas CD3, CD4, CD8 and CD25 positive T lymphocytes are increased in biopsy specimens from atopic asthmatics only [101]. Also, cytokine expression is different between the two phenotypes, with IL-4 and IL-5 being expressed in airway tissue from atopic asthmatics and IL-8 in non-atopic patients with asthma [101]. The mechanism by which T cells are activated in non-atopic asthma, where no causative antigen is identified, is not fully understood.

Recently, an *ex vivo* study demonstrated that T cells infiltrating in the lower airways of non-atopic patients with asthma recognize relatively limited epitopes of antigens and are clonally expanded by antigen-driven stimulation [102], which may, at least in part, explain cellular activation pathways in non-atopic asthma.

Asthma as risk factor for COPD

Recent studies show that asthma, in some patients, is a risk factor for the development of COPD [103]. In addition, the presence of 'asthmatic features', including bronchial hyperresponsiveness and IgE, are significant predictors of the rate of FEV_1 decline in patients with COPD [104]. These studies are in line with the 'Dutch Hypothesis' from the early 1960s, stating that asthma and COPD should be considered as different expressions of one disease entity, in which both endogenous (host) and exogenous (environmental) factors have a role in the pathogenesis [105]. According to this hypothesis, the phenotype of the patient (i.e. clinical expression of asthma or COPD) is the result of a combination of genetic and environmental factors, modulated by age and sex.

Primary prevention

In view of the increasing prevalence of asthma and allergic diseases, primary prevention in at-risk infants is a public health priority. Several risk factors have been identified with potential for primary prevention of asthma, of which the most important is indoor allergen avoidance [106]. Recently, it was shown by Koopman *et al.* [107] that when house dust mite impermeable mattress encasings are applied to the beds of atopic, expecting parents and of the infant, there is a 35% risk reduction for cough at night at the age of 2 years. When indoor allergen avoidance measures are extended (the combination of mattress and pillow encasings, use of high filtration vacuum cleaner, removing wall-to-wall carpets from the bedroom, and chemical cleaning of carpets and soft furnishings), there is a 50–80% risk reduction for the infant to wheeze at the age of 1 year [108]. Interestingly, in genetically at-risk children, such interventions, when combined with breastfeeding during infancy, may reduce the risk for current wheeze, nocturnal cough, asthma and atopy by approximately 80% [109]. Further follow-up of these cohorts of children is needed to determine the effect of the interventions on the development of atopic disease, including asthma.

Several reports have suggested that exposure to environmental endotoxin might prevent the development of atopy and asthma [61,110,111]. Remarkably, in farm children

who are frequently exposed to dust in stables and consume raw milk, both of which contain high levels of endotoxin, there is a very low prevalence of asthma, hay fever and atopic sensitization [61,110]. This may be explained by the fact that endotoxins reduce IgE production, Th2 cytokine production and airway eosinophilia [112].

A number of other environmental factors are known to be associated with a lower incidence of allergic diseases early in life. Oral supplementation with *Lactobacillus rhamnosus* (probiotics) during pregnancy and breastfeeding [113,114], the presence, from birth onward, of a furred pet in the home [115], and attendance at day care during the first year of life [116] are all environmental factors that protect against the development of allergies and asthma in childhood. Furthermore, active immunoprophylaxis [114,117,118] and anthroposophic lifestyle [119] have been associated with lower prevalence of allergies and asthma.

The role of breastfeeding in the prevention of atopy and asthma is controversial. Some studies show a protective effect of exclusive breastfeeding during the first 4 months of life for atopy and asthma during childhood [120], while this is associated with an increased risk for allergies and asthma during adulthood [121]. A suggested explanation for this complex relation might be that breastfeeding reduces the effect of bacteria and endotoxins on the immune system, either by direct reduction of exposure or by passive transfer of immune responses from the mother. This may lead to incomplete development of mature immune response mechanisms in the infant, resulting in a lower prevalence of atopy and asthma early in life, and a reversed trend in adulthood [121].

In addition to these issues, smoking (during pregnancy) clearly has an effect on fetal growth and preterm delivery [122]. More importantly, a lower birth weight is associated with worse lung function at adult age, and with death from chronic obstructive airways disease [123]. Furthermore, smoking has been identified as a risk factor for the development of persistent asthma later in life [124]. As such, cessation of smoking by pregnant mothers should be considered as primary prevention of both asthma and COPD.

Current treatment

Treatment of asthma consists of two parts: first, avoidance of the sensitizing trigger and, secondly, pharmacological treatment.

Avoidance of allergen exposure is an integral part of the management of atopic asthmatic patients [4,125]. Effectiveness of avoidance measures was first demonstrated in patients with atopic asthma moving to a low allergenic environment at high altitude, resulting in large improvements in clinical

outcomes [126–128]. Measures aimed at reducing indoor allergen levels, including house dust mite impermeable mattress and/or pillow covers, and chemical approaches, are much more practical. However, conflicting data on the effectiveness of such allergen avoidance have been reported [129,130].

At present, pharmacological treatment of asthma aims at reducing symptoms and optimizing lung function [4]. In most patients, daily treatment with inhaled corticosteroids with or without the addition of long- and/or short-acting β_2 -agonists is sufficient to obtain control of asthma [4,125].

In asthmatic patients, treatment with inhaled corticosteroids improves lung function and bronchial hyperresponsiveness, and reduces eosinophil numbers in induced sputum [131–133], even at very low doses of inhaled steroids [134]. Furthermore, the exacerbation rate is reduced during treatment with inhaled corticosteroid treatment [135]. These changes are accompanied by a decrease in mucosal mast cells, eosinophils and T lymphocytes [136], a reduction in reticular layer thickness [137] and in submucosal vascularity [138]. During treatment with long-acting bronchodilators alone, lung function improves, but inflammatory parameters in sputum remain unchanged [139]. However, the combination of inhaled steroids with long-acting bronchodilators is very effective and widely recommended for treatment of persistent asthma [4].

Patients at the severe end of the spectrum may still have recurrent exacerbations and non-optimal control of their disease, despite treatment with inhaled steroids and (long-acting) bronchodilators. Addition of theophylline, oral corticosteroids and/or leukotriene receptor antagonists is optional and may improve disease outcomes in these patients [4]. Nevertheless, novel treatments are needed for the management of severe disease. At present, many different specific anticytokine treatments are being developed for the indication of persistent asthma [140,141], but these seem to have limited clinical effect. Among the few effective novel therapies for severe allergic asthma is treatment with antibodies directed against IgE [142].

Finally, an integral part of the treatment of persistent asthma (as in COPD) should always be smoking cessation. Several studies have demonstrated that smokers with chronic asthma have a reduced response to corticosteroid therapy [143,144], requiring higher doses of corticosteroids to obtain clinical control. Patients with COPD show a form of steroid resistance, which appears to be caused by decreased histone deacetylase activity [145]. Such a decrease in histone deacetylase activity allows a pro-inflammatory state, as is seen in COPD. It has been hypothesized that histone deacetylase activity in COPD is impaired by cigarette smoking and oxidative stress, and that this leads to a pronounced reduction in the responsiveness to corticosteroids [146]. This mechanism may also have a role in steroid insensitivity in smoking asthmatics. Together,

this underlines the importance of smoking cessation in both asthma and COPD.

Limitations of current treatment

Surveys investigating clinical management of asthma globally have shown that asthma control is suboptimal for many patients despite the availability of effective therapies [147]. In part, this is because of lack of compliance to prescribed therapy [148], which in turn may be caused by lack of patient education [148] and difficulties with inhaler devices [4]. An additional finding of these surveys was that education of treating physicians may be suboptimal and could be improved [149].

Current guidelines state that treatment of patients should be aimed at reducing symptoms and optimizing lung function [4]. However, in patients with ‘controlled’ asthma, the disease management can be improved if treatment is aimed at additional outcomes. For instance, when reducing airways hyperresponsiveness is included in the treatment algorithm, patients have fewer exacerbations of asthma, better FEV_1 , and a reduction in mast cell numbers and reticular layer thickness in bronchial biopsies when compared with the patients who are treated by the conventional treatment strategy [150]. In addition, inclusion of normalizing sputum eosinophilia in the treatment algorithm results in a reduction in sputum eosinophil count and bronchial hyperresponsiveness, together with a 70% reduction in exacerbation rate [151]. Together, this suggests that monitoring of (markers of) inflammation, in addition to symptoms and lung function, improves the long-term management and control of asthma. More importantly, these studies imply that the current treatment regimens are far from optimal, leaving room for further clinical improvement. In COPD, studies aiming treatment at outcomes other than those conventionally included (symptoms and lung function) has not yet been performed and, intuitively, seem more difficult.

Asthma versus COPD

As reflected in this and previous chapters, both asthma and COPD can (in general) be described as airways diseases that are characterized by airflow limitation and chronic persistent airways inflammation [1,4]. Otherwise, however, the two airways diseases are distinctly different (Table 14.1). The main cause of asthma is atopic sensitization to (inhalant) allergens, while that in COPD is tobacco smoking [152], although a sizable proportion of asthmatics are non-atopic and smoke. Both diseases have a genetic component, albeit at different genetic locations [153]. The pathological findings implicated in asthma consist of increased influx of eosinophils, mast cells and $CD4^+$ T lymphocytes, whereas

Table 14.1 Similarities and differences between asthma and COPD.

	Asthma	COPD
Aetiology		
Environmental	Atopic sensitization	Tobacco smoke

Main limits of current treatment	Severe asthma	Across all severity groups

in COPD this is characterized by macrophages, mast cells and CD8⁺ T lymphocytes [154,155]. During stable disease, the sputum of patients with asthma is characterized by eosinophilia, with an additional increase in neutrophils during exacerbation of the disease. COPD is characterized by massive influx of neutrophils within the airway lumen [156]. The physiological abnormalities seen in asthma are bronchial hyperresponsiveness and reversible airflow limitation as opposed to the progressive, irreversible airflow limitation seen in patients with COPD [1]. Furthermore, the mechanisms underlying airflow limitation are different for asthma and COPD. Primary prevention can be achieved in both diseases by avoidance of the trigger: sensitizing allergens in asthma, tobacco smoke in COPD [1]. At present, treatment of both asthma and COPD consists of trigger avoidance and pharmacological intervention. Patients with asthma can achieve trigger avoidance mainly by reducing the indoor allergen load; in patients with COPD this is smoking cessation [1,157]. However, in patients with asthma, smoking cessation is also an important issue. Pharmacological options of asthma and COPD are essentially the same. All interventions aim at reducing or preventing symptoms and consist of inhaled bronchodilators in combination with corticosteroids [1]. However, for milder forms of disease the approaches are markedly different: a patient with asthma who has few symptoms may be of particular concern as symptoms may be underestimated. On the other hand, the current concept for COPD would suggest that a patient with this disease and no symptoms

should not be treated at all. Furthermore, the benefits of treatments, for example with the combination of inhaled steroids and bronchodilators, are markedly different for asthma and COPD. Following inhalation of bronchodilators, a bronchodilator response can be demonstrated in patients with asthma, which is usually absent in patients with COPD. Furthermore, lung function, bronchial hyperresponsiveness and eosinophilia improve upon inhaled corticosteroid therapy in asthmatics. In contrast, neither lung function [158–160] nor airway inflammation [161–163] is affected by inhaled corticosteroid therapy in patients with COPD.

Conclusions

Given the increasing prevalence of and morbidity from asthma and COPD, and the increasing costs of treatment, it is becoming more important to tailor treatment to individuals. In patients with asthma, current pharmacological treatment in general is effective, but there is room for improvement in the subset of patients who suffer from severe asthma and in those who do not use or receive adequate treatment. However, current pharmacological treatments have real but limited benefits in patients with COPD and none of the drugs available influence the accelerated loss of lung function observed in these patients. Novel drugs are needed for the treatment of patients with severe asthma and patients with COPD, in order to improve the long-term outcome of disease in these

patients. Finally, physicians need to differentiate, wherever possible, between asthma and COPD in order to tailor treatment more accurately. This is more difficult in more advanced forms of asthma and COPD.

CHAPTER 15

COPD: clinical presentation and evaluation

Bartolome R. Celli

The American Thoracic Society and the European Respiratory Society (ATS/ERS) [1] have recently defined chronic obstructive pulmonary disease (COPD) as a preventable and treatable disease state characterized by airflow limitation that is not fully reversible.

The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases, primarily caused by cigarette smoking. In some areas of the world where biomass fuel is used as a source of energy primarily for cooking, persons exposed to the particles can develop airflow obstruction that is indistinguishable from that characteristic of COPD [2].

Although COPD primarily affects the lungs, it also produces significant systemic consequences which are very important because their presence is associated with significant morbidity and mortality and also because some of them are amenable to therapy. Indeed, as detailed elsewhere in this book, oxygen therapy, an intervention that does not reverse airflow limitation, has been shown to prolong survival [3,4].

Clinical manifestations

The clinical evaluation is based on a medical history and physical examination. Although a complete examination is indicated for all patients, there are specifically important elements for patients with suspected COPD. These elements include specific symptoms and signs that relate to the respiratory system and the presence of certain risk factors.

Symptoms

Several symptoms should alert the clinician to the possible presence of COPD. Although not pathognomonic for the disease, they are intimately associated with the exposure

to the risk factor and the manifestations of COPD. They include cough, sputum and dyspnoea.

Cough

The cough may initially be intermittent (early morning), progressively becoming present throughout the day, but is seldom entirely nocturnal [1,2,5]. Once it becomes chronic, the cough is usually productive and is very often discounted by the patient as being an expected consequence of smoking. Thus, the patient may not offer the information and the astute clinician should always ask for its presence and its specific characteristics. If the cough is severe and persistent, syncope or cough rib fractures may occur.

Sputum

The presence of sputum is associated and usually follows the development of progressive cough. It initially occurs in the morning but later may be present throughout the day. It is usually tenacious and mucoid in small quantities [5]. The production of sputum for ≥ 3 months in 2 consecutive years is the epidemiological definition of chronic bronchitis [1,2]. This definition has been useful to attempt to characterize the phenotypical presentation of certain patients with COPD. A change in sputum colour (purulent) or volume suggests an infectious exacerbation [6].

Dyspnoea

Perhaps the most alarming symptom of COPD is the presence of dyspnoea. It is usually progressive and becomes persistent over time. At the onset it occurs during exercise (climbing up stairs, walking up hills) and may be avoided entirely by appropriate behavioural changes (e.g. using a lift or avoiding exercise or physical effort). However, as the disease progresses dyspnoea is elicited even during minimal exertion or at rest.

A quantification of dyspnoea using the Modified Medical Research Council scale is indicated. This simple scale

Table 15.1 Modified Medical Research Council scale recommended to evaluate grade of functional dyspnoea.

0	Not troubled with breathlessness except with strenuous exercise
1	Troubled by shortness of breath when hurrying or walking up a slight hill
2	Walks slower than people of the same age because of breathlessness or has to stop for breath when walking at own pace on the level
3	Stops for breath after walking approximately 100 m or after a few minutes on the level
4	Too breathless to leave the house or breathless when dressing or undressing

(Table 15.1) objectively grades the level of functional dyspnoea and should become part of the evaluation of all patients with COPD because it predicts quality of life and survival independent of the degree of physiological airflow limitation [7,8]. Furthermore, the evaluation of functional dyspnoea may be the single most helpful way to evaluate the effect of therapy [1,2].

Dyspnoea with activities can also be objectively evaluated with the use of scales such as the visual analogue scale (VAS) or the modified Borg dyspnoea scale (Fig. 15.1a,b) [9]. These scales are simple and provide information regarding the level of dyspnoea perceived by the patient, for example with a known exercise load. These scales have been very useful in evaluating the beneficial effect of therapy using cardiopulmonary exercise testing or timed walked distance as the load.

Although there is some correlation between the degree of airflow limitation and dyspnoea, this correlation is weak at best [8,9]. The same can be said for the correlation between arterial blood gas abnormality and the presence and degree of dyspnoea [9]. These findings are best explained by the fact that dyspnoea is a very complex symptom where several factors interact. There is evidence that the intrinsic response of the central controller [10], the dissociation

between the demand to breath and the mechanical response [11], the action of the respiratory muscles [12] and the nature of the mechanical load and the final output can all relate to the genesis of dyspnoea. However, independent of the mechanism, the presence of dyspnoea with previously well-tolerated activities or, worse yet, with daily activities, should alert the clinician to the possible presence of COPD.

Other symptoms

Patients may report the presence of wheeze, especially during episodes of respiratory tract infection or heavy exercise. Similarly, some patients may complain of chest pain associated with cough or increased activity. This may be caused by increased respiratory muscle effort or stress on ribs or vertebrae.

The development of leg oedema could indicate development of right-side heart failure *cor pulmonale*. In such cases, the possibility of associated sleep apnoea should also be explored as the coexistence of two highly prevalent diseases is very common [13].

In more advanced disease, the development of weight loss and skeletal muscle wasting should be cause for concern. Indeed, a low body mass index ($BMI < 21 \text{ kg/m}^2$) is an independent predictor of mortality [14,15]. This has led to the recommendation that all patients with COPD should have their weight and height determined and the BMI calculated using the simple formula:

$BMI = \text{weight in kilograms} / \text{height in metres squared}$.

Many patients with COPD complain of fatigue and are often depressed. The latter may be manifested by the presence of its characteristic complaints of malaise, change in appetite, lack of interest in life, sleepiness and insomnia. Clinicians should be aware of this problem because treatment of depression may become a therapeutic goal in itself.

The development of haemoptysis is unusual in COPD and should raise the possibility of lung cancer. Seasonal exacerbation during spring or summer, or the development of symptoms with exposure to specific agents, suggests

Figure 15.1 The Borg (a) and the visual analogue scale (b) are validated scales that can be used to estimate the perception of dyspnoea during activities.

asthma. The presence of large amounts of purulent sputum is more consistent with bronchiectasis. The presence of chest pain can also be caused by concomitant coronary artery disease or pulmonary embolism.

Presence of risk factors

A history of exposure to risk factors, such as smoking, or occupational or environmental noxious agents, should be noted. A detailed smoking history is essential. A useful tool to express the exposure to cigarettes is the calculation of pack-years. This is obtained by multiplying the number of pack equivalents smoked every day by the total number of years; thus, 20 pack-years can result from smoking one pack per day for 20 years. The number of pack-years calculated in this way correlates well with objective determination of cigarette exposure [16]. The possibility of passive smoking should also be ascertained, with special emphasis on early exposure to smoking parents, a factor that has been shown to relate to early development of lung disease [17].

In patients from areas of the world where biomass fuel is used as a source of energy or heat, the history of closed environment exposure (i.e. cooking with wood) should also raise the possibility of COPD [18].

In addition to exposure, other risk factors known to be associated with COPD should be investigated. The most important is the presence of a family history of COPD, with α_1 -antitrypsin as the main risk [19,20].

Signs

As part of the vital signs, all patients should have their respiratory rate measured, weight and height determined, and their BMI calculated. A normal physical examination is frequent in early COPD [1,2]. As the disease progresses some signs become apparent and in the advanced stages many are almost pathognomonic.

The examination should be aimed at eliciting the presence of the respiratory and systemic effects of COPD. On inspection, check for barrel chest deformity, pursed lips breathing, chest or abdominal wall paradoxical movements and use of accessory respiratory muscles. All these are signs of severe airflow limitation, hyperinflation and impairment of the mechanics of breathing [21].

Percussion can reveal decreased motion of the diaphragm and tympanic sounds resulting from hyperinflation or bullae; in addition, the liver becomes easily palpable. During auscultation, a forced expiratory manoeuvre that is unduly prolonged (> 6 s) suggests significant airflow limitation. Adventitious rhonchi and wheezing may help differentiate COPD from congestive heart failure or pulmonary fibrosis, which are often associated with rales. The heart sounds

may be distant as a result of hyperinflation. However, with advanced disease they may show signs of cor pulmonale, such as split of second sound (pulmonic), murmurs of pulmonic or tricuspid insufficiency. In addition, atrial arrhythmias such as fibrillation and flutter may be detected in patients with significant compromise. Cyanosis or bluish colour of the mucosal membranes may indicate hypoxaemia. Clubbing is not a usual feature of COPD and its presence should direct the physician to evaluate other possible explanations such as the presence of lung cancer, idiopathic pulmonary fibrosis or bronchiectasis.

Laboratory tests

The suspected clinical diagnosis of COPD needs to be confirmed with the rational use of laboratory testing. Mandatory tests for all patients include spirometry using the forced vital capacity (FVC) manoeuvre and the chest roentgenogram [1,2]. Other tests that can complement and help in a more comprehensive evaluation of a particular patient are listed as optional.

All patients

Spirometry

Spirometry should be performed in all patients suspected of COPD. This is necessary for diagnosis [22], assessment of the severity of the disease [23] and for following the progress of the disease [24]. Without spirometry, the diagnosis of persistent and partially reversible airflow limitation cannot be confirmed. Spirometry should include an evaluation of bronchodilator reversibility using an inhaled bronchodilator. This should be performed at least once to exclude asthma, to establish the best lung function for the individual patient and, to a lesser degree, to estimate the prognosis. The increase in forced expiratory volume in 1 s (FEV_1) should be expressed as a percentage of the predicted value which is less dependent on the baseline FEV_1 . Although some bronchodilation may be present in some patients with COPD, a large increase in postbronchodilator FEV_1 supports the diagnosis of asthma [23].

A typical spirogram of a patient with COPD is shown in Figure 15.2. The FEV_1 and its ratio to the FVC remain as the gold standard to diagnosis and follow-up in patients with COPD. The FEV_1 should also be expressed as a percentage of the predicted values obtained from population studies of non-smokers without lung disease. The factors known to determine lung function include gender, age, height and race. After the diagnosis is established, the exact frequency and timing of repeat spirometry has not been determined. However, it is advisable to repeat the test 2–4 weeks after initiation of therapy, whenever the patient reports changes

Figure 15.2 The forced vital capacity manoeuvre is needed to confirm the diagnosis of airflow limitation, as shown in this tracing. The small increment in postbronchodilator FEV_1 confirms poor reversibility characteristic of COPD. BD, bronchodilator; FEV_1 , forced expiratory volume in 1 s; FVC, functional residual capacity.

in symptoms or at least every year. The advent of portable and reliable pneumotacograph-based spirometers should make testing easier and more widely available [25].

Chest roentgenography

Chest radiography [1,2,26] should be obtained in all patients. It is not used for the diagnosis, but is helpful in excluding other diseases (pneumonia, cancer, congestive heart failure, pleural effusions and pneumothorax). It is also of value to detect bullous disease. Common but not specific signs of emphysema are (Fig. 15.3): flattening of the diaphragm, irregular lung radiolucency and reduction or absence of vasculature (rapid tapering). The presence of cardiomegaly with encroachment of the cardiac silhouette on the retrosternal space and increased width of the

descending branch of the right pulmonary artery (> 20 mm) suggests the diagnosis of cor pulmonale. The presence of other abnormalities, such as infiltrates, hilar node enlargement, parenchymal nodules and interstitial infiltrates, should suggest an alternative diagnosis.

Selected patients

Lung volumes

The measurement of static lung volumes is useful in the evaluation of patients because the level of hyperinflation helps to determine the degree of air trapping and loss of lung elastic recoil [21,27]. Lung volumes are best measured using body plethysmography. This method is more precise than the simpler method of gas dilution because with increasing disease severity, the amount of non-communicating portions of the lung results in an underestimation of air-trapping by dilution methods [28]. The total lung capacity (TLC), residual volume (RV), functional residual capacity and the ratio RV/TLC are all characteristically increased in advanced COPD. The increase in TLC is the consequence of loss of lung elastic recoil, which allows the inspiratory muscles to stretch the lungs to a greater volume. The increase in RV occurs because of premature closure of narrowed airways at higher lung volumes. Usually, the increase in RV is greater than the change in TLC and therefore the RV/TLC increases. The most important lung volumes are shown in Figure 15.4.

The evaluation of the degree of hyperinflation has gained popularity because it has been related to the development of dynamic hyperinflation with increased ventilatory demand, such as during exercise [29–31]. A good index of hyperinflation is the measure of the inspiratory capacity, which in essence represents the mirror image of the end-expiratory lung volume (EELV). Figure 15.5(a,b) represents the inspiratory capacity as determined during flow

Figure 15.3 (a,b) The chest roentgenograms of patients with severe COPD characteristically show hyperlucent fields, flattened diaphragm and increased retrosternal and retrocardiac air space.

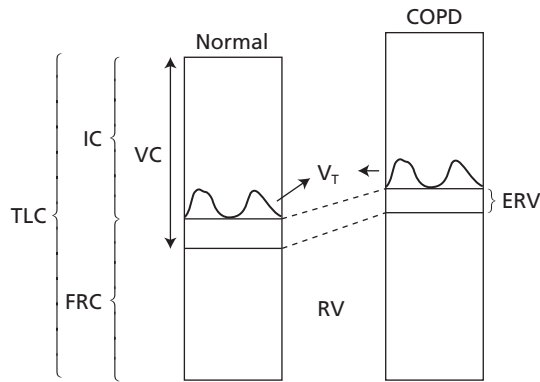

Figure 15.4 The lung volumes are useful in determining degree of inflation. The most important lung volumes are: total lung capacity (TLC), inspiratory capacity (IC), functional residual capacity (FRC), vital capacity (VC), residual volume (RV), end-expiratory reserve (ERV) and tidal volume (V_T). All except VC increase in COPD, especially in patients with predominant emphysema. However, because RV increases more than TLC, the ratio of RV/TLC decreases as the disease progresses.

volume manoeuvres at rest and during exercise in a patient with COPD who does not hyperinflate with exercise and that of a patient with COPD who develops significant air trapping during exercise. The importance of this measurement stems from the fact that the degree of dynamic hyperinflation relates better to the degree of dyspnoea measured with increased ventilatory demand than more conventional measurements of lung function such as the

FEV_1 . Further, lesser increases in EELV have been associated with the symptomatic benefit observed after bronchodilators [30,31]. Indeed, measurements of static lung volume and lung volume response to exercise have become important physiological independent outcomes after interventions [31,32]. Finally, the determination of lung volumes is useful in patients with advanced disease who are being considered for surgery [33,34] (see Chapter 55).

Diffusing capacity for carbon monoxide

Transfer factor of the lung for carbon monoxide (TLCO) is usually reduced in COPD, particularly in emphysema [35] because of the destruction of alveolar and capillary beds. The TLCO is interchangeable with the term diffusing capacity for carbon monoxide (DLCO) as used in North America. The term is very indicative of the test itself. In essence, it provides information regarding the ease of transfer of CO molecules from alveolar gas to pulmonary capillary haemoglobin. The diffusion capacity for CO is low in smokers compared with non-smokers even in the absence of spirometric abnormality. Of interest, if DLCO is reduced, asthma can be excluded. The measurement of DLCO is important in the evaluation of patients being considered for lung volume reduction surgery because values lower than 20% of predicted implies undue risk of poor outcome [34].

Arterial blood gases

As COPD progresses, there is development of progressive ventilation/perfusion mismatch. This results in hypoxaemia

Figure 15.5 The two flow–volume loops shown correspond to those of two patients with COPD. (a) The patient is flow-limited so that increase in ventilatory demand (as during exercise) results in air-trapping and an increase in end-expiratory lung volume (EELV). Because total lung capacity (TLC) does not change, the inspiratory capacity decreases. These changes have been shown to relate to degree of breathlessness during exercise. (b) The other patient has no flow limitation, the EELV does not increase during exercise and inspiratory capacity remains unchanged.

easily shown while the patient breathes room air. The hypoxaemia may determine compensatory hyperventilation, which, at least at the beginning, may cause mild hypocarbia. As the disease progresses and hypoventilation becomes more manifest, hypercapnia may be seen. Hypoxaemia and hypercapnia are independent predictors of morbidity and mortality [36]. As a consequence of the progressive increase in P_{aCO_2} , there is compensatory bicarbonate retention and the serum bicarbonate may be elevated (respiratory acidosis with compensatory metabolic alkalosis).

In stable patients, the measurement of arterial blood gases while the patient breathes room air is recommended in moderate and severe stages of the disease. The documentation of hypoxaemia ($P_{aO_2} < 55$ mmHg) indicates the need to consider long-term oxygen therapy (LTOT) because it reverses hypoxaemia and has been shown to improve life expectancy [3,4].

In some patients with low but not critical hypoxaemia ($P_{aO_2} > 60$ mmHg), the P_{aO_2} usually worsens during exacerbations and may reach levels consistent with respiratory failure [37]. Indeed, arterial blood gases should be obtained during exacerbations as the level of P_{aO_2} should be used to guide oxygen treatment. In addition, arterial blood gases provide the level of P_{aCO_2} , which, in combination with the degree of acidosis, determines the need for non-invasive or invasive mechanical ventilation [38,39].

The determination of oxygen saturation is very helpful in clinical practice [40]. Non-invasive pulse oximetry SpO_2 is useful for assessing changes in SaO_2 as well as adjusting oxygen flow settings; it is less reliable in exercise studies than at rest (although newer pulse oximeters may be less sensitive to movement artefact and may be more accurate during exercise). Patients with values $< 94\%$ at sea level breathing room air suggests the need for blood gases. However, a word of caution must be raised. Some patients may manifest borderline oxygen desaturation easily correctible with supplemental oxygen. This correction may hide the development of hypercapnia [41]. Therefore, arterial blood gases should be obtained in patients with low oxygen saturation requiring progressive oxygen supplementation to maintain the targeted oxygen saturation.

Assessment for air travel

Commercial airliners can cruise at altitudes over 40 000 feet (12 000 m) with cabins pressurized from 6000 to 8000 feet (from 1800 to 2400 m). This is equivalent to an inspired O_2 concentration at sea level of approximately 15%. Patients with severe COPD experience falls in P_{aO_2} that average 25 mmHg but may be more than 30 mmHg at 8000 feet (2400 m) during this exposure to hypobaric hypoxia. Because their sea level P_{aO_2} values are on the steep part of the

oxygenhaemoglobin dissociation curve, the fall in SaO_2 with falls in P_{aO_2} may be quite sharp [42].

The preflight assessment should incorporate the following steps:

- 1 Estimate the expected degree of hypoxaemia at altitude;
- 2 Identify comorbid disease conditions;
- 3 Prescribe oxygen if necessary [43].

Counselling the patient and documenting recent clinical condition and laboratory tests are also desirable elements of preflight patient care, particularly if the patient is travelling abroad. Most national and international airlines will provide supplemental oxygen on request.

Exercise tests

Exercise testing is of practical value in patients with a disproportional degree of dyspnoea to FEV_1 because it may help establish the physiological cause of dyspnoea [44,45]. Exercise tests can also help in the evaluation of candidates who are not hypoxaemic at rest for oxygen therapy. In addition, an increasing body of evidence has shown that exercise capacity is a predictor of mortality [46,47] independent of the FEV_1 . There are several exercise protocols. For simplicity they can be classified as laboratory tests (the cardiopulmonary exercise test) and field tests (timed walked distance and the shuttle walk test).

Cardiopulmonary exercise test

The cardiopulmonary exercise test (CPET) can be performed on a cycle or treadmill ergometer. The CPET provides very accurate information regarding the physiological response to exercise [48]. The variables measured include: mechanical work performed, oxygen consumption ($\dot{V}O_2$), carbon dioxide output ($\dot{V}CO_2$) and ventilatory response with its components (minute ventilation [\dot{V}_E], tidal volume [V_T] and respiratory rate). In addition, continuous monitoring of the cardiac rhythm and electrocardiography as well as blood pressure allows an accurate evaluation of the cardiac response to exercise. The measurement of blood gases at rest and at peak exercise provides information related to gas exchange, dead space and alveolar ventilation. Finally, the measurement of dyspnoea using the VAS or Borg scale at intervals during the test and at its end, add very important information. Indeed, the systematic evaluation of dyspnoea during exercise has helped to explain the mechanisms underlying the genesis of dyspnoea and the effect of bronchodilators on this symptom. Recent evidence indicates that peak exercise $\dot{V}O_2$ is an excellent predictor of long-term survival [46] and also helps in the prognosis of postoperative outcome in patients being considered for lung resection [49]. The response to a cardiopulmonary exercise test also helps to plan the exercise intensity to be used in pulmonary rehabilitation [50]. The use of CPET should be encouraged

because the completeness of information obtained from its performance compensates for the need for special equipment and resources.

Field exercise tests

Field exercise testing should be available to everyone. These tests are becoming increasingly popular because they not only provide information of functional capacity, but the 6-minute walk distance has also been shown to be an independent predictor of mortality in COPD [47,51] and of morbidity and mortality after lung volume reduction [52].

Six-minute walk test

This test has recently been standardized by the ATS [53]. In summary, the test should be performed in a corridor 30–40 m long. The patient is instructed to walk as far as possible at his or her own pace for a total of 6 minutes. The dyspnoea induced by the exercise is scored using the VAS or modified Borg scale. The distance walked over that time is measured and reported. Two tests performed at least 30 minutes apart are recommended because more than two tests do not provide additional information. Two recent studies have provided values from control subjects which can be used to normalize the results [54,55]. The predictive formulas are summarized in Table 15.2. They are very helpful because the distance walked is influenced by gender, age and height, and the formulas help to correct for these differences. The 6-minute walk test is highly reproducible, simple and easy to administer. It represents the functional capacity of patients very well and is an excellent predictor of mortality [47]. There is increasing support for the inclusion of the 6-minute walk test in the routine evaluation of patients with moderate to severe COPD.

Incremental shuttle walk test

Although it is a field test, the incremental shuttle walk test truly represents an intermediate test between the CPET and the 6-minute walk test. It is easy to conduct in a monitored

setting and involves walking at ever faster speed around cones placed 10 m apart [56]. Increasing speed is encouraged by the use of an audio signal from a tape cassette. In essence, it is a symptom-limited maximal performance test. Indeed, the values of oxygen uptake measured during this test approximate those achieved during a formal CPET [57]. Thus, the maximum heart rate, oxygen uptake and ventilatory demands are higher than those seen during the 6-minute walk test.

Stair climbing

Walking up stairs is a less explored test that correlates very well with cycle ergometry [58]. It is more demanding than walking but it has not been compared with the shuttle walk test. However, it has recently proven very useful in predicting postoperative pulmonary complications [59]. Like the incremental shuttle walk test, its applicability remains to be more widely explored.

Respiratory muscle testing

The function of the respiratory muscles is invariable affected in patients with COPD. With disease progression there is flattening of the diaphragm which results in the incapacity of this muscle to generate adequate inspiratory pressure [60]. The diaphragm adapts by shortening the number of sarcomeres and adopting a new optimal length-tension relationship [61]. Indeed, studies from biopsies of patients with severe COPD have revealed an increase in the proportion of fatigue-resistant muscle fibres type IA and a reduction of the less fatigue-resistant muscle fibres type II [62]. In order to maintain appropriate ventilation, especially in situations of increased ventilatory demand, the accessory muscles increase their participation in pressure generation. This results in the frequent observation of accessory muscle recruitment during tidal breathing in patients with severe COPD.

The tests used to evaluate respiratory muscle function have been recently updated by the ATS/ERS [63] and include tests of strength and endurance. In general, respiratory muscle function should be tested in patients with evidence of poor nutrition or with suspected myopathy, including that induced by continuous use of corticosteroids. In addition, one should consider testing respiratory muscle function if dyspnoea or hypercapnia is disproportionately increased with respect to FEV_1 .

The maximum inspiratory pressure is impaired usually because of hyperinflation or abnormal mechanics of breathing. In contrast, a reduction in maximum expiratory pressure could be attributed to muscle weakness (see Chapter 3).

Pulmonary vasculature and heart function

Pulmonary vascular pressure and right ventricular function

Table 15.2 Spirometric classification of severity of COPD.

Severity	Postbronchodilator FEV_1/FVC	FEV_1 (% predicted)
At risk	> 0.7	≥ 80
Mild COPD	≤ 0.7	≥ 80
Moderate COPD	≤ 0.7	50–80
Severe COPD	≤ 0.7	30–50
Very severe COPD	≤ 0.7	< 30

FEV₁, forced expiratory volume in 1 s; *FVC*, functional residual capacity.

can be assessed using non-invasive methods, such as two-dimensional and Doppler echocardiography [64,65]. Left ventricular function is usually normal in patients with COPD. However, in patients with a significant degree of emphysema it may be technically difficult to obtain adequate imaging because of the greater distance between the probe and the heart resulting from the hyperinflation. In these patients, transoesophageal echocardiography appears to offer an advantage and can provide information not otherwise routinely obtainable. The most frequent echocardiographical findings in patients with cor pulmonale include: increased right ventricular size, moderate to severe tricuspid regurgitation with widened right ventricular to right atrial pressure drop, and a delayed onset of right ventricular filling. However, the gold standard method of measuring pulmonary hypertension and its possible response to therapy remains right heart catheterization.

Electrocardiography

Frequently performed in all patients needing medical services, the electrocardiogram (ECG) is not a good tool to detect the cardiac consequences of pulmonary disease. The ECG is relatively insensitive to detect pulmonary hypertension and right ventricular enlargement. However, it is very good in diagnosing and helping to monitor the presence of arrhythmias, such as atrial fibrillation and flutter, frequently found in patients with COPD. The ECG finding of an R or R' inflection greater or equal to the S wave in V₁, the presence of an R wave smaller than the S wave in V₆, or right axis deviation greater than 110° without right bundle branch block are all supportive of the presence of coexisting cor pulmonale [66].

Computed tomography

Computed tomography (CT) should be recommended if the diagnosis is in doubt or for preoperative assessment for bullectomy or lung volume reduction surgery. However, as this relatively new and ever-expanding technology is increasingly used, more indications are found for its use [67–70].

High-resolution CT is defined as thin section images (1–2 mm collimation scans). Spiral CT provides continuous scanning as the patient is moved through the scanner. High-resolution CT has helped to visualize early interstitial and vascular disease, as well as help in diagnosing bronchiectasis and detecting small lesions [71]. Experimentally, it has been used to detect and follow-up emphysematous changes as well as attempt to quantify bronchial size and infer the degree of bronchitis [71,72]. There are recent reports of the capacity of CT to detect emphysematous changes in patients with α_1 -antitrypsin deficiency earlier than the development of pulmonary function

Table 15.3 Current indications for computerized tomography (CT) in patients with COPD.

<p>1 Evaluation for surgery</p> <ul style="list-style-type: none"> bullectomy lung volume reduction transplant lung resection <p>2 Consideration of pulmonary embolism (spiral CT with contrast)</p> <p>3 Suspicion of bronchiectasis</p>
--

changes [73]. Spiral CT with the use of intravenous contrast is very good at detecting pulmonary embolism, a diagnosis frequently suspected in patients with COPD who develop worsening dyspnoea.

The use of CT in the evaluation of patients with moderate to severe COPD has been expanded with the results of the National Emphysema Therapy Trial (NETT), which studied the value of lung volume reduction surgery compared with pulmonary rehabilitation and optimal medical care [34]. The results of NETT, conducted in 1277 patients, showed CT to be instrumental in the selection of candidates who may benefit from surgery as well as those for whom surgery may confer a poor outcome. Indeed, the most important factor to predict outcome was the tomographical distribution of emphysematous lesions. The presence of inhomogeneous lesions of upper lobe predominance indicates a good prognosis after surgery while the converse, the presence of homogeneous distribution with non-upper lobe predominance was indicative of a poor outcome. Table 15.3 shows the indications for CT scans based on current available information. With the expansion of its use, this list is likely to increase.

Blood tests

Haemography

The effects of hypoxaemia on compensatory erythrocytosis have been well studied [74]. However, the red blood cell line response of patients with COPD to the effects of hypoxaemia is less well characterized. Indeed, normal, decreased or increased responses have all been documented. This may in part be caused by the difficulty in studying patients with 'pure' COPD and also to the multiple factors influencing the red cell life cycle. There is evidence of erythrocytosis in smokers and also increased red cells in patients with sleep apnoea and associated hypoxia. However, many patients with COPD have normal values, especially if receiving supplemental oxygen, and others may present with anaemia. However, severe anaemia (haemoglobin values < 10 g/dL) should alert the clinician to the possible presence of coexisting disease.

Smokers without airflow obstruction also have an increased number of peripheral neutrophils, which is also present in patients with COPD even after having stopped smoking [75]. The actual reason for this and its pathophysiological implications are under investigation. Elevation of white blood cell counts during exacerbations should suggest the presence of bacterial infection of the respiratory tract, especially if there is coexisting fever and purulent sputum.

α_1 -Antitrypsin

The α_1 -antitrypsin levels should be measured in young patients (< 45 years) who develop COPD, especially if the disease predominantly affects the lower lobes [1,2]. The diagnosis is even more likely if there is an associated strong family history. A serum value of α_1 -antitrypsin < 15–20% of the normal limits is highly suggestive of homozygous α_1 -antitrypsin deficiency. If the diagnosis is confirmed, it may be followed by a family screening. A deficiency of the ZZ allele is the best documented genetic factor for COPD. This recessive trait may lead to emphysema even if the person has never smoked and certainly accelerates the development of COPD in patients with the deficiency who smoke. Heterozygotes usually have intermediate levels of the inhibitor and are therefore more susceptible to the development of emphysema than normal subjects without the trait [76–78].

Sputum examination

In spite of providing information on the functional dynamic of the airways and the lungs, the routine analysis of the sputum has not gained wide acceptance in clinical practice. Present in patients whose main expression of the disease is that of chronic bronchitis, it is often contaminated by mouth secretions, thereby rendering any finding somewhat difficult to interpret. In the stable state, the sputum should be mucoid and if examined under the microscope it usually shows a predominance of macrophages with neutrophils and in some cases bacteria. The presence of the same bacteria in cultures of the sputum suggests chronic colonization. Recent evidence indicates that mutations in the typing of the same bacteria may be associated with exacerbations of COPD [79]. During exacerbations, the sputum becomes purulent, changing its colour and viscosity. The most frequent bacteria associated with exacerbations include *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis*. Using polymerase chain reaction (PCR) techniques, careful evaluation of sputum from patients during exacerbations has documented a significant proportion of them to be caused by viruses, which apparently confer a slower recovery [80].

There is new interest in attempting to standardize the appropriate collection, examination and interpretation of

sputum [81–83]. Indeed, because many patients produce it in significant amounts and sputum induction using nebulized hypertonic saline is safe and effective, there is reason to expect that more use of this technique will be made in future.

Bronchoalveolar lavage and biopsy

These techniques have proven useful in providing new insights into the inflammatory nature of COPD. Indeed, results from such studies have shown that in COPD the inflammation is primarily characterized by the presence of CD4 lymphocytes, neutrophils and macrophages. In addition, the effect of therapy on the type and number of cells has also been explored using this technique [84–86]. The possibility that lung volume reduction could be accomplished with the insertion of one-way valves or airway sealing material via the bronchoscope will probably accelerate the use of these techniques in the management of COPD.

Exhaled breath

This is a recently applied technique that is finding its true role in the evaluation of patients with COPD. A number of substances can be identified and their presence and levels measured [87]. These substances include: leukotrienes, prostaglandins, cytokines, isoprostanes, products of lipid peroxidase, ethane and, most frequently, nitric oxide (NO). There have been problems with standardization and reliability; however, its simplicity and the fact that exhaled breath could provide a window to metabolic lung function make this a very attractive tool. Of all of the substances reported, NO is the one that has been most consistently detected [88]. The findings suggest that the levels of NO are lower in smokers and patients with COPD than in normal individuals [89]. In contrast, the levels appear elevated in patients with asthma [90]. Although it may be premature to use the levels as a specific disease marker, it is possible to conceive that a high level of NO in a patient suspected of COPD could actually represent an overlapping case of asthma and may suggest a possible reason for the use of corticosteroids. There have already been studies reporting increased levels of interleukin-6 (IL-6) and leukotriene B₄ (LTB₄) in patients with COPD.

Sleep studies

Sleep has effects on breathing, which include changes in central respiratory control, airways resistance and muscle contractility. These do not have an adverse effect in healthy individuals but may cause problems in patients with COPD [91]. The sleep-related disturbances in gas exchange in COPD are a consequence of the disease itself, and are different from sleep apnoea. Sleep-related hypoxaemia and hypercapnia in COPD are most pronounced during rapid eye movement (REM) sleep. Oxygen desaturation in COPD

is considerably greater during sleep than during maximum exercise [92] and predisposes to nocturnal cardiac arrhythmias [93], pulmonary hypertension and possibly death during acute exacerbations [94].

Patients with COPD have a higher prevalence of insomnia, fragmentation with frequent arousals, nightmares and daytime sleepiness than the general population, with close to 50% of patients reporting significant disturbance in sleep quality. Sleep disturbance probably contributes to the non-specific daytime symptoms of chronic fatigue, lethargy and overall impairment in quality of life [95].

Disturbances of breathing during sleep are highly prevalent in the population at large and increase with increasing age. This makes the possible coexistence of sleep apnoea in patients with COPD a frequent problem. A polysomnogram is indicated in these patients. Treatment of the apnoea and the COPD can lead to improvement above and beyond that expected from the treatment of the hypoxaemia or airflow limitation [96].

Classification of severity and staging of COPD

COPD is characterized by poorly reversible airflow limitation [1]. Since it was first described by Fletcher *et al.* [97], the rate of decline of lung function has become the hallmark of the progression of COPD. This is expressed in a modified version in Figure 15.6 which not only shows the change in FEV_1 over time, but also adds the theoretical change brought about by early smoking and also the effect of smoking cessation on that rate of decline. It is interesting that therapy has been directed at reversing what has been

Figure 15.6 The forced expiratory volume in 1 s (FEV_1) increases from birth until about age 21 years and then progressively decreases with age. In patients susceptible to the effects of cigarette smoke, the decline is steeper so patients become symptomatic by the 5th or 6th decade. Notice that smoking cessation results in an early increase in FEV_1 and, very importantly, a normalization of the rate of decline, which tends to return to that of non-smokers of similar age.

defined as being irreversible and to altering the accelerated rate of decline of the FEV_1 in patients with the disease. So far, only smoking cessation [98] has been shown to reduce the rate of lung function, as shown in Figure 15.6. However, supplemental oxygen in hypoxaemic patients [3,4], lung volume reduction surgery in patients with non-homogeneous emphysema of upper lobe predominance [34], and non-invasive ventilation during acute on chronic respiratory failure [99] have all been proven to increase survival in patients with COPD.

Unfortunately, the fact that several trials of medication failed to show any effect on the rate of lung function decline [100,101] has led to a dangerously nihilistic attitude towards the disease. Traditionally, the severity of COPD has been graded using a single physiological variable, the FEV_1 [1,2]. However, COPD is associated with systemic consequences such as dyspnoea and exercise limitation [102], pulmonary hypertension [103], peripheral muscle weakness [104] and malnutrition [105]. Furthermore, the FEV_1 is not the only predictor of mortality in COPD. Several studies have identified other risk factors such as hypoxaemia or hypercapnia [106], the timed walk distance [47,51], degree of functional breathlessness [107] and a low BMI [108]. Therefore, grading COPD solely on the FEV_1 does not adequately reflect the clinical manifestations of the disease and its ultimate prognosis. The ATS recently expressed the need for a multicomponent staging system that in addition to the degree of impairment could express the heterogeneous manifestations of COPD.

Using the FEV_1 , the disease has been classified arbitrarily in five stages (see Table 15.2). This classification has proven useful in epidemiological and large group and drug studies, but the simple grading by spirometry fails to fully represent the different dimensions that are affected by the disease. COPD could be represented as a pulmonary disease that affects several domains: the respiratory, systemic and perceptible. All of these domains can be evaluated with relatively simple tools (Fig. 15.7) and provide important prognostic information. Indeed, the measurement of dyspnoea with the Medical Research Council (MRC) scale [107], of exercise capacity with the cardiopulmonary exercise test or the 6-minute walk distance [47] and the BMI [108] have been shown independently to predict survival. We have expanded this concept to develop a grading system that includes all of these domains in a single index, the BODE index (body mass index, airflow obstruction, dyspnoea, exercise performance). The BODE index proved to be a better predictor of all cause and disease-specific mortality than the FEV_1 [109]. The measurement of outcomes different from the FEV_1 is important because it changes the way in which we interpret the course of the disease. Based on this concept, several medical therapies that failed to show changes in FEV_1 have been deemed ineffective [100,101]. However, the same studies demonstrated improvement

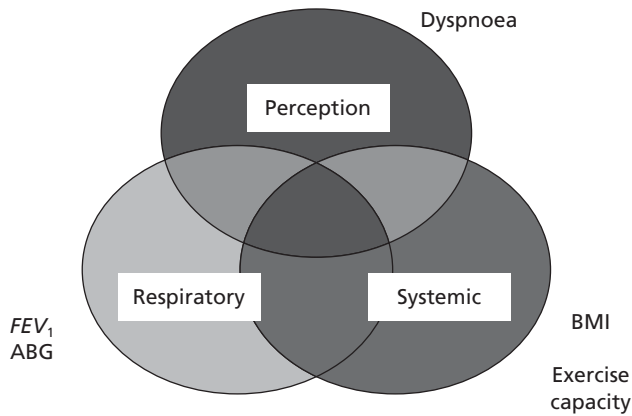

Figure 15.7 The patients with COPD may be affected in several domains. Although primarily a disease of airways and thus leading to respiratory impairment, COPD can also result in changes in perception and alterations in other non-pulmonary areas (systemic effects). This is represented in this schema with the details of simple tests that can help measure the affection in each one of the domains. An integrative score of these domains helps provide a better assessment of patient's outcomes. ABG, arterial blood gas; BMI, body mass index; FEV_1 , forced expiratory volume in 1 s.

in other outcomes such as rate of exacerbation, dyspnoea and health status, all of which are of extreme importance to patients with COPD. These contradictory findings can be reconciled by acknowledging that COPD is not just a pulmonary disease and is therefore incompletely described by the FEV_1 .

Prognosis

The disease has been termed progressive and irreversible. However, this is not so and therapeutic interventions such as smoking cessation, supplemental oxygen for hypoxaemic patients, non-invasive ventilation in patients with acute on chronic respiratory failure and lung volume reduction surgery in selected patients with inhomogeneous emphysema have all been shown to prolong survival. In addition, pharmacological therapy and pulmonary rehabilitation improve dyspnoea, exercise capacity and health status. Finally, preventive measures such as vaccination have decreased the rate of complications and, more specifically, the dreaded exacerbations. Perhaps the most important problem facing this disease is its lack of recognition and the lack of use of spirometry [110]. Currently, patients who are diagnosed at an early stage have a very good prognosis. Once symptomatic, treatment is very effective in improving symptoms and smoking cessation usually helps to reverse the progression of the disease. In more severe disease, which unfortunately represents most of the patients who are seen by specialists, there are many therapeutic tools

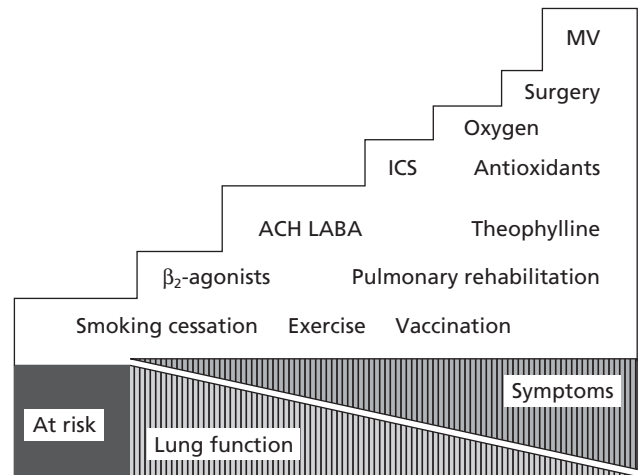

Figure 15.8 There are many available therapeutic options for patients with COPD. A nihilistic attitude is not justified. ACH, anticholinergics; ICS, inhaled corticosteroids; LABA, long acting β -agonists; MV, mechanical ventilation.

that can help patients to maintain a productive life. Figure 15.8 represents the therapeutic options that are available to patients with COPD. With these tools at hand, a negative attitude is not justified.

CHAPTER 16

Monitoring and outcomes

Paul W. Jones

COPD is a complex disease. Its primary effects are symptoms arising from the lungs – principally cough, sputum production and breathlessness on exercise. However, it is now clear that there are major secondary effects on other organs. The impact of pulmonary hypertension and chronic hypoxia on right ventricular function has been recognized for a long time, but there is now good evidence, discussed elsewhere in this book, concerning the link between the lungs, skeletal muscle and lean body mass. While breathlessness is recognized universally to be important in COPD, the impact of fatigue is less well known, although it has been described as a major factor in COPD for a long time [1,2]. Mechanisms responsible for fatigue are almost completely unknown, but progress is being made, because recent studies have shown that quadriceps strength is linked to circulating proinflammatory cytokines, which rise during an exacerbation [3]. Sleep disturbance resulting from respiratory symptoms is a common feature of COPD, affecting half of patients [4], and disturbances of mood state occur [5].

Put together, a picture emerges of a disease affecting many organ systems through many different mechanisms. Specific measurements are available for many of the effects of COPD: physiological tests including lung function, exercise capacity and muscle strength; psychophysiological tests of breathlessness and fatigue during exercise; diary cards for symptoms; questionnaires for disability and mood. While all of these build up a picture of the components of the disease and their effects, they do not provide a measure of the overall impact of COPD on the patient. This can only be achieved through formal measurement of health status.

Outcomes and markers

Two general terms are used when discussing the effects of a disease: outcomes and markers. They are often used

interchangeably, but it is useful to retain a distinction between them; indeed, markers should not be confused with outcomes:

- *Outcome*: consequence of the disease, as experienced by the patient.
- *Marker*: disease-related factor known to be associated with a clinical outcome.

Examples of outcomes in COPD include: symptoms, weight loss, exercise intolerance, disability, exacerbations, impaired health-related quality of life (HRQoL), increased health resource use and death. Quantification is important in medicine, both for routine care and research, so outcomes should be measured, but many patient-experienced outcomes are difficult to quantify in a standardized manner. By contrast, a marker should be a standardized measurement. For example, exercise intolerance in daily life is an outcome resulting from COPD, but it is difficult to quantify each patient's unique and subjective experience of his or her exercise intolerance. Exercise capacity, on the other hand, is a standardized measurement obtained in the laboratory. It can be used as a marker of exercise intolerance because there is good evidence that exercise capacity correlates with patients' reports of the effect of exercise limitation on their daily physical activity (reviewed in [6]).

The distinction between an outcome and its associated markers is also important when considering the impact of disease on the patient's quality of life. A number of terms are used in this setting, often interchangeably: 'health status', 'functional status', 'well-being', 'quality of life' and 'health-related quality of life'. Well-being is usually reserved for subjective perceptions, but may include symptoms as well as global evaluations of health status. The concept of quality of life is much broader than health status, because it includes aspects of the patient's environment that may not be affected by health or treatment. Because there are so many other influences on a patient's quality of life, the term health-related quality of life (HRQoL)

was coined to indicate that the measurement is focused on the specific effects of health conditions. Unfortunately, it has also come to be used loosely as a synonym for all self-reported health status measures. The factors that determine an individual's quality of life are unique to that person, so the quality of life effects of disease will also be unique to each patient. Methods of measuring individual HRQoL have been developed [7], but they are difficult to standardize. Nearly all so-called HRQoL questionnaires are standardized and treat each patient as if they were a 'typical' patient. As a result, the capacity for a patient to express the individuality of their experience is very limited. For that reason these questionnaires should be called health status instruments. Health status scores provide a marker of the patient's HRQoL – which is an outcome that is currently not measurable.

The term 'surrogate' is used often in the context of outcomes and markers. In one respect this is quite appropriate because a marker is measured when it is not possible to measure its associated outcome, but in medicine the term 'surrogate marker' takes on a specific meaning where one marker is used in place of the marker of interest. A good example is emphysema – which is difficult to measure directly *in vivo*, so diffusing capacity is often used in practice as a surrogate. Another term in wide use is biomarker, which is a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes or pharmacological responses to therapeutic interventions. An example in COPD is exhaled nitric oxide (NO), when used as a biomarker for an inflammatory process in the airways.

An important feature of markers is that there should be a known and well-characterized relationship between the marker and its outcome. It is important to appreciate that this relationship may be modified by other factors, and those factors may change. These modifiers may be internal to the patient (e.g. presence of comorbidities) or external (e.g. level of family or social support). The influence of modifiers is yet another reason why it is important to maintain a clear distinction between markers and outcome. The relationship between the two is probabilistic. For example, a low forced expiratory volume in 1 s (FEV_1) is a marker for an increased risk of exacerbations (an outcome), but that does not mean that all patients with low FEV_1 have many exacerbations, or that patients with relatively well-preserved FEV_1 may not also have frequent exacerbations [8].

Use of markers

Markers are used for different purposes and the same variable can be used as a different type of marker, depending upon the application.

Diagnostic marker

In this context, markers are used mainly as a dichotomous variable (i.e. it is either present or absent). This does not mean that the marker has to be measured on a dichotomous scale, but that the measured value is assigned to one of two states (normal or disease), based on ranges defined from experience (e.g. α_1 -antitrypsin level, or FEV_1 , when used for COPD diagnosis).

Measure of disease severity

A marker may be used to define different levels of disease severity, or stage. When used in this way, measured values for the marker are categorized into predefined ranges. The chosen ranges for these categories may or may not be evidence based. Examples include: body mass index (BMI), or FEV_1 – as used in ERS and Global Initiative for Chronic Obstructive Lung Disease (GOLD) staging.

Marker of disease progression

In this application, the marker is used as a derived parameter, usually as a value per year (e.g. exacerbation rate, decline of FEV_1 or deterioration of health status score).

Marker of treatment effect

These are the familiar markers used to measure response to treatment (e.g. dyspnoea score, lean body mass, exercise capacity, health status, FEV_1). Confusion around terminology can arise in this setting, because in clinical trials these markers are often termed 'outcome variables'. They are, of course, outcomes for the trial, not clinical outcomes.

Patient-reported outcomes

This term has come into use to describe outcomes that depend on the patient's self-report or self-assessment. This dependence is entirely appropriate, although the terminology is slightly tautologous, because outcomes are consequences of disease experienced by the patient. The remainder of this chapter discusses outcomes concerned with symptomatic well-being and what used to be termed impairment, disability and handicap. The concept of disability has changed over time and in some respects has become quite complex. The current World Health Organization (WHO) definition uses the word as an umbrella to include impairment, activity limitation and participation restriction:

- *Impairments*: include problems in body function (e.g. lung function or exercise capacity).

- *Activity limitations*: difficulties an individual may have in executing activities (such as mobility or self-care).
- *Participation restrictions*: problems an individual may experience in involvement in life (what an individual does in his or her current environment).

Impairments and activity limitations can usually be measured as markers, whereas participation restriction is an outcome that is difficult to assess in a standardized way.

Measures of activity limitations

Scales used to quantify limitation of activity in daily life in COPD come under a number of labels.

Dyspnoea scales

Breathlessness can be measured directly using the Visual Analogue and Borg Scales during laboratory exercise tests. Unfortunately, the term 'breathlessness measurement' is also used to describe methods of recording patients' self-report of activities that cause them breathlessness, or more usually are limited by breathlessness. The most widely used example is the Medical Research Council (MRC) Dyspnoea Scale (Table 16.1). Although described as a dyspnoea scale, this is really a scale of activity limitation resulting from breathlessness. It is simple to use and can be translated into different languages with little ambiguity. Its principal application is as a marker of severity, because it categorizes patients into five levels of breathlessness-associated disability. A recent validation in COPD patients has shown that it discriminates between different levels of disability, at least in the three most severe grades [9]. However, it has two minor weaknesses. The first is that its simplicity is achieved at the cost of precision. The five-point scale is adequate for assessing severity, but is too coarse for measuring treatment effects or disease progression. The second weakness arises

from the combination of two activity limitations within one grade (e.g. grade 5: difficulty dressing and leaving the house). Using factor analysis of a range of activities limited by breathlessness, we found that these limitations were highly correlated (P.W. Jones, unpublished observations), but no formal analysis has ever been published of the validity of combining these different aspects of dyspnoea-induced disability. When using this scale, it is important to be aware of the existence of two methods of scoring: 0–4 (widely used in the USA) and 1–5 (used in the USA, UK and elsewhere). Whenever the MRC grade is reported, the scale must also be clarified. Despite these minor deficiencies, this questionnaire is a very good marker of disability in chronic lung disease.

A more sophisticated measure of disability resulting from breathlessness is the Baseline Dyspnea Index (BDI) [10]. It provides an index of functional impairment by addressing the magnitude of the task and the magnitude of effort associated with it. Unlike the other instruments described in this chapter, it is currently only available as a clinician-administered instrument. The BDI could be used as a marker of severity, but does not appear to be used in this way very often. Its usual application is to provide a baseline for the Transition Dyspnoea Index (TDI) which quantifies the change in breathlessness. Like the BDI, this is clinician administered, but a computerized patient self-administration method has been developed. The TDI was developed as a marker of treatment efficacy and has been shown to be responsive in a number of studies [11, 12]. It is not yet clear whether it has properties that make it suitable for use as a marker of disease progression.

The UCSD Shortness of Breath Questionnaire is a comprehensive 24-item dyspnoea questionnaire that measures disability resulting from breathlessness [13]. It has good reliability and validity and has found application in trials of pulmonary rehabilitation [14].

Functional limitation questionnaires

These questionnaires record limitations of function, not necessarily limited to physical activity. They are used as markers of treatment efficacy. The most comprehensive is the Sickness Impact Profile (SIP) [15]. It has 136 items and is often also classified as a general health measure because it covers a wide range of functions, both physical and psychosocial. It was widely used in COPD studies in the past [16], but has been abandoned, largely because of its size and the fact that its content results in low severity scores even in patients with severe disease.

There are two comprehensive function limitation questionnaires, developed specifically for COPD, the modified Pulmonary Functional Status and Dyspnea Questionnaire (PFSDQ-M) [17] and the Pulmonary Functional Status

Table 16.1 Medical Research Council (MRC) Dyspnoea Scale.

MRC breathlessness questionnaire

I only get breathless with strenuous exercise

I get short of breath when hurrying on the level of walking up a slight hill

I walk slower than people of the same age on the level because of breathlessness, or I have to stop for breath when walking at my own pace on the level

I stop for breath after walking about 100 yards or after a few minutes on the level

I am too breathless to leave the house or I am breathless when dressing or undressing

Scale (PFSS) [18]. These cover physical functions and are used most widely in the context of pulmonary rehabilitation, especially in the USA.

Activity of daily living scales

Activity of daily living (ADL) scales are usually restricted to basic self-care and mobility around the home, so questionnaires of this type tend to be more suitable for patients with severe COPD. The Nottingham Extended Activity of Daily Living Scale, developed for patients with stroke, has been shown have validity in COPD [19] and a new ADL questionnaire specifically for COPD has also been described [20].

Health status questionnaires

Health status questionnaires cover a wider range of effects of disease than measures of activity limitation and include well-being. They fall into two types: generic and disease-specific. The most widely used general health status measure is the SF-36 (www.sf-36.org). This questionnaire is a population-based marker of disease severity. It is used as a marker of treatment efficacy in COPD, and can be used as a marker of disease progression [21], but is not consistently responsive to effective treatments for COPD [22–24].

The two most widely used disease-specific health status measures for COPD are the CRQ [25] and St George's Respiratory Questionnaire (SGRQ) [26,27]. They differ a little in content, but more significantly in their design philosophy and scoring systems. The CRQ was designed as an evaluative instrument (i.e. as a marker of therapeutic outcome). The SGRQ was designed not only as a marker of outcome, but also to have discriminative properties so that it could be a marker of disease severity. It was developed to be suitable for long-term trials and be used as a marker of disease progression. These different design considerations led to the use of different methods of collecting responses to the constituent items and for scoring the instrument. The CRQ uses Lickert scales that offer seven severity response categories to each item. The SGRQ uses mainly dichotomous (yes/no or true/false) responses, and each response in the questionnaire has an empirically derived weight. The SGRQ falls very clearly into the category of a health status measure, but the CRQ has one element that permitted it to be designated as an HRQoL instrument. As originally designed, the dyspnoea component of the CRQ required the patient to identify activities restricted by breathlessness that are important to them (i.e. a component of quality of life). More recently, a standardized and self-administered version has been developed and validated [28,29], although this means loss of its HRQoL designation. Direct compar-

ison of the sensitivity of the two instruments in rehabilitation studies is now possible. Overall, they appear to have similar levels of sensitivity and responsiveness [23,24,30]. Direct comparisons of the two instruments in pharmacological studies have not been made. There have also been few long-term comparisons, but in a large 1-year follow-up of patients in a rehabilitation trial, differences between treatment and control arms of the study were more apparent with the SGRQ than the CRQ [23].

The CRQ and SGRQ are complex instruments, but the development of the standardized self-complete version of the CRQ should make it easier to apply. To improve ease of scoring of the SGRQ, a Microsoft Excel-based scoring system has been available for users of paper-based questionnaires for some time, but the development and validation of a computerized patient-entered and scored system is a significant step forward. The advantage of computer systems for patient questionnaire completion is that data capture is always 'clean' with no missed responses. Both are available from the author (pjones@sghms.ac.uk). Other shorter questionnaires have become available, but there are fewer data about them than the two more established instruments. One is the Quality-of-life for Respiratory Illness Questionnaire (QOLRIQ), developed originally in Dutch, but available in English [31]. Two other questionnaires are the Breathing Problems Questionnaire (BPQ) [32] and the AQ20. The latter has been validated in COPD in Japan and in the USA [33,34]. A UK study concluded that the BPQ provided more valid assessments of health status than the CRQ [35], although a Japanese group found that the CRQ and SGRQ discriminated between patients with different degrees of severity better than the BPQ [36]. There is one report that the BPQ was not as sensitive as the CRQ in detecting change following a pulmonary rehabilitation programme, but the AQ20 did discriminate between patients as well as the CRQ and SGRQ and was also responsive to changes following pulmonary rehabilitation [33].

Health status as a marker of disease severity

The standard method of assessing and categorizing COPD severity is through the FEV_1 , but COPD is characterized by disability that results, not only from breathlessness, but also through secondary effects on other organs such as musculoskeletal function. For that reason, the association between FEV_1 and health status is weak. Within each GOLD category of COPD severity, there is a very wide range of health impairment (Fig. 16.1). Quite clearly these two measurements provide complementary information. This has been confirmed by the demonstration that health status scores, when measured using the SGRQ or the SF-36

Figure 16.1 Correlation between forced expiratory volume in 1 s (FEV_1) and St George's Respiratory Questionnaire (SGRQ) score. High SGRQ score indicates poor health. Global Initiative for Chronic Obstructive Lung Disease (GOLD) categories for COPD severity are superimposed. (Data derived from Burge *et al.* [46].)

predicted death in patients with COPD independently of age, FEV_1 and BMI [37]. A similar observation was made in another study, in which exercise capacity appeared to be the key determinant of health status (measured using the SGRQ) that linked it to risk of death [38]. It should be noted that these authors found that the CRQ did not predict COPD mortality [39].

Health status as a marker of treatment efficacy

These questionnaires are designed to provide a measure of the overall impact of COPD on patients' health and an overall measure of treatment efficacy. This requires an estimate of the threshold for clinical significance. Such estimates are available for both the CRQ and the SGRQ. Issues around the development of these thresholds are too complex to be addressed here, but they have been reviewed recently [40]. The first demonstration that health status measurement can make a major contribution to trials of pharmacological therapy in COPD was the demonstration that clinically worthwhile improvements in health could be obtained with salmeterol in COPD, despite only modest improvements in FEV_1 [22]. Since then, health status measurements have been incorporated into nearly all major trials in COPD. In addition to providing estimates of the overall efficacy of the treatment, these trials have provided new insights into COPD. This is illustrated well in a comparison of the long-acting bronchodilator tiotropium compared with regular ipratropium (Fig. 16.2). The benefit of the

(a)

(b)

Figure 16.2 Changes in (a) trough (morning pre-dose) forced expiratory volume in 1 s (FEV_1) and (b) St George's Respiratory Questionnaire (SGRQ) score with tiotropium and four times daily ipratropium in COPD. A fall in SGRQ score indicates improved health. The difference in FEV_1 and differences in SGRQ score at day 50 and day 182 onwards were significant at $P < 0.05$. (From Casaburi *et al.* [42] with permission.)

long-acting drug on trough FEV_1 over the short-acting agent was apparent within a few days, but there was little further change during the following year. By contrast, the improvements in SGRQ score continued to improve over the next 6 months and the difference between treatment arms increased throughout the study [41]. A very similar pattern was seen when tiotropium was compared with placebo [42]. The different time course of response is almost certainly caused by different mechanisms of action of the drug. Exercise capacity with tiotropium improved over 6 weeks of treatment [43]. Thereafter, the accumulating benefit may be a result of the reduction in exacerbations that occurs with this drug [41], because there is evidence that the effect of inhaled corticosteroid on health status in COPD is attributable to a reduction in exacerbations [44]. Demonstration that the benefit of modern therapies for COPD increases progressively over time is a major

Figure 16.3 Rate of deterioration in St George's Respiratory Questionnaire (SGRQ) score (higher score indicates faster deterioration) in patients who had no exacerbations over a 3-year period and patients split into those with infrequent and frequent exacerbations. (From Spencer *et al.* [44] with permission.)

contribution of health status markers to current understanding of the disease.

Health status as a marker of disease progression

COPD is a progressive disease. The rate of deterioration in health is quantifiable with use of appropriate questionnaires, such as the SGRQ and SF-36 [21], although it has proved difficult to detect longitudinal changes with the CRQ [45]. Mechanisms responsible for the deterioration include decline in FEV_1 and exacerbation rate (Fig. 16.3), but these explain only part of the deterioration [44]. There is evidence from the ISOLDE study [46], that reducing exacerbations with fluticasone reduces the rate of deterioration in health status.

Use of health status measurement has forced a re-evaluation of the importance of acute exacerbations of COPD. Using standard clinical criteria for treatment success following an Anthonisen type 1 exacerbation of COPD, in a recent trial of antibiotics 85% of patients were judged cured or improved 2 weeks after the start of treatment [47]. In a similar study, measurements using the SGRQ showed that it took much longer for health to recover [48]. The improvement between 4 and 12 weeks after the exacerbation was greater than the threshold for a clinically significant improvement and even between 12 and 26 weeks there was a further small but statistically significant improvement (Fig. 16.4). Equally important was the observation that patients who had a further exacerbation within 6 months of

Figure 16.4 Rate of recovery of St George's Respiratory Questionnaire (SGRQ) score following an Anthonisen type 1 acute exacerbation of COPD. Error bars are 95% confidence intervals.

the first had a much smaller improvement in health. Early pulmonary rehabilitation greatly improved the degree of recovery of health following hospital admission for a COPD exacerbation [24].

Measurements of health status in routine practice

Assessment of health status clearly has an important role in COPD that complements spirometry. Reliance on the FEV_1 would fail to identify the true impact of the disease in many patients with COPD, as shown in Figure 16.1. It is clear that simple markers of the severity of health status impairment are needed for use in routine practice. Most of the available questionnaires are still too complex for everyday practice, but the MRC Dyspnoea Scale is easy to use, standardized and can be used in any clinical setting whether primary care or specialist clinic. It correlates well with health status measured using the SGRQ (Fig. 16.5). The development of health status questionnaires for use as markers of treatment efficacy in individual patients provides a complex challenge. There are many technical issues concerning methodology that have to be resolved before practical and reliable methods can be applied in routine practice. There is, however, good evidence that patients' retrospective estimates of overall treatment efficacy correlate with assessment made prospectively using the SGRQ [22]. An assessment that the treatment was effective was associated with a clinically significant change in SGRQ score.

Figure 16.5 Relationship between Medical Research Council (MRC) dyspnoea grade and St George's Respiratory Questionnaire (SGRQ) score. Error bars are 95% confidence intervals. (Data from Jones *et al.* [27].)

Conclusions

Health status measurement provides an important marker of COPD severity and complements spirometry. Measurements made with well-validated questionnaires can now provide reliable markers of treatment efficacy and disease progression. In recent years they have provided major insights into COPD, but they still remain largely research tools, except in rehabilitation where they are often used to monitor a programme's effectiveness. In routine practice, the MRC Dyspnoea Scale provides a reliable marker of impaired health, but for the foreseeable future the patient's global estimate of treatment efficacy will remain the only practical marker of treatment efficacy in individual patients.

SECTION 3

Host defences and
inflammation

CHAPTER 17

Mucociliary clearance

Souheil El-Chemaly, Adam Wanner and Matthias Salathe

The lungs fulfil the unique task of gas exchange, requiring a human body to ventilate approximately 20 000 L of air during quiet breathing every day. This task exposes the conducting airways and the alveoli to a significant burden of organic and inorganic particulate and gaseous material that must be either prevented from entering or, if it has entered, be constantly removed from the airways. An initial mechanical barrier at the entrance of the nose, nasal hair, serves as a coarse filter. Turbulent flow in the nose, pharynx and larynx causes larger particles to settle before they can enter the trachea. Furthermore, turbulent flow in large airways also enhances the deposition of particles onto the liquid/mucus blanket covering the epithelium. At locations of extreme turbulent flow, such as airway bifurcations, particle deposition rate is enhanced and reaches values that are approximately 100 times higher than elsewhere [1]. While the body has developed multiple mechanisms to prevent growth of organic infectious materials that have been deposited onto the airway surface (be it in the nose or lower airways), these organisms still need to be removed from these sites together with inorganic substances before they can cause harm, a task handled by the mucociliary transport system. Like other transport mechanisms, this system contains a motor for propulsion provided by cilia beating in the periciliary fluid layer on the airway surface and a vehicle provided by a mucus layer which is transported out of the airways by cilia. When this system fails, regardless of the underlying mechanism, respiratory secretions accumulate in the airways, leading to airflow obstruction and an increased susceptibility to bacterial colonization of normally sterile airways.

This chapter reviews the main concepts of mucociliary clearance, focusing on ciliary function and the collective clearance mechanism.

Cilia

Each human airway cilium is approximately 6 μm long and 0.3 μm in diameter and contains an array of microtubules in the classic '9 + 2' configuration (the detergent-resistant structure called axoneme). This morphological configuration is a hallmark of almost all motile cilia (with the exception of cilia in the embryonic node, which are motile despite their '9 + 0' structure [2]), indicative of their structural preservation throughout evolution [3]. The microtubules are constructed primarily from heterodimers of α - and β -tubulin and dynein, but more than 200 other proteins are associated with a variety of circumferential, spoke and radial linkages which serve to maintain the axonemal structure and play a part in the control of ciliary movement [3–5]. Bridges between the ciliary membrane and the outer nine doublet microtubules along the length of the cilium seem to participate in the regulation of ciliary beating [6]. Along the entire axonemal length (except for the tip region and the base), the doublet is a repetitive structure with a unit length of 96 nm consisting of four outer dynein arms, three to four inner dynein arms, one spoke group (three radial spokes) and one pair of inter-doublet links [3]. The outer arm dynein from mammalian tracheal cilia is a two-headed bouquet-like molecule with a molecular size of 1–2 million daltons (MDa) [8]. Each head contains a heavy chain ATPase of 400 000–500 000 Da.

During ciliary movement, dynein arms originating from outer microtubule doublets interact transiently with adjacent microtubules and undergo a conformational change using energy from ATP hydrolysis. This conformational change causes microtubules to slide relative to each other [9]. To date, several distinctly different axonemal dynein genes have been cloned; for instance, seven cDNAs were cloned from rat airway epithelium [10]. Although it seems logical that this dynein variety has biological consequences,

the exact location of assembly of the different dynein isoforms is not known. *In vitro* data, however, suggest that at least the inner and outer dynein arms are functionally distinct [11], a finding confirmed in *Chlamydomonas* mutants where outer arm dynein was found to be responsible for ciliary beat frequency (CBF) regulation and inner arm dynein for bend formation and beating form [12,13]. The correlation between outer dynein arm and CBF regulation seems to hold true in humans based on evidence from subjects with primary ciliary dyskinesia [14].

The beating of airway cilia has been adjusted to the unique task of mucus transportation [15,16]. The cycle consists of a resting state as well as effective and recovery strokes. Through its recovery stroke, the cilium swings almost 180° backwards close to the cell surface. The ability of the cilium to do so in a watery environment (i.e. within the periciliary fluid level) is critical for adequate mucociliary clearance (see below). After the recovery stroke, the cilium fully extends and goes directly through its effective stroke in a plane perpendicular to the cell surface, reaching a maximal velocity of 1 mm/s at its tip. The extended cilium engages the overlying mucus describing an arc of approximately 110°. This engagement has been thought to be critical for adequate mucociliary clearance; however, recent data have challenged this concept (see below). After completion of the effective stroke, the cilium rests shortly and then resumes its recovery and effective strokes. Distal to the larynx, the effective stroke has a cephalad orientation and is about two to three times faster than the recovery stroke [17,18]. When CBF increases, all three phases of the beat cycle are shortened, but the resting period is most markedly affected [17]. The power that the cilium produces is related to the number of dynein-microtubule interactions [19,20] and can be, at least partially, adjusted to different loads of varying viscosity [21]. Ciliary beating in the airways seems coordinated (i.e. cilia beat as part of a metachronal wave). As cilia are densely packed onto the airway epithelial surface, significant hydrodynamic forces exist between single cilia. These hydrodynamic interactions are likely the most important factor for ciliary coordination [22] and may explain why the lengths of metachronal waves are limited, restricting the field of metachrony [16,23].

Human cilia beat at approximately 12–15 Hz at body temperature when measured *in vitro*. CBF is adjusted by the regulation of dynein-microtubule interactions, but the cellular and molecular mechanism by which this is accomplished is incompletely understood. Evidence has been accumulated showing that mammalian CBF changes in response to changes in the phosphorylation state of ciliary targets (mainly through cyclic adenosine monophosphate [cAMP]-dependent phosphorylation) and to changes in cytoplasmic calcium ($[Ca^{2+}]_i$).

Many different experimental methods have been used to increase cAMP levels inside cells, and all have been

shown to increase human, bovine, ovine and rabbit CBF. Manipulations of cAMP were achieved with β -adrenergic agonists that stimulate transmembrane adenylyl cyclases (tmAC) [24–29], forskolin that directly activates tmAC, and membrane-permeable cAMP analogues. CBF increases upon cAMP rise were blockable by non-specific protein kinase inhibitors, implicating a role for cAMP-dependent protein kinase (PKA) [27,30–32]. The molecular mechanism by which PKA increases mammalian CBF is likely analogous to the stimulation of *Paramecium* ciliary activity by PKA. Hamasaki *et al.* [33] showed that a ciliary PKA phosphorylation target of 29 kDa in *Paramecium* was an outer dynein arm light chain [34] and that the phosphorylation of this light chain was sufficient to increase the velocity of microtubule gliding across dynein-coated surfaces *in vitro* and the swimming speed *in vivo* [34]. Since then, mammalian respiratory axonemal targets of PKA with similar molecular weights have been identified by their cAMP-dependent phosphorylation [35–37]. It is also clear that a ciliary PKA is localized to mammalian axonemes [35–37], a fact supported by the presence of a specific A-kinase anchoring protein in human airway cilia [35].

cGMP-dependent protein kinase (PKG) has also been shown to be involved in the regulation of CBF in certain mammalian species [27,38,39]. There is controversy whether or not a combined signalling by $[Ca^{2+}]_i$ is required [38,39] and some experiments suggest that PKG may act through PKA to stimulate CBF [27].

The intracellular calcium concentration ($[Ca^{2+}]_i$) has a crucial role in the regulation of CBF but the mechanism by which calcium influences frequency seems to differ between unicellular organisms and mammals. In *Paramecium*, rising $[Ca^{2+}]_i$ slows CBF to the point where the beat direction is reversed [40]. Mammalian cilia, on the other hand, never reverse their beating direction and elevations of $[Ca^{2+}]_i$ increase CBF [24,25,41–46] whereas decreases in $[Ca^{2+}]_i$ below baseline decrease CBF [43]. Some reports, using inhibitors of calmodulin, have suggested that $[Ca^{2+}]_i$ may act through calmodulin via Ca^{2+} /calmodulin-dependent kinase (CaM kinase) [41,47] and ciliary targets of CaM kinase have been described at least in *Tetrahymena* [48]. However, some of these calmodulin inhibitors are ciliotoxic and CaM kinase targets were not found in mammalian cilia [49]. More recent evidence suggests that Ca^{2+} in mammalian cells acts directly on the axoneme, presumably on a Ca^{2+} -binding protein that is not calmodulin [50], to change CBF [39,51–53]. However, increases in intracellular calcium may also rise cAMP [54,55] and potentially cGMP via an NO pathway to activate PKG inside cilia that modulates CBF as well [56]. This complicates interpretation of the calcium-related CBF increase. Whether or not an elevation of cyclic nucleotides is required for calcium to change CBF is currently under intense investigation [38,39,57].

The cAMP and Ca^{2+} pathways have been shown to interact at several levels with respect to ciliary function. β -Adrenergic agonists, for instance, have been shown to stimulate CBF not only through a cAMP-dependent pathway, but also through an initial calcium-coupled mechanism [25,30]. Furthermore, Smith *et al.* [58] reported that CBF of human nasal cells was rendered insensitive to $[\text{Ca}^{2+}]_i$ changes upon continued exposure to increased intracellular cAMP levels and that the cAMP-mediated changes of the CBF sensitivity to $[\text{Ca}^{2+}]_i$ were dependent on PKA activation.

A large body of literature has been published on mediator- and drug-induced changes of ciliary beating. It is beyond the scope of this chapter to discuss all these publications (reviewed in [59]). However, under normal conditions, paracrine actions of secreted adenosine triphosphate (ATP), primarily via $[\text{Ca}^{2+}]_i$ and secondarily via cAMP, have been identified to be crucial in regulating CBF [54,55,60,61]. There is also some evidence that acetylcholine, made within the airway epithelium itself, may be used in a paracrine fashion to stimulate M3 receptors [56,62,63]; however, there seems to be a vast difference in the importance of this pathway between different mammalian species.

It is interesting that many inflammatory mediators stimulate ciliary beating *in vitro* [64–67], although mucociliary transport velocity is usually decreased during established airway inflammation, including COPD (see below). Exceptions are platelet-activating factor [68,69] and major basic protein of eosinophils which accumulates in the sputum of asthmatic patients [70]. Furthermore, serum proteins released into the airway lumen during inflammation [71,72], leucocyte elastase [73,74], and neutral protease are cilioinhibitory [75]. The latter mediators of inflammation are especially relevant in COPD.

Periciliary fluid

The periciliary fluid is a watery environment allowing the cilia to beat without interacting with mucus at all times. In the presence of mucus, the fluid depth is approximately equal to the extended cilium in length [76]. The height of this fluid above the airway epithelial cells is tightly regulated, as recently shown in cell culture systems [77–79]. The regulation mechanisms are still poorly understood but are related to the ion transport characteristics of airway epithelial cells [80]. A small osmiophilic film is present on the luminal surface of the periciliary fluid layer and represents surfactant [81], likely produced locally by epithelial cells rather than stemming from the alveoli [82–84].

For a long time, it was assumed that ciliary tips could not interact with mucus if the periciliary fluid level was too high and thus mucus could not be moved under these

conditions. However, this concept has been challenged by showing that the whole periciliary fluid layer actually moves in a cephalad direction together with the mucus blanket (but only if mucus is present [85]), suggesting that cilia may not need to interact directly with the mucus blanket. In support of this hypothesis, it has been found that patients with a genetic defect in an apical sodium channel, resulting in increased water amounts in the airways, actually have significantly increased mucociliary transport, again suggesting that an excess of apical water is not deleterious, but in fact beneficial to mucociliary transport [86].

On the other hand, if the periciliary fluid level is too low, the mucus blanket itself impedes ciliary beating by interacting with cilia during the recovery stroke. That this mechanism truly impedes mucus transport has been shown in culture models of cystic fibrosis [80]. Restoring appropriate depth of the periciliary fluid level in these models restores mucociliary transport [87].

The periciliary space is not only filled with electrolyte solution; close to the apical surface of the epithelium, high molecular weight structures such as glycosaminoglycans and membrane-bound mucins can be found. These structures fulfil their own functions on the apical surface. Glycosaminoglycans, for instance, immobilize host defence molecules at the surface thereby protecting them from clearance [88]. The glycocalyx also prevents viruses from infecting ciliated cells [89]. Many of these functions have not been examined in detail but are currently under investigation.

Mucus

Mucus is mandatory for mucociliary transport; if no mucus is present the system fails [85,90]. Mucus is a mixture of glycoproteins, proteoglycans, lipids, other proteins, and sometimes DNA. Mucus contains secretory IgA immunoglobulins that form an immunological barrier against bacterial colonization, lysozyme that is bactericidal, and lactoferrin that scavenges oxygen radicals and traps iron ions, thereby preventing biofilm formation [91]. Multiple other innate host defence molecules such as defensins [92–94] and the lactoperoxidase system can be found in mucus and the periciliary fluid [95–97].

Gel-forming mucins form the basic polymer structure of mucus. The gel phase is initially formed by rapid hydration of mucins secreted from vesicles where they are stored in a condensed form. Secretion of mucus from these granules has been compared to a ‘jack-in-the-box’ mechanism [98]. To stay in a condensed form inside the cell, the charges of the mucin polyions are rendered neutral by acidic pH and counterion shielding, achieved by high $[\text{Ca}^{2+}]$ inside the vesicles [98]. Upon secretion, the condensed mucus undergoes a polymer phase transition by

hydration according to Tanaka's [99] polymer gel theory. This hydration is aided by an exchange of calcium in the vesicles with sodium ions which are weaker supporters of the condensed phase form. Thus, hydration of mucus results in rapid expansion of the gel with a volume increase of several hundred-fold in only a few seconds.

The rheological properties of mucus, a non-Newtonian fluid, are expressed by its viscosity and elasticity; these are mainly determined by the mucin tangle density in the gel [100], which decreases during mucus hydration. Thus, one of the most critical factors regarding mucus rheology is mucus hydration (another would be mucin molecule length), a fact shown by the inability of cilia to move mucus with high solute concentrations [87]. The ability of cilia to transport mucus is indirectly proportional to viscosity and directly proportional to elasticity [101]. Other physical properties of mucus such as adhesivity, cohesivity and wettability [102] are also important in particle-mucus interactions and mucus transportability, but are less well defined.

Multiple substances have been shown to stimulate mucus or glycoconjugate secretion from goblet cells or submucosal glands. Physiologically, purinergic agonists released from the airway epithelium as well as from goblet cell granules [103] have a major role in releasing mucus [104–106]. Cholinergic input also stimulates mucus secretion (reviewed in [107]). Controversy exists, however, on whether or not human airways secrete mucus upon β -agonist stimulation. While human tissues mounted in Ussing chambers revealed increased glycoprotein release in one study upon salbutamol stimulation [108], isoproterenol did not elicit radiolabelled glycoconjugate release in human preparations [109,110]. In addition, mucus secretion by human bronchial epithelial cell xenograft cultures was non-responsive to membrane-permeable cAMP analogues while ATP stimulated it (C. William Davis, University of North Carolina Chapel Hill, personal communication). Thus, β -agonist stimulation of mucus secretion in humans is likely not very relevant. Mediators that stimulate mucus secretion or production in disease are discussed below.

Mucociliary clearance

Mucociliary transport velocity and mucociliary clearance rates have been assessed by several methods *in vivo*. Using a fiberoptic bronchoscope to measure the motion of small Teflon discs insufflated into the trachea, the tracheal transport rate was estimated at approximately 20 mm/min [111]. Using a radiographical technique to assess the motion of bronchoscopically insufflated bismuth-coated Teflon discs in the trachea, tracheal transport rates were estimated at approximately 10 mm/min [112]. Finally,

using a radioaerosol bolus technique and radiolabelled microspheres inhaled with adjusted flows to enhance central deposition, tracheal transport rates are estimated at 4–5 mm/min [113]. These rates decrease towards the periphery of the lung; they reach the lowest value in the bronchioles with rates of less than 0.4 mm/min. Transport rates also decrease with age.

Radiolabelled particle techniques can also be used to assess overall mucociliary clearance of the lung [114,115]. An initial exponentially decreasing phase with a half-life of approximately 4 h represents mucociliary clearance in the tracheobronchial tree. A much slower phase with a half-life of several weeks to months represents clearance from alveoli by mechanisms unrelated to mucociliary transport. As initial particle deposition influences measured overall clearance rates (differences of transport rates in the periphery of the lung and the central airways), it is critical to match particle deposition in all subjects by altering breathing patterns during inspiration if necessary. This is especially important when studying older subjects, smokers, or subjects with airflow obstruction where central deposition of particles is enhanced [116]. If assessed correctly, mucociliary clearance is reduced in the elderly, in chronic smokers (even if they are asymptomatic) and in chronic obstructive lung diseases such as chronic bronchitis, bronchiectasis, bronchial asthma and cystic fibrosis [116–118].

Mucociliary dysfunction

Mucociliary function can be disturbed by inappropriate mucus rheology and amount or decreased ciliary activity. Because rheology mainly depends on hydration, breathing air with a relative humidity of less than 30% through the mouth produces transport stasis in the trachea [119]. Dehydration of mucus may not be the only problem in this situation as low temperatures also decrease CBF. Because humans normally breathe through the nose (a highly efficient air conditioner), this issue only has a role in patients who bypass nose breathing (e.g. in patients with tracheostomies).

Exogenous pollutants such as cigarette smoke and SO₂ or NO₂ as well as anaesthetic gases, high inspiratory oxygen concentrations, and inhalations of platelet-activating factor decrease transport rates [120], at least in part through reduction of CBF [68,121].

Drug effects on mucociliary clearance

Cholinergic agonists stimulate mucociliary clearance, possibly by increasing CBF, at least in some species, although

this effect is not certain in humans (see above and [63]), and by optimizing mucus hydration through increased fluid secretion from submucosal glands [122,123], if glycoprotein release does not overwhelm fluid secretion. Locally produced acetylcholine may act as a paracrine signalling molecule under physiological conditions, but cholinergic agonists cannot not be used therapeutically in a patient with mucociliary dysfunction because of their bronchoconstrictive effects. Atropine, a tertiary ammonium compound and anticholinergic drug, decreases mucociliary clearance [124,125], possibly because of decreased hydration of mucus. However, ipratropium bromide, a quaternary ammonium compound, has no effect on mucus clearance [126].

α -Adrenergic agonists have little or no influence on the mucociliary clearance rate in the lower airways. β -Adrenergic agonists including the long-acting salmeterol on the other hand increase CBF in a variety of mammalian airway epithelial cells [24–27,30,127–136]. However, β -agonists have a relatively small effect on overall ion and water transport, as originally evaluated in excised human bronchi [123], they do not seem to significantly stimulate secretion from submucosal glands in humans [122] and do not seem to stimulate mucus release. Thus, the general increase in transport and clearance rates seen in most healthy individuals and patients upon β -agonist administration (at least in the trachea [137–141]) is likely because of their effect on ciliary beating.

Chronic bronchitis and COPD

Mucociliary clearance is dysfunctional in chronic bronchitis [139,142–144] and COPD [145,146]; however, cough clearance may be able to compensate for some of the loss of ciliary clearance [147]. The fact that cough is effective in these patients may indicate that abnormally high mucus production may be present, a hypothesis supported by a study that did not find mucociliary dysfunction in pure emphysema in patients with α_1 -antitrypsin deficiency but no airways disease or mucus hypersecretion [148].

In chronic bronchitis, lower clearance is present in patients with a high neutrophil count in their sputum compared with patients without purulent sputum [149]. This finding indicates that infections, frequently encountered by patients with chronic bronchitis and COPD, may play an important part in decreasing mucociliary clearance. In support of this hypothesis, several lines of evidence link products from neutrophils and bacteria to mucociliary dysfunction. For instance, neutrophil elastase, a potent mucus secretagogue [150–152] and inducer of mucin gene expression [153], also causes abnormal ciliary function, possibly by disruption of epithelial barriers [73–75]. The combined

effect of these changes results in mucociliary dysfunction [154].

Bacterial colonization of airways, seen in patients with COPD [155], can also contribute to mucociliary dysfunction. Bacteria have been shown to release proteases that cause human nasal epithelial disruption as well as CBF slowing *in vitro* [73,156]. Bacterial products such as hydroxyphenazine, pyocyanin and a rhamnolipid as well as bacterial culture supernatants have been shown to decrease CBF [157–161] and mucus clearance [162,163]. In addition, *Haemophilus influenzae*, a bacterium commonly encountered in chronic bronchitis, can induce epithelial cell damage [164] and ciliary dysfunction [157], thereby leading to a decrease in mucociliary clearance. Extensive destruction of the epithelium during infections with *Mycoplasma pneumoniae* [165], viruses especially from the influenza group [166] and after aspiration of gastric acid [167] decreases mucociliary transport rate if the epithelial cell destruction includes more than 50% of ciliated cells even if the remaining cilia beat normally [168]. Finally, airway inflammation can cause acquired ciliary disorders including misalignments of the central microtubules between adjacent cilia, compound cilia, supernumerary microtubules and other malformations [169], all of which may contribute to mucociliary dysfunction.

Conclusions

Mucociliary clearance is an important host defence mechanism. Mucociliary transport is tightly regulated. Effective mucociliary clearance depends on ciliary beating as well as appropriate rheology and amount of mucus. This chapter reviews basic regulatory mechanisms of ciliary beating, the effects of mucus secretion and hydration on mucociliary transport, as well as scenarios in which mucociliary clearance fails. Possible treatments for mucociliary dysfunction in these diseases are reviewed in Chapters 57–62. It is hoped that with a better understanding of the fundamental mechanisms that make mucociliary clearance efficient, more effective treatment strategies can be developed to prevent or treat mucociliary dysfunction in airways diseases, including COPD.

CHAPTER 18

Mucosal immunity

Hugues Chanteux, Charles Pilette and Yves Sibille

The mucosal surface, in particular in the gut and the respiratory tract, represents by far the largest interface of the host with its environment and therefore requires efficient protective mechanisms against potentially noxious agents. Thus, the epithelial monolayer represents a filter between the environment and the mucosa that is able to prevent or facilitate the passage of molecules from the lumen to the submucosa and vice versa. Specifically, the mucosal epithelium regulates the active transport of immunoglobulins A and M (IgA and IgM) produced in the lamina propria, into mucosal secretions, as a major component of mucosal immunity. This suggests a key role for secretory (S) immunoglobulins, mostly SIgA in both innate and specific immunity [1].

Although the respiratory tract shares many characteristics including defence mechanisms with other mucosae, the airways also exhibit some properties specific for the tracheobronchial tree. In particular, mechanical functions such as sneeze, cough and the mucociliary escalator represent major defence mechanisms to eliminate exogenous material reaching the upper and lower airways (Table 18.1).

The respiratory epithelium is divided into two compartments with different functions: the airways and the lung parenchyma. While the conducting airways (from the nose to membranous bronchioles) exhibit a typical mucosal epithelium (ciliated brushes, mucus secretion, secretory Igs production), the lung (from distal respiratory bronchioles to the alveoli) differs considerably from mucosal including bronchial surfaces, with a characteristic epithelial profile; mostly flat, non-ciliated, type I epithelial cells and a few cuboidal type II epithelial cells, the latter accounting for the production of surfactant. This relates clearly to the different functions of the bronchial tree as compared to the lungs. The airways only conduct the inhaled and exhaled air, eventually trapping particulate material to prevent its deposition in the alveolar space. By contrast, the alveoli represent the unit controlling gas exchange between

Table 18.1 Defence mechanisms of the respiratory tract. (Adapted from Pilette *et al.* [1,99].)

First-line defence mechanisms

Airways

- Mechanical: nasal hairs, sneezing, cough, bronchial branching, mucociliary clearance
- Epithelial cell-derived products: mucus, lactoferrin, defensins, lysozyme, lectins, Clara cell protein
- Innate immunity: SIgA, complement, proteases
- $\gamma\delta$ Intraepithelial T cells

Alveoli

- Alveolar macrophages: phagocytosis, oxygen and nitrogen metabolites, lysozyme, hydrolases
- Surfactant (SP-A, SP-B, SP-D)

Second-line defence mechanisms

- Alveolar macrophages and epithelial cells-derived product: cytokines and chemokines
- Recruited granulocytes (mostly neutrophils): phagocytosis, oxygen and nitrogen metabolites, cytokines, chemokines, antimicrobial products (defensins, natural antibiotics), proteolytic enzymes
- Adaptive immunity: antigen-presenting cells, $\alpha\beta$ T cells, B cells (production of antigen-specific immunoglobulins)

airspace and the pulmonary capillary bed. Therefore, impairments in defence mechanisms have a completely different impact in the airways than in the alveoli, explaining the heterogeneous pattern of disorders affecting the airways and lungs.

In normal conditions, defence mechanisms aim at preventing inflammatory and immune reactions in the airways and alveoli. Little is known about the mechanisms underlying this relative tolerance but mechanical filters in the upper airways and mucociliary clearance are likely

to have crucial roles. Thus, only few leucocytes can be observed in the respiratory tract lumen and the bronchial-associated lymphoid tissue (BALT) is virtually absent in healthy humans. By contrast, in pathological conditions, especially during infections, both inflammatory and immune cells can be easily, rapidly and often massively recruited [2,3]. The regulatory mechanisms involved in this recruitment are now better understood, providing potential new therapeutic targets.

Lymphocyte trafficking to the respiratory mucosa

Orchestration and memory of immune responses mounted at mucosal surfaces depend on the presence of T and B lymphocytes within mucosal tissues. The distribution of lymphocytes around the airways is organized differently according to the level of the respiratory tract. In the upper airways, most lymphocytes are located within the surface mucosa, in the lamina propria and in epithelium-associated lymphoid structures referred to as nasal associated lymphoid tissues (NALT). Lymphocytes are normally only rarely observed within the bronchial mucosa, peribronchial lymph nodes containing most mononuclear cells. Thus, primary immune responses require an efficient system to recruit selectively lymphocytes to the airways.

Several molecular mechanisms underlying the recruitment of lymphocytes to mucosal tissues have been unravelled in recent studies. Naive lymphocytes continuously recirculate through lymph nodes using L-selectin, the peripheral lymph node addressin PNA^d [4] and corresponding chemokines. In contrast, tissue-specific migration of memory/activated lymphocytes to mucosal tissues use different addressin/homing receptor pairs and chemokines, with differences between T cells, B cells and IgA⁺ cells. Traffic of T and IgA⁺ B cells committed to populate the intestinal mucosa depends primarily on the $\alpha_4\beta_7$ integrin–mucosal addressin cellular adhesion molecule 1 (MadCAM-1) (mucosal homing receptor) interaction occurring in gut venules, and thereafter on CCR9/CCL25 (TECK) [5,6]. The selective pathway(s) related to trafficking to the respiratory mucosa remain(s) so far elusive. The β_7 integrin and MadCAM-1 molecules are weakly expressed in the lung and therefore other mechanisms should take place to direct immune cells toward the airway mucosae.

While $\alpha_4\beta_7^+$ CCR9⁺ blood T cells are committed to the gut, cutaneous lymphocyte antigen (CLA)⁺ CCR4^{high} population traffic to the skin [7]. The $\alpha_4\beta_7^-$ CLA⁻ CCR4⁺ blood subpopulation has been suggested to target the airways, but BALT cells seem to express low levels of CCR4 and poorly respond to CCR4 chemokine ligands [7]. CCR10 is expressed by circulating IgA plasmablasts and IgA-secreting

plasma cells in various intestinal and non-intestinal mucosal tissues [8,9]; mucosal epithelial cells producing the CCR10 ligand, CCL28 (MEC). Recently, it was shown that L-selectin⁺ $\alpha_4\beta_1^+$ memory T cells traffic to BALT, through recognition of PNA^d and vascular cell adhesion molecule 1 (VCAM-1) in the bronchial mucosa microvessels [10]. $\alpha_4\beta_1^{\text{high}}$ –VCAM-1 interaction, followed by activation of CCR10 by CCL28, could thus be involved in trafficking of lymphocytes, including IgA⁺ B cells to the respiratory mucosa.

Once B cells have been primed by mucosal T cells, they recirculate and migrate to the primary mucosal site of antigen exposure and elsewhere; a phenomenon referred to as ‘cross-dissemination’ in the so-called common mucosal immune system [11]. Thus, immunization through the upper airway (intranasal or intratonsillar) activates local B cells that can reach remote sites such as the urinogenital tract [12], but without affinity for the gastrointestinal tract, suggesting a regional compartmentalization within mucosal immunity. The bronchi and the gut appear segregated in terms of humoral immune responses generating secretory antibodies [13]. Similarly, intranasal immunization evokes an antibody response in the nasopharyngeal tonsil but not in the palatine tonsil [14]. Once in the effector site, activated B cells undergo several functional changes related to terminal differentiation: class switching, clonal proliferation and somatic hypermutation of variable regions. Class switch from C μ to C α depends on the local expression of transforming growth factor β (TGF- β) [15], probably provided by epithelial cells under normal conditions or by macrophages during inflammatory responses. Interleukin 10 (IL-10), along with IL-2, IL-5 and IL-6, promotes the clonal proliferation of antigen-specific IgA-committed B cells [16].

It has been recently shown that the terminal B-cell differentiation occurs only in organized mucosal associated lymphoid tissue (MALT), and not in the diffuse lamina propria of mucosal effector sites [17]. This observation is of importance because a true BALT organization is only observed in humans in pathological conditions, such as in diffuse bronchiolitis or rheumatoid arthritis [18]. In contrast, NALT, consisting of the Waldeyer ring (lingual, nasopharyngeal and palatine tonsils) and lymphoepithelial structures (lymphoid aggregates, microfold cells) within the nasal mucosa, are much more developed than in lower airways and share features with the Peyer patches in the gut (GALT). Thus, under normal circumstances, mucosal immune responses to inhaled antigens are triggered in the nose, whereas immunity to inhaled microparticles that reach the bronchial mucosa rely on the peribronchial glands and thereby on systemic immunity to elicit primary specific immune responses. Interestingly, the presence of lymphoid follicles has been recently observed around small airways of patients with COPD [19].

IgA transcytosis

Located in the underlying mucosal epithelium, plasma cells secrete IgA mainly in its dimeric form. Dimeric IgA contains two conventional immunoglobulin subunits and an intersubunit joining (J) chain. The incorporation of this J chain into polymeric IgA endows these antibodies with high affinity for the polymeric immunoglobulin receptor (pIgR) [20]. The pIgR is a transmembrane protein with an external IgA-binding domain, a transmembranous domain and a cytoplasmic tail that contains cellular sorting signals. The extracellular region of pIgR is divided into the leader peptide and five Ig-like domains (D1–D5) [21,22]. A sixth non-Ig-like domain connects the extracellular domain to the transmembrane region. The pIgR is crucial for the generation of SIgA because it mediates transport of pIgA to mucosal secretions. Polymeric IgA binds efficiently to pIgR on the basolateral surface of epithelial cells. The pIgA–pIgR complex is then endocytosed from the basolateral pole and translocated by vesicular transport to the apical surface of

the epithelium. At the apical surface, proteolytic cleavage splits the external domain of the pIgR (termed the secretory component, SC) from its membrane-spanning domain; this releases the dimeric IgA–SC complex, known as SIgA, into the mucosal secretions.

Mucosal immunity (SIgA and SC) in defence of respiratory tract

Secretory IgA participates in the first line of specific immune defence that protects the mucous membranes from inhaled pathogens. The mucosae largely rely on this mucosal immune system because it is continuously exposed to airborne agents that are potentially harmful. In recent years, it became obvious that beyond its well-recognized activity in scavenging particles and microorganisms at the mucosal surface, IgA has additional roles in mucosal defence. This is particularly evident at the level of the epithelial barrier [23] and of the regulation of phagocyte functions (Fig. 18.1) [24].

Figure 18.1 Immunoglobulin A (IgA) contribution to first-line defence mechanisms in the airways and alveoli. In upper conducting airways, IgA is produced by plasma cells as J chain-containing polymeric IgA (pIgA) and is transported across the airway epithelium through the pIgR into the mucosal lumen where it can synergize with the mucociliary system to clear inhaled antigens ①. IgA can also interact with antigens within the epithelial cell ② and in the lamina propria ③. In distal airways and alveoli, IgA mainly arises as monomeric IgA from plasma exudation and possibly from local synthesis by infiltrating plasma cells. Both monomeric IgA and SIgA (originating from proximal airways) can interact with the alveolar macrophage, the resident phagocyte of the lung which expresses a spliced variant of FcαR (CD89). FcαR triggering by IgA on macrophages may modulate the release of proinflammatory mediators such as tumour necrosis factor-α (TNF-α).

Immune exclusion in the lumen

The first role recognized for SIgA in the lumen is to neutralize bacteria by interfering with their motility and by competing for epithelial adhesion sites [25]. The ability of IgA to agglutinate microbes and to interfere with the action of their flagella renders them less motile and thereby more susceptible to be cleared by respiratory ciliary movements. As bacterial adhesion may operate through lectins, the oligosaccharides in the constant region of IgA may bind and therefore compete with carbohydrate moieties on epithelial cells that act as receptors for pathogens [26]. These two properties of IgA have a major role in protecting airway mucosal surfaces against colonization and invasion by pathogenic microorganisms. This so-called immune exclusion has been extended to viruses, parasites and bacterial toxins [27,28].

Intraepithelial neutralization

It is generally believed that all antibody classes are only active against the extracellular form of pathogens. Once a pathogen enters the cell and is sheltered intracellularly, it is considered to be inaccessible and protected from the actions of antibodies. Phagocyte-mediated immunity is thought to be the only immune system to fight these intracellular infections. However, recent studies have shown that intracellular pathogens such as viruses may be neutralized by IgA antibodies within epithelial cells during their assembly [29,30]. This particular property of IgA is possible through its mucosal transport mechanism; pIgA binds to pIgR on the basolateral surface of epithelial cells and the pIgA–pIgR complex is then transcytosed to the apical surface where a proteolytic cleavage leads to the release of pIgA–SC (SIgA) [31]. During this transport, IgA, in transit in the epithelial cell, could interact with the antigens of a virus infecting that cell. Both *in vitro* and *in vivo* experiments showed that IgA antibodies are able to neutralize intracellular viruses with different degrees of effectiveness according to the reactivity to the epitope. The capacity of neutralizing viruses is not only dependent on intrinsic properties of IgA, but also on the chance that IgA meets viral proteins during the virus' life cycle.

This virus neutralization by IgA appears as a compensation system within the epithelium which can trap antigens missed by the initial SIgA barrier ('immune exclusion') in the lumen.

A recent study has shown another role for intracellular IgA, demonstrating that pIgA transcytosed through the pIgR has the ability to down-regulate lipopolysaccharide (LPS) induced inflammation within epithelial cells [32]. This anti-inflammatory role for intracellular pIgA represents

an additional protective mechanism contributing to IgA-mediated protection of the host.

Excretory immune function

In addition to these two properties in the lumen and within the epithelium, IgA has also a role in lamina propria. Indeed, pIgA binds to pIgR by its Fc region and this allows epithelial cells to transport not only free IgA but also IgA complexes [33]. The transcellular route for IgA immune complexes and for free IgA appears to be identical, in that everything is transported intact into secretions, with no major diversion to an intracellular degradation pathway. Such mechanism leads to the removal of antigens and pathogens out of the underlying lamina propria.

In most cases, this excretory function of IgA is beneficial for the host. However, in certain situations the IgA transcellular routing could be misused by pathogens and thereby become detrimental. In particular, after initial pharyngitis, it was shown that Epstein–Barr virus (EBV) spreads to regional lymph nodes where lymphoid cells are chronically infected. When the virus is released from this region, it forms a complex with IgA which can therefore be excreted in the mucosal lumen. However, EBV is the most important identified aetiological factor for nasopharyngeal cancer. Recent studies have shown that a specific mutation in the gene encoding for pIgR is associated with a higher risk of nasopharyngeal cancer [34]. This mutation could involve a failure in the transcytosis of EBV–IgA complex, leading to an alteration of the release of this complex in the secretion and consequently to an increase in susceptibility in the population of endemic areas to develop nasopharyngeal cancer.

Other studies have implicated the pIgR transcytosis in promoting rather than preventing invasion by pathogens. Thus, *Streptococcus pneumoniae*, one of the most common pathogens in respiratory infections, frequently colonizes the nasopharynx. This property reflects the capacity of *S. pneumoniae* to resist host immunity by expressing a polysaccharide capsule and to adhere to mucosal epithelia. Several surface-associated molecules of *S. pneumoniae* have been identified as contributing to pneumococcal adhesion to respiratory epithelia. Among them, choline binding protein A (CbpA) has been shown by mutagenesis studies to be required for pneumococcal nasal colonization [35,36] and lung infection [37,38]. This protein exhibits a specific binding with free SC or the SC portion of SIgA and pIgR [39]. This interaction is of pathogenic significance because it provides a mechanism of adherence of pneumococci to nasopharyngeal pIgR-expressing cells. Recent studies have identified D3 and D4 regions of pIgR as the binding sites for CbpA providing a mechanism for colonization [40,41].

However, three factors normally prevent pIgR-mediated internalization of pneumococci:

- 1 cleavage of pIgR from the apical surface;
- 2 the relative inefficiency of apical-basolateral transcytosis; and
- 3 the presence of free SC and SIgA antibodies in the respiratory secretions.

Nevertheless, an imbalance in any of these factors, or an overwhelming infection with pneumococci, could tip the scales in favour of invasion.

Constant pIgR transcytosis could occur efficiently with unoccupied receptors leading to the release of free SC at the apical surface of mucosal epithelial cell [42]. The amount of free SC in the respiratory secretions is relatively abundant (up to 60% of the total SC) [43], suggesting that this product of pIgR transcytosis may serve biological functions distinct from its association with IgA.

For decades, the main role attributed to SC has been to protect IgA from proteolytic degradation [44]. Recently, improved pIgA-antibody stability on SC binding was demonstrated in the oral cavity [45]. Moreover, free SC can also neutralize bacterial toxins and act as a non-specific microbial scavenger by binding to fimbriae colonization factor and preventing bacterial adhesion [46,47]. However, its susceptibility to proteolytic degradation limits its efficacy. This means that on association with specific IgA, SC can add to the capacity of SIgA to intercept and clear pathogens. SC has also been shown to bind to and inhibit the chemotactic activity of IL-8, a potent neutrophil chemoattractant [48], which is critical for the recruitment of neutrophils to sites of infection but also contributes to the persistence of the chronic inflammatory response in COPD or cystic fibrosis airways [49]. In cystic fibrosis, the binding of IL-8 to SC is reduced, probably because of an overglycosylation of free SC [50].

A new role for SC has been described recently. It has been shown that SC contributes to efficient IgA-mediated protection by ensuring, through its carbohydrate residues, the appropriate localization of the antibody molecules, which therefore results in optimal prevention of infection of mucosal surfaces by immune exclusion [51].

Because inflammation is not triggered via the three mechanisms described above, IgA is considered as a non-inflammatory antibody. This was further suggested by the fact that IgA is a poor activator of complement. Although IgA has been shown to be capable of triggering the alternative complement pathway (via C3b binding), IgA complexes fail to activate the classical pathway [52].

However, IgA may also bind to its receptor present on the surface of leucocytes and trigger cell activation through the Fc α receptor (CD89).

Although the main role of IgA is to scavenge bacteria

in mucosal lumen through its Fab fragment, its immunomodulatory function appears relevant to the inflammatory response triggered by infectious, toxic or allergic stimuli. Indeed, bacterial exoenzyme, exotoxins, LPS, lipoteichoic acid released by bacteria exhibit a strong proinflammatory activity affecting the immune system [53], mainly by triggering the complex cytokine network. Therefore, the modulation of inflammation appears critical because the role of cytokines and chemokines in the severity of the disease, or even death resulting from infection is evident [54]. Fc α R expression is restricted to cells of the myeloid lineage including neutrophils, eosinophils, most of monocytes-macrophages including alveolar macrophages [55–58]. Under normal conditions, mucosal secretions of the upper airways contain only few leucocytes, in contrast to distal airways occupied by resident alveolar macrophages. However, in the presence of inflammation, granulocytes and mononuclear cells are recruited to the airways and participate in SIgA-mediated immune response through their Fc α receptor (Fc α R). Fc α R participates in many aspects of host defence through engagement with antibodies complexed to antigens, initiating several biological processes including phagocytosis, antigen presentation, antibody-dependent cell-mediated cytotoxicity (ADCC), superoxide generation and release of cytokines and inflammatory mediators [24]. The cellular functions triggered by IgA binding to Fc α R depend mostly on its association or not with the FcR γ -chain [59]. Indeed, the FcR γ -chain is essential for antigen presentation [60] and cytokine production but not for endocytosis [61]. It contains a so-called ITAM (immunoreceptor tyrosine-based activation motif) signalling motif [62], which is phosphorylated after IgA binding and triggers phosphorylation of several tyrosine kinases and mitogen-activated protein (MAP) kinases [63]. In monocytes, this activation leads to the production of several cytokines (IL-6, TNF- α , IL-1 β , IL-8) [64,65] as well as superoxide release [66]. Similarly, pIgA and SIgA trigger a respiratory burst inducing superoxide release in neutrophils as well as in alveolar macrophages [63,67].

Although γ -less Fc α R represents the majority of cell surface receptors, they seem unable to mediate downstream functions. They recycle internalized IgA complexes and protect them from degradation, putatively playing a role in serum IgA homeostasis [61].

Another function initiated by Fc α R is ADCC. Cells primed by IgA antibodies mediate lysis of target cells such as bacteria and erythrocytes, as well as tumour cells [68].

In addition to Fc α R, eosinophils, unlike neutrophils, express a receptor specific for SC [69]. This receptor, which has not yet been characterized, is able to bind SC and SIgA but not serum, monomeric IgA and triggers the degranulation of eosinophils [70].

Exogenous compounds could also have an important

role in the regulation of airways inflammation. It is now largely accepted that some classes of antibiotics are endowed with anti-inflammatory properties in addition to their antimicrobial activities. Among them, macrolides and quinolones are the most studied. This is of particular interest considering the use of antibiotics in respiratory disorders including COPD [71]. Macrolide antibiotics, 14- and 15-membered ring compounds, exhibit immunomodulatory functions that are distinct from their anti-infective properties. Several *in vitro* studies have shown that erythromycin reduced IL-6, IL-8 and ICAM-1 levels [72,73]. In addition, treatment with macrolides reduces neutrophil influx to the airways [74] and sputum production in patients with mucus hypersecretion [75]. The molecular target of these effects seems to be nuclear factor κ B (NF- κ B), as recently shown for clarithromycin [76]. Indeed, it inhibits NF- κ B activation in pulmonary epithelial cells and in peripheral blood monocytes, as observed with erythromycin [77]. These studies have led to the evaluation of long-term treatment with macrolides in inflammatory respiratory disease such as diffuse panbronchiolitis, cystic fibrosis, asthma, chronic rhinosinusitis and COPD, with some promising results because both symptoms and airways function were improved by macrolides [78,79]. Telithromycin, a ketolide derived from clarithromycin, was also reported to have immunomodulatory activity because it down-regulates IL-1 α and tumour necrosis factor α (TNF- α) production by human monocytes [80]. However, no clinical studies are yet available.

Clinical studies showing the beneficial immunomodulatory effects of quinolones are not available. However, several *in vitro* data indicate that most fluoroquinolones derivatives, while inducing IL-2 synthesis [81,82], inhibit the synthesis of IL-1, TNF- α [83–85] and IL-8 [86]. Quinolones increase the cellular level of cyclic adenosine monophosphate (cAMP), probably through the inhibition of phosphodiesterase [87,88]. The accumulation of cAMP increases protein kinase A (PKA) activity, which is known to suppress the expression of TNF- α [89]. Quinolones may also exert their effects through modulation of nuclear transcription factors. The inhibition of TNF- α , IL-1 and IL-8 are associated with inhibition of NF- κ B activation, resulting most likely from the inhibition of I κ B degradation, while the induction of IL-2 is associated with increased API activation [90]. Although progress has been made in understanding the mechanisms involved in the effects of fluoroquinolones, in-depth research is required to fully identify host targets of quinolones. Moreover, well-designed clinical studies should be performed to assess the potential immunomodulating effects of quinolones *in vivo*.

Both macrolides and fluoroquinolones are promised a successful future and it appears likely that a better understanding of the mechanisms of interplay between the host,

pathogens and inflammatory cells will provide potential targets for the use of drugs, including antibiotics, in chronic inflammatory disease of the airways.

Mucosal immunity in obstructive airways disease

IgA production in COPD

IgA levels have been determined in bronchoalveolar lavage (BAL) fluid and sputum of smokers with and without COPD [91–94], but these studies are difficult to compare because of the different methods used and the different patient populations assessed. Despite this limitation, standard techniques used to distinguish between the molecular forms of IgA, as well as the correction of IgA levels for albumin exudation, suggested that the local bronchial production of IgA is decreased in patients with COPD [93,94]. In contrast, systemic antibody responses do not seem to be affected in COPD [95,96]. A decrease in pIgR expression in the bronchial epithelium was proposed as the underlying mechanism accounting for impaired local IgA responses in patients with COPD [97]. The decrease in pIgR content in COPD airways appears closely related to proteinases (elastase, proteinase-3) released by activated neutrophils, which can degrade this receptor and its soluble form, SC [98]. Impaired IgA responses within the airways can contribute to further enhance neutrophil infiltration through several mechanisms [99] and to disease pathogenesis, as supported by the relationship between pIgR expression and lung function tests of airways obstruction in patients with severe COPD [97]. The hypothesis that pIgR deficiency could reflect the epithelial impairment associated with an increased risk of COPD will be tested by assessing pIgR knockout mice for their susceptibility to develop COPD when exposed to smoke-related toxics.

IgA response in asthma and allergy

Allergen-specific IgA antibodies have been detected in the airways of patients with allergic rhinitis and/or asthma to dust mite or pollens [100,101], and display different epitope specificities as compared with IgE [101]. It has been suggested that IgA contributes to eosinophil activation during allergic reactions in the airways. Thus, IgA represents a highly potent stimulus for eosinophil degranulation *in vitro* [70,102], and correlation between the IgA response and markers of eosinophil activation has been observed *in vivo* in several studies of patients with allergic rhinitis or asthma. In addition, SIgA complexes can inhibit the release of γ -interferon (IFN- γ) by eosinophils triggered through CD28 [103], thereby promoting a Th2 profile.

Despite these data suggesting IgA as a pathogenic factor

Table 18.2 Main changes in defence mechanisms associated with asthma and COPD. First-line defence mechanisms are profoundly affected in both diseases, whereas adaptive immune response to inhaled antigens is only documented in asthma and different effector cells are involved.

	Asthma	COPD
<i>First-line defence</i>		
Mucociliary clearance	Decreased	Decreased
Secretory IgA	?	Decreased*
Epithelium	Denuded and activated	Hyperplasia
<i>Adaptive immunity</i>		
T-cell activation	Th2 cytokines	IFN- γ , CD8 ⁺ T cells?
Antibody response	IgE	?
Effector cells	Eosinophils, mast cells	Neutrophils, macrophages
* May be increased during exacerbations of mild COPD patients. IFN- γ , γ -interferon; IgA, immunoglobulin A; IgE, immunoglobulin E.		

during allergic responses, several observations indicate that IgA can have protective roles against the development of allergic diseases:

- 1 selective IgA deficiency or delayed IgA production in childhood is a risk factor for atopy [104];
- 2 unlike IgE, allergen-specific IgA is detected in BAL from healthy subjects;
- 3 epidemiological evidence suggests a protective role of mucosal gut IgA production against cow's milk allergy [105,106];
- 4 intranasal treatment of mice with antigen-specific monoclonal IgA antibody prevented increases in bronchial hyperresponsiveness, tissue eosinophilia, and IL-4 and IL-5 production after allergen challenge [107];
- 5 increases in serum IgA is observed during high-dose allergen immunotherapy, along with IgG4, probably as a result of the induction of TGF- β and IL-10-producing regulatory T cells and monocytes [108] as observed in healthy subjects exposed to very high levels of allergen such as bee keepers.

The IgA response could therefore be part of the normal mucosal immune response to allergens.

Impaired first-line defence

The increased susceptibility of COPD patients to airways colonization and infection is probably multifactorial, and probably mainly relates to epithelial changes. First, mucociliary clearance is impaired in COPD [109], probably as a consequence of neutrophilic inflammation which increases mucus production (mucins MUC5AC and 5B) but reduces ciliary beating [110] and viscoelastic properties [111]. Activated neutrophils can also degrade both IgA and the epithelial pIgR [98], leading to impaired secretory IgA immunity. IgA normally acts within mucosal secretions by inhibiting adherence of microbes to the epithelium and thereby potentiates their clearance through the mucociliary mechanisms. Mucosal IgA deficiency in COPD could thus

favour the chronic presence of pathogens at the level of the bronchial tract. In addition, bacterial enzymes can also cleave IgA (classically the IgA1 subclass), leading to a vicious circle of impaired mucosal immunity and exaggerated inflammatory response, underlying the airway damage associated with COPD.

In asthma, mucociliary clearance is also impaired [112], both in large and small airways, and correlates with airflow limitation. Although mucus overproduction is observed in asthma, the epithelial changes are quite different than those observed in COPD. Mucous metaplasia (and hyperplasia) is a classical pathological feature in COPD, reflecting usual clinical symptoms, while epithelial denudation and/or shedding characterizes asthma, particularly severe stages of the disease (Table 18.2) [113].

Role of the bronchial epithelium

Beyond its role in mucociliary clearance and IgA transport, the bronchial epithelium can actively participate in the response to inhaled antigens and toxics through the production of cytokines and chemokines. After appropriate stimulation, epithelial cells can release molecules involved in the regulation of trafficking and activation of neutrophils (IL-8), eosinophils (IL-5, eotaxins), lymphocytes (IL-16, TARC/CCL17) and IgA⁺ B cells (TECK/CCL25). In asthma, the production of the T-cell chemokine IL-16 mainly arises from the bronchial epithelium [114]. TARC/CCL17, along with MDC/CCL22, is induced after segmental allergen challenge [115] and selectively attracts Th2 cells expressing CCR4. The role of the epithelium in first-line defence mechanisms of the airways has been further illustrated in the recent study by Zhu *et al.* [116]. They showed that asthma epithelial cells, along with alveolar macrophages, produce acidic chitinases putatively targeting chitin-containing allergenic organisms such as house dust mite, cockroaches and fungi [116]. Beyond inhibition of the growth of chitin-containing organisms, the epithelial production of chitinases

(which depends on IL-13) could potentiate the release of chemokines (MCP-1, eotaxin-1) involved in the recruitment of mononuclear cells and eosinophils. However, the relevance of chitinases to asthma pathogenesis requires further investigation. Also it remains poorly understood in COPD and asthma whether epithelial changes represent intrinsic changes or consequences of the ongoing airway inflammation. It has been recently shown that C/EBP- α deficiency characterizes asthmatic airway smooth muscle cells [117] and may underlie increased proliferative capacity [118] and shortening velocity. Interestingly, the increased proliferative capacity of airway smooth muscle cells in asthma appears intrinsic, as the phenotype was maintained through multiple passages in culture [118] – long after any inflammatory mediators present in the tissue would have been washed away. It would be of great interest to assess potential intrinsic changes of epithelial cells in COPD and asthma, and determine to what extent these changes relate to cell exposure to cigarette smoke or allergens in susceptible individuals.

CHAPTER 19

COPD and pulmonary surfactant

Carola Seifart and Bernd Muller

Composition, structure and function of the surfactant system

Normal lung function and effective gas exchange is strictly related to an essential lung structure termed ‘pulmonary surfactant’. This phospholipid–protein rich material lines the inner surface of the alveoli as well as the terminal bronchioles. Its clinical importance became obvious when neonatal infants died from the infant respiratory distress syndrome (IRDS), which occurs when there is a lack of surfactant. In the acute respiratory distress syndrome (ARDS) in adults, surfactant exists but is severely impaired in structure and function [1]. Apart from these acutely life-threatening situations, there are inflammatory diseases in which pulmonary surfactant is structurally and functionally impaired [2]. This chapter summarizes the current knowledge of surfactant structure and function and its potential role in COPD.

Composition and structure of pulmonary surfactant

Pulmonary surfactant is synthesized in the alveoli by type II pneumocytes, which make up only 4% of alveolar cells. After synthesis, surfactant is secreted into the alveolar lumen [3]. Surfactant is harvested from patients by lung lavage procedures. Subsequent procedures exhibit its complex composition of lipids and proteins. The main portion (80.7%) consists of several species of phospholipids, which contain 76% phosphatidylcholine. Other components are cholesterol (5.6%), glycerol (6.7%), free fatty acids (1.6%) and surfactant associated proteins (5.4%) (Fig. 19.1). The proteins found in pulmonary surfactant are hydrophilic (surfactant proteins A and D, SP-A, SP-D) and hydrophobic (surfactant proteins B and C, SP-B, SP-C).

The structure of surfactant varies. Within type II cells

pulmonary surfactant occurs as a lamellated structure (lamellar bodies). Upon its secretion into the hypophase of the alveolar lumen the structure is converted into tubular myelin and finally into a monolayer at the air–liquid interface (Fig. 19.2). Only correct composition and structure guarantees normal function in the lung.

Biophysical function and homoeostasis of surfactant

The most prominent surfactant function became obvious from studies of neonates with IRDS, who lack surfactant and as consequence show atelectasis. This observation was followed by biophysical studies revealing the potential of surfactants to prevent the distal lung from collapse. However, a prerequisite for this is normal surfactant composition and the ability to adsorb at the air–liquid interface of the alveoli. This is achieved by the hydrophobicity of the phospholipids and their interaction with SP-B and SP-C. Once the surfactant film is formed it reduces surface tension and prevents collapse of the alveoli and distal airways, keeping the lung open at low lung volume and preserves bronchiolar patency during normal and forced respiration [4].

From the hydrophilic surfactant proteins, SP-A is considered to be a modulator of surfactant homoeostasis. After its secretion from type II pneumocytes it prevents these cells, at least *in vitro*, from secreting surfactant phospholipids. It also stimulates type II cells to internalize phospholipids from the alveolar space. These functions regulate the amount of alveolar surfactant [5].

Surfactant in pulmonary defence

In the last decade, SP-A and SP-D became of interest for lung innate immunobiology [6]. Both hydrophilic proteins are multimeric complexes belonging to type C lectins (*syn.*

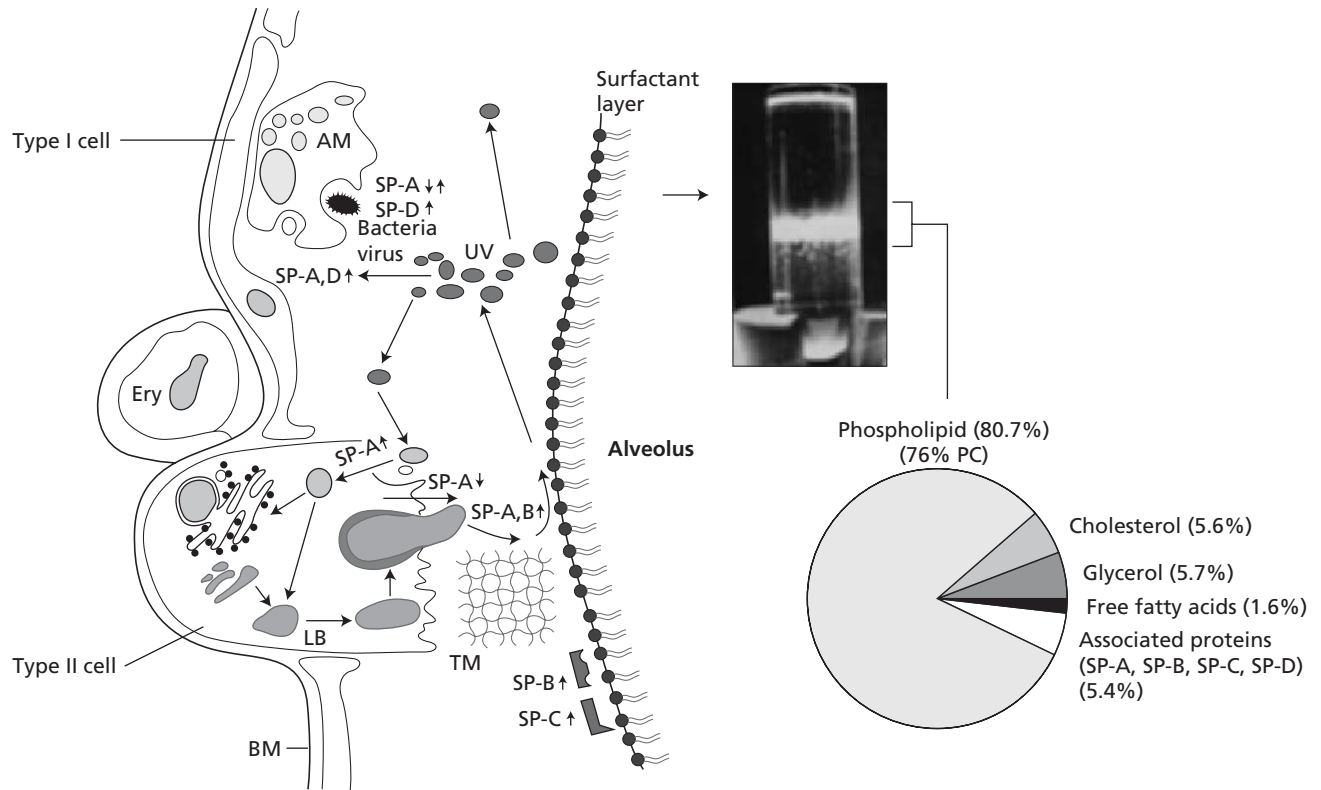

Figure 19.1 Surfactant structures and functions. When lamellar bodies (LB) containing surfactant are secreted into the alveoli they appear as lamellar structure, as tubular myelin (TM) and the surfactant layer. For this structural conversion surfactant proteins SP-A, SP-B and SP-C are necessary. In addition, SP-A and SP-D participate in the innate immunity modulating phagocytosis and killing pathogens by alveolar macrophages (AM). After bronchoalveolar lavage, surfactant appears as a distinct band after centrifugation and sedimentation, containing surfactant proteins and several classes of lipids.

Figure 19.2 Microscopic graph of surfactant secreted from epithelial type II cells (Ep) showing lamellated structure, tubular myelin (TM) and at the air (A)-liquid interface as lining layer (LL). (Picture courtesy of Professor H. Fehrenbach, University of Marburg.)

collectins). Of all structural elements the carbohydrate recognition domain (CRD) is the most important because of its binding to carbohydrate residues of pathogens and allergens.

It was seen from *in vitro* studies that SP-A is involved in innate immunity. It was shown that SP-A stimulated phagocytosis of alveolar macrophages and accelerated superoxide anion production. Additionally, SP-A opsonized a number of pathogens. These data clearly suggest the involvement of SP-A in first-line defence of the lung. SP-D is involved in stimulation of phagocytosis and respiratory burst, and serves as opsonin for several pathogens. Recently, the antimicrobial capacity of both collectins was described [7]. A number of *in vitro* data were confirmed by *in vivo* studies using surfactant protein knockout mice. It was shown that individuals lacking SP-A and SP-D had a higher risk of infection, whereby the immune reaction depends on the type of pathogen [8]. However, surfactant has a role in general immunomodulatory mechanisms of the lung. Inflammatory cytokines that are involved in airway inflammation, such as tumour necrosis factor α

(TNF- α) and interleukin 1 β (IL-1 β), are capable of inducing nuclear factor- κ B (NF- κ B), a ubiquitous transcription factor. By suppressing the activity of NF- κ B, surfactant provides inhibitory effects on pro-inflammatory cytokine production, a mechanism that is important in disease pathogenesis of inflammatory airway diseases such as asthma and COPD [9].

There are an increasing number of studies on SP-A and SP-D that suggest the involvement of these collectins in acquired immunity of the lung [10–15]. So far, known functions in acquired immunity are binding to pollen and allergens, suppression of histamine release and suppression of T-cell proliferation and immune reaction after allergen challenge. Whereas expression of the collectins in immune response to allergens from pathogenic microorganisms show both increased and reduced levels of SP-A and SP-D, there is an increase of both proteins after ovalbumin challenge.

Surfactant in lung injury

Data on surfactant structure and function in injured lungs have mostly been obtained from inhalation studies with oxidants. Influx of inflammatory cells into the alveolar lumen is a general observation. In addition, the alveoli are flooded with serum proteins that inactivate the surface activity of surfactant. Lung injury caused by inhalation of deleterious agents can also directly impair the surfactant components such as phospholipids and proteins. The underlying mechanism is mostly oxidation of the components, resulting in reduced surface tension lowering capacity.

Pathophysiology, alteration and importance of the surfactant system in COPD

In addition to other physiological functions that may be of importance in airway obstruction (Fig. 19.3), pulmonary surfactant is essential for normal lung function. Surfactant proteins are part of the innate and adaptive immune system of the lung. Thus, the surfactant system may be involved in the regulation of inflammation in the lung and in the development and progression of COPD. However, current knowledge of the biology, function, potential dysfunction and alteration of the surfactant system in COPD are limited.

Cigarette smoke-induced alteration of the surfactant system

Cigarette smoking is the main single risk factor for the development of COPD. Therefore, the influence of cigarette smoke on the surfactant system was evaluated in order to

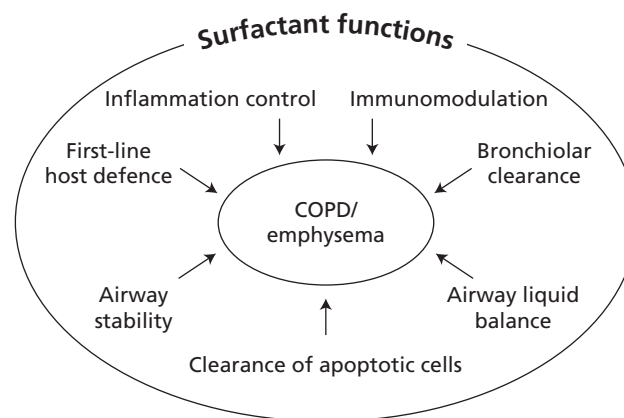

Figure 19.3 Physiological functions of the surfactant system of potential importance in the development and progression of COPD.

establish the potential importance of surfactant in the development or progression of COPD. Several studies provided evidence for a disturbed surfactant system in smoking individuals, as cigarette smoke was demonstrated to alter surfactant composition and activity, as well as reduce the elastic recoil pressure of the lungs [16–18].

Early in surfactant research, a rise of surface tension was observed in endobronchial washings of long-term cigarette smokers [19], and in human emphysematous lung tissue specimens [20]. Nevertheless, conflicting data exist with regard to the content of phospholipids in bronchoalveolar lavage (BAL) from smokers, the main component of pulmonary surfactant that provides surface tension lowering properties. In some studies, no differences in total phospholipid content in BAL between smokers and non-smokers were found [21–23], while others described significantly reduced [24,25] or increased phospholipid content [26] in BAL of smokers. However, there are consistent findings concerning altered phospholipid composition in BAL of smokers [22,26–28]. Furthermore, cigarette smoke-treated medium inhibited stimulated phospholipid secretion in a dose- and time-dependent fashion in cultured type II pneumocytes, while basal secretion remained unaffected [29]. Figure 19.4 summarizes the known effects induced by cigarette smoke on the surfactant system.

Additionally, studies of surfactant-specific protein content emphasize the role of surfactant in the pathogenesis of cigarette smoke-related disease. The content of SP-A and SP-D, both important components of the first-line host defence of the lung, were shown to be significantly decreased in BAL of smokers [21,23]. SP-B, an important modulator of physical surfactant function, was also shown to be significantly reduced in BAL of rats chronically exposed to cigarette smoke, while SP-A and SP-B lung tissue protein and mRNA levels remained unchanged [30].

Figure 19.4 Influence of cigarette smoke on the surfactant system: surfactant composition is altered, surfactant specific proteins are reduced and surface tension is increased with lower airway stability.

The underlying mechanisms resulting in altered (reduced?) surfactant phospholipid and protein content in BAL of smokers have not yet been clarified, but may be related to the increased number of alveolar macrophages in smokers' lung tissue and consecutive increased phagocytosis of surfactant material [24,31] and/or alveolo-capillary leakage induced by cigarette smoke.

Interestingly, in a model analysing the influence of surface tension and intraluminal fluid on the mechanics of small airways, the area of air-liquid interface decreased if the amount of intraluminal fluid was > 2%, whereby surface tension contributed to airway compression [32]. It was concluded that instability of small airways is correlated to intraluminal fluid and surface tension.

Pulmonary surfactant in emphysema

Pulmonary emphysema is a feature of COPD showing progressive destruction of alveolar structures. An imbalance of proteases (e.g. neutrophil elastase) and antiproteases seem to be of distinct importance in disease pathogenesis. On the one hand, neutrophil elastase is capable of cleaving surfactant specific proteins, the modulators of surfactant homeostasis. These altered surfactant proteins have been shown to affect surfactant function by reducing the adsorption rate of surfactant lipids at the air-liquid interface [33]. On the other hand, protective effects of exogenous surfactant with respect to elastase-induced emphysema *in vivo* were demonstrated, as administration of surfactant in the first 4 days after elastase instillation resulted in significantly reduced enlargement of airspace [34].

Additionally, morphological studies indicate a role for pulmonary surfactant in emphysema. Synthesis and secretion of surfactant is a main function of type II pneumocytes. The number of these cells is significantly reduced in patients with emphysema [35]. As the evaluated patients had

already been diagnosed with established disease, it is not clear if the limited number of type II cells could also be observed early in the disease process. Nevertheless, it was postulated that the reduced number of type II cells may result in decreased surfactant synthesis or secretion. This could be of distinct importance under certain circumstances, such as in chronic cigarette smoke exposure known to induce increased elastase activity in lung tissue, where undisturbed surfactant function and composition are needed to serve as a protective screen.

Lessons learned from gene-targeted mice

Direct evidence for the hypothesis that the surfactant system is relevant for the development of COPD has been obtained in studies of gene-targeted mice. Targeted ablation of SP-D in mice resulted in chronic inflammation, emphysema and fibrosis of the lungs (Fig. 19.5) [36]. Homozygous SP-D knockout mice exhibit increased metalloproteinase (MMP) activity in BAL (MMP-2 and MMP-9) and in alveolar macrophages (MMP-9 and MMP-12). Furthermore, hydrogen peroxide production by isolated alveolar macrophages was significantly increased.

Cigarette smoke induces alveolar macrophage apoptosis *in vitro* [37] and *in vivo* [38] in a dose-dependent fashion, in particular in smokers with emphysema [39]. As apoptotic cells lining the airways may promote ongoing airway inflammation and lung tissue destruction, accumulation of apoptotic macrophages and consecutive enhanced alveolar wall cell turnover were postulated to be of distinct importance in COPD and emphysema [39,40]. Necrotic and apoptotic alveolar macrophages were five- to 10-fold increased in SP-D deficient mice. Treatment with recombinant SP-D resulted in reduced accumulation of apoptotic macrophages, suggesting a specific role for SP-D in promoting clearance of apoptotic cells from the lungs [41].

Figure 19.5 Spontaneous emphysema is observed in 7-month-old SP-D (-/-) knockout mice compared with wild type mice [36].

Gene-targeted mice of both SP-A and SP-B show pathophysiological alterations similar to those observed in patients with COPD. SP-A is involved in immunomodulation and inflammation control of the lung. SP-A knockout mice are deficient in clearing bacteria from their lungs [42]; thus, it was postulated that SP-A deficiency correlates with a higher risk for pulmonary infections. SP-B is essential for maintaining undisturbed physical function of the surfactant system [43] and normal lung function. Homozygous SP-B (-/-) knockout mice [44] die shortly after birth and heterozygous SP-B (+/-) mice exhibit decreased lung compliance and increased residual lung volume [45], as well as higher susceptibility to oxidant lung injury [46]. Currently, the exact correlation between surfactant specific proteins and COPD disease development or progression needs to be further elucidated. However, the data suggest that SP-A, SP-B and especially SP-D are relevant for the development and progression of COPD.

Genetic background

Current studies concerning the genetic background of patients with COPD provide novel insights and emphasize a potential correlation of altered surfactant composition and function with the disease. Genetic heterogeneity of the surfactant protein genes could result in different concentrations of surfactant proteins in the lung [47], directly influencing protein and surfactant functions. In the gene-environment context of the disease, the surfactant protein genotype may influence airway defence systems, resulting in altered risk to developing respiratory infections, and in turn to different susceptibility to COPD, or be correlated to other mechanisms associated with higher susceptibility to COPD.

The SP-A and SP-D genes have been mapped to human chromosome 10q21-q24. Two functional genes, *SP-A1* and *SP-A2*, have been described, with four *SP-A1* (6A, 6A², 6A³, 6A⁴) and six *SP-A2* (1A, 1A⁰, 1A¹, 1A², 1A³, 1A⁵) alleles found in more than 1% in the population and several others in less than 1% (6A⁶⁻⁸, 6A¹⁰, 6A¹²⁻¹⁵; 1A⁶, 1A⁹, 1A¹⁰, 1A¹², 1A¹⁴, 1A¹⁵). Functional human SP-A consists of products of both SP-A genes at a ratio of 2 : 1 (*SP-A1* : *SP-A2*). Quantitative and functional differences of the SP-A alleles have been demonstrated, such as different carbohydrate-binding characteristics and TNF stimulatory capacities [48,49].

For SP-D, three biallelic polymorphisms are known. Each one is localized in the amino-terminal part (Met11Thr), in the collagenous domain (Ala160Thr) and in the carbohydrate recognition domain (Ser270Thr). Four polymorphisms in the SP-B gene (-18(A/C), 1013 (A/C), 1580 (C/T) and 9306 (A/G)) and one large intron variation had been described.

Several studies show associations of these surfactant protein polymorphisms with pulmonary disease. Associations with infectious diseases were demonstrated for *SP-A2* : 1A3, *SP-A1* : 6A4 and *SP-D* 11_C, which seems to be associated with higher risk for tuberculosis in a Mexican population [50]. *SP-A2* : 1A3, *SNP* AA223_A and *SP-D* 11_T were significantly increased, while *SP-A2* : 1A seemed to be protective in infants with severe respiratory syncytial virus (RSV) infection [51]. In COPD patients from Mexico, several surfactant protein polymorphisms have been found, with significantly higher frequencies in the COPD group compared with healthy smokers: one SP-A (AA62_A) and two SP-B alleles (B1580_C/D2S3388_5) [52]. The association of the *SP-B* polymorphism B1580-C (SFTPBThrl3lSie) with the presence of COPD was replicated in the Boston Early-Onset Study [53]. Another large SP-B gene variation was associated with acute respiratory failure in COPD [54].

Exogenous surfactant application in COPD

Exogenous surfactant application is used routinely and successful in IRDS. However, data concerning surfactant application in patients with COPD are rare. One clinical surfactant treatment study suggests that aerosolized surfactant may improve mucociliary clearance and lung function in patients with stable chronic bronchitis [55]. In two studies, patients with acute asthma attacks and mild airflow limitation, respectively, were treated. These revealed an improvement of lung function parameters (*FEV*₁, *FVC*, *Pao*₂) in acute asthma, but not in patients with mild airflow limitation [56,57]. One case report describes successful surfactant application in a patient with severe exacerbation in COPD requiring mechanical ventilation [58].

Recombinant surfactant protein D therapy has recently become available. Interestingly, nasal application of recombinant SP-D was shown to reduce chronic inflammation

and accumulation of apoptotic macrophages in SP-D deficient mice [41].

Conclusions

Pulmonary surfactant lines the inner surface of the lung and is essential for normal lung function, airway stability, airway inflammation control and in first-line host defence of the lungs. Several studies emphasize the potential importance of pulmonary surfactant in smoking-related diseases, such as COPD. Direct evidence for a relation between disturbed surfactant and COPD comes from studies evaluating gene-targeted mice.

It is known that disturbed surfactant function or composition contribute to small airway closure, as well as to an increased risk for recurrent and prolonged airway infections and altered mucociliary clearance; mechanisms that are thought to be of central importance for the development and progression of COPD. Nonetheless, many questions remain, including the usefulness of surfactant application in severe COPD, the significance of genetic heterogeneity of the surfactant system and the importance of surfactant components in host defence and repair mechanisms.

CHAPTER 20

The macrophage and its role in the pathogenesis of COPD

Kellie R. Jones and Jordan P. Metcalf

Through its release of elastase and destruction of connective tissue, the neutrophil has traditionally been viewed as the principal inflammatory cell involved in the pathogenesis of chronic obstructive pulmonary disease (COPD). However, a series of elegant studies involving clinical science, cell biology and genetic manipulations have broadened the narrow and simplistic view of this complex disorder. Through these investigations, it is now understood that the action of many cells, including cells of the haematopoietic system as well as those of other origins, likely have a role in the development of COPD. With regards to haematopoietic cells, there is overwhelming evidence that the macrophage both directly and indirectly participates in disordered inflammation, which leads to the tissue destruction seen in patients with emphysema.

The purpose of this chapter is to familiarize the reader with the macrophage and its role in the pathogenesis of COPD. Although other types of lung macrophages are discussed, the focus is on the alveolar macrophage. This is partially of necessity, as the limits of technology have made the cell most accessible to the bronchoscope, the alveolar macrophage, the one for which the most data exists. First, the phylogeny of the lung macrophage is discussed. The increased density of macrophages in patients with the clinical diagnosis of COPD and in healthy smokers is the simplest evidence of the importance of this cell type. The data demonstrating this increased density and the mechanisms responsible for this finding is reviewed. Then, information demonstrating the importance of elastolytic products of the macrophage in COPD is covered. Finally, evidence demonstrating macrophage activation in COPD results in oxidant production and release of cytokines is discussed.

Origin and classification of the lung macrophage

The cellular origin of alveolar macrophage precursors is ultimately pluripotent stem cells residing in the bone marrow. This is supported by the demonstration of donor macrophages repopulating the alveoli in bone marrow transplant recipients [1]. Landmark studies from the 1970s confirmed that a large component of the stable alveolar macrophage population originates directly from infiltrating bone marrow-derived monocyte/macrophages [2]. More recent studies have shown that a small proportion of alveolar macrophages do not arise directly from the peripheral blood monocytes, but instead are the result of replication of a local population of more mature cells of monocyte/macrophage lineage. In leukaemic patients with prolonged monocytopenia, normal numbers of alveolar macrophages are present [3]. Approximately 0.5% of macrophages from normal subjects can synthesize DNA, and presumably can replicate. This amount can increase fourfold in patients who smoke or have pulmonary inflammatory conditions [4].

The pluripotent stem cell becomes committed to the monoblast cell line, with the final step of differentiation resulting in the macrophage (Fig. 20.1) [5,6]. The macrophage reaches the lung through the blood stream, and then migrates to various lung compartments. Approximately 15% of monocytes in the circulation ultimately become pulmonary macrophages. Pulmonary macrophages consist of three types: airway, interstitial and alveolar.

An additional cell considered to be related to the macrophage, although it appears to branch early from the monocyte differentiation pathway, is the dendritic cell. This cell resides in many of the same regions as the macrophage, as well as the bronchial-associated lymphoid tissue and the mediastinal lymph nodes. When found in the alveolar

Figure 20.1 Macrophage/monocyte differentiation. (From Hoffman [5] with permission.)

compartment, these cells reside at or below the epithelium. Relative to macrophages, these cells are more effective at antigen presentation, but less effective at phagocytosis [2,7,8]. Thus, they appear to potentiate T-cell activation in the lung, playing a part in the connection between the innate and the adaptive immune systems. In terms of their role in innate immunity, dendritic cells, as well as alveolar macrophages and polymorphonuclear leukocytes (PMNs), have pattern-recognition receptors. These receptors bind to molecular structures that are basic to different microbes, in order to provide an immediate cellular response. This allows the cells of the innate immune system to begin phagocytosis, release cytokines or upregulate cell receptors, depending on which cellular signalling is activated [9]. The dendritic cell is not discussed in further depth in this chapter.

Another potential macrophage population is the pulmonary intravascular macrophage (PIM). Although plentiful in lower animals, in the normal human lung there are likely few PIMs but increasing evidence suggests that they are induced during inflammation [10].

With regards to macrophages that reside in the tracheo-bronchial tree, the alveolar macrophage dwells at the surface of the alveoli, while airway macrophages are in the final generations of respiratory bronchioles [6]. For all

practical purposes, there are no absolute physiological differences in the function of airway and alveolar macrophages. Alveolar macrophages are most often investigated in the role of emphysema. There is evidence of relative differences between these populations as the initial aliquots of bronchoalveolar fluid, which should be enriched for airway macrophages, contain larger and less active macrophages than subsequent aliquots. It would be expected that these later aliquots should consist of primarily alveolar macrophages [11]. This finding, of two distinct lavage macrophage populations, has been contested [12]. Because of their more proximal anatomical location, airway macrophages may be more important than alveolar macrophages in killing of bacteria and reaction to other foreign materials that are inhaled or aspirated. Also, the airway macrophage is an intrinsic part of the mucociliary transport system, a process, which when disrupted, may have a role in the pathogenesis of COPD [4].

The alveolar macrophage (Fig. 20.2 [13]) originates directly from either local proliferation of pulmonary macrophages or from differentiation of infiltrating bone-marrow-derived blood monocytes [14–19]. Typical bronchoalveolar lavage (BAL) from non-smokers recovers 1×10^7 total cells [20]. These cells are predominantly macrophages, typically

Figure 20.2 The alveolar macrophage. (From Fraser [13] with permission.) Lysosomes denoted by arrows ($\times 8500$).

90–95% of the total cell number. Animal models have revealed a life span of the alveolar macrophage of approximately 3–4 weeks [21]. From work carried out on human bone marrow transplant recipients, the life span appears to be between 27 days [2] and several months [1]. Within an alveolus of the normal lung, there exists approximately 50–70 inflammatory cells. Approximately 80% of these cells are macrophages [22].

Interstitial macrophages are monocyte-derived cells that reside between the pulmonary vasculature and the airway. They are viewed as precursors to the alveolar macrophage, but differ in some respects from their alveolar counterparts. These cells are somewhat difficult to study, because they require special techniques to harvest, and because preparations are frequently contaminated by residual alveolar macrophages. Likely because of these problems, estimates of relative number of interstitial macrophages to alveolar macrophages range widely, even within studies [23,24]. Recent studies in animals and human tissue show interstitial macrophages are smaller than alveolar macrophages and are not as proficient at phagocytosis or oxidant production [23,25,26]. In contrast, these cells are better at antigen presentation than alveolar macrophages [27]. As precursors to alveolar macrophages, and in their role in antigen presentation, they likely play a similar part in the pathogenesis of COPD, although this has not been thoroughly studied.

Increased macrophage density in the lung in COPD

The simplest and earliest evidence suggesting the role of the macrophage in the pathophysiology of COPD was the consistent finding that macrophage numbers are increased in

the lower respiratory tract of smokers and patients with COPD. The following section attempts to review these data. The mechanisms for the increased macrophage density in COPD is also discussed.

There are several methods to investigate the cellular composition of the lung parenchyma, including the alveolus. The most frequently used means have been bronchoalveolar lavage, transbronchial biopsies and sputum (induced or spontaneous).

The primary technique to quantify cellularity in the distal airways is BAL. In normal BAL specimens, macrophages are the predominant cells [20]. In an early study to evaluate BAL as a means of comparison of controls with affected patients, a series of non-smokers were evaluated by Merchant *et al.* [28]. The lower respiratory tract cellularity of 111 volunteers who had never smoked and who had no evidence of respiratory disease or significant toxin exposure was compared by BAL. All of the lavage cell counts revealed a majority of macrophages, with only 3.6% of patients having less than 80% macrophages [28]. In an additional group of 19 healthy smokers, total cell counts, as well as the percentage of macrophages and lymphocytes, were increased when compared with the non-smokers [28].

In an additional study by Thompson *et al.* [29], both the initial lavage aliquots and distal aliquots, representing bronchial and distal airway samples respectively, were compared in patients with chronic bronchitis with a history of smoking, asymptomatic smokers and controls. Concentrations of cells in the lavage aliquots was also adjusted to estimate their actual concentration in the fluid lining the airways (epithelial lining fluid, ELF) using lavage urea level to correct for sample dilution. Subjects with chronic bronchitis had significantly greater numbers and concentration of cells in the bronchial BAL fluid and estimated bronchial ELF when compared with the other patient populations. There was no increase in the bronchial lavage or bronchial ELF macrophage concentrations, although neutrophil concentrations were increased. In the alveolar sample, only asymptomatic smokers had increased concentrations of macrophages in the raw lavage samples, but both smoking groups had increased macrophage concentrations as determined in the ELF [29]. Thus, both studies suggest that, at least in the distal airway, macrophage density is increased in smokers.

Bronchial biopsies have also been used to evaluate lower respiratory tract cellularity. In a study comparing 10 smokers with chronic bronchitis with six non-smokers, macrophages and T lymphocytes were significantly increased in the patients with chronic bronchitis. Cells that indicated lymphocytic activation ($CD25^+$ cells) were also increased in the affected patients, although it could not be determined that this increased lymphocyte number and activation status was attributable to macrophages. $CD4$

and CD8 cells were not significantly different between the patient groups [30].

Evaluation of sputum has also been used to evaluate lung cellularity in patients with COPD. In patients with COPD, Domagala-Kulawik *et al.* [31] compared sputum samples from current smokers with those from a group of patients who had quit smoking for at least 1 year. There was no difference in cell count, including macrophage quantity, in the two patient sets. The macrophages present were subjected to further scrutiny, with subtypes expressing CD11b, CD14, CD54 and CD71 identified. This confirmed that the cells present in induced sputum were of similar phenotype to macrophages recovered in other studies by BAL. The distribution of these macrophage subtypes was also studied and revealed no difference between current and former smokers [31]. These data indicate that smoking cessation does not rapidly normalize cellular constituents in induced sputum samples.

Mechanisms responsible for increased macrophage density in the lung in COPD

Healthy smokers, smokers with COPD and ex-smokers with COPD have increased numbers of macrophages in the lower respiratory tract. There are three likely mechanisms that could be responsible for this phenomenon. First, increased numbers of macrophage precursors could be recruited to the lung. Second, local proliferation of macrophage precursors could be increased. Finally, the life span of terminally differentiated macrophages already present in the lung could be increased. A discussion follows of how each of these mechanisms contributes to the increased density in the lower respiratory tract of patients with COPD.

Enhanced recruitment of macrophages in COPD

Recruitment of macrophages is generally thought to be the primary mechanism responsible for increased macrophage density in the lung. Recruitment occurs through a subset of cytokines known as chemotactic cytokines or chemokines. Generally, cytokines in the lung are important mediators of cellular signalling. They are also referred to as peptide growth factors or biological response modifiers [32]. These proteins typically affect cells in close proximity, at relatively low concentrations.

There is evidence that enhanced recruitment of monocytes contributes to the increased macrophage density in the lung of patients with COPD. Koyama *et al.* [33] compared the monocyte chemotactic activity in BAL fluid (BALF) from 15 smokers with 16 non-smokers. They found enhanced monocyte chemotactic activity in the BALF of smokers. This activity correlated with BALF macrophage

numbers and several physiological markers of lung function decline including forced expiratory volume in 1 s (FEV_1) and diffusion capacity for carbon monoxide (DLCO) [33]. Hoogsteden *et al.* [34] showed that BALF from smokers has higher percentages of alveolar macrophages with monocyte-like morphology, which suggests recent recruitment. There are several cytokines with known monocyte chemotactic activity including tumour necrosis factor α (TNF- α), transforming growth factor β (TGF- β) and monocyte chemoattractant protein-1 (MCP-1) that are increased in tissue or BALF of smokers or patients with COPD [35–38].

These data are supported by *in vitro* studies. Smoke extract stimulates both lung fibroblasts and bronchial epithelial cells to release monocyte chemotaxins in response to cigarette smoke extract [39,40]. Furthermore, degradation products of the basement-membrane proteins collagen and elastin, which are formed during the lung destruction seen in emphysema, are chemotactic for monocytes and macrophages [41,42].

Increased macrophage replication in COPD

In the normal lung, the replication of the macrophage is nominal. In experiments with alveolar macrophages labelled with ^3H -thymidine, the pulmonary alveolar macrophage was found to have minimal division. This supported the theory that, in the steady state of the normal lung, maintenance of the alveolar macrophage population is by cellular migration from peripheral blood [2].

In contrast, inflammation clearly alters macrophage kinetics. One of the first studies showing this occurred was carried out by van Oud Alblas *et al.* [14], who demonstrated that exposure of mice to bacillus Calmette–Guerin (BCG) increased the replicating macrophage population to six times the usual number, with peak induction at 72 h after exposure. Of specific relevance to the current discussion, in a human study comparing non-smokers with both smokers and patients with chronic inflammatory lung disease, macrophage replication was quadrupled in smokers, and further increased in the subset of patients with inflammatory lung disease. Interestingly, only 5 pack-years of cigarette smoke exposure was required to cause significant elevation in the actively dividing macrophage population [4]. The division of macrophages serves to continue increasing the total number of macrophages after the initial influx triggered by cytokines. Thus, increased macrophage replication from both resident and recruited macrophages contributes to the increased macrophage density seen in COPD.

Increased macrophage survival in COPD

Macrophage half-life is limited by programmed cell death,

or apoptosis. There is evidence that this process is inhibited in patients with COPD. This prolongs macrophage survival, which at baseline is already longer than other inflammatory cells such as neutrophils and eosinophils. In smokers, the antiapoptotic protein Bcl-Xl is increased, potentially delaying the turnover of macrophages in the alveoli [43]. Additionally, interleukin 4 (IL-4), which is increased in smokers, significantly decreases the amount of TNF- α induced apoptosis in the monocyte/macrophage [44]. Another cytokine upregulated in COPD, macrophage-inhibiting factor, also delays apoptosis [45]. This occurs by suppression of p53 dependent apoptosis.

Thus, many different mediators are likely to be responsible for delaying macrophage death in smokers and patients with COPD. The net effect contributes to the increased macrophage burden in the lower respiratory tract in patients with this disorder.

Macrophage activation in COPD

Alveolar macrophages are the most numerous resident phagocytic cells in the lower respiratory tract in normal adults, and these cells have a variety of responses to infectious pathogens and foreign materials. Not only do macrophages remove soluble materials from the lung via fluid-phase pinocytosis, they also engulf infectious agents and particulate debris by phagocytosis. In their housekeeping role, they are armed with various elastases to facilitate breakdown of tissue debris. They also respond to stimuli by producing oxidants that interfere with infecting organisms, and cytokines to activate other components of the immune system.

Although these products are designed primarily to deal with pathogens, toxins or damaged tissue, they may, of course, damage normal lung components, and participate in the pathogenesis of emphysema.

Elastases

Elastin is usually a relatively insoluble protein component of the infrastructure of the lung. The idea that emphysema was caused by proteolysis was confirmed by induction of pathology by various proteases in animal models. Previously, several theories had been proposed to explain the pathogenesis of emphysema. These included the mechanical theory, which explains the airway damage as being caused by expiratory obstruction. The expiratory obstruction was explained by air trapping during bronchiole obstruction, leading to overdistention. The ischaemic explanation attempted to explain the disappearance of lung capillaries [46]. These theories have become less popular with the discovery that direct application of elastases to the

lung causes emphysema. Animals that received papain (a plant protease with elastolytic action) intratracheally uniformly develop emphysema. The effect of papain on the development of experimental emphysema is specifically caused by its elastolytic properties, as other proteases such as collagenase and trypsin have not been shown to induce emphysema [47].

Another protease with elastolytic properties, pancreatic elastase, has also been demonstrated to cause emphysema in animal models. When pancreatic elastase was administered to hamsters, the animals were found to have a reduction of total elastin by two-thirds. New connective tissue was synthesized, and the elastin and collagen amounts normalized within weeks [45]. When living alveolar macrophages were cultured with elastin, the macrophages demonstrated significant elastolytic properties within 24 h of culture. The elastolytic process could also be predominantly inhibited by the addition of cysteine proteinase inhibitors, and therefore was likely a result of the cysteine proteases cathepsin G and L [48]. Proteases may interact, as when trypsin or chymotrypsin was given 24 h after pancreatic elastase; the resultant emphysema was more severe than in animals receiving elastase alone [49]. In additional studies, both activated and inactivated radio-labelled porcine pancreatic elastase was administered intratracheally to hamsters. Only the animals that received the activated enzyme were found to have emphysema [50], showing that active protease activity was necessary for the development of emphysema.

A human phenotypic correlate for the elastase-antielastase theory was found when it was discovered that some patients with premature emphysema had decreased serum levels of α_1 -antitrypsin [51]. Subsequent studies supported the role of this protein in maintenance of the elastase-antielastase balance in the lung. Furthermore, data now suggest that a subset of patients with mild COPD and α_1 -antitrypsin deficiency benefits from supplementation [52]. This is the ultimate proof-of-concept model for the elastase-antielastase theory.

Historically, the focus on elastolytic enzymes in COPD has been on elastolytic products of the neutrophil, and thus neutrophils were viewed as the 'first responder' in COPD. This view was supported by animal studies showing that neutrophil elastase induced emphysema, and human studies showing, for example, correlation of neutrophil number in BALF with the amount of airway obstruction and smoking history [29].

In contrast, for many years the role of the macrophage in disrupting normal lung architecture through digestion of elastin was questioned. More recently, however, through the work of Shapiro and others, the macrophage is now recognized as an important source of enzymes involved in the pathogenesis of emphysema.

Table 20.1 Matrix metalloprotease nomenclature. (From Kadoglou and Liapis [53] with permission.)

MMPs	Enzyme	Substrates
<i>Collagenases</i>		
MMP-1	Collagenase-1 (interstitial collagenase)	Collagens (I, II, III, VII, VIII, X), gelatin, proteoglycans, MMP-2, MMP-9
MMP-8	Collagenase-2 (neutrophil collagenase)	Collagens (I, II, III, V, VII, VIII, X), gelatin, proteoglycans
MMP-13	Collagenase-3	Collagens (I, II, III, IV, IX, X, XIV), gelatin, MMP-9
MMP-18	Collagenase-4 (<i>Xenopus</i> collagenase)	Not determined
<i>Gelatinases</i>		
MMP-2	Gelatinase A	Gelatin, collagens (I, IV, V, VII, X, XI, XIV), elastin, fibronectin, laminin, MMP-1, MMP-9, MMP-13
MMP-9	Gelatinase B	Gelatin, collagens (IV, V, VII, X, XIV), elastin, fibronectin, plasminogen
<i>Stromelysins</i>		
MMP-3	Stromelysin-1	Collagens (III, IV, V, IX, X), gelatin, fibronectin, laminin, MMP-1, MMP-7, MMP-8, MMP-9, MMP-13
MMP-10	Stromelysin-2	Collagens (III, IV, V), gelatin, casein, MMP-1, MMP-8
MMP-11	Stromelysin-3	Gelatin, collagen IV, fibronectin, casein, proteoglycans
<i>Matrilysins</i>		
MMP-7	Matrilysin-1	Collagens (IV, X), gelatin, fibronectin, laminin, MMP-1, MMP-2, MMP-9, MMP-9/TIMP-1 complex
MMP-26	Matrilysin-2	Collagen IV, fibronectin, gelatin, proMMP-9, fibrinogen
<i>Membrane type</i>		
MMP-14	MT1-MMP	Collagens (I, II, III), gelatin, casein, elastin, fibronectin, laminin, MMP-2, MMP-13
MMP-15	MT2-MMP	Gelatin, fibronectin, laminin, MMP-2
MMP-16	MT3-MMP	Collagen III, gelatin, casein, fibronectin, MMP-2
MMP-17	MT4-MMP	Gelatin, proMMP-2
MMP-24	MT5-MMP	Proteoglycans, proMMP-2, collagen I, gelatin, fibronectin, laminin
MMP-25	MT6-MMP	Collagen IV, proMMP-8, proMMP-9
<i>Other MMPs</i>		
MMP-12	Macrophage metalloelastase	Collagen IV, gelatin, elastin, fibronectin, casein, fibrinogen, plasminogen, MMP-2
MMP-19, 20	–	Aggrecan, cartilage oligomeric matrix protein

MMP, matrix metalloproteinases; MT, membrane type; TIMP, tissue inhibitor of metalloproteinase.

Products of the macrophage that are thought to participate in the pathogenesis of emphysema include the matrix metalloproteinases (Table 20.1 [53]) and tissue inhibitors of metalloproteinases (TIMPs). The first indication that an enzyme with elastolytic properties existed in macrophages were experiments by Werb and Gordon [54] demonstrating elastin degradation by mouse macrophage-conditioned media. Inhibition of this activity by chelators showed that it was caused by a metalloproteinase. The proteinase was first isolated in mice [55], and a human homologue was shown to be capable of degrading elastin as well as all basement-membrane components [56].

This human analogue of the mouse macrophage elastase,

also termed matrix metalloproteinase-12 (MMP-12) has very similar biochemical properties, and was sequenced in 1993 [56]. Human MMP-12 is produced as a 54-kDa proenzyme which is activated by amino terminal cleavage and by COOH-terminal domain processing to a 22-kDa mature species. The COOH terminal domain appears to be important for substrate binding with the inhibitors. This complex processing creates an active elastolytic product, and a site for regulation of the elastolytic process by binding of inhibitors [56].

The matrix metalloproteinases are an ever-expanding family of active enzymes, with currently 20 recognized members. Prior to identification and classification of the

numerous MMPs, knockout mice were created that did not have macrophage elastase (MMP-12). In normal MMP-12 +/- mice, exposure of mice to 6 months of cigarette smoke resulted in emphysematous changes similar to that seen in mice with pulmonary instillation with neutrophil elastase. Smoke exposure also caused upregulation of MMP-12 in alveolar macrophages as determined by immunohistochemistry. Despite chronic exposure to cigarette smoke, the MMP-12 -/- animals did not develop emphysema. Even when MCP-1, a monocyte chemoattractant, was introduced to equalize the number of macrophages present in both control and MMP-12 -/- mice, MMP-12 -/- mice did not develop emphysema. On the other hand, treatment of MMP-12 +/- smoke-exposed mice with MCP-1 further enhanced the development of emphysema [57].

There are additional MMPs produced by macrophages that may contribute to the pathogenesis of emphysema. The presence and activity of gelatinase A (MMP-2) and gelatinase B (MMP-9) are significantly increased in patients with COPD (as defined by spirometry) [58]. Macrophages from patients with emphysema, suggested by pulmonary function tests (PFTs) and further confirmed by computed tomography (CT), have higher mRNA levels of MMP-1 (collagenase) and MMP-9 than controls [59]. The MMPs gelatinase and collagenase are also significantly elevated in the BALF of patients with the diagnosis of COPD [59].

Production of MMPs by macrophages is also regulated by other cells of the immune system. IL-13 is a Th2 cytokine thought to be important in the pathogenesis of asthma. However, when IL-13 is overexpressed in mice, the resultant lung pathology is very similar to that of human emphysema. Physiologically, these animals also had enhanced pulmonary compliance as one would expect with COPD with emphysema [60]. These changes were accompanied by induction of MMP-2, -9, -12, -13 and -14. The primary source of the MMP-12 was, as expected, the macrophage. Further studies with MMP-9 and -12 knockout mice in the setting of IL-13 overexpression have shown decreased amounts of alveolar enlargement, compliance changes and death when compared with controls. The roles of the two MMPs studied appeared to be quite different, with MMP-9 being linked to inhibition of neutrophils recovered in BAL, while MMP-12 deficient mice had reduced numbers of eosinophils and macrophages in their respective BALs [61]. This further implicates both the macrophage and its products in the pathogenesis of COPD.

There are additional data implicating these enzymes in the pathogenesis of COPD. During the maturation process of macrophages, there is a shift in metalloproteinase species produced towards MMP-2 and -9. Since MMP-9 has emerged as an enzyme in the forefront of elastin degradation, its production in different patient populations has been evaluated. When patients with COPD were compared

with healthy smokers and non-smokers, the patients with COPD released greater amounts of MMP-9. The MMP-9 released in the COPD patients was more biologically active. Another important observation in the same study was that non-smokers produced greater amounts of tissue inhibitor of MMP (TIMP-1, specifically) than their smoking counterparts, regardless of whether or not the smokers had been diagnosed with COPD [62]. This suggests that not only is macrophage elastase production and activity enhanced in smokers, but the ability of the lung to protect itself with antielastases is also inhibited by tobacco smoke.

Macrophage elastase (MMP-12) may be the final mediator of emphysema induced by alteration of other structural molecules such as integrins. The α v- β 6 integrin binds and activates TGF- β . Knockout mice (Itgb6-) deficient in expression of the β 6 integrin subunit express 200 times the mRNA of MMP-12 than that of their Itgb6+ counterparts. Furthermore, while Itgb6+ had no pulmonary histological changes suggestive of emphysema, the mice deficient in this integrin subunit had progressive spontaneous age-related emphysema that was comparable to that seen in humans [63]. This, together with the finding that MMP-12 knockout mice do not become emphysematous, even with long-term smoke exposure [57], and do not have an influx of macrophages with cigarette smoke exposure implicates this macrophage-produced elastase in the pathogenesis of emphysema. One explanation for these findings is that MMP-12 mice do not degrade elastin, so lung architecture is preserved, and elastin fragments, which are chemotactic for macrophages, are not produced [42,64]. Also, active MMP-12 appears to be important in the release of pro-inflammatory cytokines [65].

Oxidants

Alterations in the elastase-antielastase balance in the lung have a clear role in the pathogenesis of COPD. Less well understood is the role of alterations in oxidant-antioxidant balance in this disease state. There are two types of oxidant species generally relevant to this discussion, reactive oxidant species (ROS) and reactive nitrogen species (RNS). Cigarette smoke contains more than 10^{14} free radicals of both species per puff [66]. As the focus of the chapter is on the macrophage, this section briefly discusses the evidence that these species are harmful to the lung, and then discusses in more detail the production of oxidants by macrophages in relevant laboratory and clinical studies.

The oxidants produced by macrophages in response to stimuli include the ROS superoxide, hydrogen peroxide and hydroxyl radicals [67]. Hypohalides, while made by neutrophils, do not appear to be generated by macrophages [68]. The RNS nitric oxide is also produced by these cells. It is generally recognized that exposure to these products

from external sources or from inflammatory cells has a role in the pathogenesis of COPD.

Exposure of rats to hyperoxic conditions where ROS would be expected to predominate induces mild emphysema [69]. This effect seems to be because of an alteration in the protease–antiprotease balance as protease inhibitors prevent collagen degradation in hyperoxic conditions [70]. The mechanism for this alteration is caused by inactivation of α_1 -antitrypsin. Hydrogen peroxide directly oxidizes the methionine residues 351 and 358 of α_1 -antitrypsin, which then loses the ability to inhibit neutrophil elastase [71].

RNS also damage the lung. The most direct evidence of this is that exposure of rats and hamsters to nitrogen dioxide causes bronchial inflammation and emphysema [72,73]. In hamsters, focal areas of pigmented macrophages mark the areas of pathological alteration [72]. Occupational exposure to nitrogen dioxide has also been implicated in lung function decline [74].

The macrophage produces the ROS superoxide through the action of a multicomponent enzyme complex of nicotinamide adenine dinucleotide phosphate (NADPH). The assembly of both cytoplasmic and membrane-bound components is necessary for activation, and is primarily designed to produce toxic oxygen products for destruction of phagocytosed pathogens [75]. Superoxide is then converted to hydrogen peroxide through the action of myeloperoxidase in immature monocytes, or through other means including superoxide dismutase in mature alveolar macrophages [76,77]. It may be significant that mature macrophages, while lacking myeloperoxidase, engulf this enzyme from the environment. This engulfed enzyme retains its activity for several hours, and its presence may be necessary for macrophages to inactivate α_1 -antitrypsin [78,79]. Although oxidative enzymes are primarily designed for use in the internalized surface membrane, which becomes the phagosome, these species are highly toxic to cell membranes, and inactivate α_1 -antitrypsin [71]. Iron is also present in the cell surface of macrophages, and can be sequestered by macrophages [80]. Iron is increased in the lower respiratory tract of smokers with and without COPD [81]. This is significant because the interaction of iron with ROS is important in the generation of hydroxyl radicals through the Fenton reaction [82].

There is specific evidence that the production of ROS is augmented in smokers and patients with COPD. In a study by Baughman *et al.* [83], alveolar macrophages from 21 of 24 smokers, but none of six non-smokers, spontaneously released hydrogen peroxide. In addition, exhaled breath condensate of asymptomatic cigarette smokers contains five times the amount of hydrogen peroxide than non-smokers, the major source of which is presumed to be alveolar macrophages [84]. These amounts are also signi-

ficantly increased during COPD exacerbations. Alveolar macrophages of young and elderly smokers, in comparison to age-matched non-smokers, have increased production of superoxide, and the older smokers have decreased antioxidant enzyme activity [85,86]. Phorbol myristate acetate (PMA) or platelet-activating factor (PAF) stimulated superoxide production is also increased in alveolar macrophages from tobacco smokers [87].

Macrophage/monocytes from animal models and from humans also are stimulated to release ROS in response to tobacco. Components of tobacco smoke increase rat alveolar macrophage oxygen consumption and superoxide release [88]. Lavaged cells, which are mainly macrophages, from rats exposed to cigarette smoke also have enhanced phagocytic-induced superoxide production [89]. Isolated human precursors of alveolar macrophages and peripheral blood monocytes increase superoxide production in response to tobacco smoke [90]. Enhanced oxidant production is not a uniform finding in smoke-exposed animal models. Chronic tobacco smoke exposure inhibits unstimulated oxidant production while causing emphysema in a mouse model [91].

There is evidence that RNS are increased in patients with COPD. Nitrogen dioxide is clearly harmful to the lung. It is produced from nitric oxide through an intermediate, nitrite, by the action of peroxidases, including myeloperoxidase [92]. For the most part, exhaled nitric oxide has been shown to be increased and may also correlate with FEV_1 decline in patients with COPD [93–95]. However, there are some studies that contest this finding [96]. This may be because of consumption of the nitric oxide by reaction with local substrate prior to exhalation [97].

It is less well established whether macrophages participate in the production of RNS in humans. Some authors have argued that neutrophils are the source, as neutrophilia in sputum appears to correlate with exhaled nitric oxide levels [95]. Furthermore, human alveolar macrophage nitric oxide synthesis appears to be less than that of lower animals *in vitro* [98]. However, macrophages in patients with COPD contain inducible nitric oxide synthase, which could be responsible for the increased levels seen in exhaled breath or indirectly determined in lung tissue [97,99].

Cytokines

Chemotactic cytokines that have a role in increasing the macrophage burden in the lung have already been discussed. This section discusses cytokines produced by macrophages that are important in the pathogenesis of COPD through other mechanisms (Table 20.2).

A number of different cytokines are increased in lavage fluids, sputum samples or tissue samples from patients with COPD. Sputum samples from patients with COPD have

Table 20.2 Macrophage cytokines.

Macrophage/monocyte mediators in COPD	
Mediator	Function in COPD
Tumor necrosis factor- α	\uparrow MMP, \uparrow oxidant burst, \uparrow cytokine release, \uparrow monocyte chemotactic activity
Interleukin-1 β	\uparrow Neutrophil degranulation, \uparrow MMP, \uparrow TIMP, \uparrow cytokine release
Interleukin-4	\downarrow TNF- α induced apoptosis
Interleukin-6	\uparrow Correlates with COPD exacerbations
Interleukin-8	Major neutrophil chemotactic factor, \uparrow neutrophil degranulation, \uparrow respiratory burst, \uparrow LTB ₄
Monocyte chemotactic protein-1	\uparrow Monocyte chemotaxis

MMP, matrix metalloproteinases; LTB₄, leukotriene B₄; TIMP, tissue inhibitor of metalloproteinase; TNF- α , tumour necrosis factor α .

increased levels of TNF- α , IL-1 β , IL-6, IL-8, growth-related oncogene- α (GRO α) and monocyte chemoattractant protein-1 (MCP-1) [35,36]. Bronchoalveolar lavage has also revealed elevated levels of these cytokines in smokers, or patients with COPD [100–102]. Current smokers with emphysema by high-resolution CAT scan have three times the IL-8 BAL levels of smokers without these changes [103]. Furthermore, sputum levels of IL-6 and IL-8 correlate with the number of exacerbations in COPD patients [104], and sputum IL-6 levels are increased during exacerbations [104]. Sputum IL-8 and TNF- α levels are also increased in exacerbations associated with bacterial infections [105].

There is both *in vitro* and *in vivo* evidence that activated macrophages contribute to the burden of inflammatory mediators in COPD. Peripheral lung tissue of patients with COPD shows MCP-1 and IL-8 are expressed in macrophages as well as other cells [37].

The physiological role of these cytokines in the pathogenesis of COPD is apparent from their biological activity in overexpression mouse models or their behaviour *in vitro*. For example, stimulation of neutrophil chemotaxis release from lung cells by infectious agents known to be associated with COPD exacerbations provides a presumptive role for this chemotaxis in exacerbations of COPD.

TNF- α , originally described as a mediator of haemor-

rhagic tumour necrosis in mice injected with BCG and endotoxin [106], is a major proinflammatory cytokine that is clearly important in the pathogenesis of COPD. TNF- α release is increased in macrophages exposed to a variety of stimuli, including bacterial cell wall components [107]. It enhances macrophage and neutrophil oxidant burst, matrix metalloprotease production and stimulation of cytokine release from macrophages [108–110]. Arguing against the role of TNF in the pathogenesis of COPD is the finding that alveolar macrophage TNF- α release appears to be inhibited in smokers or with acute exposure to cigarette smoke [111–113]. However, cigarette smoke exposure enhances whole lung TNF- α levels and alveolar macrophage TNF- α secretion in animal models, which is dependent on MMP-12 [65]. Also, overexpression of TNF- α in mouse lungs causes chronic inflammation and emphysema-like pathology and decreased elastic recoil [114]. Further evidence that TNF- α is, in fact, important in smoke-induced lung destruction comes from a TNF- α receptor knockout mouse model. These mice have no cytokine response and no increase in lavage neutrophil or macrophage counts or markers of elastolysis when exposed to cigarette smoke compared with controls, which have both a cytokine response and evidence of elastin degradation [115]. The TNF- α receptor knockout mice also have markedly reduced emphysema in response to intratracheal pancreatic elastase [116].

IL-1 β also is a potent mediator of inflammation, partly through stimulation of release of cytokines from macrophages [117]. Alveolar macrophages release this cytokine in response to a variety of stimuli including bacterial cell wall components, although this effect is less than that of its monocyte precursors [118]. Chronic smoking stimulates IL-1 β release from alveolar macrophages in some, but not all studies [119–123]. IL-1 β stimulates release of MMP-9 and TIMP-1 from alveolar macrophages [62]. The most convincing evidence that IL-1 β is involved in the pathogenesis of lung destruction that occurs in COPD is the fact that knockout of the IL-1 receptor in mice prevents emphysema induced by intratracheal administration of pancreatic elastase [116].

IL-8 has been described as the major neutrophil chemotactic factor in the lung [124]. Its release from macrophages is stimulated by numerous stimuli, including bacterial agents [125]. A major source of this chemokine is the macrophage, and one of its original names was 'monocyte-derived neutrophil chemotactic factor'. Although it is a potent chemokine, it is also a potent proinflammatory cytokine. It stimulates numerous activities of neutrophils including degranulation and respiratory burst [126,127]. It also stimulates release of the lipid mediator and neutrophil chemotaxis leukotriene B₄ (LTB₄) from neutrophils [128]. Although BALF levels of IL-8 have been reported to be

elevated in smokers, spontaneous or lipopolysaccharide (LPS)-induced secretion from alveolar macrophages may be lower in smokers [129]. There are several reasons why it is presumed that much of the neutrophil accumulation in COPD is a result of IL-8. Most of the neutrophil chemotactic activity in sputum from COPD patients is neutralized by IL-8 antibody [130]. Inhibition of IL-8 induction by macrophages in cigarette smoke exposed animals prevents neutrophil accumulation in the airways [131]. Finally, many forms of neutrophilic lung inflammation are inhibited by neutralizing antibody to IL-8 or animal homologues [132–134].

Conclusions

The macrophage, once thought to be an innocent bystander in the pathophysiology of COPD, is now accepted as a central figure in this disorder. It produces enzymes, which degrade lung tissue components *in vitro*. It produces numerous modulators of the inflammatory response, both by recruiting additional cells of the immune system, and by amplifying these cells' activity. *In vivo* studies using genetic knockouts have presented clear and convincing evidence that these macrophage products are important in the pathogenesis of COPD. Perhaps because they are not directly targeted at pathophysiological causes of COPD, current therapies have not yet demonstrated the ability to change the natural history of this disorder. Future therapies, which will likely be directly aimed at modulating the function of the lung macrophage or its products, may finally achieve this goal.

CHAPTER 21

Eosinophils and COPD

Andrew J. Wardlaw

COPD has generally been considered to be a neutrophilic disease, in contrast to asthma which is thought to be more eosinophil-related. While these broad statements hold true, there is increasing evidence that a significant subgroup of patients with stable COPD have chronic airway eosinophilia and that the influx of eosinophils into the airways becomes more marked during exacerbations. There is also tantalizing evidence that in COPD, as is the case in asthma, airway eosinophilia defines a subgroup of patients with more steroid-responsive disease. If this is confirmed it could have major implications for the management of the disease, by using measurement of the sputum eosinophilia to target those patients who would benefit from treatment with steroids but avoid side-effects in those who would not respond to treatment. This chapter covers recent understanding of the biology of eosinophils and their role in disease processes, and then gives an overview of clinical studies relating to eosinophils and COPD.

Eosinophils are end-stage granulocytes which are usually present in relatively small numbers in peripheral blood and, in health, are scanty in tissues other than the intestine. Eosinophils are closely associated with helminthic parasite infections where they are considered to play an important part in host defence. In industrialized countries, the most usual cause of a peripheral blood and tissue eosinophilia is an allergic disease such as asthma, rhinitis or atopic dermatitis. There is an extensive literature detailing the, albeit circumstantial, evidence for a proinflammatory role for eosinophils in asthma and other allergic diseases [1]. This is based on three lines of evidence: the close relationship between clinical evidence of asthma and the presence of eosinophils in the bronchial mucosa; the relevance of eosinophil-derived mediators to the pathophysiology of asthma; and the intimate association between the beneficial effects of glucocorticoids in asthma and their anti-eosinophilic properties. Eosinophils are closely associated with immune responses caused by the activation of Th2

lymphocytes through the production of eosinophilic-specific growth factors such as interleukin 5 (IL-5) and the generation of IL-4 and IL-13, which promote selective trafficking of eosinophils to tissue [2]. Activation of Th2 lymphocytes is associated with specific T-cell responses to allergens, which for the most part are otherwise harmless foreign proteins derived from foods, plants, fungi, and animal and insect excreta and fur delivered to the mucosal surfaces of the gut and respiratory tract. Generally, although not invariably, these Th2-associated eosinophilic responses are associated with production of specific immunoglobulin E (IgE).

It is common practice to compare and contrast asthma and COPD (by which is meant smoking-related obstructive airways disease) as two sides of the same coin in which asthma is caused by antigen-specific Th2 responses characterized by eosinophilia, and COPD is associated with neutrophil-associated innate responses to the toxic effects of cigarette smoke complicated by Th1-associated immune responses to repeated respiratory tract infections [3]. However, just as some studies have suggested a role for the neutrophil in asthma [4], others have demonstrated the presence of eosinophils in the airways for patients with COPD [5], which has blurred the demarcation between these two conditions. This cross-over is mirrored by those patients with COPD who present with clinical and physiological features more suggestive of asthma. There is an unresolved debate as to whether such patients should be labelled as having asthma or COPD, or both. Understanding the mechanism of the eosinophilia in some patients with COPD and the extent to which this relates to the clinical and physiological presentation may shed light on this question.

Another ongoing debate in asthma that is relevant to the role of eosinophils in COPD is the extent to which this cell type has a proinflammatory as opposed to a bystander or even ameliorative function. This debate has been informed by the use of an anti-IL-5 antibody in clinical trials.

This antibody profoundly inhibited the blood and tissue eosinophilia but had no effect on the early or late phase response to allergen challenge [6]. In addition, it had no effect on symptoms or lung function in an as yet unpublished clinical study. However, the antibody had a much less marked effect on tissue eosinophils, reducing numbers by only approximately 50% so that the interpretation of the effects of this antibody have been less conclusive than originally thought [7].

In this chapter, eosinophil biology is reviewed, focusing on more recent insights relevant to airway inflammatory disease and then evidence for a potential role for eosinophils in the pathogenesis of COPD is discussed. The biology of eosinophils has been extensively reviewed over the years [8–11] and this chapter focuses on those aspects that either offer new insights into their function or are directly relevant to their role in COPD.

Eosinophil biology

Causes of eosinophilia

The normal eosinophil count, which is best expressed as total numbers rather than a percentage, is less than $0.4 \times 10^6/\text{mL}$. Moderate eosinophil counts of up to $1.5 \times 10^6/\text{mL}$ are found in a number of conditions, in particular the atopic diseases of asthma, rhinitis and atopic dermatitis. A more dramatic eosinophilia is uncommon and associated with severe asthma syndromes, drug reactions, pulmonary eosinophilia and hypereosinophilic syndromes [12]. The peripheral blood eosinophil count reflects a balance between the rate of egress of eosinophils from the bone marrow (which itself depends on the rate of eosinophil production and the rate of migration through bone marrow sinus endothelium) and the rate of entry into tissues, which is dependent on signals associated with organ-specific inflammation. There is therefore an inconstant relationship between peripheral blood eosinophil count and tissue eosinophilia. Although generally speaking there is a correlation between the two measurements, it is far from uncommon for a dramatic tissue eosinophilia (e.g. in diseases such as eosinophilic oesophagitis and chronic pulmonary eosinophilia) to be associated with only a modest elevation in the eosinophil count. Similarly, in some patients with hypereosinophilic syndrome (HES), the tissue eosinophilia is not prominent. Although a raised blood eosinophil count therefore alerts the physician to a possible eosinophilic-related disease, it is the tissue eosinophilia that is usually more relevant to what is happening in disease.

It has been known for many years that in most cases where it has been studied, an eosinophilia is T-cell dependent. In the 1970s, Basten and Beeson [13] established

that T-cell depletion abrogated the eosinophilic response to parasite infection. It was subsequently shown that T-cell-derived supernatants contained growth factors for eosinophils and this led to the characterization of IL-5 and awareness of the pivotal role that this cytokine has in eosinophil development [14]. IL-5 seems to be a rate-limiting step for eosinophil production in that administration of IL-5 either exogenously or through transgenic manipulation in mice results in a marked eosinophilia [15] and anti-IL-5 in humans dramatically diminishes the peripheral blood eosinophil count [6]. Increased eosinophilopoiesis as a result of increased IL-5 synthesis appears to be a feature of a number of diseases including parasitic and allergic diseases. For example, pulmonary eosinophilia resulting from *Necator americanus* infection in mice was IL-5-dependent [16], and both the eosinophilia and host defence to filiriasis and *Trichinella spiralis* was markedly impaired in IL-5-deficient mice [17]. In asthma, IL-5 mRNA can be detected in increased amounts in the airways as well as the serum of steroid-dependent asthmatics [18,19]. However, IL-5 gene deleted mice still have a baseline eosinophilia and can develop pulmonary eosinophilia after infection with paramyxovirus, demonstrating that cytokines other than IL-5 can cause late differentiation [20]. It is therefore an accepted paradigm that a blood and tissue eosinophilia in IgE-mediated diseases such as atopic asthma and helminthic parasite infections are caused by antigen-dependent activation of Th2 cells, leading to IL-5 production and increased eosinophilopoiesis and tissue recruitment of eosinophils. The control of Th2 and Th1 cell development is beyond the scope of this chapter but the current understanding has recently been reviewed [21]. However, many eosinophilic diseases, including many cases of pulmonary eosinophilia, are not associated with atopy and IgE production and therefore do not entirely fit with the Th2-driven eosinophilic paradigm. Intrinsic asthma is generally assumed to be associated with IL-5-producing T cells; however, the evidence for this is limited. One model for non-IgE-associated eosinophilic disease is those cases of eosinophilic oesophagitis caused by a defined food allergen in which there is no specific IgE [22]. In some of these cases, the patients are patch test positive to the food allergen concerned, which raises the possibility of a Th2 type IV cell-mediated immunity, but this is still unexplored.

There is increasing interest in the role of T-regulatory cells (Tr) in controlling inappropriate immune responses including those associated with Th2 cell activation. Tr were first identified as mediating some aspects of immune tolerance and were then found to have an important role in suppressing immunomediated inflammatory bowel disease in mice. This is a rapidly developing area and the exact identity of Tr is still unclear. However, three types of Tr cells have been identified: CD4⁺/CD25⁺ cells, which require

direct contact to mediate their immunosuppressive effects; Tr cells producing transforming growth factor β (TGF- β); and Tr cells producing IL-10 [23–25]. Increasing understanding of the pivotal role that Tr have in controlling immune responses has led to the interesting refinement of the ‘hygiene hypothesis’, which suggests that the increase in allergic disease – which is also paralleled by an increase in autoimmune disease – is not caused by a Th1 to Th2 switch as a result of lack of immune stimulation in infancy but by a failure to develop Tr responses, which leads to enhancement of both Th1 and Th2 immunity [26,27]. IL-10-producing Tr are of particular interest in the context of pulmonary eosinophilia because of evidence that immunotherapy works by inducing expansion of antigen-specific IL-10 producing Tr cells [28]. In addition, regulatory T cells were able to suppress ovalbumin-induced pulmonary eosinophilia in mice [29,30].

Eosinophil morphology and receptor phenotype

Eosinophils are 8- μ m end-stage non-dividing leucocytes derived from the bone marrow under the influence of granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3 and IL-5. The electron microscopic (EM) morphology of the mature eosinophil has been well described (Fig. 21.1) [31,32]. The relatively specific features that distinguish the eosinophil from other leucocytes are the bilobed nucleus, the 20 or so specific granules with their electron-dense core, the paucity of mitochondria (approximately 20 per cell) and endoplasmic reticulum, and the dense network of cytoplasmic tubulovesicular structures or secretory vesicles which contain albumin and cytochrome b558 and are

Figure 21.1 Electron microscope view of an eosinophil (courtesy of Ann Dewar) showing the characteristic morphology; in particular the specific granules with an electron dense core. The major mediator classes produced by the eosinophil are listed.

therefore thought to be involved in superoxide production. Eosinophils also contain approximately five lipid bodies, which are the major site of eicosanoid synthesis, primary granules and small granules. Small granules are particularly prominent in tissue eosinophils and contain arylsulphatase B, acid phosphatase and catalase. They may be derived from specific granules and act as a lysosomal compartment especially as specific granules have been shown to express lysosome-associated membrane proteins 1 and 2 (LAMP1/2) as well as lysosome integral membrane protein 1 (LIMP-1: CD63) [33]. Eosinophils also contain multilaminar bodies that contain TGF- α . Eosinophil precursors derived from cord blood can be first identified morphologically when specific core-containing granules appear, although expression of Charcot Leyden Crystal (CLC) protein and the basic granules proteins can be detected by immunohistochemistry or mRNA expression at the promyelocyte stage where they are found in the endoplasmic reticulum (ER), golgi apparatus and large round coreless granules, most of which develop into specific granules. EM can clearly distinguish activated from resting peripheral blood eosinophils by the increased number of lipid bodies, primary and small granules, secretory vesicles and endoplasmic reticulum. Cytoplasmic crystals of CLC protein may also be present. Activated eosinophils are also often less dense than resting cells although, with the advent of immunomagnetic selection rather than density gradients to purify eosinophils, density is less often used as a marker of activation [34]. Eosinophils are thought to be relatively poorly phagocytic although they can ingest opsonized zymosan, which gets taken up into phagolysosomes formed in part by fusion with specific granules. The eosinophil also degranulates onto large opsonized surfaces such as a sephadex bead or parasitic larvae in the process of ‘frustrated phagocytosis’.

The ultrastructure of *in vitro* activated and tissue-infiltrating eosinophils has suggested three potential mechanisms of degranulation: necrosis or cytolytic degranulation, exocytosis or ‘classical degranulation’, and piecemeal degranulation [35]. Cytolytic degranulation is associated with loss of eosinophil plasma membrane integrity and results in the release of clusters of free membrane-bound granules (termed Cfegs). This is commonly observed in eosinophilic inflammation, being particularly marked in severe disease such as asthma deaths where large quantities of basic proteins can be detected in the tissue by immunohistochemistry, often with relatively few intact eosinophils [36]. This type of degranulation is also a feature of milder disease such as allergic rhinitis [37,38] as well as Fc-mediated degranulation *in vitro* [39]. Exocytosis or classic degranulation occurs in mast cells and basophils after cross-linking of IgE receptors. It describes a process whereby granules migrate to the plasma membrane and fuse with it, leading to the extrusion of membrane-free granule contents. This has

been described in the gut, but not in airway mucosa. Piecemeal degranulation was described in cord blood derived eosinophils by Dvorak *et al.* [40]. This term describes the appearance of empty or partially empty granules, which retain their structure, together with small granule protein-containing vesicles in the cytoplasm which transport the granule proteins to the cell surface where they are released [41]. These appearances are common in tissue eosinophils in asthma and other allergic diseases.

Many studies have used a mouse model involving ovalbumin challenge to generate a lung eosinophilia and increased airway hyperresponsiveness (AHR). An interesting and striking feature of this model is that the lung eosinophils do not have the appearance of having undergone degranulation either by cytolysis or piecemeal degranulation [42]. Immunostaining of the mouse lung in this model locates all the basic proteins within intact eosinophils and bronchoalveolar lavage (BAL) contains no free major basic protein (MBP) [43,44]. This is quite unlike human disease where cell free basic proteins can be readily detected in both tissue and BAL. Consistent with this observation, mice in which the gene for eosinophil peroxidase (EPO) or MBP has been deleted had the same phenotype as wild type mice in this model [45]. This observation may explain, in part, the paucity of epithelial damage seen in the mouse asthma model. It also further calls into question the physiological relevance of this type of experiment as well as emphasizing the complex and poorly understood relationship between eosinophil recruitment and degranulation.

Apoptotic eosinophils are small cells with a shrunken nucleus and condensed chromatin but an intact plasma membrane [46]. They are readily identifiable in aged cell populations *in vitro* and in cells from the airway lumen such as sputum, but are more difficult to identify in tissue. This has led some investigators to argue that the majority of airway eosinophils, at least in asthma and rhinitis, are removed through luminal entry rather than by undergoing apoptosis in tissue [35].

Like all leucocytes, eosinophils express a large number of membrane receptors which allow them to interact with the extracellular environment. These include receptors required for locomotion, activation, growth and mediator release. Most of the receptors are shared to some extent with other leucocytes but some have a degree of specificity in terms of level of expression and function. An important feature of tissue eosinophils is that they express a different pattern of receptors to peripheral blood eosinophils consistent with a more activated phenotype. This includes induction of expression of CD69, intercellular adhesion molecule-1 (ICAM-1) and Fc γ R1 and increased expression of HLA-DR and Mac-1. Changes in expression can be induced *in vitro* by culture with cytokines such as IL-5, but also occur to some extent as the result of transmigration

through endothelium [47]. A major difference between eosinophils and neutrophils, which has been exploited to purify eosinophils by immunomagnetic selectin, is the expression of CD16 by neutrophils but not eosinophils. Another important difference is the expression of VLA-4 by eosinophils but not to any great extent by neutrophils. Most recently, Siglec 8 has been identified as a receptor expressed only by eosinophils, mast cells and basophils [48–50]. Siglecs are sialic acid-recognizing animal lectins of the immunoglobulin superfamily. Eosinophils, as well as monocytes and a subset of dendritic cells, also express Siglec 10 [51]. In contrast, neutrophils express Siglec 9 [52]. The function of the Siglec 8 on eosinophils remains uncertain but may be involved in triggering apoptosis [53].

Eosinophil trafficking and tissue accumulation

Eosinophils are not normally found in tissues other than the gut, and the appearance of increased numbers of these cells can be a notable feature of the pathology of a number of diseases. The normal pattern of gut homing of eosinophils is mediated by eotaxin, which is constitutively expressed in the gut, and the integrin $\alpha 4\beta 7$ binding to MAdCAM-1 which is selectively expressed in the intestine [54]. Although an eosinophilia can accompany a general inflammatory response, as for example in fibrosing tissue alveolitis where increased numbers of eosinophils and neutrophils can be seen in BAL fluid, it often occurs without a marked increase in other leucocytes so raising the question of the mechanism behind the specific tissue accumulation of these picturesque leucocytes. Selective eosinophil accumulation occurs as a result of the coordinated effect of a number of adhesion, chemotactic and growth/survival orientated signals at each stage in the life cycle of the cell. Generally speaking, these events are controlled by mediators released by Th2 cells, in particular the cytokines IL-4, IL-5, IL-13, possibly IL-9 and most recently IL-25. This latter cytokine appears to act through an intermediate cell type to produce IL-5 and IL-13 dependent effects [55].

Eosinophil trafficking has been extensively investigated in recent years [56–58], and will only be briefly reviewed here. As well being crucial for differentiation, IL-5 is also important in promoting emigration from the bone marrow. In particular, it acts as a priming factor for specific chemoattractants such as eotaxin [59]. Eosinophil emigration from the bone marrow in guinea pigs is inhibited by blocking anti-CD18 antibodies, but interestingly IL-5-dependent emigration is promoted by blocking anti-VLA-4 antibodies [60]. One explanation for this finding is that VLA-4/VCAM-1 is responsible for eosinophil precursors binding to bone marrow stromal cells as has been shown for a range of cell types, although it has not been formally demonstrated in eosinophils. The interesting observation that eotaxin

decreased adhesion to VCAM-1 while increasing adhesion to the CD18 ligand BSA may be a mechanism for promoting egress from the bone marrow [61]. A localized inflammatory response causing systemic effects has been demonstrated after allergen challenge in mice in which IL-5-producing cells (both T cells and non-T cells) increased in the bone marrow [62,62].

Accumulation of leucocytes in tissue is a highly regulated process with the aim of being able to respond effectively to noxious insults without causing an inappropriate inflammatory response. An obligate step in the migration of all leucocytes from the systemic circulation into tissue is their capture by endothelium as they flow at high shear rates through the postcapillary endothelium. A key receptor mediating eosinophil capture is P-selectin whose low level surface expression is selectively induced on endothelium by IL-4 and IL-13. Eosinophils express higher levels of PSGL-1 (the primary receptor for P-selectin) than other leucocytes and this results in increased avidity for P-selectin compared with neutrophils, especially at the low levels of expression induced by Th2 cytokines [64]. Increased expression of PSGL-1 leading to enhanced recruitment has also been reported in allergic disease [65]. IL-4 and IL-13 can also induce low levels of VCAM-1 expression which can bind eosinophils through VLA-4 and also capture flowing cells, albeit at lower shear stresses. VLA-4/VCAM-1 and PSGL-1/P-selectin cooperate as a major endothelial control point for selective eosinophil migration [66]. Once captured, eosinophils roll along the surface of the blood vessel until they are activated, which allows the CD18 integrins binding to ICAM-1 and ICAM-2 to non-selectively promote transmigration, although VLA-4/VCAM-1 can also exert selective pressure at this stage.

The activation step mediated by chemoattractants expressed on the endothelial surface is another potential point of eosinophil selection as shown by the effect of exogenously added chemoattractants such as eotaxin, but the identity of the endogenous chemoattractant involved and the extent to which it is selectively expressed in eosinophilic inflammation remains to be resolved [67].

The blood supply to the bronchi via the bronchial arteries is part of the high flow systemic circulation. In contrast, cell migration into the alveoli and interstitium of the lung occurs through the low-pressure pulmonary circulation including the pulmonary capillaries. In this low shear circulation, selectins are not necessary to mediate the capture step and consistent with this neither E- or P-selectin are expressed on pulmonary capillaries, whereas P-selectin is very well expressed in the bronchial circulation [68,69]. In some inflammatory insults in mice, such as *Streptococcus pneumoniae* infection, CD18 and VLA-4 integrins are also not required for neutrophils to migrate into the alveolar bed [70].

Once the eosinophil has transmigrated through the endothelium it has to migrate through the basement membrane and into the tissue. Interestingly, in a mouse model in which CCR3, the major chemokine receptor on eosinophils, had been deleted the cells appeared to be able to migrate through the endothelium, suggesting that CCR3-binding chemokines such as eotaxin were not essential for the activation step, but not through the basement membrane either because they lacked a chemotactic signal or were unable to digest the extracellular matrix [71]. Once in the tissue, the eosinophil has a number of potential fates: it can remain within the bronchial mucosa where it may become associated with one of several mesenchymal structures such as nerves or mucous glands; it can migrate into the lumen, undergo apoptosis and be expectorated; or, in some circumstances, it may migrate via the efferent lymphatics to the regional lymph nodes [72]. If it remains in the tissue it may undergo apoptosis and be engulfed by macrophages or undergo cytolytic degranulation.

Apoptosis is the universal mechanism by which cells undergo cell senescence in a manner that allows them to be removed efficiently by macrophages without inducing an inflammatory response. Erjefalt and Persson [35], based on morphological observations, have argued persuasively that eosinophil apoptosis is an unusual event in tissue and that most eosinophils either die by cytolysis or migrate into the lumen where they become apoptotic [73]. A slow rate of apoptosis in tissues is consistent with the survival signals delivered to eosinophils by the extracellular matrix as part of normal homeostasis as well as increased production of eosinophil growth factors during Th2-mediated inflammation [74,75]. The importance of prolonged survival of eosinophils in tissue as a mechanism for selective accumulation has been emphasized by the studies using anti-IL-5 which effectively inhibits blood and sputum eosinophil numbers but has a much less marked effect on tissue eosinophils [7]. Glucocorticoids (GC) directly enhance the rate of eosinophil apoptosis through an unknown mechanism, unlike neutrophils where they prolong survival [76]. It is tempting to suggest that the dramatic effect of GC in resolving eosinophilic inflammation (e.g. in simple pulmonary eosinophilia) is a result of this direct effect. However, GC only induce eosinophil apoptosis at high concentrations and the effect is modest over and above the spontaneous rate of apoptosis. It is more likely that GC are working by inhibiting the production of eosinophil growth factors such as IL-5, IL-3 and GM-CSF generated both in an autocrine fashion by eosinophils in response to matrix signal and as part of the inflammatory process [77]. Recently, TRAIL, another family of survival modulating mediators related to TNF, has been reported as prolonging eosinophil survival both *in vitro* and *ex vivo* after allergen challenge [78].

The biochemical mechanism by which growth factors mediate eosinophil survival is still poorly understood. The effect is dependent on both new protein synthesis and phosphorylation events. The survival effects of IL-5 are dependent on activation of the Ras-Raf-MEC pathway and the Jak-2 Stat 1 and 5 pathway and involve lyn kinase which binds to the IL5-R alpha chain [79]. The roles of p38 and PI3 kinase are less clear and in our hands wortmannin, which blocks PI3 kinase, had no effect on eosinophil apoptosis although it did inhibit IL-5 enhancement of adhesion to fibrinogen. Eosinophils express significant amounts of the pro-apoptotic Bax and the antiapoptotic Bcl-xl but very little Bad or Bcl-2 [80]. As in other cell types, both spontaneous and Fas-induced eosinophil apoptosis is associated with the migration of Bax into the mitochondria. This led to loss of mitochondrial membrane potential, cytochrome c release and activation of downstream caspases. These events were inhibited by IL-5, demonstrating that IL-5 works by blocking Bax translocation [81,82]. Treatment of eosinophils with dexamethasone also leads to loss of mitochondrial permeability [83].

A recent study used a gene microarray approach to identify genes whose expression is modulated by IL-5 [84]. *Pim-1* was one of the genes up-regulated by IL-5 both in human peripheral blood eosinophils and an IL-5-dependent cell line. *Pim-1* was also found to be relatively highly expressed in human eosinophils. *Pim-1* is a serine/threonine kinase that was first identified as a putative lymphoma-associated oncogene. Expression of *Pim-1* in a myeloid leukaemia cell line was found to be closely linked to IL-3 and GM-CSF stimulation [85]. Subsequently, *Pim-1* was shown to be involved in IL-3-mediated survival, although not proliferation, of bone marrow derived mouse mast cells downstream of Jak2 and Stat 5 signalling [86]. In an IL-3-dependent murine cell line, ectopic *Pim-1* expression was able to replace the survival prolonging effects of IL-3 and was also able to counteract the effects of overexpression of Bax on apoptosis [87]. *Pim-1* is therefore a good candidate signalling molecule mediating the downstream effects of IL-5 and related growth factors on eosinophil survival.

Another potential mechanism involved in eosinophil tissue accumulation is *in situ* differentiation from eosinophil precursors. Eosinophil precursors can be identified in an IL-5R α ⁺ CD34⁺ population in peripheral blood, which are increased after allergen challenge and in atopic disease. These cells have also been found in asthmatic airways [88].

Of equal importance as endothelial interactions to the kinetics of eosinophil migration are the factors controlling the fate of the eosinophil once it enters the tissue. There are three possible outcomes. The eosinophil can remain in the tissue interacting with matrix proteins, other leucocytes or structural cells such as in the bronchial mucosa, the epithelium, airway smooth muscle, mucous glands and nerves; alternatively, the cell can migrate into the lumen of the

gut or airway where it is likely to undergo apoptosis and be removed; or it can return to the circulation via the lymphatics. There is limited evidence that eosinophils can recirculate although they have been reported to be present in lymph nodes where it has been speculated that they are involved in antigen presentation [89]. The length of time that eosinophils remain in tissue before migrating into the lumen is unclear as there are virtually no studies of the kinetics of eosinophil migration *in vivo* in humans. However, studies using anti-IL-5 in which there remained a significant tissue eosinophilia even after the blood eosinophilia was almost completely inhibited would suggest that eosinophils can remain in the tissue for at least 12 weeks [7]. Anti-IL-5 also completely inhibited migration into the lumen, which suggests that transepithelial migration is IL-5 dependent. It is of interest that in the mouse model of asthma, eosinophil migration into the lumen did not occur in the MMP-2 gene deleted mouse which caused the animals to asphyxiate [90]. IL-5 may therefore be important in activating the eosinophils to digest the epithelial basement membrane in an MMP-2 dependent manner [91]. It is interesting to speculate that, as has been shown with senescent neutrophils, when tissue eosinophils become senescent they start to alter their receptor phenotype in a way that inhibits tissue retention and promotes migration into the lumen [92]. The factors controlling the retention and survival of eosinophils in tissue are likely to involve the integration of chemoattractant, adhesive and survival signals delivered by interactions with matrix proteins and structural cells.

There are very few kinetic studies to provide a basis on which to calculate which of the various mechanisms described above make the largest contribution to eosinophil accumulation in tissues. In the mouse, after allergen challenge, 80% of the eosinophils appeared to be newly arrived from the bone marrow [62]. In contrast, the anti-IL-5 study by Flood-Page *et al.* [7] suggested that prolonged survival in tissues is of central importance. It is likely that each pathway contributes, with the emphasis varying between individuals and over time within one individual.

Animal models of eosinophilic lung disease

Animal models, particularly the mouse model of ovalbumin challenge, which results in a selective and marked pulmonary eosinophilia, have been used extensively to analyse the molecular basis of eosinophil trafficking to the lung and the pathological consequences of this. The combination of transgenic, gene deletion and antibody-based manipulations in the mouse make this a powerful tool for analysing the biology of eosinophil migration, although the relevance of the findings to human disease must always be treated with caution, particularly as the eosinophils do not appear to be particularly activated when they migrate into

the tissue [42]. Generally speaking, these studies have supported the concept of eosinophil migration as being the result of a series of interlinked and obligate steps with IL-5 necessary for providing a pool of circulating eosinophils, priming eosinophils for chemotactic responsiveness and prolonging eosinophil survival, and IL-4 and IL-13 controlling adhesion-related events in the endothelium and enhancing the release of eosinophil chemoattractants, particularly CCR3-binding chemokines from mesenchymal cells within the airway [93]. However, there are a number of other studies that challenge this neat concept, by looking at other aspects of the immune response, in particular showing potential roles for innate immunity as well as other inflammatory mediators such as platelet-activating factor (PAF), tryptase and prostaglandin D₂ (PGD₂).

Eosinophil functions

The eosinophil exerts its effects largely through its mediators (see Fig. 21.1). These are either newly generated, as is the case with leukotrienes and other lipid mediators, or stored preformed in various compartments within the cytoplasm and released when the eosinophil receives a degranulating stimulus. The eosinophil is relatively biosynthetically inactive and, although new protein synthesis does occur, the majority of its protein mediators are stored. Although the eosinophil can phagocytose particles, its interactions with larval forms of helminthic parasites have formed the model by which eosinophil function has been described.

In this situation, the eosinophil adheres tightly to the organism and releases its granule contents in high local concentrations onto the surface in a process described as frustrated phagocytosis. The paradigm of eosinophil effector function in host defence was developed from the observation that the basic granule proteins in particular were highly toxic for larval parasites, and was extended to include a pro-inflammatory role when they were also shown to be toxic for bronchial epithelium and therefore associated with the epithelial desquamation that is a well-established feature of severe asthma. In recent years, it has been demonstrated that eosinophils can also release a plethora of cytokines and chemokines although many of these are generated in low amounts compared with other cells and the extent to which they are important in eosinophil function is not clear [94]. The eosinophil has also been shown to have the capacity to present antigen to T cells, although how efficient they are compared to professional antigen-presenting cells is uncertain [89]. Eosinophils can release a number of lipid mediators and are one of the relatively few sources of sulphidopeptide leukotrienes although they release approximately 10-fold less per cell than mast cells and basophils. Eosinophils certainly release significant amounts of TGF- β and TGF- α and this has stimulated interest in a potential role in causing

structural changes in the lung that come under the heading of airway remodelling. There is evidence that TGF- β released by eosinophils can promote the generation of fibromyocytes and anti-IL-5 reduced the amount of tenascin in the reticular subepithelial membrane [95,96]. Certainly, thickening of this membrane is closely associated with eosinophilic airway inflammation although not with airway hyperresponsiveness or airflow obstruction [97]. Airway remodelling is also a feature of COPD, although this is more often described as a destructive process involving loss of the alveolar wall in emphysema and obliteration of the small airways. A BAL eosinophilia in cryptogenic fibrosing alveolitis (CFA) has been shown to be associated with more rapid progression of fibrosis in idiopathic pulmonary fibrosis (IPF) [98].

Eosinophils in COPD

The idea that eosinophils have an effector role in asthma is based on evidence of increased numbers of eosinophils in asthmatic airways, a correlation between severity of asthma and eosinophils especially in severe exacerbations [99], a link with responsiveness to corticosteroids and the relevance of eosinophil-derived mediators to the pathophysiology of the disease. To what extent do these tenets hold true for COPD? Three types of studies have been performed: those involving lung resection specimens from patients with lung cancer, bronchoscopy studies and studies of induced sputum. The first has the advantage of sampling the small airways where much of the disease is thought to occur; the second has the advantage of combining pathology with accurate and detailed physiology; and the third has the potential advantage of allowing sampling of larger numbers of subjects on more than one occasion.

Lung resection studies

Saetta *et al.* [100] examined the alveolar walls of patients undergoing lung resection and found increased numbers of CD8⁺ tissue lymphocytes, which appears to be a reasonably consistent finding in COPD, but no increase in eosinophils (or neutrophils) in smokers with COPD versus smokers without COPD. However, Lams *et al.* [101] investigated the immunopathology of small airways disease in patients undergoing lung resection comparing current with ex-smokers or non-smokers, and patients with and without airflow obstruction. Increased numbers of eosinophils were found in current smokers although there was no correlation with airflow obstruction. However, there was a correlation between lung function and the numbers of neutrophils, which were increased in smokers compared with lifelong non-smokers. Grashoff *et al.* [102] found increased numbers of mast cells and macrophages in the

epithelium but not the submucosa in the small airways of patients with COPD undergoing lung resection compared with those without. No differences in T cells were found and eosinophils were generally very scanty.

Bronchoscopy studies

Lacoste *et al.* [103] investigated patients with asthma, chronic bronchitis and COPD and compared findings with normal controls by bronchial biopsy and BAL. They found increased numbers of eosinophils in all the patient groups with no difference between asthmatics and patients with COPD. They did observe that the eosinophils in asthma but not COPD appeared degranulated, and unlike asthma there was no increase in eosinophil cationic protein (ECP) in BAL in COPD compared with normal controls. In contrast there was no increase in neutrophils in the submucosa of patients with COPD but there was an increase in neutrophils and elastase in BAL [103]. However, O'Shaughnessy *et al.* [104] found no increase in the number of eosinophils (or neutrophils) in the submucosa of patients with COPD compared with normal controls although they did find an increase in CD8⁺ cells. Pesci *et al.* [105] found an increase in the number of eosinophils and ECP in BAL in patients with COPD compared with non-smoking normal subjects (1.6% vs 0.15% and 21.5 µg/L vs 2 µg/L) as well as neutrophils and MBP. Rutgers *et al.* [106], in a study of patients with COPD who were current non-smokers, found evidence of ongoing inflammation compared with normal controls with increased numbers of eosinophils ($P < 0.49$) in the submucosa and eosinophils, ECP and neutrophils in BAL. There was an increase in CD4⁺ but not CD8⁺ cells. This does raise the question as to whether these patients were the same as those with raised CD8⁺ T-cell numbers [107]. In a study comparing asthmatics with fixed airflow obstruction to patients with COPD, the asthmatics had significantly more eosinophils and CD4 cells and less neutrophils than patients with COPD [108].

Sputum studies

Ronchi *et al.* [109] compared the sputum (a mixture of induced and spontaneous) differential cell count between patients with asthma and COPD and found that neutrophils predominated in the sputum of patients with COPD and eosinophils in asthma. Similarly, Balzano *et al.* [110] found that eosinophils were markedly raised in the sputum of asthmatics (22%) but only slightly raised in COPD (0.7% vs 0.2% in controls), whereas neutrophils were more raised in COPD. ECP was raised in both groups but concentrations correlated with eosinophil counts. Some patients with COPD exhibit features of asthma with greater bronchodilator reversibility and steroid responsiveness. The possibility that

this subgroup also has a more asthmatic inflammatory pattern with an airway eosinophilia was supported by the study of Papi *et al.* [111] who found that only patients with COPD with significant reversibility had increased numbers of eosinophils compared to normal controls. Similarly Rutgers *et al.* [112] found that patients with COPD who were hyperresponsive to adenosine 5'-monophosphate had increased numbers of airway eosinophils compared with those without. Eosinophilic inflammation is a feature of induced sputum in asymptomatic smokers where 14 out of 34 had increased numbers compared with controls and these subjects had a lower forced expiratory flow (FEF) 25–75% and increased number of pack-years smoking history [113]. Most studies have been undertaken in patients with stable disease; however, more striking increases in eosinophils have been seen in sputum during exacerbations of the disease [114].

COPD, eosinophils and corticosteroids

The evidence that corticosteroids are beneficial in COPD is mixed, with apparently only minor benefits of inhaled steroids in preventing exacerbations and slowing the rate of decline in lung function, and limited evidence that oral steroids are beneficial in acute exacerbations as they clearly are in asthma [115]. There is no good evidence that steroids prevent deaths from COPD or alter the natural history of the disease in any major way. Nonetheless, anecdotally it is clear that some patients with COPD benefit from oral corticosteroids. Some of these patients have other features suggestive of asthma and probably represent an overlap syndrome, but others appear to have otherwise typical COPD. There is increasing evidence that steroid responsiveness to COPD is seen in a subgroup of patients with an airway eosinophilia [116]. In an open uncontrolled study of the effects of prednisolone on lung function, Chanez *et al.* [117] found that 12 of 25 patients had a greater than 200 mL increase in FEV₁ after a 2-week course of steroids and that these patients had more eosinophils and ECP in the BAL and increased thickness of the reticular basement membrane than non-responders. No difference in eosinophils was seen, however, in bronchial biopsies. In a randomized controlled trial of a course of oral prednisolone for 2 weeks in patients with stable clinically typical irreversible COPD, Brightling *et al.* [118] found that approximately one-third of patients had a sputum eosinophilia of greater than 3% and that this subgroup of patients had a significant improvement in FEV₁, quality of life score and exercise tolerance, which was not seen in the patients with a normal sputum eosinophil count. This study adds further weight to the hypothesis that there is a subgroup of patients with COPD who have more eosinophilic disease and that the benefit of steroids is confined to this group.

Conclusions

Although broadly speaking the general paradigm that asthma is an eosinophilic disease and COPD a neutrophilic disease holds true, it is an oversimplification of a complex picture. Just as there appear to be a subset of asthmatics with non-eosinophilic disease, there is a subset of patients with COPD who have a significant airway eosinophilia most clearly seen in the luminal compartment sampled by BAL or sputum. The discrepancies between the various studies highlighted above are presumably a result of different compartments being sampled or patient selection. For example, most studies have involved non-atopic patients. It would seem that up to one-third of COPD patients with stable disease have a significant airway eosinophilia and this finding could have major implications for targeting corticosteroid treatment to this subgroup. There is little information on why some patients with COPD should have an airway eosinophilia. The large amount of data investigating Th2-mediated mechanisms involved in recruiting eosinophils into the airways in asthma has not been extensively replicated in COPD, although it is likely that many of the mechanisms are similar. However, Th1 inflammatory stimuli can also recruit eosinophils in a non-selective way and it is possible that the eosinophilia in COPD, which is generally modest in degree, represents a non-specific inflammatory process particularly in exacerbations of the disease. The evidence for a role for specific eosinophil mediators in COPD is limited. The function of the eosinophil basic proteins and bronchoconstricting mediators such as the sulphidopeptide leukotrienes appear more relevant to asthma than COPD. Important eosinophil-derived cytokines such as TGF- β and TGF- α are more related to fibrotic than destructive processes. Interestingly, there are very few data on eosinophil proteases that could be responsible for the development of emphysema, although eosinophils are potent producers of superoxide ions, which have been strongly implicated in the pathogenesis of COPD [119]. What could be triggering eosinophil mediator release in COPD is also not clear. Nonetheless, the link between corticosteroid responsiveness and eosinophils discussed above does suggest that in some patients at least they may be playing a pathogenic part. More studies of the natural history and treatment response of this eosinophilic subgroup are required.

CHAPTER 22

Airway epithelial defence, repair and regeneration

Christelle Coraux, Jean-Marie Tournier, Jean-Marie Zahm and Edith Puchelle

Airway epithelial cells: mechanisms of defence and injury

Defence mechanisms

The airway epithelium represents the first line of lung defence. The diversity of the cells lining the airways is adapted to airway mucosa protection through a variety of defence mechanisms that act together in order to protect the airway epithelium from injury. The airway surface liquid covering the mucociliary epithelium contains critical molecules for innate airway defence which maintain the sterility of the airways. The integrity of the fluid balance and optimal physical and biochemical properties of the airway secretions allow the mucociliary clearance of inhaled particles and create a protective interface between the external environment and the underlying epithelial cells. In the upper (nasal), lower (bronchi) and distal airways (bronchioles), several epithelial cell types contribute to the defence functions of the airway epithelium:

- Brush border cells (in the upper airways).
- Ciliated cells along the surface epithelium from the upper up to the distal airways, including the bronchioles.
- Secretory cells: mucous (goblet) cells in the surface epithelium and serous and mucous glandular cells in the submucosa.
- Clara cells in the distal bronchioles.
- Basal cells in the upper, lower and non-terminal distal airways (bronchioles).

The first protection barrier of the airways is the airway surface liquid and mucus, which form a continuous filter at the cell–air interface and serve as a physical barrier to noxious particles and bacteria [1]. Ciliated cells are not only involved in the mechanical mucous transport function, but also contribute to the regulation of ion and water content in the airway lining fluid through chloride channel activity

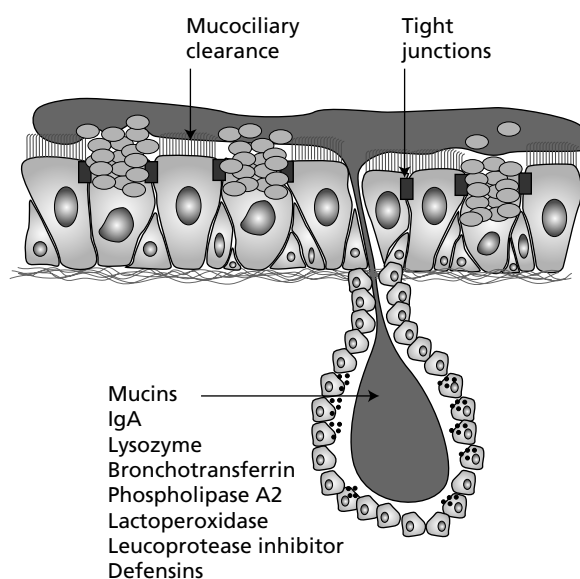

Figure 22.1 Schematic representation of airway epithelium defence mechanisms. IgA, immunoglobulin A.

[2,3]. The biochemical constituents of the airway surface liquids are numerous, and actively participate to the antibacterial, antioxidant and antiprotease defence of the epithelium (Fig. 22.1) [4]. Mucin glycoproteins directly interfere in the protective role of mucociliary clearance. The heterogeneity of their glycan chains represents a mosaic of receptors allowing the recognition and adhesion of bacteria to mucus, then eliminated from the airways by the ciliary transport mechanism, therefore avoiding the microorganisms being recognized and adhering to the surface of the underlying epithelial cells [5]. Several other proteins possess antibacterial properties: secretory immunoglobulin A (IgA), lysozyme, bronchotransferrin, secretory phospholipase A₂, lactoperoxidase and secretory leucoprotease inhibitor [6]. These molecules exhibit

microbicidal activity and are mainly produced by the serous cells of airway glands. Other molecules such as defensin peptides are also involved in the defence of the airway epithelium. It has been recently reported that the human cathelicidin antimicrobial peptide has a central role in innate immunity by linking host defence and inflammation with angiogenesis and arteriogenesis [7,8]. Surfactant proteins (SP-A, SP-B, SP-D), also called collectins, have an important role in the defence of the epithelium [9]. These human lung collectins are synthesized by alveolar epithelial cells, non-ciliated bronchiolar cells and some epithelial cells lining the larger airways and airway glands. At bronchiolar level, the Clara cell secretory protein (CCSP), also called CC16, CC10 or uteroglobin, is able to modulate lung inflammatory and immune response [10,11].

In response to reactive oxygen and nitrogen molecules induced by the inhalation of pollutants and generated by phagocytes, glutathione peroxidase is synthesized by the airway epithelial cells. Glutathione acts as a first line of defence against inhaled reactive oxygen and nitrogen species [12].

Unlike most of the matrix metalloproteinases (MMPs) synthesized and released by epithelial cells following injury, MMP-7 (matrilysin) may serve as a defence MMP and is constitutively expressed by the airway epithelium of peribronchial glands and conducting airways. Matrilysin also functions in host defence by activating the latent form of the defensin antimicrobial peptides [13].

The airway epithelial cells can rapidly alter their structure and functions, either to adapt to changes in the local environment or to repair the epithelium following injury. The 'plasticity' or remodelling of the airway epithelium has been described after irritation or injury which leads to increased cell proliferation and changes in the proportion of specific cell types. Whether the cellular changes observed reflect a response to injury or a normal repair process is not clearly defined.

At the cellular level, the tight junction (TJ) proteins play a central part in epithelial cytoprotection by maintaining a physical selective barrier between external and internal environments. Apart from their barrier function, the TJ intercellular proteins (ZO-1, claudin, occludin) interact with actin filaments and actively participate in epithelial signalling. The TJs are highly labile structures whose formation and structure may be very rapidly altered following injury. Their function may be perturbed by airway inflammation. Coyne *et al.* [14] have shown that TJ proteins are regulated by pro-inflammatory cytokines on primary cultures of airway epithelial cells and that the combined exposure to tumour necrosis factor (TNF) and γ -interferon (IFN- γ) induces drastic effects on TJ expression and barrier functions with significant alterations in the epithelial permeability.

Apart from inflammatory cytokines, bacterial toxins are also able to induce TJ degradation and to alter the epithelial integrity [15]. The disruption of TJ in bronchial biopsies from asthmatics described by Elias [16] has been reported to be associated with extensive epithelial damage. In infected airways, the neutrophil products may decrease the transepithelial resistance with a reduced number and width of TJ strands.

Main sources of airway epithelial injury

Infectious as well as non-infectious agents may significantly alter the integrity of the epithelial barrier. Bacteria interfere with the airway mucociliary transport by disorganizing or slowing ciliary activity. Microorganisms, such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus* and *Pseudomonas aeruginosa* are responsible for inducing hypersecretion of mucus, slowing of ciliary beating and epithelial shedding. Non-infectious agents, such as inhaled oxidants (NO₂, SO₂, O₃), may exert a toxic effect on airway epithelium, the gravity of the injury being dependent on the physicochemical characteristics of the inhaled gas, its concentration, solubility and the duration of exposure. Whatever the source, the response of the airway surface epithelium to an acute injury includes a succession of cellular events, varying from the loss of surface epithelial impermeability to the shedding of the epithelium (only basal cells still being attached to the basal lamina), or to a complete denudation of the basement membrane (Fig. 22.2).

Epithelial shedding, even to the point of airway denudation, has already been described as a common and unifying feature of asthma. However, the capacity of basal cells to take over the barrier properties of the epithelium after a selective loss of columnar cells was described more recently [17]. Very few studies have been devoted to the relationship between airway epithelial damage and inflammation in patients with recurrent bronchitis and frequent exacerbation episodes. In most cases in children with recurrent

Figure 22.2 Chronology of the different steps of airway epithelium injury. Mucus release (1), loss of junctional integrity (2), compound cilia (3), loss of cilia (4), loss of polarity (5), epithelium shedding (6) and basement membrane denudation (7).

bronchitis outside of recent acute infections, bronchial biopsies showed extensive epithelial damage and a significant correlation between the degree of shedding and oedema of the airway mucosa [18].

***In vivo* and *in vitro* models of airway epithelial repair and regeneration**

Animal models of airway epithelium regeneration

Different sources of injury (oxidants, cigarette smoke, mechanical injury, and viral or bacterial infections) have been analysed using a variety of animal models including dogs, rabbits, guinea pigs, hamsters, rats and mice. These models of airway epithelium injury and repair demonstrate progressive restoration of TJs, premitosis dedifferentiation followed by squamous metaplasia, active mitosis leading to basal and mucous cell hyperplasia and progressive redifferentiation with emergence of 'preciliated' cells (a mixed phenotype of ciliated and mucous cells) and ciliogenesis allowing the regeneration of a functional mucociliary epithelium [19].

Regeneration of the hamster tracheal epithelium after mechanical injury has demonstrated rapid re-epithelialization of the denuded basement membrane and has shown that cell migration, rather than cell proliferation, occurs first [20]. Epithelial cells at the border of the wounded area are able to dedifferentiate, spread and migrate over the denuded basement membrane to cover the de-epithelialized area. Ramphal *et al.* [21] have shown that, after influenza virus infection, complete desquamation of the epithelium occurs within 3 days, then regeneration begins within 5 days and is completed after 2 weeks.

In vivo studies in animal models suggest that several categories of stem cells and progenitor cells, including columnar, basal and ciliated duct cells, can participate in airway epithelium regeneration and renewal [22–25]. Nevertheless, histological differences exist between human airways and those of other animal species. Mouse tracheal epithelium is composed mainly of ciliated and Clara cells, the latter being present only in human distal airways and only a few submucosal gland cells are identified at the upper tracheal level in mice.

Human airway xenografts in tolerant mice

We explored regeneration and maturation of the adult human airway epithelium [26], adapting the tracheal xenografts in nude mice initially developed by Engelhardt *et al.* [27]. Epithelial cells dissociated from human nasal polyps were seeded into the lumen of rat tracheas denuded

of their own epithelium by successive cycles of freezing and thawing. The rat tracheas, tied at their distal end to sterile polyethylene tubing, were inoculated with the human adult epithelial cells and implanted subcutaneously into the flanks of recipient nude mice. We analysed, in terms of cell proliferation, differentiation and integrity of the epithelial barrier, the sequence of events involved in the regeneration of the human airway epithelium, which were partly similar to those described in epithelial regeneration *in vivo* after airway injury. At 3 days after implantation in nude mice, tracheas were partly repopulated with a flattened, non-ciliated and poorly differentiated untight epithelium. By the end of the first week, cell proliferation produced a squamous-type epithelium on the entire surface of the host rat trachea which was stratified into multiple layers and tightly sealed. This squamous epithelium phenotype, which represents a highly protective phenotype, previously described after injury, reflects a protective dynamic regenerative process. During the following weeks, cell proliferation decreased markedly and the epithelium became progressively columnar, secretory and ciliated but was still partly untight, although already polarized. After 4–6 weeks, the regenerated airway epithelium was well differentiated and pseudostratified (Fig. 22.3; see also Plate 22.1; colour plate section falls between pp. 354 and 355). This chimeric model has the main advantage of reconstituting a human adult airway epithelium exposed to the air environment in the same way as in adult human airways. Pharmacological application of this air-opened humanized airway graft has been successfully assayed with an anti-inflammatory molecule in cystic fibrosis (CF) [28]. Other important applications of this model will be to identify molecules able to activate epithelial regeneration in respiratory diseases such as chronic bronchitis, asthma and CF. Ultimately, this xenochimera may be very useful to analyse the capacity of recombinant viral vectors to target progenitor cells for surface epithelium [29].

A model of human airway development *in vivo* relying on the transplantation of embryonic and fetal lung rudiments into xenotolerant severe combined immunodeficient (SCID) mice has been described [30,31]. Proximal or distal airway primordia grew rapidly in SCID mice and differentiated after 6–12 weeks into tracheal or pulmonary structures, including a pseudostratified ciliated and secretory surface epithelium, submucosal glands and cartilage rings as well as alveolar structures and interstitium. Irrespective of initial stages of development, fragments of human fetal tracheas implanted subcutaneously into SCID mice developed as closed fluid-filled xenografts, lined on their whole inner surface with a pseudostratified and secretory epithelium. The presence of airway fluid inside the lumen of these tracheal grafts resulted from surface cell and submucosal gland secretion and from transepithelial active transport of

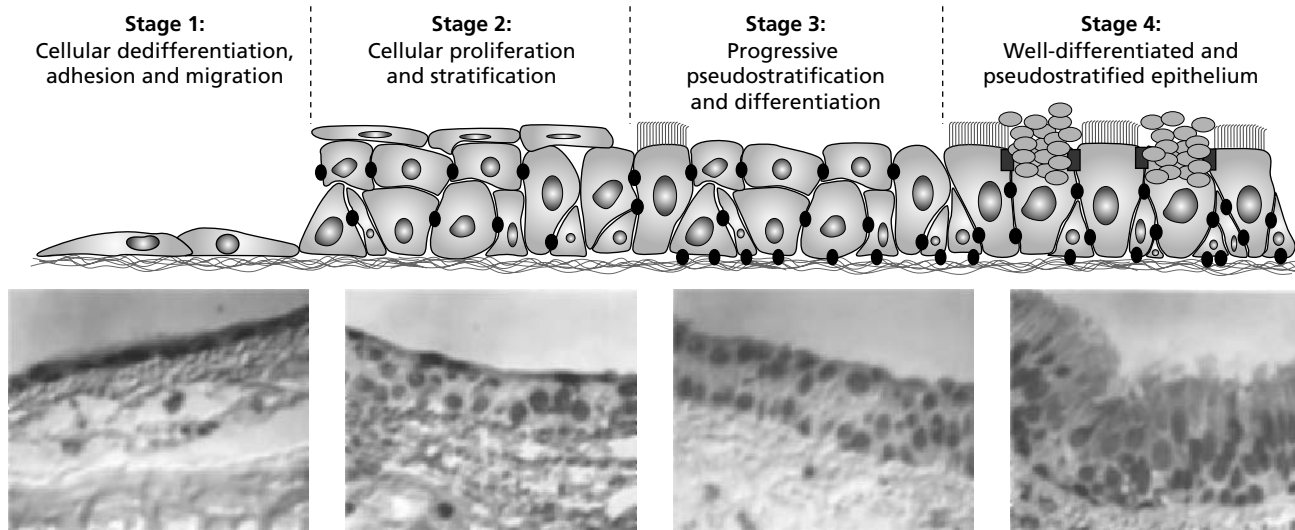

Figure 22.3 Sequence of events in the regeneration of airway epithelium. See also Plate 22.1; colour plate section falls between pp. 354 and 355. (From Dupuit *et al.* [26] with permission.)

ions and water. The bioelectric properties of these human tracheal grafts implanted in SCID mice were stable over several months and showed that the mature and well-differentiated lining epithelium acted as a selective barrier to ion transport [32]. Xenografts were similar to postnatal normal airways with respect to transepithelial potential difference, short-circuit current and transepithelial resistance as well as to responses to amiloride, forskolin and extracellular adenosine triphosphate (ATP). A lower baseline electrogenic ion transport activity, similar to that described in CF postnatal airways, was observed in CF fetal grafts. A limitation of this model is that the xenograft is not exposed to air and probably mimics the prenatal rather than the postnatal human airway environment.

***In vitro* and *ex vivo* models of airway epithelial repair and regeneration**

Several assays have been described to analyse *in vitro* the wound repair following airway cell culture damage. After bronchial or alveolar cell culture at confluence, the cell layer is mechanically damaged by gently scraping the epithelium, and the area of denuded epithelium is quantified over 24 h at regular time intervals.

Chemical injury has been also used for inducing a wound [33]. Primary cultures of confluent airway cells were injured by depositing a 1 μ L drop of 1 mol/L sodium hydroxide rapidly neutralized with phosphate buffer saline at the centre of the culture. The advantage of this technique is that the wound surface is well standardized. Evolution of the remaining surface of the wound area can be examined using a videocamera connected to a microscope and the corresponding wound surface is calculated. A cell migration assay was also developed in parallel to analyse the migra-

tion speed of the airway cells in culture after injury. After wound induction, cell nuclei were stained with a fluorescent dye and the wounded culture was placed in a small transparent culture chamber of an inverted microscope. Images of the cell nuclei are digitized and cell migration is quantified through the detection of cell nuclei, the computation of the trajectories of these nuclei and the analysis of these trajectories. From each nucleus trajectory, the computer calculated the cell migration speed.

In order to analyse the molecular mechanisms involved in airway epithelial repair, it is of major interest to create a wound where only surface epithelial cells are damaged without any alteration of the underlying extracellular matrix molecules. Freshly collected human bronchial tissues can be locally injured using a small metallic probe frozen with liquid nitrogen and applied for 10 s to the tissue sample with a calibrated pressure. Under these conditions, only cells of the surface epithelium are eliminated, but the underlying extracellular matrix is not altered [34].

Another *in vitro* model of three-dimensional culture of human airway epithelial cells in suspension has been developed that allows the analysis of the regeneration of nasal epithelium [35]. Using this three-dimensional airway spheroid culture model, the kinetics of differentiation, polarization and ciliated and secretory epithelial regeneration have been analysed [36]. After complete dissociation of human airway epithelial cells, the expression of apical membrane proteins disappears and the re-establishment of cell–cell junctionality, polarity and differentiation observed after approximately 1 month of culture is associated with the apical plasma membrane localization of cystic fibrosis transmembrane conductance regulator (CFTR) and of associated proteins such as ezrin and a glycoposphatidylinositol-anchored protein: CD59.

Cellular and molecular mechanisms of airway epithelial repair and regeneration

The cellular and molecular factors involved in the repair and regeneration of airway epithelium are numerous and closely interact. Early repair events have been examined in detail by Erjefält *et al.* [37] who have shown that, immediately after epithelial denudation without any damage to the basement membrane, the epithelial cells from the wound border dedifferentiate into 'repair cells' that migrate rapidly to recover the wounded area.

Cell migration involves protrusion of the plasma membrane (lamellipodium extension) at the leading edge of the cell which implies cytoskeleton reorganization. Cell movement also implies the formation of new sites of adhesion to the extracellular matrix at the front of the wound but also the release of adhesion sites at the back of the cells. This necessarily implies a coordinated sequence of events involving contraction of the actin and actomyosin cytoskeleton, interaction with extracellular matrix proteins (ECM) and MMPs, with regulation between MMPs and their inhibitors. Furthermore, production of ECM by the airway epithelial cells during the migration process requires signalling pathways through specific receptors on the airway cell surface.

In the *in vivo* situation, such as in asthma, chronic obstructive pulmonary diseases (COPD) and CF or in *in vivo* experimental models where the host-tissue responses are preserved (such as in human airway xenografts), there is a rapid increased plasma exudation associated with a deposition of fibrin and plasma-derived proteins on the denuded plasma membrane and an efflux of plasma-derived growth factors, cytokines, MMPs, associated with recruitment of leucocytes, as well as proliferation of fibroblasts and myofibroblasts, which may contribute to the initiation of the repair process. In normal conditions, this inflammatory host-tissue response progressively decreases in order to allow the reparative processes to occur (wound closure, redifferentiation and regeneration of the airway epithelium). To accomplish successful wound repair and tissue regeneration, the inflammation response must be tightly regulated *in vivo*. Among the regulatory cytokines, it can be expected that, as in cutaneous wound healing, IL-10 has a major role in suppressing the inflammatory response and inhibiting the synthesis of proinflammatory cytokines observed at the onset of wound repair [38].

Role of matrix metalloproteinases in the repair and regeneration of airway epithelium

During spreading and migration, cells adhere to the ECM molecules through focal and primordial contacts that

enable the anchorage by which the cells can exert traction on the matrix. These contacts are transient structures that are required for traction but have to be rapidly cleaved during migration. MMPs are directly involved in airway epithelial wound repair, especially in the remodelling of the provisional matrix on which the epithelial cells migrate. Buisson *et al.* [39] have shown, using the *in vitro* model of airway epithelium wound repair, that MMP-9 and MMP-3 (stromelysin-1) are strongly expressed by the repairing airway cells. Furthermore, a MMP-9 antibody, known to inhibit MMP-9 activation, resulted in a dose-dependent decrease of the wound repair speed. These observations suggest that MMP-9 acts at the interface between repairing epithelial cells and the ECM and is involved in the remodelling of the newly synthesized ECM. According to Planus *et al.* [40], MMPs play a major part in tissue repair by several mechanisms: first by remodelling ECM but also by releasing growth factors such as vascular endothelial growth factor (VEGF), transforming growth factor β (TGF- β) or basic fibroblast growth factor (bFGF) from the proteoglycans where they are stored, or by cleaving some growth factor receptors such as FGF receptor. MMPs could also facilitate de-adhesion during the cell migration process, as suggested by the fact that alveolar cell migration on type I collagen is promoted by collagenases. Matrilysin (MMP-7) is an important MMP that functions in defence and repair as well as in inflammation. MMP-7 is expressed in migrating epithelium in injured airway [41]. In matrilysin null mice airway tissues, tracheal wound does not repair, whereas it repairs rapidly in tracheas of wild-type mice. Moreover, it has been recently shown that matrilysin shedding of syndecan-1 regulates chemokine mobilization and confines neutrophil influx to sites of injury [42]. Both collagen IV and MMP-9 are involved in airway epithelial cell migration. Legrand *et al.* [34] have shown that when cell-collagen IV interaction is blocked, cells spread slightly but do not migrate and when MMP-9 activation is prevented, cells remain fixed on primordial contacts and do not migrate. These observations suggest that MMP-9 controls cell migration by remodelling the provisional ECM implicated in primordial contacts. MMP-7 and MMP-9 act also as modulators of airway epithelial differentiation. It was recently demonstrated in the nude-mice xenograft model that incubation of the epithelial cells with MMP inhibitors in the course of epithelial regeneration led to an abnormal epithelial differentiation attested by immature and mature squamous metaplasia with areas of basal cell hyperplasia [43].

Role of cytokines and growth factors in airway epithelial repair

Cytokines represent a large group of heterogeneous proteins with diverse biological activities. These polypeptide mediators include chemokines, interleukins, tumour

necrosis factors, growth factors and colony-stimulating factors. During airway inflammation, great attention has been devoted to the mediators involved in the early inflammatory and chemotactic response and in the resolution of inflammation. Less information is available on the cytokines such as growth factors that are involved in airway epithelial wound repair and regeneration. These growth factors are mainly secreted by mesenchymal cells and macrophages but also by epithelial cells. The incubation of wounded human airway epithelial cell cultures with recombinant epidermal growth factor (EGF) increases significantly the wound closure rate [44]. EGF stimulates migration and wound repair of guinea pig airway epithelial cells [45]. Other growth factors, such as insulin-like growth factor 1 (IGF-1), platelet-derived growth factor (PDGF), TGF- β or keratinocyte growth factor (KGF) can enhance the wound repair by acting as chemotactic or growth-stimulating factors, stimulating the synthesis of ECM and interacting with MMPs through specific cell receptors.

Airway epithelial migration is induced by several 'motogen' peptides including insulin, insulin-like growth factors (IGF), calcitonin gene-related peptide (CGRP) and EGF. Another group of peptides, the trefoil factor family (TFF) has been shown to promote migration and repair in the gastrointestinal tract and, more recently, in wounded airway epithelial cell cultures where they exhibit a synergistic effect with EGF [46]. TFF peptides would act as motogens in the human respiratory epithelium, triggering rapid repair of damaged mucosa in the course of airway diseases such as asthma.

Extracellular matrix proteins, integrin and non-integrin receptors

Cell-cell and cell-extracellular matrix interactions represent vital aspects of the repair mechanisms. These cellular processes are mediated by the ECM constituents that represent ligands for specific transmembrane cellular receptors, the integrins. Each integrin consists of two subunits, α and β , and the resulting heterodimer mediates cell adhesion to one or more matrix proteins such as collagen, laminin, fibrinogen or fibronectin [47]. The migrating cells attach to a provisional matrix that includes the inflammatory glycoproteins fibronectin and vitronectin as well as components of basement membrane, laminin and type IV collagen. It has been shown that the matrix proteins themselves can serve as stimuli for migration of bronchial epithelial cells *in vitro* [48]. Among the ECM proteins, fibronectin appears to have a key role in airway epithelium repair. By immunocytochemistry, Hérard *et al.* [49] have shown that fibronectin is deposited at the airway cell-matrix interface during the wound repair process. In addition, the incubation of wounded cultures with antifibronectin antibody partially

inhibits the wound closure. In association with the deposition of fibronectin, they also observed that the $\alpha_5\beta_1$ -integrin, which is one of the fibronectin cellular receptors, was up-regulated in the migrating cells of the repairing area. Using an *in vivo* human/SCID mouse chimeric model of airway repair, Pilewski *et al.* [50] reported a similar induction of the $\alpha_5\beta_1$ -integrin during wound repair. Airway epithelial cells may use other matrix receptors such as α -dystroglycan (a non-integrin laminin receptor) to facilitate spreading and migration during repair [51].

Non-integrin receptors such as CD44 and the receptor for hyaluronic acid mediated-mobility [52] may be also implicated in respiratory injury and repair. CD44 is responsible for binding to hyaluronic acid that serves as an anchor for secreted proteins and could possibly retain mitogenic and mitogenic molecules involved in airway epithelial repair.

Apart from its functional role in cell adhesion via integrin receptors, cell surface glycosylation may mediate repair of human airway epithelial cells [53].

Airway stem cells and progenitor cells

The repair of injured airway epithelium involves stem cells and progenitor cells. Much evidence supports the presence of stem and or progenitor cells in the airways. Although the proliferation index is less than 0.2% in healthy bronchial epithelium [54], tissue homeostasis exists, and denuded-graft experiments have shown the ability of airway epithelial cells to reform a complete array of tracheal and bronchial epithelial cells. For example, epithelial cells from human undifferentiated fetal trachea rudiments seeded on denuded human fetal tracheas and grafted on the back of tolerant mice are able to reform a fully differentiated airway epithelium [31]. In the same way, the presence of stem or progenitor cells in adult human bronchi [55] and adult human nasal polyps [26] has been suggested. Despite these results, the exact identity of airway stem cells remains to be determined.

The airways are classically subdivided in large cartilage-containing airways (trachea and bronchi) and small airways without cartilage (bronchioles). Although the concept of a single stem cell common to the epithelium of the whole respiratory organ has been proposed (for review, see Emura [56]), it is now accepted that each subdivision of the lung possesses its own stem cell.

Stem cells are quiescent undifferentiated cells able to divide slowly but indefinitely under particular conditions such as injury, to self-renew for their entire life span and to give rise to less proliferative committed daughter cells, called transient amplifying cells or progenitor cells [57]. Stem cells differentiate to form all the cell types of the tissue [58,59] and are therefore multipotent.

Tracheal and bronchial airway stem/progenitor cells

In order to determine the identity of stem cells in the tracheal and bronchial epithelium, metabolic labelling or Ki67 antigen immunodetection has been used to study the epithelial cell kinetics. The proliferation capacity of basal and secretory cells suggested that these cells were good candidates for stem or progenitor cell status [60–62]. In animals, the differentiation potential of purified subpopulations of airway epithelial cells has also been investigated by using xenograft models. After an initial step of cell separation based on elutriation or cell sorting, basal or secretory epithelial cells were seeded on tracheas depleted of their own epithelium and then transplanted. Authors reported the capacity of both basal and secretory cells to dedifferentiate into a similar highly proliferative phenotype called ‘poorly differentiated cells’ and then to redifferentiate and regenerate after 3–4 weeks of engraftment a pseudostratified mucociliary airway epithelium [63–65] with a respiratory gland network [66]. Based on evidence of stem cell niches in many organs such as intestine or skin, Borthwick *et al.* [24] have reported the existence of stem cell niches in airways characterized by slow-cycling cells able to retain the nucleotide analogue BrdU in their genomic DNA for long periods of time. These stem cell niches were principally localized in the gland ducts in the upper trachea of mice.

Bronchiolar stem cells

As in large cartilage-containing airways, the nature of proliferative cells in bronchioles has been investigated using Ki67 antigen immunodetection. In the terminal bronchioles of normal human airways, 15% of proliferating airway epithelial cells were Clara cells, and this percentage increased up to 44% in the respiratory bronchioles [67]. In the airways depleted of Clara cells, a normal epithelium could not be regenerated [68]. In rabbits, Clara cells separated by elutriation following Percoll density centrifugation and inoculated into denuded rat trachea were able to regenerate a cuboidal epithelium resembling that seen in normal bronchioles [69]. These data favour the concept that the Clara cells represent stem or progenitor cells of the bronchioles.

Bone-marrow-derived airway stem cells

It was previously thought that stem cells were tissue-specific but in the last decade, a number of studies has demonstrated that stem cells from one organ can differentiate into cells of another, and this is particularly true for bone-marrow-derived stem cells. This notion of ‘cell plasticity’ in the airways has primarily been reported by Krause *et al.* [70]. This group showed that a single stem cell from

the bone marrow could not only repopulate an irradiated host, but was also able to generate cells found in several tissues. In the bronchi, these cells represented 3.7% of the total tissue cells. In humans, Kleeberger *et al.* [71] reported approximately 10% integration of recipient-derived cells in the bronchial epithelium for the patients with lung allograft, with a markedly high degree of chimerism (24%) in structures displaying signs of chronic injury. However, these exciting results apparently contradict the data of Davies *et al.* [72] who did not observe any differentiation of airway cells from bone marrow cells into the upper airway respiratory epithelium in the absence of infection and inflammation. These data suggest that airway injury is a prerequisite to the differentiation of bone-marrow cells into airway epithelial cells.

Although airway stem cell research extensively progressed during this last decade, the precise identity of human airway stem cells remains to be elucidated.

Strategies for future therapy of airway cytoprotection, repair and regeneration

Repair of the airway epithelium after injury is critical for the maintenance of the barrier function and the limitation of airway hyperreactivity. Future therapy of airway epithelial injury and repair should aim to improve the protection of airway epithelium against injury. In the case of severe injury, these therapies should enhance wound repair and epithelial function regeneration.

Based on *in vitro* and *in vivo* studies, growth factors have been shown to be able to stimulate cell proliferation and differentiation after injury. Among the different growth factors, EGF has been shown to promote wound repair almost *in vitro* [73]. Moreover, EGF enhances the number of β_2 -adrenergic receptors (β_2 -AR) [74]. The increase in β_2 -AR could improve the effect of β_2 -AR agonists such as salmeterol, which has been shown to protect the airway epithelial integrity via an increase in the TJ protein ZO-1 [75]. Recombinant EGF and β_2 -AR agonists could therefore prevent the airway epithelium from deleterious insults and accelerate the re-epithelialization of wounded epithelia, which frequently occurs in viral and bacterial pathologies. Among the proteins able to limit airway epithelial injury, recombinant CC10 (rh CC10) protein has been reported to inhibit phospholipase A₂ and to possess anti-inflammatory properties. We can speculate that rh CC10 could represent a promising therapy not only for the prevention of lung therapy in preterm infants [76], but also for the prevention of airway and lung epithelial injury.

Other growth factors such as KGF have been reported to enhance alveolar epithelial repair by non-mitogenic mechanisms. Atabai *et al.* [77] have shown in rats that

administration of KGF markedly improves the epithelial repair by altering cellular adherence, spreading and migration through stimulation of the EGF receptors. KGF is also able to accelerate wound closure in airway epithelium during cyclic mechanical strain and to protect from oxidant injury [78,79].

Apart from growth factors, antibiotics such as tetracyclins and cefazolin [80] have been shown to increase cell proliferation and differentiation and be helpful in protecting from cell damage and augmenting the healing of acute airway epithelial injury [79]. Future drugs should also include molecules that are capable to increase wound closure and to induce a completely reconstituted and regenerated functional airway epithelium.

In the long term, future therapy of repair and regeneration should be orientated toward the development of pharmacological molecules active on airway epithelial progenitor and stem cells. The identification of these cells represents a major challenge in the perspective of a reparative therapeutic approach to airway epithelium.

CHAPTER 23

The role of the neutrophil in the pathogenesis of COPD

Ian S. Woolhouse and Robert A. Stockley

The neutrophil is the most abundant circulating leucocyte. It is derived from pluripotential stem cells in the bone marrow and is characterized by the presence of a multi-lobed nucleus and cytoplasmic granules. The primary, or azurophilic granules contain many of the important proteins required in host defence, including the proteinases (elastase, proteinase-3 and cathepsin G), antibacterial proteins (such as the defensins, lysozyme and azurocidin) and the enzyme myeloperoxidase. However, the capacity of the neutrophil and its products for bacterial killing carries with it an implicit capacity for host tissue destruction.

The neutrophil has been implicated in the pathogenesis of chronic lung disease for over 30 years. The association dates back to an observation in 1963 that severe early-onset emphysema was associated with deficiency of α_1 -antitrypsin, the serum inhibitor of the proteolytic enzyme neutrophil elastase [1]. This led to the proteinase-antiproteinase theory of the pathogenesis of emphysema and subsequent studies, both in animal models and human subjects, have led to this theory being widely accepted as a key mechanism of disease development.

This chapter reviews the data implicating the neutrophil in the pathogenesis of COPD, summarizes the process of neutrophil recruitment to the lungs from bone marrow production through to migration into the airways, outlines the mechanisms of neutrophil-mediated connective tissue destruction and, finally, discusses the neutrophil as a target for anti-inflammatory therapy in COPD.

Evidence for the role of the neutrophil in the pathogenesis of COPD

Animal models

Animal studies have been critical in understanding the role of the neutrophil and its products in the pathogenesis of

COPD. Early studies using intrapulmonary challenges demonstrated that proteinases, including human neutrophil elastase, can lead to the development of emphysema, when instilled into the lungs of experimental animals [2,3], as a result of elastin degradation. Subsequent studies confirmed that neutrophil elastase is also able to induce other features of COPD, including mucous gland hyperplasia, excessive mucus secretion, bronchial hyperresponsiveness and tissue damage a short time after instillation into the airways [4–6].

However, recently it has been shown that a variety of metalloproteinases can also degrade elastin and that mice lacking macrophage metalloelastase 12 (MMP-12) do not develop smoke-induced emphysema [7,8]. These findings led to an alternative hypothesis in which macrophages and macrophage-derived metalloproteinases were thought to be responsible for the development of emphysema. However, new studies have re-emphasized the importance of neutrophil-derived proteases and their inhibitor α_1 -antitrypsin. Using a mouse model, Dhimi *et al.* [9] and Churg *et al.* [10] have demonstrated that both MMP-12 and neutrophils are required for acute smoke-induced matrix breakdown, the precursor of emphysema. This process appears to be mediated by MMP-12 induced release of tumour necrosis factor- α from alveolar macrophages, with subsequent endothelial activation, neutrophil influx and connective tissue destruction by neutrophil-derived proteases [11]. In addition, the same group has demonstrated that exogenous administration of α_1 -antitrypsin ameliorates both the acute and chronic connective tissue destruction seen in this mouse model of cigarette smoke-induced emphysema [9,12], providing further evidence for the role of neutrophil-derived proteases in the pathogenesis of COPD.

Human studies

Early studies on patients with chronic bronchitis

Figure 23.1 The proportion of neutrophils identified in induced sputum samples is shown for healthy control subjects and subjects with COPD. In addition, the proportion of neutrophils is shown for COPD patients who have chronic cough and sputum expectoration.

demonstrated an increased percentage of neutrophils in bronchoalveolar lavage fluid compared with asymptomatic smokers, which was greater the worse the airflow obstruction [13–15]. In addition to greater numbers of neutrophils in the bronchoalveolar fluid from patients with COPD, subsequent studies also demonstrated the presence of increased markers of neutrophil activation, in particular myeloperoxidase and interleukin 8 (IL-8) [16,17].

These results have been reproduced in studies examining neutrophil counts and markers of neutrophil activation in sputum from patients with COPD, confirming the presence of neutrophilic inflammation in the larger airways, as well the peripheral airways of smokers with COPD (Fig. 23.1) [18–20]. Furthermore, the observed association between neutrophilic airway inflammation and the severity and rapidity of airflow obstruction [20,21] provides further support for the role of the neutrophil in the progression of the disease.

Although the airway lumen in smokers with COPD displays a neutrophilic inflammation, studies of tissue inflammatory cell response in these patients have produced conflicting results. Saetta *et al.* [22] and Di Stefano *et al.* [23] have demonstrated increased numbers of neutrophils in the bronchial glands of smokers with chronic bronchitis and in the bronchial subepithelium of smokers with severe airflow obstruction. However, the same group found that numbers of CD8⁺ lymphocytes, not neutrophils, were increased in the peripheral airways epithelium and alveolar walls of smokers with COPD, compared with smokers without airflow obstruction [24,25]. Other histological studies have confirmed increased numbers of CD8⁺ lymphocytes in the alveolar walls of smokers with emphysema [26], although patients with severe airflow obstruction also had significantly increased numbers of neutrophils [27]. The

precise role of the lymphocyte in the pathogenesis of COPD remains unclear and the discrepancy between the increased presence of neutrophils in the airway but not tissues may be explained by selective passage of neutrophils across the epithelium into the airway lumen.

During exacerbations of COPD there is a further increase in the number of airway neutrophils [28], although the role of the neutrophil in exacerbations is uncertain. Many of these episodes are related to bacterial infection, therefore the neutrophil response is likely to represent an important component of secondary host responses. However, the recruitment of neutrophils during exacerbations is also associated with a rise in neutrophil activation markers, in particular neutrophil elastase, myeloperoxidase (MPO), leukotriene (LT) B₄ and (in severe episodes) IL-8 [29–31], all of which have the potential to perpetuate the inflammatory process and hence lead to further bronchial damage. Studies of bronchial neutrophilic inflammation during exacerbations show resolution usually within 5 days following treatment, and this parallels clinical recovery [30].

Neutrophil differentiation and maturation

Neutrophil differentiation occurs entirely within the bone marrow, where several distinct stages can be recognized. In the first stage, which takes 5–7 days, the cells divide and differentiate from myeloblasts to form promyelocytes. During this period the primary, or azurophilic, granules, which contain the proteinases elastase, proteinase-3 and cathepsin G, antibacterial proteins such as the defensins, lysozyme and azurocidin and the enzyme myeloperoxidase are produced. The secondary, or specific granules, which contain collagenase, lactoferrin and gelatinase, among other proteins, are formed as the cell proceeds to the metamyelocytic stage. Cell divisions ensure that all cells contain a full complement of primary and secondary granules. From the metamyelocyte stage onwards the cells no longer undergo division but mature through a recognized band cell stage to form adult neutrophils. At maturity, neutrophils develop highly mobilizable secretory granules with adhesion molecules and cytochrome *b*₅₅₈ on their surface. This whole process takes approximately 2 weeks, with the mature cells remaining in the bone marrow for a further 2 days before being released into the circulation, where they have a half-life of 8 h [32].

A number of studies have demonstrated that cigarette smoke exposure has a stimulatory effect on this process within the bone marrow causing peripheral blood leucocytosis and neutrophilia [33,34]. In addition, total peripheral blood leucocyte count has been found to correlate inversely

with absolute forced expiratory volume in 1 s (FEV_1) values [35,36]. These observations are consistent with the hypothesis that the neutrophil is of major importance in the pathogenesis of COPD, and higher numbers of this cell within peripheral blood (resulting from increased bone marrow production) may be related to the severity of airflow obstruction, as increased numbers of neutrophils are available for recruitment to the airways which would lead to increased elastase-mediated connective tissue destruction.

Neutrophil recruitment to the lungs

The walls of the bronchi and bronchioles are supplied with systemic blood through the bronchial arteries, which are derived from the descending aorta and the intercostal and internal mammary arteries [37]. Microvascular injection techniques demonstrate an extremely rich vascular network supplying the airway wall [38]. The alveoli receive their blood supply from the pulmonary circulation via branches of the pulmonary artery, which divides to form a meshwork of short capillary segments in close contact with the alveolar space.

The relative contribution of the bronchial and pulmonary circulation to the blood supply of human lungs is not known. Although studies in dogs using fluorescent microspheres have demonstrated that 97% of the blood supply to the intraparenchymal airways down to 1 mm in diameter comes from the bronchial circulation [39], whether this is the same in humans remains unknown and very little is known of the relative contributions of the two circulations to neutrophil recruitment in COPD. In healthy sheep, 50–60% of radiolabelled neutrophils in the bronchial vasculature are retained, compared with 80% of those in the pulmonary circulation being retained [40]. Given the presence of neutrophils and their products at bronchial and alveolar level in patients with COPD, one may assume that neutrophil migration occurs from both the bronchial and pulmonary circulations. The mechanisms of neutrophil recruitment to the lung are thought to differ according to the site of migration, which may have implications in terms of the pathological features of COPD and potential new therapies.

Neutrophil migration in the bronchial circulation

Neutrophil traffic into the bronchial submucosa occurs via the bronchial circulation and is assumed to follow the complex multistep process seen elsewhere in the systemic circulation (i.e. cell capture, rolling, activation and arrest) [41,42].

Initiation of migration begins with capture of neutrophils from flowing blood and subsequent rolling along the endothelial surface in postcapillary venules, which is a normal feature of circulating neutrophils. This process is mediated through reversible binding of a group of transmembrane glycoprotein adhesion molecules known as the selectins. Leucocyte (L) selectin is constitutively expressed on projecting microvilli of circulating neutrophils. It is responsible for early, rapid and short-lived binding to an endothelial ligand that has yet to be fully characterized, but is thought to be a fucosylated variant of CD34, a member of a group of sialomucin oligosaccharides that share affinity for selectins [43–45]. Platelet (P) selectin, which is stored intracellularly in Weibel–Palade bodies of endothelial cells, is mobilized to the endothelial surface within minutes of exposure to inflammatory mediators such as histamine, thrombin and various cytokines [46,47]. The neutrophil counterligand for P-selectin is glycoprotein ligand-1, and binding to this receptor results in slower rolling velocities and eventual tethering of the neutrophil to the vessel surface [48]. Endothelial (E) selectin can also support rolling and tethering of neutrophils in a similar fashion to P-selectin [49]. The ligand for E-selectin has not yet been fully characterized; however, it may be a uniquely modified mucin known as E-selectin ligand-1 [50]. E-selectin, unlike P-selectin, is not stored intracellularly and therefore peak expression is not seen until 4–6 h after exposure to pro-inflammatory cytokines [51]. Thus, the role of E-selectin may be to maintain neutrophil rolling after P-selectin has been down-regulated [52].

The next step in transendothelial migration is the transition from neutrophil rolling to firm adhesion to the vessel wall. The initiating signal for this may be either a receptor-mediated response to endothelial presented cytokine [53,54] or an event propagated by selectin activation [55], leading to up-regulation of a group of heterodimeric transmembrane glycoproteins on the neutrophil surface known as integrins. Neutrophil binding to activated endothelium is mediated primarily by two integrins that consist of β_2 (CD18) subunits. These are lymphocyte-associated function antigen-1 (LFA-1; CD11a/CD18) and macrophage antigen-1 (Mac-1; CD11b/CD18). A third CD18 integrin, p150,95 (CD11c/CD18) can also promote neutrophil trafficking; however, Mac-1 has emerged as the critical CD18 integrin in many models of neutrophil migration [56,57]. Preformed Mac-1 is stored within neutrophil granules [58] and can be rapidly mobilized to the neutrophil surface after exposure to stimuli such as bacterial peptides including formyl-methionyl-leucyl-phenylalanine (fMLP), LTB_4 and the CXC chemokines such as IL-8 [54,59]. β_2 -Integrins, and especially Mac-1, have high affinity for intercellular adhesion molecule-1 (ICAM-1) [56], an immunoglobulin-like

molecule expressed constitutively in low levels on endothelial cell membranes and rapidly up-regulated following exposure to inflammatory cytokines such as tumour necrosis factor α (TNF- α) and IL-1 β [51,60].

The final step of neutrophil recruitment from the blood stream into the lungs is transendothelial migration; however, the mechanisms of neutrophil extravasation are incompletely understood. Transmigration through endothelial cell monolayers *in vitro* occurs preferentially at tricellular junctions [61] and the immunoglobulin G (IgG) type adhesion molecule, platelet-endothelial cell adhesion molecule-1 (PECAM-1; CD31) appears to be critical [62]. PECAM-1 is found on neutrophils and endothelial cells, where it is concentrated at intercellular junctions [63]. Treatment of neutrophils or endothelial monolayers with antibodies to PECAM-1 can block transmigration [64].

Even less is known of the mechanisms of migration through the subendothelial matrix. Adhesion and migration is accompanied by release of neutrophil-derived proteases [65] and both chemotaxis and migration through artificial substances can be inhibited by antiproteases [66]. However, protease inhibitors appear to have no effect on neutrophil migration through intact endothelial cell monolayers [67].

In COPD, studies examining the expression of the adhesion molecule thought to be important in neutrophil migration from the bronchial circulation have produced conflicting results. Noguera *et al.* [68] demonstrated increased surface expression of Mac-1 (CD11b) in smokers with COPD compared with those with normal lung function. However, Gonzalez *et al.* [69] found similar levels of neutrophil adhesion molecule expression in lungs resected from smokers with and without airflow obstruction, although neutrophil activation during the migration process may have affected these results. Similarly, conflicting evidence exists for the expression of the endothelial ligands for neutrophils in COPD. In one study, increased plasma levels of the soluble adhesion molecules ICAM-1 and E-selectin were demonstrated in COPD patients with chronic bronchitis [70], whereas another found that levels of soluble ICAM-1 were lower in the COPD group compared with healthy controls [71].

Nevertheless, neutrophils from patients with chronic bronchitis and emphysema do demonstrate enhanced chemotaxis across an inert membrane [72] and data from our laboratory show that neutrophil endothelial interactions under flow are increased in smokers with COPD compared with smokers without the disease (Fig. 23.2) [73]. This was associated with increased expression of Mac-1 upon neutrophil stimulation, suggesting that the up-regulation of this molecule is responsible for the enhanced endothelial interactions seen in COPD.

Figure 23.2 The adhesive and migratory response of purified neutrophils from never smokers (NS), healthy smokers (HS), COPD patients with normal levels of α_1 -AT (PiM) and COPD patients with α_1 -AT deficiency (PiZ). Data are mean \pm SE. Black bars indicate total neutrophil-endothelial interactions, open bars indicate adherent neutrophils and light grey bars indicate migrated neutrophils. * $P < 0.05$.

Neutrophil migration in the pulmonary circulation

The basic mechanisms of neutrophil trafficking in the pulmonary circulation are far less well understood but there appear to be differences compared with the systemic circulation.

In normal lungs, the pulmonary capillary bed contains a large pool of marginated neutrophils [74], and in animal models of acute pulmonary inflammation neutrophil sequestration occurs from the pulmonary capillary bed, not from the postcapillary venules [75,76], with no requirement for conventional adhesion molecules [77,78].

Human studies examining the passage of radiolabelled autologous neutrophils through the pulmonary vasculature in patients with stable COPD and in resected lung specimens confirmed slower neutrophil transit times (relative to red blood cells) but no difference in sequestration compared with disease-free controls [79,80]. The exception were neutrophils from COPD patients experiencing an acute exacerbations, where sequestration in the pulmonary vasculature was increased. The clinical relevance of this observation is not clear given that the neutrophilic inflammation seen during exacerbations of COPD occurs predominantly at the bronchial level [81].

The increased transit time and sequestration of neutrophils in the capillary bed is thought to be a result of the need for neutrophils to deform to an oblong shape to pass through the 40–60% of pulmonary capillary segments that are narrower than spherical neutrophils [82]. This delayed

passage of neutrophils through the relatively narrow vessels may be increased further during acute inflammatory responses, as neutrophils become less deformable upon activation [83,84].

Once sequestered in the pulmonary capillaries, neutrophil transmigration can occur through at least two pathways: one that uses the adhesion molecule CD11/CD18 and one that does not. The pathway selected appears to depend upon the stimulus and the level of neutrophil activation. In animal models, stimuli that can induce CD11/CD18-independent neutrophil emigration include *Streptococcus pneumoniae*, *Staphylococcus aureus* and hydrochloric acid. In humans, CD11/CD18-independent neutrophil migration has been demonstrated towards the host-derived chemoattractants IL-8 and LTB₄ but not towards the bacterial-derived peptide fMLP [85,86]. The mechanisms of CD11/CD18-independent migration are not understood; however, γ -interferon might be an important regulator of the response [41].

The only study examining the role of CD18 in transendothelial migration of neutrophils from patients with chronic pulmonary inflammation, including those with COPD, found that the requirement for this adhesion molecule did not differ from control neutrophils [87]. However, these studies were performed using static transwell assays with pulmonary artery endothelium, which has a different adhesion molecule profile to pulmonary microvascular endothelium. This may explain the surprising observation of a higher percentage of migrated neutrophils in the control group compared with both the acute and chronic pulmonary inflammation groups in this study.

Soluble mediators of neutrophil migration

Pro-migratory stimuli for neutrophils can be classified generally as either non-chemotactic cytokines, chemoattractants or chemotactic cytokines (chemokines).

Two of the most important pro-adhesive cytokines that are present in most inflammatory responses are TNF- α and IL-1 β . The macrophage-monocyte is the primary cellular source of TNF- α and IL-1 β , but these cytokines are also produced by airway epithelium, endothelial cells and mast cells [88,89]. Both neutrophils and endothelial cells possess receptors for TNF- α and IL-1 β . Neutrophils respond to TNF- α and IL-1 β by activating and expressing integrins, and likewise, endothelial cells mobilize selectins and up-regulate ICAM-1 [51,90]. Thus, the early appearance of TNF- α and IL-1 β in plasma during inflammation is likely to be critical for the capture and firm adhesion of neutrophils to vascular endothelium. Although TNF- α and IL-1 β are not themselves chemotactic for neutrophils, their exposure to endothelial cells can elicit transendothelial migration through production of endothelial-derived chemoattractants [91].

Sputum levels of TNF- α are increased in smokers with COPD, both in the stable clinical state and during exacerbations [31,92,93]. Similarly, alveolar macrophage release of IL-1 β is increased in COPD [94] and in one study the concentration of IL-1 β in the sputum of patients with chronic bronchitis and bronchiectasis was an order of magnitude higher than TNF- α [95], suggesting an important role for IL-1 β , in conjunction with TNF- α , in the pathogenesis of COPD.

In addition to non-chemotactic cytokine receptors, neutrophils have at least five different receptors for chemotactic stimuli. A number of chemotactic stimuli have been implicated in the pathogenesis of COPD, in particular the potent neutrophil chemoattractant LTB₄ and the chemokine IL-8.

Leukotriene B₄ is produced from arachidonic acid, a major component of cell membranes [96], mainly by monocytes, alveolar macrophages and activated neutrophils. The release of LTB₄ can be stimulated by a number of other inflammatory mediators, including complement factor C5a, IL-1 β , TNF- α , granulocyte-macrophage colony-stimulating factor (GM-CSF), platelet-activating factor (PAF), neutrophil elastase and LTB₄ itself [97,98]. As well as being an important and potent neutrophil chemoattractant, LTB₄ also increases aggregation and chemokinesis of these cells [99]. Its activity is mediated by two sets of neutrophil surface receptors. Low-affinity receptors mediate degranulation and increased oxidative metabolism and their high-affinity counterparts influence aggregation, chemokinesis and increased adherence, via the neutrophil adhesion molecule Mac-1 [59]. LTB₄ can also promote neutrophil transendothelial migration *in vitro* by directly activating endothelial cell monolayers, although the mechanism underlying this observation remains unclear [100].

Interleukin-8 is a 16-kDa protein that is produced by endothelial cells, bronchial epithelial cells, monocytes, macrophages and activated neutrophils [54,101]. It is a potent neutrophil chemoattractant and activator, resulting in up-regulation of the adhesion molecule Mac-1 [59,102]. Production of IL-8 can be stimulated by exposure to IL-1 β and TNF- α [103], cigarette smoke extract [104], bacterial endotoxin [105] and possibly neutrophil elastase [106]. Thus, IL-8 is involved in both the neutrophil adhesive process within the vessel, via its endothelial production and presentation following cytokine stimulation, and chemotaxis into the airway, via the directional gradient found across the bronchial wall resulting from the production of IL-8 by activated epithelial cells, macrophages and neutrophils.

In COPD, a number of studies have demonstrated increased sputum levels of LTB₄ and IL-8 [92,107]. In addition, the concentrations of LTB₄ and IL-8 correlate with markers of neutrophil activation and elastase activity [20] in these patients. Taking these data together suggests an im-

portant role for these two chemoattractants in the neutrophil recruitment seen in COPD. This has been confirmed in two recent studies with an LTB₄ receptor antagonist and mouse anti-IL-8 antibody. Both studies demonstrated that approximately 50% of the chemotactic activity of sputum in COPD is accounted for by LTB₄ and 30% by IL-8 [108,109]. In addition, Woolhouse *et al.* [108] found that sputum concentration of LTB₄, but not IL-8, correlated with overall chemotactic activity, suggesting that LTB₄ is of particular importance with respect to sputum chemotactic activity in the stable clinical state, and may be central to the increased neutrophil recruitment seen in COPD patients (Fig. 23.3).

The remaining sputum neutrophil chemotactic activity, unaccounted for by LTB₄ or IL-8, could come from other chemoattractants such as the chemokines GRO α and

ENA-78, which are known to be present in the bronchial secretions of patients with COPD [110,111]. Other chemotactic agents that could have a role in the airways include C5a [112]; elastase-inhibitor complexes [113]; protein and peptide components of damaged extracellular matrix such as collagen [114], elastin [115] and laminin [116]; α_1 -antitrypsin polymers [117] and bacterial products such as fMLP [118]. However, to date there are no studies examining the contribution of these chemoattractants in the secretions of patients with COPD.

Neutrophil effector function in COPD

Once the neutrophil has passed from the blood stream into the interstitium and then the airways, there are a number of mechanisms through which it can cause the pathological features seen in COPD.

The first and, as discussed above, probably the most important mechanism is via the release of the serine proteinases from the azurophil granules, in particular neutrophil elastase, which leads to the breakdown of connective tissue and subsequent airflow obstruction. The mechanisms by which neutrophils degranulate are not completely understood, but studies have shown that granule release is dependent either on protein kinase C and/or on cyclic guanosine 3',5'-monophosphate-dependent kinase activation [119,120].

It has been known for some time that neutrophils from patients with COPD exhibit greater extracellular proteolysis when compared with those from smokers without the disease [72]; however, it is only relatively recently that studies have helped to explain how neutrophil elastase causes connective tissue damage in patients with COPD, despite normal serum and lung levels of the antiprotease α_1 -AT [121].

Neutrophil elastase is stored within the azurophil granules at a concentration of approximately 5 mmol. Following neutrophil activation, the granules undergo exocytosis and as the enzyme diffuses away from the granule, its concentration decreases. Antiproteases, such as α_1 -AT, inactivate neutrophil elastase on a 1 : 1 molecule : molecule basis. The concentration of α_1 -AT in the interstitium is unknown; however, albumin (which is the same molecular size as α_1 -AT) is thought to be present in the interstitium at approximately 80% of the concentration in the serum [122]. Because the serum concentration of α_1 -AT in healthy subjects is approximately 30 μ mol, the predicted concentration of α_1 -AT in the lung interstitium of healthy subjects should be approximately 24 μ mol, which is 200 times lower than the concentration of elastase in the azurophil granule. Thus, active neutrophil elastase diffuses away from the granule until the concentration has fallen sufficiently for the enzyme to be completely inactivated by the local

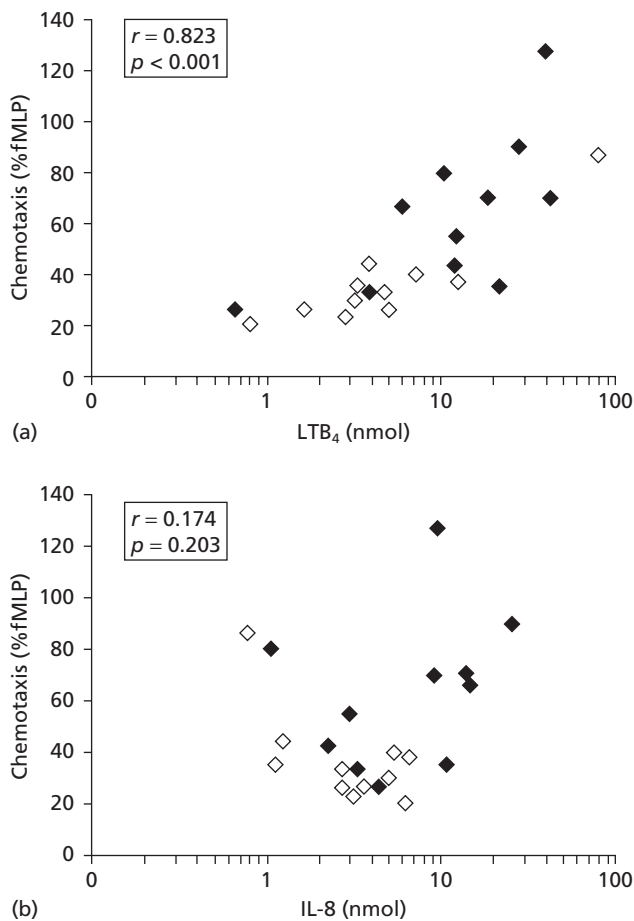

Figure 23.3 Relationship between total chemotactic activity and the contribution made by: (a) LTB₄; and (b) IL-8 in COPD patients with and without α_1 -AT deficiency. Closed symbols indicate patients with α_1 -AT deficiency (PiZ) and open symbols indicate patients with normal α_1 -AT levels (PiM). Correlation coefficients (r) and significance (p) for all data are shown. fMLP, formyl-methionyl-leucyl-phenylalanine; IL-8, interleukin 8; LTB₄, leukotriene B₄.

Figure 23.4 Diagrammatic representation of the mechanism involved in neutrophil elastase (NE) release from a neutrophil azurophil granule. Once the granule undergoes exocytosis from the neutrophil, elastase diffuses away. The high intrinsic concentration rapidly decreases initially and subsequently decreases more slowly. The individual arrows on the figure indicate representative concentrations at given distances from the granule. Note: in patients with normal levels of α_1 -AT, the enzyme activity would be completely blocked at a distance away from the granule when the concentration falls to less than 30 μmol . On the other hand, in patients with α_1 -AT deficiency, the enzyme activity would not be inhibited until it is diffused far enough away for the concentration to fall to 5 μmol .

concentration of α_1 -AT, allowing a degree of tissue damage to occur within the immediate vicinity of the degranulating neutrophil. This theoretical relationship, in conjunction with the increased neutrophilic burden seen within the lungs of patients with COPD, may explain the elastase induced connective tissue destruction that occurs, even in the absence of α_1 -AT deficiency. This process is summarized in Figure 23.4.

The second mechanism of neutrophil-mediated lung destruction in COPD is via the release of oxidative molecules following the neutrophil respiratory burst. The neutrophil respiratory burst results in the release of oxidative molecules, originating from the membrane-bound nicotinamide adenine dinucleotide phosphate (NADPH) oxidase system. Superoxide production starts with the reduction of oxygen by NADPH to form the superoxide radical (O_2^-). These radicals either react spontaneously with water to produce molecular oxygen and hydrogen peroxide, or the process can be catalysed by the enzyme superoxide dismutase. The reduction of hydrogen peroxide to water, or to the highly reactive hyperchlorous acid in

the presence of chloride, is catalysed by myeloperoxidase present in the azurophil granules. These products are usually released into the phagolysosome, where they destroy ingested bacteria. However, the neutrophil products of the respiratory burst also have the ability to damage normal cells directly resulting in cell death [123]. In health, the potential damaging effects of these oxidants are controlled by antioxidants [124]; however, there is evidence of oxidative stress in smoking-related lung disease with reduced plasma antioxidant capacity and increased lipid peroxidation [125]. Furthermore, neutrophils from patients with COPD demonstrate enhanced respiratory burst compared with smokers with normal lung function [68]. In addition, oxidants themselves can be proinflammatory [126,127], hence amplifying the inflammatory process and potential tissue damage.

A schematic summary of the cells and stages thought to be involved in the process of neutrophil recruitment and subsequent inflammation and tissue damage in COPD are shown in Figure 23.5.

The neutrophil as a target for anti-inflammatory therapy

Increasing our understanding of the processes of neutrophil recruitment and activation within the lung during the development and progression of COPD has allowed the identification of a number of potential therapeutic targets. These therapeutic strategies can act at a variety of stages along the pathogenic pathway, including the processes of neutrophil activation, adhesion, transmigration and proteolytic tissue damage.

Cytokine-chemoattractant antagonists

Blockade of cytokines produced early in the inflammatory cascade, such as IL-1 β , TNF- α and PAF, would be expected to abrogate subsequent events including neutrophil adhesion, migration and activation. Humanized TNF- α antibodies have been found to be effective in chronic inflammatory conditions such as rheumatoid arthritis and Crohn disease [128,129], and this approach may be effective in COPD.

Blocking the effects of more distal mediators, such as IL-8, might regulate neutrophilic inflammation more specifically and antibodies directed against IL-8 have been shown to block neutrophil-mediated tissue injury in animal models [130]. Another approach would be to block binding of IL-8 to its neutrophil receptors (CXCR1 and CXCR2) via disruption to the transmembrane spanning structures common to these receptors. Peptides have been developed to prevent the receptor binding of IL-8 [131], although the long-term safety and efficacy of these drugs has yet to be assessed.

Figure 23.5 Schematic summary of the cells and inflammatory mediators involved in the pathogenesis of COPD. Activation of airway macrophages and epithelial cells causes the release of proinflammatory mediators **1** which leads to adhesion molecule upregulation on the endothelial surface and subsequent neutrophil capture (in the bronchial circulation), firm adhesion and transmigration **2**. As the neutrophil migrates through the interstitium and into the airway the release of proteases and oxygen free radicals (O_2^-), leads to connective tissue and epithelial cell damage **3**. The inflammatory cycle is perpetuated by the further release of proinflammatory mediators by activated neutrophils within the airway **4**.

The potent neutrophil chemoattractant LTB_4 is another distal mediator with potential as a therapeutic target in COPD. Indeed, a recent randomized placebo-controlled trial of the LTB_4 synthesis inhibitor BAYx1005 demonstrated modest reductions in some measures of neutrophilic bronchial inflammation in patients with COPD [132]. Potent selective LTB_4 receptor antagonists have now been developed that may prove to be more effective.

Neutrophil adhesion molecule antagonists

Glycomimetics with structural similarities to the saccharide residues on endogenous ligands for L- and P-selectin, such as fucoidan and sialyl-Lewis_x, have been shown to block selectin binding *in vitro* and have been used effectively in a variety of pulmonary disease and injury models [133–135]. Newer generations of glycomimetics are being developed with structural modifications that increase specificity for individual selectins, which may therefore limit inflammation with less potential to disrupt the immune system or repair processes [136], and such an approach may prove to be of benefit in chronic pulmonary diseases such as COPD.

For instance, leumedins are a class of small molecular weight drugs that inhibit CD18-dependent neutrophil adhesion [137] and can block pulmonary leucocyte recruitment in a number of acute inflammatory and allergic conditions [138,139]. The mechanism of action of leumedins is not completely understood, but appears not to be specific to integrin-mediated adhesion [140].

Antiproteases

Given that the final common pathway in the pathogenesis of COPD is thought to be lung destruction by neutrophil elastase, a logical form of therapy would be to supplement or enhance the protective antiprotease screen within the lung. Indeed, this approach has already been taken in patients with α_1 -AT deficiency, and augmentation therapy has proved to be safe [141], although there has yet to be a significantly powered, controlled study to prove that is effective. Synthetic inhibitors of neutrophil elastase have also been developed that inhibit elastase-mediated lung injury in experimental animals [142] and inhibit elastase-induced mucus secretion *in vitro* [143]. There are few clinical studies of such inhibitors in COPD, although one short study showed no overall effect on plasma levels of elastin-derived peptides or urinary levels of desmosine, which are markers of lung elastin destruction [144].

Corticosteroids

The effects of corticosteroids are multicellular, limiting both the production of inflammatory mediators by leucocytes and the response to those mediators by target cells (e.g. other leucocytes, endothelial and parenchymal cells). Glucocorticoids modulate the function of nuclear factor κB (NF- κB) [145], a transcription factor associated with the regulation of an array of genes that code for cytokines and other inflammatory mediators. NF- κB is also involved in

the regulation of the expression of endothelial and leucocyte adhesion molecules [146,147]. In COPD, corticosteroids can reduce the neutrophil chemotactic activity of sputum [148], but neither inhaled nor oral steroids have been shown to have any effect on sputum neutrophil counts, granule proteins or inflammatory cytokines in induced sputum [149,150]. This is consistent with the lack of effect seen with inhaled corticosteroids on disease progression [151], although corticosteroids are effective in preventing and treating acute exacerbations in COPD [152], presumably via some as yet undetermined anti-inflammatory effect.

Non-steroidal anti-inflammatory drugs

The effects of non-steroidal anti-inflammatory drugs (NSAIDs) are most often attributed to their ability to inhibit the inducible form of cyclo-oxygenase-2 (COX-2), which mediates the conversion of arachidonic acid to prostaglandins, thromboxanes and other lipid mediators involved in inflammation and normal physiological responses. Inhibition of the adhesive and migratory processes between neutrophils and endothelial cells can occur after treatment *in vitro* with NSAIDs such as aspirin [153]. *In vivo*, 14 days treatment with the NSAID indometacin can change the population of circulating neutrophils, resulting in reduced chemotaxis and decreased potential to destroy connective tissue [154]. Clinical trials of indometacin in chronic bronchitis have demonstrated reductions in airway prostaglandins, sputum volume and dyspnoea [155]; however, there are currently no published data demonstrating a beneficial effect on disease progression in COPD.

Neutrophil inhibitors

Inhibition of phosphodiesterases (PDE) increases the cyclic adenosine monophosphate (AMP) content of neutrophils and reduces chemotaxis, activation, degranulation and adherence [156–159]. Theophylline is a weak and non-selective PDE inhibitor that has inhibitory effects on neutrophil function *in vitro* [156], and one study has demonstrated reduced sputum neutrophil counts following treatment *in vivo* [160]. The predominant PDE isoenzyme in neutrophils is PDE4 and several selective PDE4 inhibitors have now been developed that may be effective at reducing neutrophil influx and subsequent inflammation in COPD [161–163].

Other neutrophil inhibitors include colchicine, which potently inhibits neutrophil activation, enzyme release and chemotaxis by disrupting cytoskeletal microtubule structure [164]. A controlled trial of colchicine in COPD showed some reduction in neutrophil elastase activity and in an observational study, smokers who were treated with

colchicine had a lower annual decline in lung function than untreated smokers [165]. Macrolide antibiotics, such as erythromycin, also have inhibitory effects on neutrophil function that are independent of their antibiotic actions [166]. These drugs have been shown to be effective in panbronchiolitis [167]; however, there are currently no published data showing efficacy of these agents as anti-neutrophil drugs in COPD.

Conclusions

In conclusion, there is substantial evidence that the neutrophil is central to the pathogenesis of COPD. The neutrophil is the only cell that contains the products that have been shown directly to cause all the pathological features of COPD. It is likely therefore, that even in the absence of α_1 -antitrypsin deficiency, the size, site and extent of neutrophil traffic is of major pathogenic importance. Understanding the mechanisms involved should lead to the identification of potential therapeutic targets and thus amelioration of the neutrophil-mediated inflammatory process.

CHAPTER 24

Lymphocytes

**Simonetta Baraldo, Maria Elena Zanin, Renzo Zuin
and Marina Saetta**

According to the most recent guidelines, COPD is a preventable and treatable disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases, primarily caused by cigarette smoking. Although COPD affects the lungs, it also produces significant systemic consequences [1,2]. A number of studies in recent years demonstrated that, in patients with COPD, a chronic inflammation is present throughout the airways, lung parenchyma and pulmonary vasculature and extends even outside the lung, involving lymph nodes, eventually reaching the systemic circulation [3–7]. The most recent definitions of COPD introduced the concept that inflammation is a key event in the pathogenesis of the disease, highlighting the need for a better knowledge of the mechanisms involved in the perpetuation of the inflammatory response.

It has long been recognized that smoking is the most important risk factor for the development of COPD and that exposure to cigarette smoke can elicit an exaggerated inflammatory response [8,9]. However, only a minority of cigarette smokers develop overt airflow obstruction and the pathogenetic mechanisms are still poorly understood. The aim of this chapter is to review the present knowledge of the inflammatory response in smokers with COPD, with a special focus on lymphocytes. In particular, we first describe how these cells are recruited to the lung in physiological conditions. We then discuss how lymphocytes could be involved in the development of structural alterations in the airways and lung parenchyma, thus promoting the establishment of airflow limitation. Finally, we consider how these events evolve when COPD progresses towards its most severe stages.

Lymphocytes in immune responses

The physiological function of the immune system is defence against infectious organisms and potentially harmful foreign substances. The pulmonary immune system is continuously exposed to pathogens and foreign antigens within inhaled air. It is therefore essential that cells orchestrating immune responses within the lung can correctly determine whether an antigenic molecule is potentially dangerous and can build an appropriate defence. The immune system can be thought of as having two lines of defence: the first represents a non-specific (no memory) response to antigens (the innate immune system); and the second displays a high degree of memory and specificity (the adaptive immune system). The innate immune system is based on the cooperation of several cell types and proteins, including epithelial cells, macrophages, neutrophils, dendritic cells, natural killer (NK) cells and complement. As the innate system represents the first line of defence to an intruding pathogen, the response evolved has to be extremely rapid. However, the innate system is unable to memorize the same pathogen, should the body be exposed to it in the future. Conversely, adaptive immune responses, which require activation of lymphocytes, have evolved to provide a more versatile mean of defence. The adaptive immune system has much slower temporary dynamics, but it possesses a high degree of specificity and evokes a more potent response to a secondary exposure to the pathogen [10].

In normal conditions, most infectious agents or foreign antigenic material may be removed by the innate immune system without requiring an inflammatory response. By contrast, when antigenic molecules are recognized as dangerous, antigen-presenting cells in the lung initiate the adaptive inflammatory response displaying the antigen to

T lymphocytes. Moreover, by releasing chemokines and cytokines, they trigger the expansion of antigen-specific B and T cells in the secondary lymphoid tissues or within the alveolar spaces [11]. Antigen-specific lymphocytes have evolved a number of effector mechanisms to fight foreign antigens, including direct cytotoxicity and secretion of lymphokines that can activate themselves or other pulmonary immunocompetent cells.

As pointed out by Cosio [12], it is important to highlight that the innate and the adaptive immune responses are not completely isolated from each other, but act as an integrated system of host defence in which numerous cells and molecules function cooperatively. Two important links exist between innate and adaptive immunity. First, the innate response to pathogens stimulates adaptive immune responses and influences their nature. Secondly, the adaptive immune response uses many of the effector mechanisms of innate immunity to eliminate microbes or other antigenic substances, enhancing the antimicrobial activity of the innate immunity system.

To have a clear view of mechanisms leading to lymphocyte accumulation and activation in COPD, it is important to review how these cells are recruited to the lung in physiological conditions. According to their specific properties and functions, human lymphocytes are functionally compartmentalized in the lung. Lung lymphoid tissue includes the bronchus-associated lymphoid tissue (BALT) as well as lymph nodes that receive drainage from the nose or lung [13]. In addition, lymphoid follicles are located throughout the bronchial tree as far down as the small bronchioles and are constituted by B-cell germinal centres surrounded by T cells, macrophages and dendritic cells (DC). Naive B and T cells keep moving continuously in the lymphoid tissue until they respond to their cognate antigen, proliferate and differentiate in memory and effector lymphocytes. Moreover, the activation of T cells after antigen presentation results in up-modulation of several adhesion molecules and homing receptors, which are necessary for migration of T cells to different compartments in the lung.

Lymphocytes in COPD

The inflammatory cells of the adaptive immune response (mainly T and B lymphocytes), which have evolved to protect individuals from infection and eliminate foreign substances, should be promptly removed as soon as the originating stimulus disappears. However, in some situations, as in COPD, the inflammatory response may persist and cause tissue injury and disease. We describe below the mechanisms through which lymphocytes may promote structural changes in the airways, lung parenchyma and pulmonary arteries of smokers with COPD.

Central and peripheral airways

To understand the immune reaction to cigarette-smoke exposure, it is important to realize that innate and adaptive immune responses are components of an integrated system. Cigarette smoke produces a clear innate immune response, as elegantly shown by Niewoehner *et al.* [14], who demonstrated that an inflammatory reaction is already present in the peripheral airways of young smokers who experienced sudden death outside of the hospital setting. Early lesions already present in young smokers included an inflammatory infiltrate in the airway wall consisting predominantly of mononuclear cells and clusters of macrophages in the respiratory bronchioles. Interestingly, the authors reported that these lesions were present in the absence of noteworthy tissue destruction and fibrosis, and suggested that this stage of the disease could still be largely reversible. Therefore, the great majority of smokers develop a chronic non-specific inflammation that should be interpreted as the innate immune response to cigarette smoke damage. In those smokers who develop COPD, beside the innate immune response, the adaptive immune response involving B and T cells becomes activated. These same smokers would also develop structural abnormalities in peripheral airways and parenchyma, which contribute to airflow limitation by increasing peripheral airway resistance and decreasing the elastic recoil of the lung. The susceptibility factors determining those smokers who would develop COPD are still poorly understood. These may involve several components, such as genetic predisposition (i.e. genetic control of the balance of helper and cytotoxic T lymphocytes, polymorphisms of cytokines and growth factors) or environmental conditions triggering or maintaining the disease (i.e. viral or bacterial infections and pollutants). It has been proposed that perpetuation of the inflammation initiated by cigarette smoke and its shift toward an adaptive response may lead to the development of structural changes in the lung, which in turn may promote the establishment of airflow limitation and its subsequent progression [15].

In central airways, the development of airflow obstruction is associated with an increase of macrophages and T lymphocytes in the airway wall and a specific recruitment of neutrophils in the airway lumen and glands [16–18]. Because the adhesion molecules E-selectin and ICAM-1 are up-regulated on submucosal vessels and on bronchial epithelium of smokers with COPD [19], these molecules seem to be important for neutrophil recruitment. Interestingly, mediators released by neutrophils may stimulate the activity of mucus-secreting cells as neutrophil elastase, which is a remarkably potent secretagogue. It is therefore conceivable that neutrophils could be crucial for the development of mucus hypersecretion in central airways, which

are indeed the main site responsible for mucus production expressed clinically as chronic bronchitis.

Conversely, peripheral airways are the major site of increased resistance in smokers, as elegantly shown by the pioneering work of Hogg *et al.* [20], who proposed that peripheral airways (less than 2 mm in diameter) represent the lungs 'quiet zone' where disease can accumulate for many years before becoming clinically relevant.

The main pathological lesions associated with the development of COPD in peripheral airways include structural changes, such as epithelial metaplasia, airway wall fibrosis, smooth muscle hypertrophy and inflammatory changes, mainly increased numbers of CD8⁺ T and B lymphocytes [3,5,21,22] (see Plate 24.1; colour plate section falls between pp. 354 and 355).

Inflammation, fibrosis and smooth muscle hypertrophy, by increasing the thickness of the airway wall, may facilitate uncoupling between airways and parenchyma, therefore promoting airway closure. In addition, airway wall inflammation could contribute to the destruction of alveolar attachments (i.e. the alveolar walls directly attached to the airway wall), allowing the airway wall to deform and thus narrowing the airway lumen. This hypothesis is supported by the observation that, in smokers, the destruction of alveolar attachments is correlated with the degree of inflammation in peripheral airways [23]. This finding suggests a pathogenetic role for airway inflammation in inducing destruction of alveolar attachments. It is possible that mediators released by inflammatory cells may weaken the alveolar tissue and facilitate its rupture, particularly at the point where the attachments join the airway wall, where the mechanical stress is maximal.

CD8⁺ T lymphocytes, which are increased not only in peripheral but also in central airways and in lung parenchyma [5,6,24], seem to have a crucial role in the pathophysiology of COPD. Traditionally, the major activity of CD8⁺ cytotoxic T lymphocytes has been considered the rapid resolution of acute viral infections, and viral infections are a frequent occurrence in patients with COPD. The observation that people with frequent respiratory infections in childhood are more prone to develop COPD supports the role of viral infections in this disease [25]. It is conceivable that, in response to repeated viral infections, an excessive recruitment of CD8⁺ T lymphocytes may occur and damage the lung in susceptible smokers, possibly through the release of tumour necrosis factor α (TNF- α) and perforins [26]. On the other hand, it is also possible that CD8⁺ T lymphocytes are able to damage the lung even in the absence of a stimulus such as viral infection, as shown by Enelow *et al.* [27], who clearly demonstrated that recognition of a lung 'autoantigen' by cytotoxic T cell may directly produce a marked lung injury. Taking into account these findings, it can be hypothesized that the

CD8⁺ cytotoxic T-cell accumulation observed in COPD could be a response to an 'autoantigenic' stimulus induced by cigarette smoking [12] (see Plate 24.2; colour plate section falls between pp. 354 and 355).

To better characterize the nature of the inflammatory response present in COPD, the pattern of cytokine profile and chemokine receptor expression has been recently investigated. A current paradigm in immunology is that the nature of an immune response to an antigenic stimulus is determined largely by the pattern of cytokines produced by activated T cells. Type 1 T cells express cytokines, such as γ -interferon (IFN- γ), crucial in the activation of macrophages and in the response to viral and bacterial infections, whereas type 2 T cells express cytokines, such as interleukin 4 (IL-4) and IL-5, involved in immunoglobulin E (IgE) mediated responses and eosinophilia characteristic of allergic diseases. It has recently been shown that the CD8⁺ T cells infiltrating the peripheral airways in COPD produce IFN- γ and express CXCR3 [28], a chemokine receptor that is known to be preferentially expressed on type 1 cells. Moreover, CXCR3 expression is paralleled by a strong epithelial expression of its ligand CXCL10, suggesting that the CXCR3–CXCL10 axis may be involved in the recruitment of type 1 cells in peripheral airways of smokers with COPD. Recently, Grumelli *et al.* [29] confirmed the presence of CXCR3 on lymphocytes isolated from smokers with COPD. Moreover, they extended those findings by showing that the interaction of CXCL10 with CXCR3 drives the release of matrix metalloproteinase 12 (MMP-12) by macrophages. Because MMP-12 is a potent enzyme which degrades elastin and can cause lung tissue destruction, these data suggest a possible mechanism through which Th1 lymphocytes can drive the progression of emphysema, thus relating the inflammation in peripheral airways to the alveolar wall destruction.

Lung parenchyma and pulmonary arteries

Emphysema is one of the most important pathological hallmarks of COPD, defined anatomically as a condition of the lung characterized by permanent abnormal enlargement of the respiratory airspaces, accompanied by destruction of their walls without obvious fibrosis. Although emphysema has long been recognized as a key component of COPD, the pathogenesis of parenchymal destruction remains enigmatic. The most widely accepted hypothesis relates emphysema to an imbalance of the lung protease–antiprotease system. This hypothesis is based on the observation that activated inflammatory cells release proteases that, overwhelming local antiprotease activity, can destroy lung parenchyma. In particular, neutrophils and macrophages, which are activated by cigarette smoking, are potential sources of proteases such as leucocyte elastase

and MMPs, which can damage lung cells and degrade the interstitium (e.g. elastin, collagen, proteoglycans). However, because many cigarette smokers and patients with other inflammatory lung diseases (pneumonia and acute respiratory distress syndrome, ARDS) do not develop significant lung destruction despite a striking inflammatory process, this hypothesis may not fully explain the loss of lung tissue in cigarette smoking-induced emphysema.

There is recent evidence that parenchymal destruction is associated with the presence of an inflammatory process in the alveolar walls [30–32], consisting predominantly of CD8⁺ T lymphocytes [5]. The observation that these cells are increased in the lung parenchyma of smokers with COPD and show a significant correlation with the degree of airflow obstruction is intriguing and supports the notion that tissue injury may be dependent on T-cell activity. One of the most important consequences of the effects of cytotoxic CD8⁺ T lymphocytes is the apoptosis of target cells, and it would not be surprising that apoptosis has a role in the destruction of lung tissue in patients with emphysema [32]. Majo *et al.* [31] have reported that, in smokers with emphysema, both the degree of apoptosis and the number of CD8⁺ T cells in the alveolar walls increased in parallel with the amount of cigarette smoke inhaled. It can therefore be hypothesized that the proliferation of cytotoxic CD8⁺ T lymphocytes observed in smokers with COPD may promote lung destruction by inducing apoptosis of alveolar wall cells.

The structural changes occurring in the lungs of patients with COPD may have an important effect on the pulmonary circulation. Indeed, pulmonary hypertension and cor pulmonale are common sequelae to chronic airflow obstruction, but the precise mechanisms of increased vascular resistance are unclear. Potential causes of pulmonary hypertension in COPD include emphysematous destruction of the capillary bed, remodelling of pulmonary vessels and hypoxic pulmonary vasoconstriction [3].

In the pulmonary arteries of subjects with COPD, the most consistent morphological change is the thickening of the intimal layer [33,34], produced by the proliferation of smooth muscle cells and by the deposition of both elastic and collagen fibres. Less frequently, some authors reported a moderate degree of muscular hypertrophy [35]. Endothelium has a crucial role in the regulation of vascular cell growth and tone, through the release of endothelium-derived relaxing factors [36]. Endothelial dysfunction, which results in an impaired release of these factors, has been shown in patients with COPD, even in the absence of hypoxaemia [37]. These functional and structural changes in pulmonary arteries are associated with the infiltration of inflammatory cells, mainly CD8 T lymphocytes, in the adventitial layer [5,38]. This observation supports a possible

role for these cells in inducing the vascular alterations in patients with COPD. As pointed out by Barbera *et al.* [33], it is possible that endothelial damage by cigarette smoke components is the first vascular alteration occurring in COPD. This early alteration may predispose smokers to develop further vascular damage as a result of additional factors, such as hypoxia and inflammation, ultimately leading to pulmonary hypertension.

Lymphocytes in severe COPD

COPD is a progressive disease that, in a minority of subjects, may worsen toward a very severe stage. It has been shown that, in COPD patients, the inflammatory response in the lung enhances as airflow obstruction progressively worsens. Two pioneering studies examined the lung pathology in patients with severe COPD undergoing lung volume reduction surgery [39,40]. Retamales *et al.* [39] demonstrated that there is an increase in the intensity of the inflammatory response in the alveolar walls and alveolar spaces of these patients, suggesting that the lung inflammation induced by cigarette smoking is amplified in severe emphysema. In a subsequent study, we extended those findings by demonstrating that in severe stages of COPD there is an amplification of the inflammatory response even in the peripheral airways. This enhanced airway inflammatory process correlated with the degrees of airflow limitation, lung hyperinflation, CO diffusion impairment and radiological emphysema, suggesting that the inflammatory response could have a crucial role in the clinical progression of the disease [40]. More recently, Hogg *et al.* [22] examined lung specimens from a large population of smokers, evaluating the evolution of pathological changes as airflow obstruction progressively worsened. The authors elegantly showed that the progression of COPD (from GOLD stage 0 to GOLD stage 4) [2] was associated with increased mucus production in peripheral airways, thickening of the airway wall and amplification of the inflammatory response, mainly because of an increase in CD8⁺ T and B cells. Moreover, they showed that, in patients with the most severe stages of COPD, inflammatory cells in the airway wall organize into lymphoid follicles to facilitate antigen presentation to the cells of the adaptive immune response. The authors suggested that these follicles represent an adaptive immune response, which may develop in relation to microbial colonization and infection occurring in the later stages of COPD.

Subjects with severe COPD are notoriously prone to develop exacerbations of the disease, which are a major cause of morbidity and mortality, being associated with a significant health and economic burden through hospital

admission and absenteeism from work [2]. Although exacerbations typically punctuate the progression of COPD, their role was underestimated until the study by Donaldson *et al.* [41] demonstrated that the frequency of acute exacerbations contributes to long-term decline in lung function. The authors showed that patients with COPD who suffered frequent exacerbations experienced a significantly greater decline in forced expiratory volume in 1 s (FEV_1) than patients who had infrequent exacerbations. The aetiology of COPD exacerbations has not been established, although there is increased evidence that both bacterial and viral infections may have a role [42,43]. The precise mechanism by which these respiratory infections may induce COPD exacerbations are poorly understood. Examination of patients during exacerbations of COPD by collecting bronchial biopsies, bronchoalveolar lavage and, more recently, spontaneous or induced sputum showed increased airway inflammation and elevated levels of airway inflammatory cytokines [44–46]. In particular, exacerbations are characterized by a marked recruitment of neutrophils, which is associated with an increased expression of IL-8, myeloperoxidase and TNF- α , suggesting a pathogenetic role for bacterial infection. In mild exacerbations of COPD, neutrophilia is paralleled by a marked eosinophilia, which is associated with up-regulation of the eosinophil chemoattractants eotaxin and RANTES [46,47]. Viral infections are the most likely causes of this eosinophilia, because respiratory viruses are able to stimulate the production of both eotaxin and RANTES. There is also evidence that RANTES may act synergistically with CD8⁺ cells to enhance apoptosis of virally infected cells. As suggested by Zhu *et al.* [47], when CD8⁺ cells predominate, as in stable COPD, the increase in RANTES occurring during exacerbations may promote tissue damage mediated by CD8⁺ cells, encouraging the development of emphysema. In this way, repeated exacerbations resulting from viral infections may accelerate the lung function decline in smokers whose CD8⁺ T-cell numbers are already increased. This hypothesis is supported by the recent observation that, as mentioned above, exacerbation frequency is an important determinant of lung function decline in COPD [41].

Finally, it is important to highlight the need for a better understanding of the mechanisms regulating the interaction between the acute inflammation activated during exacerbations and the underlying inflammatory response in patients with COPD. This is a critical issue when considering that hospital admission for severe exacerbations of COPD is associated with a mortality rate of 49% at 2 years, a dramatic figure resembling that of lung cancer [48]. This knowledge could help to prevent or treat exacerbations and hopefully to improve the otherwise inexorable clinical outcome of these patients.

CHAPTER 25

Cytokines

Jack A. Elias and Robert J. Homer

Chronic obstructive pulmonary disease (COPD) is a pressing clinical problem. In the USA, it affects 16 million people including 4–6% of males and 1–3% of females over 45 years of age, accounts for 13% of hospitalizations and is the fourth leading cause of death. In addition, despite antismoking campaigns, approximately 48 million people in the USA smoke cigarettes and 3000 people, mostly teenagers, take up the habit each day. Worldwide, 1.5 million deaths per year due to COPD are predicted in China alone over the next half century. Thus, COPD is and will continue to be a major health care issue.

The GOLD guidelines recognize COPD for the first time to be a chronic inflammatory condition [1]. Cytokines are extracellular signalling peptides critically important in the regulation of inflammation as well as having important effector functions of their own. Cytokines generally are produced in patterns characteristic of a particular disease. A description of the cytokines involved in COPD would not only further our understanding of the basic biology of the process, but would also shed light on clinical subgroups of patients and would provide novel targets for therapeutic intervention.

A basic understanding of cytokine biology is needed before discussing their role in COPD [2]. Cytokines can be divided into several subgroups including inflammatory cytokines, immune cytokines, chemokines and anti-inflammatory cytokines. Inflammatory cytokines include tumour necrosis factor α (TNF- α) and interleukin 1 β (IL-1 β). These cytokines are characterized by participation in virtually any non-specific inflammatory process. They are made by a wide variety of cells, although IL-1 β and TNF are principally made by macrophages. They induce a variety of acute phase reactions including fever, leucocytosis, production of other cytokines from a variety of cells, and expression of adhesion molecules on endothelium. Chemokines are important chemoattractants and growth factors. Biochemically they are generally in the 8–10 kDa

range and can be subclassified into four different structural families. The two most important subfamilies are the CC and the CXC families based on the presence of two cysteine residues either adjacent to each other (CC family) or separated by another amino acid (CXC family). The CC chemokines including eotaxin, RANTES and macrophage chemotactic protein-1 (MCP-1) are involved in chemoattraction of eosinophils, monocytes and T cells and function through the CCR family of receptors. The CXC chemokines including IL-8, GRO- α , and ENA-78 are involved in the recruitment and activation of neutrophils and function through the CXCR family of receptors. Immune cytokines include interleukin-4 (IL-4), IL-13 and γ -interferon (IFN- γ). These cytokines are produced predominantly, although not exclusively, by T cells and are generally thought to reflect specialized differentiation of T cells into Th1 (IFN- γ) and Th2 (IL-4, IL-13) subsets. Th1 T cells are thought to be critically important in resistance to intracellular infections such as tuberculosis while Th2 T cells are thought to be critically important in parasitic infections and allergy. Cytolytic T cells may have similar divisions into Tc1 and Tc2 cells. Cytokines such as IL-10 and transforming growth factor β (TGF- β) are generally considered anti-inflammatory and may be critically important in so-called regulatory T cells.

Expression in human disease

Investigators have attempted to define the inflammatory profile of COPD by examining the inflammatory cell and cytokine pattern seen in these patients. The interpretation is complex because the function of each cytokine depends on the overall inflammatory context (e.g. the presence of other cytokines). Neutrophils, T cells, macrophages and eosinophils are involved in the inflammatory response in patients with COPD. However, the importance of each is difficult to ascertain because of confounding influences

relating to methods of assessment (sputum vs bronchoalveolar lavage [BAL] vs biopsy), site of assessment (central vs peripheral airway vs parenchyma) and the compartmentalization of the inflammation in these patients [3]. As a result of the latter, neutrophils are more readily appreciated in sputum and BAL than biopsies, eosinophils are seen with equal efficacy in all assessments and lymphocytes are predominantly noted in tissues [3–5].

It is not known whether this reflects differences in transit time in tissue or transit from other anatomical sites, such as from airway rather than parenchyma. Another major problem is interpreting the results with appropriate control groups. Many studies have attempted to include patients with COPD, ‘healthy’ smokers and non-smokers. However, because all studies to date have been cross-sectional rather than longitudinal, it is not clear whether some of the ‘healthy’ smokers simply were identified early in their disease progression and ultimately will become ‘unhealthy’ smokers. Finally, because of COPD clinical heterogeneity, it is hard to know how comparable different patient groups are among different studies.

Studies using BAL have demonstrated at least a fivefold increase in cell recovery with 95% or more of these cells being macrophages. Increases in neutrophil recovery have also been noted [3]. Comparisons of central airway biopsies from smokers and non-smokers demonstrate increased numbers of macrophages and T lymphocytes, without significant differences in neutrophils, eosinophils or mast cell [3,6]. In addition, a number of studies have demonstrated that eosinophilia is a prominent finding in sputum, BAL and tissues from patients with COPD during exacerbations [3,7] and that eosinophilia can be seen in the submucosa of bronchioles from smokers [8]. Eosinophils may be present in some patients, which may correlate with corticosteroid responsiveness [7]. Eosinophil degradation products are found in virtually all COPD patients, however, in levels higher than in asthmatics [9]. It has been suggested that the discrepancy between the number of cells vs cell products is caused by increased cell death, possibly because of concurrent presence of neutrophils. In patients with exacerbations of COPD or severe COPD, increases in neutrophils have been noted [3].

A mononuclear inflammatory response has also been noted in biopsies from the peripheral airways and parenchyma of smokers [10,11]. Even after smoking has ceased, the inflammatory response continues [12]. Importantly, comparisons of tissues from smokers with and without COPD demonstrated that many of the lymphocytes in COPD tissues are CD8⁺ cells [11]. At present it is not clear if these CD8⁺ cells are the result of the recurrent viral infections experienced by these patients [11] or perhaps associated with an occult viral infection. One group has long proposed that occult adenoviral infection is related to COPD and has shown that there is a correlation of number

of CD8 cells and of number of epithelial cells expressing adenoviral E1A protein [13]. Experimentally, coinfection with adenovirus increases CD8 cells in a smoking model [14]. CD8⁺ cell number correlates directly with the number of pack-years of cigarette smoke exposure [11].

In an attempt to understand the importance of these cell populations, investigators have looked for correlations between their presence and number, and disease severity. Lymphocyte counts correlate directly with indices of alveolar destruction [15] and the number of CD8⁺ cells correlates with the degree of airflow limitation [6,11]. The importance of neutrophils is less clear with correlations between neutrophil number and airflow limitation [3], and neutrophil number and integrity of pulmonary function being reported [15]. In the latter study, it was proposed that, as long as the inflammatory response was composed of granulocytes, there was no destruction of the lung.

The lymphocytes express CXCR3, a chemokine receptor preferentially expressed on Th1 lymphocytes [16,17]. The number of CXCR3⁺ cells in the epithelium and submucosa is increased in smokers with COPD compared with non-smoking subjects, but not compared with smokers with normal lung function. Immunoreactivity for IP10, the ligand for CXCR3, is present in the bronchiolar epithelium of smokers with COPD but not in the bronchiolar epithelium of smoking and non-smoking control subjects. Most CXCR3⁺ cells coexpressed CD8 and produced IFN- γ [16,17]. The Th1 cells also show evidence of activation with increased expression of the transcription factor STAT-4 [18]. This is consistent with the demonstration that the adoptive transfer of Th1 cells to the lung elicits a neutrophilic inflammatory response [19]. A Th1 predominance can also be seen in peripheral blood [20]. Experimentally, IFN induces emphysema by itself (see below). CD8 T cells also make granzyme and perforins which may injure the lung. Finally, these cells may either make cytokines, which recruit other inflammatory cells that injure the lung, or they may induce parenchymal cells to produce such signals [21].

Concentrations of TNF- α , IL-1 β , IL-6, IL-8 and MCP-1 are elevated in the lungs of smokers [22–24]. Furthermore, IL-1 β and IL-8 are elevated in a cigarette dose-dependent manner and TNF- α and IL-8 are elevated in the patients with COPD compared with the smoking and non-smoking control subjects [22,23]. TNF is particularly important as it activates macrophages to produce proteases ([25] and see below). IL-8 may be the most significant of the neutrophilic chemokines. Significant correlation was found in lavage fluid of COPD patients between IL-8 and neutrophils [4]. Of five chemoattractants examined in one study (IL-8, ENA-78, leukotriene B₄ which are primarily chemotactic for neutrophils; MCP-1 and macrophage inflammatory protein-1 α [MIP-1 α] which are predominantly chemotactic for mononuclear leucocytes) only the level of IL-8 in BAL fluid clearly distinguished between subjects with and

without emphysema among current smokers [26]. Both GRO- α and MCP-1 are also overexpressed in patients with COPD but not healthy smokers or controls [27].

Not only are there increased amounts of cytokines in COPD lungs at baseline, but lung macrophages from patients with COPD can be stimulated to produce enhanced amount of IL-8, TNF and IL-10 [25]. Other CXC chemokines (GRO- α , ENA-78) also show enhanced release [28]. *In vitro*, cigarette smoke causes increased expression of IL-8 and G-CSF (neutrophilic activity) and MCP-1 (monocytic activity) by bronchial epithelial cells, and TNF and IL-6 by alveolar macrophages [29–31]. Not only does smoke cause enhanced release of cytokines from COPD macrophages, but IL-10 inhibits release of proteases in macrophages from controls but not smokers [25].

COPD is characterized by recurrent exacerbations during which there is an acute decline in respiratory function. During these exacerbations, eosinophils and T lymphocytes represent common features in the airways. Despite the presence of eosinophils, no increased IL-5 is seen in tissue [32]. Results have differed among groups concerning other products known to regulate eosinophils, with either eotaxin or RANTES correlating with pulmonary eosinophilia [33–35]. All of the IL-4 and IL-5 positive T cells were CD4 and none were CD8.

Recently, it has been recognized that systemic effects are commonly seen in patients with COPD. These effects are clinically relevant because they modify and can help in the classification and management of the disease [36]. These include affective disorders, cardiovascular and musculoskeletal abnormalities, and metabolic and nutritional disturbances. At least some of these may be caused by systemic levels of cytokines produced in the lung. It is known that patients with COPD have increased skeletal muscle atrophy and apoptosis [37]. Circulating levels of TNF- α may cause increased apoptosis of skeletal muscle as well as weight loss [38–41]. Some authors have associated hypoxia per se with production of TNF- α or associated greater energy expenditure to TNF- α levels [42–45].

Another approach to determine the role of cytokines in COPD is to look at genetic polymorphisms that alter expression or activity of these products [46]. TNF- α polymorphisms have attracted considerable attention [47–55]. Unfortunately, no consensus is apparent, with some papers strongly supporting a claim of association and others opposing one. Fewer papers have examined other cytokines. Polymorphism in the *IL4RA* gene has been associated with accelerated decline in lung function [56]. In this study, association with IL-13 was much weaker. Other studies have shown a stronger association with IL-13 polymorphism [57]. The redundancy of the cytokine or inflammatory system may make it impossible to see any but the strongest effects unless enormous populations are examined.

Experimental models of emphysema

It is crucial to have a theoretical understanding of the biology of emphysema in order to interpret the results of necessarily descriptive human data and to guide future human experimentation. This requires intensive analysis of animal models. Groups have taken a variety of approaches to this problem [58]. The most straightforward approach is simply to expose an appropriate animal to cigarette smoke. This model has the advantage of being perhaps the most relevant but is very slow and the effects are relatively small. Some groups still use intratracheal applications of protease, because it is more rapid than cigarette smoke exposure and effects are large. The most recent approach involves genetic modification of mice, either through transgenic overexpression or knockout of specific genes. A potential drawback of genetic manipulation of mice is that development-dependent phenotypes must be distinguished from acquired adult-onset phenotypes more relevant to human COPD. One group has approached this problem by use of tightly controlled externally regulated promoters [59]. Other groups have simply ensured that any effect is not apparent until adulthood. We discuss only those models most relevant to the role of cytokines in COPD.

Any description of COPD ultimately requires an understanding of the relationship of proteases, inflammation and cytokines. The current dominant model in emphysema is the so-called protease–antiprotease hypothesis [60]. In this concept, the normal lung is believed to be protected by an antiprotease ‘shield’ which negates the function of proteolytic enzymes that are released into the airway or parenchyma. The increase in proteinase burden is thought to derive from inflammatory cells which are recruited to the lung in response to cigarette smoke and possibly other agents. Ineffective or disordered repair of elastic fibres and or collagen and oxidant-induced injury may also contribute to the pathogenesis of these disorders [61].

This classic model suggests that proteases work primarily via proteolytic digestion of the extracellular matrix, particularly elastin. This theory has been challenged recently by the concept of lung apoptosis or vascular insufficiency as a major source of lung parenchymal loss [62,63]. The two approaches may be reconciled because it is possible that proteases may contribute to tissue destruction by promoting apoptosis [64,65]. Direct experimental evidence also suggests that proteases are upstream from at least a portion of the inflammatory response [66,67].

The specific proteases and antiproteases involved in COPD are still unclear [60]. Candidate proteases include members of the serine protease family (e.g. neutrophil elastase [NE]), cysteine protease family (e.g. cathepsin B) and the matrix metalloproteinase family (MMPs, e.g. MMP-12) [68]. The MMPs have attracted considerable

attention because expression of various MMPs are seen in smokers' lungs but not in controls, genetic polymorphisms of MMPs have been implicated in human emphysema and overexpression of MMP-1 in the murine lung leads to acquired adult-onset emphysema [58,69–74]. Numerous antiproteases have also been implicated in the control of pulmonary proteolysis. They include α_1 -antitrypsin, secretory leucocyte protease inhibitor (SLPI) and elafin (inhibitors of various serine proteinases), α_2 -macroglobulin (a broad-spectrum protease inhibitor) and the tissue inhibitors of metalloproteinases (TIMPs). Members of the cystatin superfamily may also be important [60]. Mice deficient in TIMP-3 develop spontaneous air space enlargement in the lung which is evident at 2 weeks after birth and progresses with the age of the animal [75].

IL-13 and IFN- γ

Although cigarette smoke exposure is the single most important predictor of the development of COPD after age 35, it is important to appreciate the complex nature of the relationship between COPD and cigarette smoke. Population-based studies such as the Lung Health Study, Normative Aging Study and epidemiological studies from the Netherlands have demonstrated that asthma and airways hyperresponsiveness (AHR) are independent risk factors for the development of COPD and for a COPD phenotype characterized by the accelerated loss of pulmonary function [76–79]. Rapid loss of lung function is also seen in asthmatic patients who smoke. The forced expiratory volume in 1 s (FEV_1) decline experienced by these patients is greater than that in non-asthmatic smokers or asthmatic non-smokers [7,80]. Smokers can also have elevated immunoglobulin E (IgE) levels and elevated levels of circulating eosinophils. In these studies, eosinophilia correlates inversely with pulmonary function, highlighting a group of patients that experience a rapid loss of pulmonary function [79]. These sorts of observations led, in 1961, to the formulation of the 'Dutch hypothesis', which proposes that the distinctions between COPD and asthma are not absolute and that some of the mechanisms that are responsible for asthma are also important in the pathogenesis of COPD. This hypothesis points to endogenous factors including AHR and atopy as markers of a basic disturbance or constitution that predisposes to the development of chronic non-specific obstructive lung disease. This contrasts with the 'British hypothesis', which focuses strictly on exogenous factors such as exposure to cigarette smoke and postulated that recurrent airway infections are responsible for the generation of chronic airflow limitation in COPD.

IL-13 is a 12-kDa protein product of a gene on chromosome 5 at q31 which is produced in large quantities by

activated Th2 cells and is thought to be critically important in allergic responses including asthma [81]. It has also been demonstrated in the airways of patients with COPD with mucus hypersecretion [82]. In light of the Dutch hypothesis, which suggests a role for allergy in COPD, studies were undertaken to define the chronic *in vivo* effector functions of IL-13 in the airway [83]. An externally regulated system was used to overexpress IL-13 in lung. These mice showed a significant increase in induced IL-13 protein production within 48 h and steady state levels of IL-13 (0.5–1.5 ng/mL in BAL fluid) within 96 h. The animals' lungs developed an inflammatory infiltrate over approximately 2–3 weeks, which was characterized by increased numbers of macrophages, lymphocytes and eosinophils (see Plate 25.1; colour plate section falls between pp. 354 and 355). During this interval, massive alveolar septal destruction and alveolar enlargement also occurred as shown by both casual inspection and morphometry. Alveolar enlargement could be appreciated within 48 h, was prominent within 7 days and continued to progress for at least 1 month. Furthermore, comparable to human COPD in which total lung capacity is increased, the transgenic mice showed a two- to threefold increase in lung volume. The overinflation was accompanied by enhanced pulmonary compliance, again as seen in human disease. Airway changes included fibrosis and mucus metaplasia. Similar to some patients with COPD, these mice had marked airway hyperresponsiveness.

To begin to understand the mechanism(s) of IL-13-induced emphysema, studies were undertaken to determine if IL-13 altered the levels of, and/or bioactivities of, a variety of proteases (Table 25.1). By a variety of techniques, IL-13 was a potent stimulator of MMP-2, -9, -12, -13 and -14. The alterations in MMP-9 and MMP-12 were quite prominent. In contrast, IL-13-induced alterations in the levels of mRNA encoding MMP-7 were not detected. Interestingly, immunohistochemistry (IHC) demonstrated that MMP-12 was most prominent in alveolar macrophages, while MMP-9 staining was most prominent in epithelial and other stromal cells. Increases in the levels of mRNA encoding cathepsin B, K and L and lesser increases in S were also seen. Antiproteases were also affected, because α_1 -antitrypsin was significantly reduced and TIMP-1 was increased, while TIMP-2, TIMP-3, SLPI and cystatin C were not significantly altered.

To further understand the importance of these pathways, specific protease inhibitors were given to the animals. Both the specific MMP inhibitor GM6001 and the cysteine protease inhibitors E-64 or leupeptin caused an approximately 70% decrease in the IL-13-induced increase in lung volume and chord length and a > 90% decrease in BAL cellularity with a > 95% decrease in eosinophil influx and lymphocyte accumulation. Neither inhibitor affected mucus metaplasia or the levels of BAL IL-13.

To further characterize the role of these proteases, the

Table 25.1 Comparison of effects of murine lung overexpression of interleukin 13 and γ -interferon.

Protease/ antiprotease/mucus	IL-13 mice	Interferon mice
<i>Proteases</i>		
MMP-2, -9, -13, -14	Increased	Unchanged
MMP-12	Increased	Increased
Cathepsin B, H, S	Increased	Increased
Cathepsin D	Unchanged	Increased

α_1 -antitrypsin	Decreased	Unchanged
<i>Mucus</i>		
	Increased	No change

IL-13, interleukin 13; MMP, matrix metalloproteinase; SLPI, secretory leucocyte protease inhibitor; TIMP-1, tissue inhibitor of metalloproteinase-1.

IL-13 mice were bred with mice specifically deficient in MMP-9 and MMP-12, which have been heavily implicated in murine and human emphysema. In both cases, the emphysema as measured by chord length, compliance and lung size was markedly reduced, showing that both enzymes are specifically required [84]. The induction of MMP-2, -9, -13 and -14 was at least partially dependent on MMP-12 because IL-13 overexpressing mice deficient in MMP-12 showed reduced induction of those enzymes. The MMP-12 deficient mice also showed a reduction in recovery of total leucocytes, eosinophils and macrophages, but not lymphocytes or neutrophils. On the other hand, loss of MMP-9 from the IL-13 overexpressing mice had no effect on induction of MMP-2, -12, -13 and -14 and did not alter eosinophil, macrophage or lymphocyte recovery, but increased the recovery of total leucocytes and neutrophils in BAL fluids. This suggests that MMP-9 is downstream in the effector cascade from MMP-12.

The role of chemokines in the development in the IL-13 phenotype was also examined [85]. IL-13 stimulates expression of a large number of CC chemokines including MCP-1, -2, -3 and -5, macrophage inflammatory protein 1 α (MIP-1 α), MIP-1 β , MIP-2, MIP-3 α , thymus- and activation-regulated chemokine, thymus-expressed chemokine, eotaxin, eotaxin 2, macrophage-derived chemokines, and C10. The role of the CC chemokine receptor CCR2 in mediating the effects of IL-13 was then examined by breeding CCR2 knockout mice with the IL-13 mice. The CCR2 knockout mice showed reduced lung size, alveolar size and lung compliance with reduced inflammation. However, CCR2

deficiency did not decrease the basal or IL-13-stimulated expression of target matrix MMPs or cathepsins but did increase the levels of mRNA encoding α_1 -antitrypsin, tissue inhibitor of MMP-1, -2 and -4, and SLPI. These studies demonstrate that IL-13 is a potent stimulator of MCPs and other CC chemokines and document the importance of MCP-CCR2 signalling in the pathogenesis of the IL-13-induced pulmonary phenotype.

CD8⁺ lymphocytes have been identified to be in excess in lungs of patients with COPD and are thought to produce IFN- γ . In order to examine the role of IFN- γ directly, mice that overexpress IFN- γ in the lung were examined [86]. These mice also developed emphysema, but there were striking differences from the IL-13 mice (see Plate 25.1; colour plate section falls between pp. 354 and 355). There was only a mild tissue inflammatory response made up of mononuclear cells and occasional granulocytes. BAL revealed an approximately threefold increase in cell recovery, with 18% neutrophils and the remainder macrophages and lymphocytes. In contrast to the IL-13 animals, no mucus was seen. In fact, IFN- γ is known to inhibit mucus production [87].

Proteases were also evaluated in these mice (see Table 25.1). IFN- γ enhanced the levels of mRNA encoding MMP-12 and cathepsins S, H and D. Lesser increases in cathepsin B were noted. Alterations in MMP-9, MMP-13 or cathepsin K were not appreciated. Zymography and Western blot confirmed the selective induction of MMP-12 and E-64 active site probe analysis confirmed the induction of cathepsins S, H and B. In contrast, IFN- γ was a potent inhibitor of the levels of SLPI mRNA and otherwise had no effect on antiproteases. Protease inhibitors prevented emphysema in these mice. In addition, the IFN- γ mice showed increased epithelial cell apoptosis. Interestingly, inhibition of either cathepsin S or caspases reduced apoptosis, inflammation and emphysema indicated that these three features are closely interrelated [88].

The data noted above demonstrate that IL-13 and IFN- γ both cause emphysema when targeted to the adult murine lung. IL-13 caused mucus metaplasia while IFN- γ did not. In addition, emphysema induced by IL-13 was associated with an inflammatory response made up of macrophages, eosinophils and lymphocytes while that caused by IFN- γ was associated with macrophages and granulocytes. The mechanisms of these emphysematous responses also appeared to differ because IL-13 and IFN- γ caused different patterns of MMP and cathepsin activation and only IFN- γ decreased SLPI expression (see Table 25.1). These similarities and differences are intriguing when one compares them with the different clinical presentations seen in patients with COPD. In many ways, the IFN- γ mice have a phenotype that is similar to patients who are commonly encountered clinically as having COPD associated with BAL neutrophilia. In contrast, the IL-13 mice may model

patients with asthma, eosinophilia or AHR who manifest accelerated rates of loss of lung function after exposure to cigarette smoke. In many ways, the IL-13 mouse is the transgenic substantiation of aspects of the Dutch hypothesis because these mice show that genes that are strongly implicated in the asthmatic diathesis can have a key role in the generation of emphysema.

Vascular endothelial growth factor and apoptosis

A striking series of experiments have shown that continuous stimulation with vascular endothelial growth factor (VEGF, a trophic and survival factor for endothelial cells), which is normally highly expressed in the lung, is required for prevention of emphysema in the rat [89,90]. Chronic treatment of rats with a VEGF receptor antagonist led to enlargement of the air spaces, indicative of emphysema. Viewed by angiography, these rat lungs showed a pruning of the pulmonary arterial tree as well as increased alveolar septal cell apoptosis. Treatment with a caspase inhibitor prevented VEGF antagonist induced septal cell apoptosis and emphysema. There was no lung infiltration by inflammatory cells. When oxidative injury, which is known to be elevated in lungs of smokers, was blocked, emphysema lessened. In support of the VEGF hypothesis, VEGF, VEGF R2 protein and mRNA expression are significantly reduced in emphysema [62,91]. Given the current clinical interest in VEGF antagonists for therapy of malignancies and the possible need to give these reagents for long periods of time, the role of VEGF in human disease is a critical issue. However, regardless of the ultimate role of VEGF in human disease, these studies established the critical concept that proteolytic matrix degradation does not need to be the primary event in the development of emphysema. The presence of apoptosis of septal cells in human disease was supported by two subsequent studies, which included multiple apoptosis assays including TUNEL, single-stranded DNA staining, caspase 3 immunohistochemistry, a DNA ligase assay and DNA laddering [62,63].

Cigarette smoke, MMP-12 and TNF- α

Mice with a targeted disruption of MMP-12 are resistant to cigarette smoke-induced emphysema [92]. Interestingly, MMP-12 deficiency also decreased cigarette smoke-induced pulmonary inflammation. RS113456, a metalloprotease inhibitor, also prevented neutrophil influx and connective tissue breakdown. Thus, acute smoke-induced connective tissue breakdown, the precursor to emphysema, requires MMP-12 and the neutrophil influx appears to be secondary

to macrophage activation [93]. Similar results are obtained with a synthetic serine elastase inhibitor or with α_1 -antitrypsin. Some proteases are therefore upstream of the inflammatory response and not simply an effector mechanism [94,95]. Both wild type (MMP-12 +/+) mice and mice lacking MMP-12 (MMP-12 -/-) demonstrated rapid increases in whole-lung nuclear factor- κ B activation and gene expression of pro-inflammatory cytokines after cigarette smoke exposure, indicating that a lack of MMP-12 does not produce a global failure to up-regulate inflammatory mediators. However, only MMP-12 +/+ mice demonstrated increased whole-lung TNF- α protein or release of TNF- α from cultured alveolar macrophages exposed to smoke *in vitro*. Levels of whole-lung E-selectin, an endothelial activation marker, were increased only in MMP-12 +/+ mice. These findings suggest that, acutely, MMP-12 mediates smoke-induced inflammation by releasing TNF- α from macrophages, with subsequent endothelial activation, neutrophil influx and proteolytic matrix breakdown caused by neutrophil-derived proteases [96]. Furthermore, mice deficient in both TNF- α receptor subunits (p55 and p75) show no increase in gene expression of TNF- α , neutrophil chemoattractant, MIP-2 and MCP-1 due to cigarette smoke. At 24 h, control mice demonstrated increases in lavage neutrophils, macrophages, desmosine (a measure of elastin breakdown) and hydroxyproline (a measure of collagen breakdown), whereas TNF- α receptor knockout mice did not [67].

Additional evidence that proteases can be upstream from the inflammatory process rather than function only as effector molecules is provided by studies with mice deficient in TNF- α receptor exposed to an exogenous protease. A single intratracheal dose of porcine pancreatic elastase, which is cleared from the lung by 24 h, was administered to wild type IL-1 β type 1 receptor-deficient, double TNF- α (type 1 and type 2) receptor-deficient, and combined TNF- α (type 1 receptor) plus IL-1 β receptor-deficient mice. There was marked reduction in the development of emphysema in the combined knockout mice and moderate reduction in the TNF- α receptor knockout mice. The level of apoptosis assessed by a TUNEL assay was increased at 5 days after elastase treatment and was markedly and similarly attenuated in the IL-1 β , the double TNF- α and the combined receptor-deficient mice [66]. This shows that the injury induced by exogenous elastase requires amplification via induction of endogenous mediators.

TGF- β 1

TGF- β 1 is a member of the TGF- β superfamily with complex effector functions. It is produced by all leucocytes and some stromal cells. It is best known for its anti-inflammatory and profibrotic activity, although in appropri-

ate settings it can induce inflammation and cell death, and inhibit wound healing. TGF- β 1 is secreted in an inactive form and requires extracellular activation. A number of activation pathways for TGF- β 1 have been identified, including interaction with the epithelial-restricted integrin α v β 6. In mice deficient in this integrin, MMP-12 was seen to be markedly up-regulated [97]. These mice consequently develop age-related emphysema. This emphysema is completely abrogated either by transgenic expression of versions of the β 6 integrin subunit that support TGF- β activation, the loss of MMP-12 or simultaneous transgenic expression of active TGF- β 1. TGF- β 1 suppresses MMP-12 production by macrophages directly. This implies a role for TGF- β 1 in preventing emphysema. Defects in fibrillin and TGF- β latent binding protein-4 also lead to reduced TGF- β activity and adult-onset emphysema [98,99]. The relevance of these findings to human disease is not clear, especially because the role of MMP-12 in human as opposed to murine emphysema has been strongly questioned [68]. Furthermore, TGF- β is overexpressed in COPD, not underexpressed [100]. It is also not clear from these results if MMP-12 is acting via matrix proteolysis directly or if it is inducing alveolar cell apoptosis.

Conclusions

A number of novel experimental findings have changed the paradigm of COPD research. The ability of IL-13 to induce COPD was unexpected and raised the issue of the relation of COPD and asthma. The significance of CD8 T cells in human COPD is enhanced by the experimental data that IFN- γ can produce emphysema. The difference in protease and antiprotease expression of those two models reinforces

the notion of COPD heterogeneity. The data on apoptosis and COPD raised an entirely new hypothesis about the pathogenesis of this disease and suggests a new relationship of proteases, inflammation and lung destruction. Our understanding of the biology of this disease is just beginning, however. For example, IL-13 induces both VEGF and TGF- β 1 [101,102]. Clearly, the presence of these mediators in the IL-13 mice does not provide complete protection from emphysema in this model. Whether these products are providing partial protection in this model is not known.

A model incorporating these newer data is shown in Figure 25.1. The canonical smoking-inflammation-protease pathway is shown in the middle. Question marks are indicated next to areas of uncertainty. It is not known how and if IL-13 and IFN- γ boxes are produced in human smokers' lungs. The presence of MMP-12 in human lungs is similarly controversial. While cigarette smoke reduces VEGF, which may lead to apoptosis, the ability of cigarette smoke to increase free radicals is well known, which may also directly lead to apoptosis independent of VEGF deficiency. TGF- β is included as a negative regulator of MMP-12, thus potentially preventing emphysema despite evidence that TGF- β is overexpressed in human emphysema.

The human data show a large number of mediators expressed but does not address the significance of any one mediator. In order to do so, clinical trials of various inhibitors will be required. TNF and IL-1 β antagonists are possible but not exclusive choices because they are already in clinical use for other indications. It seems likely that many of these mediators will be important in specific subsets of patients. Data correlating expression with specific clinical phenotypes will therefore be critical in order to direct therapeutic trials.

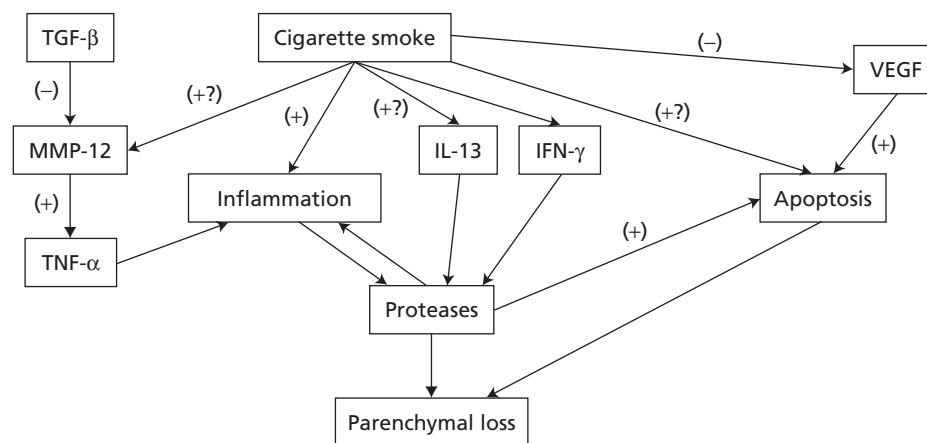

Figure 25.1 Model of human COPD. Canonical model of inflammation leading to elastolytic proteases is shown in the centre. Note that data now show that some elastases require induction of additional inflammation to induce parenchymal loss. In addition, it is known that proteases can lead to an alternative mode of parenchymal loss, namely apoptosis (see text for discussion). IFN- γ , γ -interferon; IL-13, interleukin 13; MMP-12, metalloproteinase 12; TGF- β , transforming growth factor β ; TNF- α , tumour necrosis factor α ; VEGF, vascular endothelial growth factor.

CHAPTER 26

Leukotrienes in COPD: the unexploited potential

Sven-Erik Dahlén

Although leukotrienes, prostaglandins and other eicosanoids are ubiquitous signalling molecules with a diverse number of biological activities, their role in COPD remains to be explained. There are few clinical studies that have directly addressed the potential functions of leukotrienes or prostaglandins in the symptomatology or pathophysiology of COPD. This is somewhat surprising in view of the established role of leukotrienes as mediators of the airway obstruction and inflammation in asthma and the use of prostaglandins in the treatment of pulmonary hypertension. In fact, the lung was one of the first organs where prostaglandins were discovered and their biological activities investigated [1]. The formation of eicosanoids in different cells within the lung is extensive [2], but their possible contribution to COPD has not received much attention. In part influenced by the 'Dutch hypothesis', this account focuses on the experience with antileukotrienes in the treatment of asthmatic airway disease, with the deliberate hope this may stimulate further studies to evaluate the role of leukotrienes and other eicosanoids in COPD. After an outline of the biosynthetic pathways for formation of leukotrienes and other eicosanoids, the focus is on the biological effects of leukotrienes that may be relevant for treatment of COPD.

Biosynthesis, receptors and metabolism

Leukotrienes constitute a class of potent biological lipid mediators derived from arachidonic acid [3]. However, leukotrienes are not to be found in a resting cell. Biosynthesis of leukotrienes requires a cellular activation, such as cross-binding of the immunoglobulin E (IgE) receptor on the mast cell surface, to stimulate cellular conversion of the substrate arachidonic acid into biologically active messenger products. Arachidonic acid is normally esterified to membrane phospholipids. The release of arachidonic

Figure 26.1 Main mammalian transformations of arachidonic acid (eicosa-5,8,11,14-tetraenoic acid) indicating the position of oxygenations in the different pathways (carbon 1 being the carboxyl end). COX, cyclo-oxygenase; HETE, hydroxy-EA; LO, lipoxygenase; LT, leukotriene; LX, lipoxin; PG, prostaglandin; TX, thromboxane.

acid is predominantly controlled by the action of different phospholipase A_2 enzymes, all of which cleave arachidonic acid from membrane phospholipids. The liberated arachidonic acid can be metabolized to prostaglandins, thromboxane A_2 (TXA_2) or leukotrienes, as well as a great number of other molecules collectively named eicosanoids (Fig. 26.1).

The name eicosanoids is derived from the Greek prefix *eicosa* (*εικοσι*, twenty) and refers to the number of carbon atoms in the substrate arachidonic acid. As indicated in Figure 26.1, oxygenation of different carbon atoms in arachidonic acid initiates different pathways. Although not covered in this chapter, it should be recognized that different lipoxygenation and p450 derived hydroxyacids and downstream metabolites make up a major proportion of arachidonic acid metabolites in human lung tissue, with 15(S)-hydroxy-eicosatetraenoic acid being predominant [2]. Recent attention has focused on the potential of lipoxins as anti-inflammatory regulators of inflammation and remodelling [4].

Figure 26.2 5-Lipoxygenase (5-LO) and cyclo-oxygenase pathways. Cyclo-oxygenase (COX, two isoenzymes COX-1 and COX-2) catalyse the formation of prostaglandins (PG) and thromboxane (TX). The biosynthesis of leukotrienes (LT) is catalysed by 5-LO in cooperation with FLAP (five lipoxygenase activating protein). The primary leukotriene intermediate LTA_4 is metabolized to LTB_4 or the cysteinyl-leukotrienes LTC_4 , LTD_4 and LTE_4 , that made up the biological activity previously known as slow reacting substance of anaphylaxis (SRS-A).

The initiating enzyme in leukotriene synthesis is 5-lipoxygenase (5-LO). The enzyme has two catalytic activities: the conversion of arachidonic acid to 5-hydroperoxy-eicosatetraenoic acid (5-HPETE) and the subsequent formation of leukotriene A_4 (LTA_4) (Fig. 26.2). LTA_4 is a short-lived compound that can be further metabolized to LTB_4 or LTC_4 , in reactions catalysed by LTA_4 hydrolase (LTA_4 -H) and LTC_4 synthase (LTC_4 -S), respectively. LTC_4 and its metabolites, LTD_4 and LTE_4 , are collectively designated cysteinyl-leukotrienes (CysLT) because of the common constituent cysteine in the side-chain.

In contrast, prostaglandin H synthase (PGHS) initiates the metabolism of arachidonic acid to prostaglandins and TXA_2 (see Fig. 26.2). PGHS is, as 5-LO, a dual enzyme catalysing two coupled reactions: an initial cyclo-oxygenation and an a subsequent hydroperoxidase reaction. However, as drugs that inhibit prostaglandin formation usually inhibit the first cyclo-oxygenase reaction, PGHS is usually functionally and pharmacologically described as the prostaglandin cyclo-oxygenase (COX). Two forms of the enzyme exist: COX-1, which is constitutively expressed in many cells and believed to be mainly involved in the production of prostanoids in physiological reactions; and COX-2, which is often induced in cells during inflammation and therefore considered primarily involved in pathological states [5]. As illustrated by the recently documented cardiovascular side-effects of selective COX-2 inhibitors [6], there are several important exceptions to the general dogma of COX-2 as an inducible and exclusively proinflammatory enzyme.

5-LO is restrictively expressed in the human body and predominantly found in myeloid cells such as granulocytes, monocytes, macrophages, mast cells and B-lymphocytes [3]. The human 5-LO gene is located on chromosome 10 [7] and the protein has a molecular weight of 78 kDa. Some mutations in the 5-LO promoter region have been reported [8]. However, it remains unclear if enzyme polymorphisms have relevance for the enhanced biosynthesis of leukotrienes found in certain patients with asthma. The cellular biosynthesis of leukotrienes involves a 18-kDa membrane-bound protein named FLAP (five-lipoxygenase activating protein). It is an arachidonate-binding protein, which stimulates the conversion of cellular arachidonic acid by 5-LO [9–11]. The human gene is located on chromosome 13q12. The FLAP protein was discovered because some inhibitors of leukotriene formation such as MK-886, MK-591 and BAYx1005 bind to this protein and thereby inhibit leukotriene biosynthesis.

LTA_4 hydrolase (LTA_4 -H) is a cytosolic 69-kDa enzyme that catalyses the conversion of LTA_4 to LTB_4 (reviewed in Haeggstrom [12]). The enzyme is a zinc metalloenzyme which also exhibits aminopeptidase activity with unknown physiological relevance. The gene is on region 12q of chromosome 22. In contrast to 5-LO, LTA_4 -H is widely distributed and has been found in almost all mammalian cells. One possible explanation for this discrepancy would be that LTA_4 -H is primarily involved in leukotriene synthesis in cells expressing 5-LO, whereas aminopeptidase activity occurs in cells that do not produce leukotrienes. Alternatively, LTA_4 -H might have a role in the transcellular metabolism of leukotrienes (see below).

LTC_4 synthase (LTC_4 -S) is an integral membrane 18-kDa protein, catalysing the final step in LTC_4 formation (reviewed in Lam and Austen [13]). The enzyme catalyses the conjugation of glutathione with LTA_4 and is active as a homodimer. Expression of LTC_4 -S is high in cells with an established role in the biosynthesis of CysLT such as mast cells and eosinophils. LTC_4 -S activity is also detected in cells that apparently do not express 5-LO such as endothelial cells and platelets. Overexpression of LTC_4 -S was reported in bronchial biopsies from aspirin-intolerant asthmatic patients [14]. LTC_4 -S is a member of the MAPEG (membrane-associated proteins in eicosanoid and glutathione metabolism) family of proteins that also includes FLAP, microsomal prostaglandin E synthase (mPGES) and several microsomal glutathione S-transferases (reviewed in Jakobsson *et al.* [15]). The gene for LTC_4 -S is on the 35q region of chromosome 5, close to the locus for genes encoding pro-inflammatory cytokines and growth factor receptors.

The mechanisms involved in the cellular biosynthesis of leukotrienes are still incompletely understood [3]. The physiological relevance of the localization of the 5-LO and FLAP to the nuclear envelope is not known, but it is

possible that 5-LO products also have a function in transcriptional regulation of genes.

Eosinophils and mast cells have high capacity to generate LTC₄ from the endogenous pool of arachidonic acid. However, several lines of evidence suggests that CysLT as well as LTB₄ can also be produced in the lung through interaction between structural and infiltrating inflammatory cells. Such transcellular metabolism means that stimulated leukocytes, and in particular neutrophils, can release LTA₄ which then can be further metabolized by other surrounding cells into LTB₄ or LTC₄ (reviewed in Lindgren and Edenius [16]). This means that cells without the initial 5-LO but with expression of distal enzymes permitting further metabolism of LTA₄ nevertheless may form the biologically active leukotrienes in such interactions. Activated myeloid cells may release LTA₄ which is subsequently metabolized by endothelial cells and platelets to LTC₄. Likewise, LTA₄ produced by neutrophils may be accepted by endothelial cells and form LTB₄, despite lack of 5-LO in the endothelial cells. Transcellular metabolism of LTA₄ in atherosclerotic plaques has recently gained considerable interest as a critical event in vascular inflammation, and altered expression of the receptors for LTB₄ seem to be involved [17].

After intracellular formation of LTC₄, the compound is released to the extracellular space. Export of LTC₄ has been demonstrated in many cells to be carried out by the multidrug-resistance protein (MRP) [3]. Mice lacking MRP have a decreased export of LTC₄ and an attenuated response to inflammatory stimuli [18]. After the carrier-mediated export of LTC₄, metabolism of LTC₄ provides the extracellular LTD₄ and LTE₄. Intracellular LTB₄ is also secreted via a specific transporter [19]. These carrier proteins are a potential future target for antileukotriene drugs.

There are four G-protein-coupled receptors that have been identified for leukotrienes (reviewed in Brink *et al.* [20]). For the cysteinyl-leukotrienes CysLT₁ and CysLT₂, and for LTB₄ BLT₁ and BLT₂ (see Fig. 26.2). There is pharmacological evidence suggesting the presence of a third receptor for CysLT, as the response to LTC₄ in the human pulmonary artery is resistant to all currently available antagonists [21,22]. Current evidence suggests that most, if not all, effects of leukotrienes with relevance to asthma are mediated by activation of the CysLT₁ receptor. For example, it was recently established that bronchoconstriction as well as ventilation-perfusion mismatch in subjects with asthma challenged with inhaled LTD₄ was completely blocked by montelukast [23]. However, with regard to events of relevance to COPD, much less is known about the involvement of leukotriene receptors. In animal models of lung fibrosis, there appears to be opposing effects of CysLT₁ and CysLT₂ receptors [24,25].

Our understanding is as yet limited with regard to how different enzymes, receptors and transporters in the

leukotriene pathway are regulated in health and disease. With airway inflammation, it must be taken into account that changes in the expression of a particular enzyme in a particular cell is only one part of the events that occur. Diseases or drugs may change the number and composition of cells in the airway tissue with dramatic effects *in vivo* on the profile and amounts of compounds formed. Therefore, *in vivo* measurements of eicosanoids are generally most conclusive regarding the amounts and profile of products formed in a particular situation.

The circulating levels of any of the CysLT are below the detection limits of immunoassays but the endogenous formation may be followed by collection of sputum, nasal or bronchioalveolar lavage fluids or by measurement of the stable urinary end product LTE₄ [26]. There are recent indications that exhaled breath condensates (EBC) may be used to measure CysLT [27], but there remain questions about the identity and source of CysLT immunoreactivity in EBC.

Measurement of urinary LTE₄ is thus a validated and sensitive method to monitor whole body production of CysLT [26]. It has been used to provide mechanistic information about the response to different bronchoprovocations. Urinary LTE₄ is typically increased following most indirect bronchoprovocations studied. This has been made possible because of the rapid excretion of CysLT into the urine. Following inhalation of LTD₄, there is a significant increase in urinary LTE₄ within 30–60 min. Likewise, allergen-induced bronchoconstriction is followed by increased urinary LTE₄ within an hour. This means that this measure may be more reflective of acute episodes of airway obstruction than chronic inflammatory changes. However, subjects with aspirin-intolerant asthma have generally, on the population level, been found to have increased urinary LTE₄ [26,28]. There are currently no definitive data on urinary LTE₄ in COPD.

In the case of LTB₄, the methods for *in vivo* measurement are even more limited. As for CysLT, the circulating blood levels are below the detection limit of reliable assays. When very high doses of LTB₄ were injected in volunteers, it was possible to measure some metabolites in urine [29]. Normally, physiological concentrations of LTB₄ are completely metabolized into water and carbon dioxide [30]. For LTB₄, we are therefore currently limited to measurements in different body fluids where the problems of erroneous formation during sampling become significant. A common approach has been to estimate the ability of blood cells *ex vivo* to generate leukotrienes [31]. The method involves normal collection of blood and subsequent stimulation of whole blood, neutrophils or any other cell of interest with, for example, calcium ionophore for a defined time period, followed by measurement of LTB₄ in the sample. However, it is not conclusively established to what extent

this measure of capacity to generate LTB_4 in the test tube reflects *in vivo* propensity to form leukotrienes.

Biological actions of leukotrienes with relevance to the respiratory system

Soon after their discovery, it was documented that LTC_4 and LTD_4 were potent inducers of bronchoconstriction in guinea-pig airways *in vitro* and *in vivo* [32,33] and caused contractions of isolated human bronchi [34–36] (Fig. 26.3). Local injection of these two CysLT also increased accumulation of intravenous injected Evans blue in the skin [32,33], suggesting an increase in microvascular permeability. In the hamster cheek pouch, it could be established that LTC_4 and LTD_4 caused exudation of plasma proteins in postcapillary venules [37]. In the guinea-pig, it was shown that LTC_4 , LTD_4 and LTE_4 were capable of plasma protein extravasation in all segments of the airways [38].

The biological effects of LTE_4 have been less studied, perhaps because this leukotriene was found to be an incomplete and less potent agonist than LTC_4 and LTD_4 in some standard bioassays such as the guinea-pig ileum [39–41]. However, LTE_4 has been documented to possess a bronchoconstrictor activity *in vitro* and *in vivo* that is closely similar to that of LTC_4 and LTD_4 [42,43]. It has also been observed that prolonged exposure to LTE_4 may produce enhancement of the responsiveness of smooth muscle to histamine [44,45]. Moreover, LTE_4 is a full agonist for contraction of human bronchi *in vitro* [46], and its potency is similar to that of LTC_4 and LTD_4 .

Of particular relevance to COPD, it has been observed that LTC_4 and LTD_4 may stimulate mucus secretion in isolated animal and human airways [47–49]. Additional effects with relevance to the role of CysLT in pulmonary inflammation have been reported. Thus, increased infiltration of eosinophils into the airway mucosa of asthmatics was observed following inhalation of LTE_4 [50], and

inhalation of LTD_4 increased the number of eosinophils in induced sputum samples from asthmatics [51,52]. However, it has been overlooked that inhalation of LTE_4 also increased the number of neutrophils in the airways [50]. The capacity of CysLT to promote eosinophil recruitment has been studied in experimental models [53,54], although the mechanisms involved remain undefined. There is also experimental data *in vitro* [55–58] and *in vivo* [59] supporting the view that CysLT may be involved in airway smooth muscle proliferation and remodelling.

The exquisite spasmogenic potency of CysLT on isolated human bronchi has been confirmed in bronchoprovocation studies of control subjects [60–62]. The CysLT are the most potent endogenous bronchoconstrictors known so far. Accordingly, CysLT have generally been found to produce bronchoconstriction in doses that were 100–10 000 times lower than those required with histamine or methacholine. Asthmatics have also been found to be hyperresponsive to inhalation of LTC_4 , LTD_4 and LTE_4 [63–65]. There are indications that LTD_4 may cause greater airway narrowing than methacholine [66]. On the other hand, at least for LTC_4 and LTD_4 , there are observations indicating that the hyperresponsiveness of asthmatics to these leukotrienes relative to methacholine was less than in controls [31,64,67]. This raises the interesting hypothesis that chronically elevated production of leukotrienes in the airways induces adaptive changes in the effector cells or at the receptor level [68]. However, concerning LTE_4 , the opposite finding has been reported, namely that asthmatics were especially hyperresponsive to this particular leukotriene [69]. Altogether, the studies where bronchial challenge with CysLT have been performed are relatively few and more work is needed. In this context, there are also indications that repeated challenge with CysLT is associated with tachyphylaxis mediated by local generation of a prostanoid, and presumably PGE_2 [70].

LTB_4 has been found to have primarily leucocytes as targets for its biological activity (see Fig. 26.3). Thus, it is a potent stimulus for activation of leucocytes, eliciting chemokinetic and chemotactic responses *in vitro* [71]. *In vivo*, LTB_4 increases leucocyte rolling and adhesion to the venular endothelium [37], followed by their emigration into the extravascular space. During a short-lasting exposure to LTB_4 , polymorphonuclear leucocytes are mainly recruited. With prolonged exposure to LTB_4 , as presumably occurs when LTB_4 is formed *in vivo*, other granulocytes, including eosinophils, are found in tissues or exudates after challenge with LTB_4 [72]. More recently, the effects of LTB_4 on T-lymphocyte migration in the lung has attracted attention [73]. Altogether, it is an attractive hypothesis that LTB_4 contributes to the neutrophilic inflammation in COPD. Indeed, there are studies where altered levels or changed responsiveness to LTB_4 have been reported in

sputum from patients with COPD [74], but the studies are limited and confirmation is required.

In addition to effects on leucocyte adhesion and migration, LTB_4 , as other secretagogues, stimulates secretion of superoxide anion and release of different granular constituents from leucocytes [75,76]. Possibly relating to effects of LTB_4 on B-cells, it has been established that sensitized 5-LO-deficient mice produced lower levels of IgG and IgE upon ovalbumin challenge than wild-type mice [77]. Furthermore, it has been reported that LTB_4 , similar to many other eicosanoids, is an agonist for the nuclear transcription factor peroxisome proliferator-activated receptor α (PPAR α) [78]. The finding may implicate a role for LTB_4 in the control of central events in lipid metabolism and inflammation, but also the possibility that LTB_4 has intracellular and nuclear targets, which may participate in long-term control of gene expression. It is noteworthy though that there have been few new publications to follow-up on the original observations.

With respect to effects of LTB_4 on the lung, it is established that LTB_4 has contractile activity in the guinea-pig lung parenchyma [79–82]. The response is indirect, involving release of TXA_2 and histamine, possible from pulmonary mast cells. It has been established that the effect in the lung parenchyma is a result of activation of the pulmonary blood vessels rather than the airway elements [83]. This particular response to LTB_4 has been confirmed in the human pulmonary artery but not in other non-vascular smooth muscle, including human bronchi.

In a dog model, LTB_4 was found to increase airway reactivity to acetylcholine [84], whereas among non-asthmatic humans there was no change in bronchial hyperresponsiveness to histamine following the inhalation of LTB_4 , alone or in combination with PGD_2 [85]. Nor was there any direct bronchoconstrictor effect of inhaled LTB_4 [86]. A subsequent study observed that inhalation of LTB_4 by healthy human volunteers was followed by distinct cellular changes in the airways, and possibly also some plasma exudation [87]. In a study where LTB_4 was inhaled by a group of asthmatics, the lack of immediate bronchoconstrictive properties was confirmed as well as prominent acute effects on leucocyte traffic in the lung and blood [88].

As COPD is a disease with many systemic and metabolic consequences, it is of interest that there are suggestions of leukotrienes as mediators in chronic inflammation in general, and cardiovascular diseases in particular. For example, there is a case for LTB_4 in atherosclerotic inflammation [17]. Thus, treatment with a leukotriene biosynthesis inhibitor has been reported to have a beneficial effect on a surrogate marker of ischaemic heart disease in a group of subjects with a particular polymorphism in 5-LO and altered capacity to biosynthesize LTB_4 [89]. Another genetic population study has suggested that certain polymorphisms

in 5-LO carry risk odd ratios of similar magnitude as diabetes or smoking [90]. However, CysLT may also be much involved in cardiovascular events. For example, experiments in isolated perfused hearts disclosed a depressive effect of CysLT on cardiac contractility [91,92]. The effect correlated with coronary vasoconstriction [93], but a direct negative inotropic effect on the myocardium may also be involved [92,94]. Such effects may be of relevance to the comorbidity between ischaemic heart disease and COPD.

There is recent experimental evidence that leukotrienes have important functions in innate immunity [95] and immunological responses including lung fibrosis [96], actions that may have bearing on the pathophysiology of COPD. There may also be intricate feedback mechanisms within the eicosanoid family as, for example, 15-HETE has been reported to inhibit LTB_4 production in sputum of patients with COPD [97].

Pharmacology of antileukotrienes

The inhibition of the leukotriene pathway may be directed towards their formation or actions (see Figs 26.2 and 26.3). The leukotriene biosynthesis inhibitors result in inhibition of both LTB_4 and CysLT, whereas CysLT $_1$ -antagonists selectively inhibit the action of CysLT at one of their receptors.

The 5-LO inhibitor zileuton was the first antileukotriene compound to be approved for treatment of asthma in the USA, but has not been registered for use in Europe [98]. Zileuton is an *N*-hydroxyurea derivative, and its mechanism of action is likely to involve chelation of iron at the active site of 5-LO, thereby blocking the redox potential of the enzyme. Among drugs that inhibit leukotriene biosynthesis, the FLAP-antagonists MK-886 [99], MK-591 [100] and BAYx1005 [101] have been documented to be potent inhibitors of leukotriene formation when given to humans *in vivo*, but none have been taken into final clinical development.

It would seem straightforward to establish the effective dose of a 5-LO inhibitor by measuring the degree by which it inhibits endogenous leukotriene formation. During the development of 5-LO inhibitors, measurements of *ex vivo* formation of LTB_4 in ionophore stimulated blood has generally been used to assess the degree of 5-LO inhibition [102]. This measure correlates well with plasma drug level, but it might have overestimated the degree of tissue inhibition of leukotriene formation [26]. For LTB_4 , there is no indicator metabolite that can be measured in urine or blood [26]. For CysLT, measurements of urinary excretion of the end product LTE_4 is currently the most reliable estimate of the degree of inhibition of endogenous whole body bio-synthesis [26].

It is worth noting that the level of inhibition of urinary LTE_4 has been consistently less than 50% in the studies

where significant effects on clinical outcome variables have been established [86,103,104]. This may indicate either that this level of inhibition is sufficient to obtain maximal clinical efficacy, or that the clinical efficacy can be increased further if the inhibition of leukotriene formation is increased. The latter possibility gains some support from the results of the only allergen challenge study performed with the highest dose of BAYx1005 so far tested [101]. There was more than 80% inhibition of allergen-induced urinary excretion of LTE_4 and more than 75% inhibition of bronchoconstriction, which incidentally is the greatest degree of inhibition reported for this particular outcome variable by any antileukotriene drug. The phase II treatment trials with BAYx1005 were subsequently performed at a lower dose level and ambiguous results led to the discontinuation of further development of this particular drug for treatment of respiratory diseases, whereas its potential for treatment of arteriosclerosis continues to be explored [89].

The other main strategy, to develop leukotriene receptor antagonists, is completely dominated by the CysLT_1 antagonists, although there are BLT antagonists that have been tested in humans [105]. A number of potent and selective CysLT_1 antagonists have been developed. The compounds are administered orally, and have been found to cause significant shifts (25- to 1000-fold) in the dose–response relation for inhaled LTD_4 in control subjects or asthmatics [106–109]. Although a great number of CysLT_1 antagonists have been developed, only three have reached the market: montelukast (Singulair®), pranlukast (Onon™) and zafirlukast (Accolate®). Montelukast and pranlukast are also registered for treatment of rhinitis. With regard to CysLT_2 antagonists, there are only early preclinical candidate substances [20], and it is unclear if the CysLT_2 receptor is an interesting target for the treatment of asthma. However, it remains possible that the pathophysiology of COPD may have significant CysLT_2 components. For example, the structure–activity relations for the effects of CysLT on mucous secretion are different from those normally exhibited at the CysLT_1 receptor [48].

Some selective and relatively potent antagonists of LTB_4 have been developed [105]. A few compounds have entered into early clinical testing in humans. The compound LY-293,111 (VML 295) was found to inhibit LTB_4 -induced neutrophil responses *in vivo* and allergen-induced neutrophil activation, but it had no effect on allergen-induced early or late phase airway obstruction in asthmatics [105]. The results with LY-293,111 in asthmatics argue against an important role for LTB_4 as a mediator of antigen-induced bronchoconstriction, but do not exclude the possibility that LTB_4 may be involved in other manifestations of chronic asthma, such as increased bronchial responsiveness, or in other lung diseases. For example, there is a case for LTB_4 in innate immunity [95], and it would seem particularly

important to assess the effects of potent 5-LO inhibitors in clinical COPD or on surrogate markers of airway inflammation in COPD. There is one pilot study of the ability of the 5-LO inhibitor BAYx1005 to inhibit leukotriene production and inflammatory markers of patients with COPD [110].

Lessons to be learned from the effects of antileukotrienes in the treatment of asthma: questions for COPD research

A number of studies of different antileukotrienes have established that leukotrienes mediate significant components of bronchoconstriction evoked by common triggers of airway obstruction (Fig. 26.4). This has been demonstrated both with different inhibitors of the biosynthesis such as zileuton and the FLAP antagonists MK-886, MK-591 and BAYx1005, and with different CysLT_1 antagonists such as MK-571, MK-679, montelukast, pranlukast, pobilukast and zafirlukast. The beneficial effects of 5-LO inhibitors and the CysLT_1 antagonists were rather similar in the challenge models and in short-term treatment studies. This led to the reasonable conclusion that it was principally the CysLT antagonists that mediated reactions with relevance to asthma, and further clinical development has been dominated by the receptor antagonists. However, the dismissal of a role for LTB_4 in airway obstruction and inflammation may be premature. In particular, studies are required where long-term effects of potent 5-LO inhibitors are compared with selective CysLT_1 antagonists. There are at least three areas where LTB_4 may be more important than previously thought. First, one of the hallmarks of asthma, bronchial

Figure 26.4 Leukotrienes as a final common path for different trigger factors causing airway obstruction. The mast cell is often a main effector cell in the responses.

hyperresponsiveness (BHR) is not extensively modified by CysLT₁ antagonists, whereas there seem to be such effects after 5-LO inhibition [86,111]. Secondly, LTB₄ is the main leukotriene formed in the nasal mucosa [112], and the 5-LO inhibitor zileuton had a striking effect on nasal symptoms in aspirin-intolerant asthma [86]. It would be of interest to investigate the effects of 5-LO inhibitors more aggressively in rhinitis and rhinopolyposis where again provocation studies support potential for this class of compounds. Thirdly, there are several indications that LTB₄ may have important effects on lymphocyte trafficking and homing in the lung [73].

Antileukotrienes do not cause relaxation of airways per se. Thus, they have no direct bronchodilatory effects on airway smooth muscle nor inhibitory effects on the bronchoconstrictor response evoked by methacholine or histamine in subjects with mild asthma. However, administration of antileukotrienes has consistently been observed to produce variable degrees of acute bronchodilatation when given to subjects with chronic asthma and baseline airway obstruction [86,113–115]. This is explained by the mode of action to inhibit the action or formation of leukotrienes in the airways. It can be shown also in an *in vitro* model of increased baseline tone that there is a component of spontaneous muscle tone that is mediated by CysLT [116]. Presumably the contribution of leukotrienes to the airflow limitation in asthma is increased because of increased production of leukotrienes in asthmatic airway inflammation. There are studies supporting that the acute bronchodilatation in response to antileukotrienes is greater in studies of subjects with more severe depression of lung function at baseline [114] or more severe disease severity [117]. The bronchodilatory effect of antileukotrienes is also present after treatment with glucocorticosteroids [113,115]. There are indications of a synergy between beta-stimulants and antileukotrienes [113,114] but this requires further studies. Interestingly, there are two preliminary studies suggesting that airway obstruction in COPD is sensitive to treatment with a CysLT₁ antagonist [118,119]. It appears highly warranted to investigate systematically the effects of 5-LO inhibitors and CysLT₁ antagonists on airway function in COPD.

One of the most well-documented effects of antileukotrienes is to protect against bronchoconstriction induced by different trigger factors. This includes the response to allergen-induced airway obstruction [99–101,120–123] as well as all other trigger factors examined (see Fig. 26.4). Both early and the late asthmatic reactions have major leukotriene-dependent components [123,124]. This supports the hypothesis that antileukotrienes protect against bronchospasm as well as oedema and cellular response that are part of the antigen-induced airway reactions. One of the first proof of concept studies was in exercise-induced

bronchoconstriction (EIB) [125]. It has subsequently been thoroughly documented that antileukotrienes have significant protective effects in that particular model, and in other models of bronchoconstriction that are considered to be 'exercise-mimetics', such as eucapnic hyperpnoea [126], cold air [127] or mannitol inhalation [128]. Although SO₂-induced bronchoconstriction is considered to primarily activate sensory nerves in the airways, the reflex apparently involves CysLT as zafirlukast was able to partially inhibit the response [129]. Adenosine-induced bronchoconstriction appears to activate mast cells in the airways [130], and this is supported by the protective effect of antileukotrienes in adenosine bronchial challenge [131].

All in all, the most likely explanation of the broad bronchoprotective effects of antileukotrienes in indirect bronchial challenges is that release of CysLT is a final common response to mast cell activation despite the particular route that is used to activate the mast cell (e.g. IgE, hyperosmolarity in EIB, COX-1 inhibition in NSAID-intolerant asthma) (see Fig. 26.4). The hypothesis is supported by the documentation of increased *in vivo* release of the sensitive mast cells marker 9 α ,11 β -PGF₂ in conjunction with these bronchoconstrictive responses [132]. Another example is aspirin-induced bronchoconstriction in aspirin-intolerant asthma where mast cell activation can be shown [133] and the protective effects of antileukotrienes have been established [105,134,135]. It has been observed that patients with COPD bronchoconstrict in response to inhalation of hypertonic saline. As this particular response is inhibited both by montelukast and cetirizine [136,137], it seems reasonable to assume that mast cell dependent bronchoconstriction may be generating symptoms also in COPD, and hence serve as a target for treatment. It has been proposed that increased responsiveness of peripheral airways is an important aspect in COPD [138].

The introduction of antileukotrienes as new asthma treatment obviously followed a conventional clinical development where the potential new medications were documented to have beneficial effects on asthma outcomes that were superior to placebo. This included treatments for a duration of weeks to months with registration of endpoints such as pulmonary function, asthma symptoms, use of bronchodilators, asthma exacerbations and asthma-specific quality of life [139–143]. A comprehensive account of the development of each individual drug can be found in Drazen *et al.* [144]. In addition, the protective effects in EIB were extensively documented both in adults and children [145,146]. There are studies that have documented that the clinically beneficial effects of antileukotrienes are associated with inhibition of inflammatory cell reactions in, for example, blood, sputum and bronchial biopsies [147,148]. When comparing different treatments in asthma, it seems

that montelukast in ordinary doses (10 mg once daily) in steroid-naïve subjects provides improved asthma control more promptly (i.e. within a few days after start of treatment), compared with low doses of inhaled steroid. After a few weeks of therapy, the group mean effect of the steroid is larger than for montelukast [149]. However, there were large variations in therapeutic response, not only to montelukast but also to the steroid treatment in this particular investigation. From studies in children, it has recently been shown that montelukast decreases the number of viral-induced exacerbations [150]. Neither inhaled [151] nor oral steroids [152] have particularly significant prophylactic effects in similar populations of children between the ages of 2 and 5 years. There are also indications that LTB₄ may have a role in the bacterial inflammation of COPD exacerbations [153], again supporting the relevance of thoroughly testing 5-LO inhibition of the disease.

A relatively recent study has compared the effects of addition of a long-acting beta-agonist, salmeterol, or montelukast, to patients not controlled on inhaled fluticasone alone. The investigation included 1490 patients with asthma treated with a constant dosage of 100 µg/day fluticasone. During 1 year, a double-blind placebo-controlled comparison of daily addition of 10 mg montelukast or 200 µg salmeterol was made [154]. For the primary endpoint, the number of asthma worsenings during the study year, there was no significant difference between the two treatments. This was achieved despite that salmeterol was significantly better as a bronchodilator, and that montelukast, in contrast to salmeterol, displayed anti-inflammatory effects. The study illustrates that the same overall therapeutic response can be obtained with two strategies that have completely different modes of action. This type of study needs to be repeated with different outcomes but, mechanistically, it illustrates that several different targets may be useful in the treatment of asthma. Perhaps a future strategy would be to combine drugs with different modes of action to an even greater extent.

The current documentation of add-on effects of antileukotrienes [155–157] in the treatment of subjects not sufficiently controlled by glucocorticosteroids has mechanistic implications. The previous textbook knowledge was that glucocorticosteroids inhibit leukotriene biosynthesis by virtue of inhibition of the phospholipase step that is required for liberation of arachidonic acid from its esterified state in the cellular membranes. However, a number of studies have established that this is not the case in humans *in vivo* [158–161]. Leukotriene biosynthesis remains unaffected by inhaled or oral glucocorticosteroids. There is even *in vitro* evidence that certain enzymes in the leukotriene cascade are up-regulated by glucocorticosteroids [162]. Irrespective of the relevance of that particular *in vitro* study,

the relative steroid resistance of the leukotriene pathway is the mechanistic explanation of why the addition of antileukotrienes for patients not sufficiently controlled by steroids has been found to be effective. In practical terms, leukotriene biosynthesis is one aspect of airway inflammation that is steroid resistant. Again, this aspect should be another impetus for evaluating the effects of antileukotriene drugs in COPD.

In the treatment of subjects with more severe varieties of asthma, it might also be of interest that addition of antileukotrienes allow for reduction of the dosage of inhaled glucocorticosteroids with maintained therapeutic response [163,164]. Such steroid tapering may be of particular interest in children with severe asthma for whom the side-effects of glucocorticosteroids become an issue. In the case of insufficient asthma control with inhaled glucocorticosteroid alone, there are observations suggesting that the addition of montelukast may provide the same therapeutic response as doubling of the dose of the current inhalation steroid [165].

The side-effects that have been observed during treatment with antileukotrienes have generally been modest, such as headache and intestinal troubles. In most clinical trials, these effects have not been different between active treatment and placebo. The low incidence of side-effects has been one reason that antileukotrienes can be administered by the oral route. The problem with reversible elevations of liver enzymes during treatment with zileuton has been discussed. The most serious suspicion of significant side-effects with antileukotrienes was reported after a few years' use of this new class of drugs in the USA. There seemed to be an aggregation of new cases with the severe vasculitic disease Churg–Strauss syndrome (CSS) [166]. However, independent panels reviewing the cases concluded that the reported cases were not directly related to the specific class of drugs but a consequence of steroid tapering in subjects with hidden CSS [167,168]. Similar episodes of CSS exacerbations have been reported also after withdrawal of oral prednisone in patients given inhalation therapy with glucocorticosteroids.

Conclusions and perspective

Approximately 25 years after the discovery of leukotrienes and the elucidation of the structure of slow reacting substance of anaphylaxis (SRS-A) [169], antileukotrienes are now established as a treatment for asthma and rhinitis. However, the cumulated clinical experience with this class of drugs is less than 10 years and in most countries of the world limited to the CysLT₁ receptor antagonists montelukast and pranlukast. It is clearly documented that

antileukotrienes have anti-inflammatory and bronchoprotective effects that alleviate symptoms in adults and children with asthma and rhinitis. Antileukotrienes may be used as monotherapy or added to inhaled glucocorticosteroids. Published studies support the use of antileukotrienes at all levels of asthma therapy, from very mild cases to treatment of subjects with very severe asthma; in the mild cases as monotherapy, in the more severe cases as combination therapy with glucocorticosteroids. The first-line therapy option dominates in the USA, whereas usage in Europe is as an add-on to inhaled steroids or prophylaxis against EIB.

One area for future research is to identify subjects with leukotriene-dependent asthma. So far, this has largely been unsuccessful, and no baseline variable including urinary levels of LTE₄ have been found to predict the therapeutic response to montelukast or zileuton. A few relatively limited studies using CysLT₁ antagonists [170] or 5-LO inhibitors [171] have suggested relations between therapeutic response to these particular drugs and genetic polymorphisms in the LTC₄-S and 5-LO, respectively. The effects are not very large and currently not of such a magnitude that a certain genetic profile can predict the therapeutic response to antileukotrienes. A recent study in subjects with asthma failed to identify biochemical factors relating to the capacity for leukotriene biosynthesis that could predict the airway responsiveness to inhaled leukotrienes [31]. Studies in subjects with aspirin-intolerant asthma [86,156] have been taken as evidence of a particularly favourable response in this peculiar subgroup of subjects, but it has been overlooked that these patients received antileukotrienes not as single therapy but as add-on to both inhaled and oral glucocorticosteroids. The remarkable therapeutic responses in these two studies may rather support that patients with more severe asthma improve further when an antileukotriene is added to baseline treatment with glucocorticosteroids. There are studies in aspirin-tolerant subjects with severe asthma that also report striking therapeutic responses after addition of pranlukast [163] or zafirlukast [155].

In conclusion, a particular challenge for clinical COPD research is now to build on the experiences with antileukotrienes in asthma and perform studies that can assess whether antileukotrienes have value in the treatment of COPD, or may contribute to the systemic and metabolic components of COPD. The research must be unbiased and not governed by today's dogmas concerning mechanisms and strategies. An additional and related challenge is to characterize the role of other eicosanoids in COPD, where a number of proinflammatory (e.g. COX-2 derived PGE₂) and anti-inflammatory molecules (e.g. lipoxins and COX-1-derived PGE₂) deserve attention.

CHAPTER 27

Cigarette smoking, emphysema and lung endothelium

Stephanie A. Nonas, Irina Petrache and Joe G. N. Garcia

Pulmonary emphysema, characterized by alveolar wall destruction and permanent enlargement of the airways distal to terminal bronchioles, is the fourth leading cause of death (along with chronic bronchitis) in the USA, with a rising incidence and prevalence. Despite the clear observation that the vast majority of emphysema is associated with chronic cigarette smoking, the complete pathogenesis of emphysema remains unclear. Historically held concepts of the biochemical and molecular basis of emphysema have highlighted the obvious critical role of tobacco smoke exposure as well as the importance of effector cells, such as inflammatory leukocytes, which target tissues such as the bronchial and alveolar epithelium (see Chapters 17 & 22). However, the increasing knowledge of complex cell biologic processes and cellular homeostasis has led to paradigm-shifting hypotheses and the identification of previously unappreciated pathogenic mechanisms in COPD development. In concert with this explosion of information in the post-genome era, attention has shifted in recent years to include the potential for the meaningful contribution of vascular components in the complex pathophysiology associated with chronic airflow obstruction.

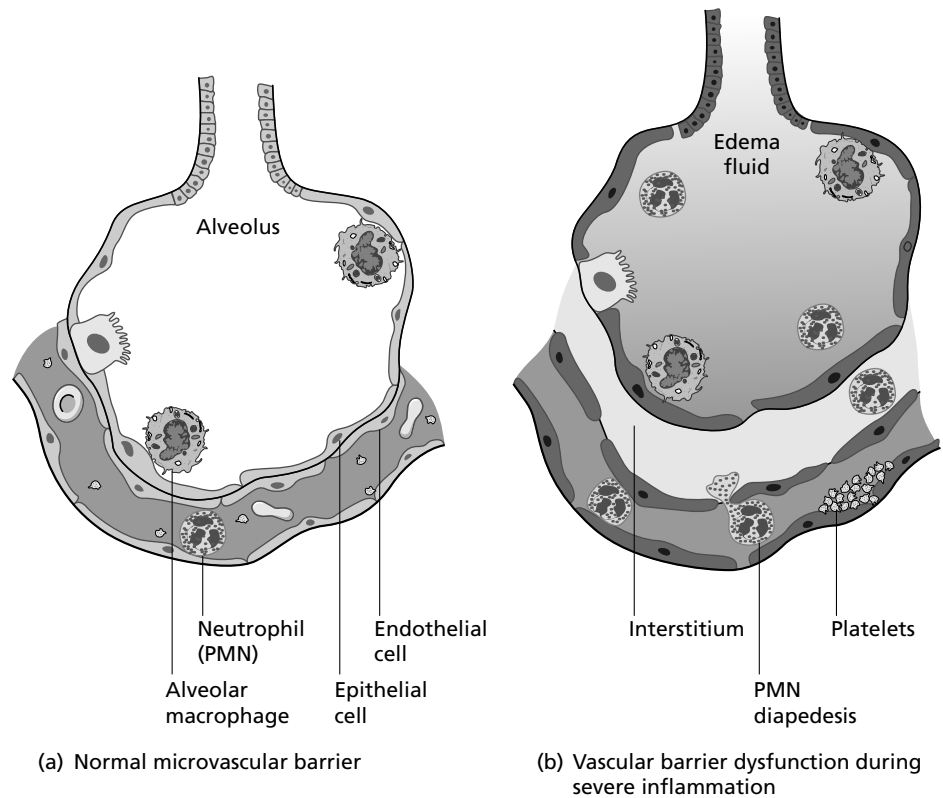

Endothelial cell barrier function in lung inflammation

The pulmonary circulation has a number of important functions including a critical role in gas exchange. Microvessels exchange solutes and water, and the mechanisms regulating the balance of fluid and solutes in extravascular spaces of the lung are central to understanding the pathophysiology of inflammatory pulmonary conditions such as acute respiratory distress syndrome (ARDS) and sepsis where increases in vascular permeability contribute to profound pulmonary oedema and physiologic derangements. Because of the enormous surface area of

the pulmonary vasculature, the pulmonary endothelium, a multidimensional tissue lining the entire vasculature, serves a specialized function as a semi-permeable barrier between the vascular space and the interstitium. The barrier function of lung endothelial cells is actively regulated. While the integrity of the endothelial cell monolayer is a critical requirement for preservation of pulmonary function, disruption of the endothelial barrier is now recognized as a cardinal feature of inflammation (Fig. 27.1). Endothelial barrier properties are not uniform throughout the pulmonary vasculature. There is greater macromolecule diffusion in postcapillary venules compared with pulmonary arterioles in whole lung models, and microvascular endothelium exhibits 10-fold higher barrier properties than macrovascular endothelium *in vitro* [1]. Although the precise mechanisms that regulate this variability in segmental barrier function are unknown, barrier regulatory components such as Ca^{2+} signalling pathways and differences in content and regulation of barrier protective cyclic adenosine monophosphate (cAMP) are likely involved [2].

The contribution of increased vascular permeability to acute inflammatory processes is much better defined than its role in chronic inflammatory disorders such as COPD, although loss of barrier integrity may be an important component of the acute exacerbation of chronic bronchitis. It remains well appreciated, however, that the pulmonary vascular endothelial barrier also actively participates in regulating cell trafficking across the vessel wall (see Fig. 27.1) and thus is essential to the entire spectrum of COPD from chronic bronchitis to emphysema. In its highly advantageous spatial locale, the endothelium serves as an integral member of both innate immunity and adaptive immunity response with highly specialized and complex signalling and regulatory pathways, which are selective for the type of inflammatory and immune effector cells allowed entry into lung tissues. The narrow dimensions of the lung capillary lumen (less than 10 μm diameter) implicate an

Figure 27.1 Pulmonary microcirculation in health and disease. (a) In the normal alveolar septum, the endothelial layer is intact and in close apposition with the alveolar epithelium, facilitating gas exchange while maintaining a tight barrier. (b) In disease states, endothelial perturbation leads to loss of barrier function with interstitial oedema and tissue inflammation. PMN, polymorphonuclear leucocyte.

intimate involvement of biophysical properties of both leukocytes as well as the mechanically challenged lung endothelium in regulating diapedesis [3,4]. In the context of the chronic low-level inflammatory status of lungs from both cigarette smokers and patients with emphysema, this leukocyte gatekeeper function of the endothelium becomes relevant to the development of irreversible lung disease.

Endothelial cell paracrine and cell survival function in lung homeostasis

In addition to serving as gatekeeper to circulating inflammatory and immune effector cells, the pulmonary vascular endothelium has an active role in maintaining both systemic and local (paracrine) feedback systems, by active processing of signalling mediators. In the lungs, alveolar septae (comprising endothelium, epithelium and a thin interstitium) form the air–blood barrier through which gas is exchanged. The endothelial and epithelial basement membranes appear to be fused for a length expanding over half of the capillary perimeter, creating the alveolar–capillary septum, an ideal site for gas transfer because of the maximal surface area available for gas exchange and minimal diffusion distance. Endothelium-dependent growth of

pulmonary vascular structures (vasculogenesis) occurs during early development and is crucial to the development of lung structures, specifically functional alveoli, and inhibition of vasculogenesis/angiogenesis decreases alveolarization of the developing lung [5]. Because of the intimate contact between septal components, mature endothelial cells continue to interact with neighboring epithelial cells in maintaining alveolar structures. One key mediator of this cell–cell cross-talk involved in septal homeostasis is vascular endothelial growth factor (VEGF), a potent mitogen and angiogenic factor involved in the development and maintenance of vascular endothelial cells as well as vascular permeability and vasodilatation. Expressed in nearly all tissues, VEGF acts as a potent survival factor for endothelial cells, inhibiting apoptosis both *in vitro* and *in vivo* [6–11]. VEGF has two major receptor tyrosine kinases, VEGFR-1 (Flt1) and VEGFR-2 (KDR/Flk1), which are expressed on vascular endothelial cells and hematopoietic cells, with VEGFR-2 responsible for the majority of the mitogenic, angiogenic and permeability enhancing properties of VEGF [7]. VEGF is abundantly expressed in normal lung tissues, where it is localized mainly to alveolar epithelial cells with receptors present on adjacent endothelial cells [12–16]. During development, expression of VEGF by mesenchymal and epithelial cells in branching airways guide endothelial cell differentiation and angiogenesis, and inhibition of

VEGF in the lungs leads to pulmonary endothelial cell death [17–19]. This key confluence of spatial localization, cell–cell cross-talk and intercellular survival dependency has led to the development of novel concepts in the pathogenesis of emphysema and airspace enlargement.

Endothelial cells in emphysema development: a historical perspective

Until recently, the pathogenic schemes of emphysema development have not incorporated an active participation of the pulmonary endothelium. The prevailing concept for the alveolar destruction characteristic of anatomic emphysema invoked a protease–antiprotease imbalance in which an excess of proteases digest the parenchymal extracellular matrix connective tissue, altering alveolar architecture [20,21]. In this model, chronic exposure to cigarette smoke leads to invasion of inflammatory cells into airspaces with release of large quantities of proteases in excess of antiproteases, leading to tissue destruction and airspace enlargement. However, this current model of inflammation and excessive proteolysis does not fully explain why alveolar cells and wall structures are lost.

In the early 1950s, researchers studying other potential contributors to the pathogenesis of emphysema first appreciated a pruning of the arterial tree in pathologic specimens from patients with emphysema [22,23]. Noting a lack of vascularity in the lungs of patients with emphysema on pathology and the presence of enlarged, almost avascular alveoli, Liebow [23] postulated that alveolar thinning might be the result of a reduction in blood supply and put forth the first hypothesis of vascular atrophy as a model for emphysema. Research into the possible vascular contribution to the pathogenesis of emphysema remained dormant until recent findings that operate entirely outside of the concept of inflammatory alveolar destruction led to a major re-evaluation of the current conceptual framework of emphysema development.

Endothelium in airspace enlargement: role of endothelial growth factors

The prominent expression of VEGFR-2 on alveolar septal endothelial cells suggested to insightful investigators that airway epithelial cells may have a significant role in regulating the maintenance of vascular structure and function, as well as repair and remodelling of alveolar structures through VEGF expression [15,16]. VEGF acts as a potent survival factor for endothelial cells, inhibiting apoptosis both *in vitro* and *in vivo* [6–11]. A seminal paper by the Tudor and Voelkel laboratories contains the series of

experiments that revisited the vascular atrophy model of emphysema using entirely novel approaches [24]. These scientists postulated that endothelial cell apoptosis, induced by antagonizing the survival signalling of VEGF, may produce decreased vascularity, induce alveolar cell apoptosis and result in the airspace enlargement characteristic of emphysema. Chronic *in vivo* blockade of VEGF receptors (with the pharmacologic specific VEGF receptor inhibitor SU5416) in rats for just 3 weeks produced alveolar wall cell death, airspace enlargement and pruning of the pulmonary vascular tree – all in the notable absence of inflammation or fibrosis (see Plate 27.1; colour plate section falls between pp. 354 and 355). Furthermore, the alveolar septal destruction caused by VEGF receptor blockade was the result of increased alveolar cell apoptosis and not of inhibited normal cellular proliferation. In these studies, the development of apoptosis preceded airspace enlargement and its inhibition with a caspase inhibitor prevented both alveolar cell apoptosis and the development of emphysematous airspace enlargement (see Plate 27.1; colour plate section falls between pp. 354 and 355). These landmark studies demonstrated that emphysema could be caused by a non-inflammatory insult and that chronic blockade of VEGF receptors causes lung endothelial cell apoptosis and the development of emphysema.

The remarkable findings of Tudor *et al.* have been confirmed in other experimental animal models. Gerber *et al.* [25] found that treatment of mice with a soluble VEGFR2 chimeric protein effectively neutralizes VEGF and results in airspace enlargement, while Tang *et al.* [26] found that lung-targeted ablation of VEGF in mice (using a Cre-Lox transfection strategy) resulted in decreased levels of both VEGF and VEGFR2 and concomitant alveolar septal destruction and loss of elastic recoil. Taken together, these studies suggest that VEGF signalling is required for the maintenance of alveolar structures, and that blockade of this important factor leads to disruption and endothelial cell death by apoptosis, and ultimately to parenchymal destruction and emphysema.

What relevance does this have for human emphysema? Following up on these animal studies, several groups have examined VEGF expression in patients with emphysema. Postulating that decreased expression of VEGF and/or VEGFR2 were involved in human emphysema, Kasahara *et al.* [27] compared lung tissue from patients with emphysema with tissue from healthy smoking and non-smoking controls, and found decreased expression of mRNA and protein of both VEGF and VEGFR2 in emphysematous lungs compared with either smoking or non-smoking controls. They also found a marked increase in apoptosis of both epithelial and endothelial alveolar septal cells in emphysematous lungs compared with controls (Fig. 27.2). Notably, as in the VEGF-blockade experimental rat

Figure 27.2 Apoptosis and vascular endothelial growth factor (VEGF) levels in non-smoking controls, healthy smokers and patients with emphysema. (a) Comparison of apoptotic cells (measured by terminal deoxynucleotidyltransferase-mediated UTP end labelling, TUNEL) in the alveolar septae of non-smokers, smokers and patients with emphysema. There are significantly more TUNEL+ cells in the emphysema lungs when compared with the lungs from non-smokers and healthy smokers. (b) Lung tissue VEGF. VEGF protein expression is significantly reduced in emphysema compared with controls. (c) Bronchoalveolar lavage fluid (BALF) VEGF in normal volunteers and healthy smokers. There is significantly less VEGF in the BALF from smokers compared with controls, even in the absence of emphysema. All data are expressed as mean \pm SEM. (Modified from Kasahara *et al.* [24] and Koyama *et al.* [30].)

model, the increased apoptosis seen in emphysematous lungs was not accompanied by a significant increase in inflammation.

In a parallel study, investigators comparing VEGF levels, spirometry and gas transfer in patients with pulmonary disease (emphysema, asthma, chronic bronchitis and healthy controls) found decreased levels of VEGF in induced sputum from patients with emphysema compared with controls, in marked contrast to patients with asthma or chronic bronchitis in whom VEGF levels were actually increased [28,29]. Furthermore, the decrease in VEGF in patients with emphysema correlated with the severity of airflow obstruction (measured by forced expiratory volume in 1 s, FEV_1) and gas transfer defect (measured by DLCO). Further studies comparing VEGF levels in the bronchoalveolar lavage fluid (BALF) of patients with pulmonary disease and healthy controls noted a marked decrease in VEGF expression both in patients with pulmonary disease and in healthy smokers compared with healthy non-smokers [30]. In fact, while healthy non-smokers had robust expression of VEGF, there was a nearly 10-fold decrease in VEGF expression in smokers, even in the absence of known pulmonary disease, suggesting that the decrease in VEGF precedes the development of emphysema in smokers (see Fig. 27.2).

The presence of apoptotic alveolar septal cells in emphysema is emerging as a key finding in experimental models beyond the VEGFR blockade model, including *in vitro* studies and traditional elastase-induced animal models of emphysema [31,32]. In addition, follow-up human studies have confirmed the presence of apoptosis of both epithelial

and endothelial cells in the alveolar septae of patients with emphysema, correlating the degree of apoptosis with the severity of disease [27,33–37]. Furthermore, studies comparing lung apoptosis rates among healthy controls, healthy smokers and emphysematous patients have shown an increase in lung cell apoptosis in chronic smokers preceding the development of clinical emphysema, with a further increase in apoptosis seen in smokers with overt emphysema [27,37].

To further explore the role of apoptosis in the pathogenesis of emphysema, Aoshiba *et al.* [38] performed a series of *in vivo* and *in vitro* experiments using active caspase-3, a direct apoptotic agent, and nodularin, a serine/threonine kinase inhibitor that induces caspase-dependent apoptosis. Although direct instillation of active caspase-3 had no effect, both instillation of nodularin and transfection of airspace epithelial cells with even a single dose of active caspase-3 caused alveolar cell apoptosis and airspace enlargement as early as 2 h after administration, with effects lasting up to 15 days, notably in the absence of inflammation or fibrosis. Using *in situ* elastin zymography, these investigators found an increase in elastolytic activity in the BALF of animals as early as 1 h after treatment that was localized to apoptotic epithelial cells. Both transfection of active caspase-3 and instillation of nodularin led to the loss of alveolar wall elastin as early as 6 h after treatment with a concomitant increase in soluble elastin products in BALF. These studies are the first to provide direct evidence that alveolar cell apoptosis, in the absence of inflammation, can trigger significant release of elastases sufficient to cause elastin destruction and emphysematous changes.

Cigarette smoke and the role of oxidative stress in endothelial dysfunction and emphysema development

However, how do we integrate these new findings in a disease that is overwhelmingly associated with cigarette smoking (Fig. 27.3)? Cigarette smoke contains more than 5000 chemical compounds and more than 10^{15} free radical molecules per puff. *In vivo*, chronic cigarette smoke causes dose-dependent increases in apoptosis of endothelial cells, bronchial and alveolar epithelial cells, and alveolar macrophages [39,40]. *In vitro*, smoke extract activates caspase-3 and induces apoptosis in cultured human umbilical and pulmonary endothelial cells as well as airway epithelial cells [41–43]. Cigarette smoke triggers apoptosis in cells through multiple pathways including direct oxidative stress, survival factor signalling, mitochondrial and nuclear DNA damage, and lymphocyte-dependent or TNF-receptor signalling. Long known to have a role in apoptosis and implicated in the development of emphysema, oxidative stress has a key role in normal cell maintenance [44]. As oxidants are known to not only cause cell damage and death, but to modulate the type of death: apoptotic versus necrotic, oxidative stress seems a likely participant in cigarette smoke-induced apoptosis and the subsequent development of emphysema. Already exposed to the highest oxygen environment of any organ in the body, the lungs of smokers are further exposed to cigarette smoke each puff of which exposes the lungs directly to,

in addition to oxidant molecules, many elements, including nicotine, which indirectly induce oxidative stress [44–48]. More recently, *in vivo* studies revealed evidence of oxidative stress, measured by markers of lipid peroxidation, including thiobarbituric acid-reactive substrates and 4-hydroxy-2-nonenal (4-HNE), in the lungs of smokers with emphysema, with levels inversely correlating with the severity of disease measured by FEV_1 [49,50]. In fact, markers of lipid peroxidation, DNA oxidation and protein oxidation have been shown to be increased in the BALF and lung tissue of smokers even in the absence of emphysema [50–54].

Using their original model, Tudor *et al.* postulated that oxidative stress was required for endothelial cell apoptosis and the development of emphysema with VEGFR blockade and demonstrated that a superoxide dismutase mimetic inhibited lung expression of markers of oxidative stress and blocked subsequent alveolar septal cell apoptosis and emphysematous changes induced by VEGFR blockade [24]. Caspase inhibition – already known to block apoptosis and emphysema in this model – also reduced lung expression of markers of oxidative stress, introducing the possibility that apoptosis itself contributes to the oxidative stress seen in these patients, creating a positive feedback loop in which oxidative stress causes apoptosis which in turn further increases the oxidative stress. The intricate link of cigarette smoke-induced oxidative stress and endothelial cell apoptosis is clearly emphasized in studies of mice in which enhanced susceptibility to oxidative stress by genetic deletion of Nrf2, a transcription factor that regulates

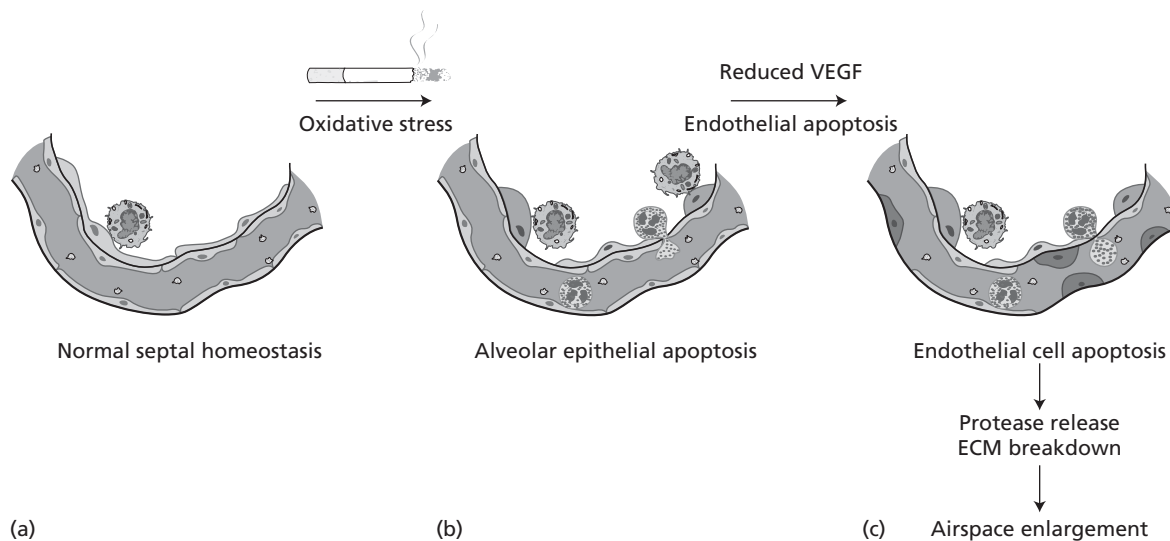

Figure 27.3 Cigarette smoke, oxidative stress and apoptosis in the pathogenesis of COPD. Oxidative stress from cigarette smoke leads to alveolar epithelial cell apoptosis and decreased vascular endothelial growth factor (VEGF) expression. This in turn induces alveolar septal endothelial cell apoptosis with release of proteases, destruction of the extracellular matrix (ECM) and eventual loss of the alveolar unit.

antioxidant enzymes, increases the risk of cigarette smoke-induced apoptosis and emphysema [55].

Direct oxidative stress does not represent the sole link between cigarette smoke and apoptosis. Cigarette smoke also down-regulates expression of the VEGF receptor, reduces VEGF expression by epithelial cells and endothelial cells, and inhibits the VEGF-dependent survival of endothelial cells in culture [56,57]. The induction of mitochondrial and DNA damage by cigarette smoke exposure also induces apoptosis of epithelial and endothelial alveolar cells. Finally, cigarette smoke evokes alveolar inflammation with the release of cytokines such as tumour necrosis factor α (TNF- α), interleukin 1B (IL-1B), IL-8, leukotriene B₄ (LTB₄) and transforming growth factor β (TGF- β), which have been shown to contribute to elastolytic damage in pulmonary emphysema [58].

These developments in the understanding of the mechanisms of lung destruction in emphysema highlight the presence of positive feedback mechanisms engaging apoptosis, oxidative stress and matrix proteolysis, which together with inflammatory mediators overwhelm the defense or maintenance mechanisms of endothelial alveolar cells [59]. Ongoing studies are identifying potentially critical mediators that link and amplify these destructive processes, and may emerge as key targets of therapeutic interventions in emphysema. A potentially central relay of endothelial cell apoptosis linked to inflammatory mediator signalling (TNF- α) and oxidative stress generation is ceramide, a signalling sphingolipid and known mediator of apoptosis and tissue injury in different organs which has been shown to mediate VEGF receptor blockade-induced emphysema and oxidative stress in both mice and rats [60,61].

Conclusions

Despite a notable hiatus from being considered as an effector or target in the pathogenesis of chronic airflow obstruction, the pulmonary endothelium has now assumed a potentially major role in the development of emphysema. Current models of apoptosis-induced emphysema are notable for lack of inflammation – a mainstay of the current protease–antiprotease theory of emphysema. These findings do not necessarily directly refute the importance of the protease–antiprotease imbalance in emphysema, but instead offer an alternative paradigm in which chronic cigarette smoke causes oxidative stress and alveolar epithelial cell apoptosis, which in turn disrupts the normal VEGF-dependent maintenance of alveolar capillary endothelial cell health. These recent studies do imply, however, that alveolar apoptosis, in addition to inflammation, constitutes a primary event leading to the release of elastolytic enzymes and alveolar wall destruction. The endothelium-

dependent models of emphysema have provided us with a new conceptual framework in which to study the links between inflammation, protease–antiprotease imbalance, oxidative stress and alveolar septal cell destruction. The finding of decreased VEGF levels in smokers, both with and without emphysema, is particularly interesting as a variety of stimuli (chronic hypoxia, TNF- α , IL-1 β , neutrophil elastase) stimulate VEGF expression and secretion by epithelial cells [16,30], resulting in an expected preservation or increase in VEGF expression in smokers. The fact that decreased VEGF levels in healthy smokers precedes the development of apoptosis and airspace enlargement suggests that a breakdown in the normal maintenance of alveolar vascular structures may be a key step in the development of COPD. Future research will explore the roles of VEGF, apoptosis and oxidative stress in human emphysema and likely identify novel endothelial cell targets for the prevention or treatment of this devastating disease.

CHAPTER 28

Mesenchymal cells of the lung

Stephen I. Rennard and J. Graham Sharp

Mesenchymal cells are a diverse class of highly specialized cells that produce and remodel extracellular matrix, modulate tissue development and epithelial differentiation, and regulate inflammatory responses. Mesenchymal cells have key roles both in normal tissue function and in the pathophysiology of many diseases including chronic obstructive pulmonary disease (COPD). Unfortunately, understanding of mesenchymal cell classification and ontogeny is incomplete. This stems in part from the lack of unique biochemical and histological markers for specific mesenchymal cells, and in part from the structural and functional plasticity of these cells. In addition, mesenchymal cells can be readily cultured *in vitro*. This has resulted in a rich investigative literature. However, because the *in vitro* culture of mesenchymal cells alters cellular phenotype, the *in vivo* significance of *in vitro* studies is not always readily apparent. Nevertheless, it is becoming clear that mesenchymal cells contribute to the pathogenesis of COPD, are attractive targets for future therapeutic interventions and may be vehicles to mediate novel therapeutic strategies such as gene-based treatments. This chapter provides an overview of mesenchymal cells, particularly as they relate to COPD. For a more comprehensive review of COPD pathophysiology, see Section 4.

Origins of mesenchymal cells

All complex multicellular organisms contain sheets of epithelial cells [1]. These cells adhere to each other through several types of junctions and rest on a specialized extracellular matrix, the basement membrane. Epithelial cells often demonstrate marked structural and functional polarity, with marked differences between the apical and the basal portions of cells. The simplest of multicellular organisms consist of a single layer of epithelial cells. More complex organisms generate multiple epithelial layers by differentiation, indentation and folding of the epithelial surface. By

this mechanism, the outer epithelial layer (ectoderm) and an inner epithelial layer (endoderm) are generated. By further folding, intermediate layers of epithelial cells (mesoderm) can also be generated. Mesenchymal cells arise by a different mechanism. (See Hay [1] for a detailed discussion of the origin of mesenchymal cells in embryology.)

In the formation of mesenchymal cells, epithelial cells undergo a pronounced morphological and functional shift, the epithelial–mesenchymal transition (EMT) [1,2]. In this process, cells detach from their neighbours, assume an elongated shape, separate from and invade the subjacent basement membrane and migrate through the connective tissue beneath the epithelium. In complex organisms, therefore, mesenchymal cells are present in the mesoderm. However, ‘mesodermal’ and ‘mesenchymal’ are not synonymous. Mesodermal structures, for example, can include epithelia. Conversely, some mesodermal organisms, such as the protochordate *Amphioxus*, lack mesenchyme. Characteristically, these organisms remain small and are structurally simple. Mesenchymal cells are key to the development of structural complexity. Specifically, mesenchymal cells migrate through the mesoderm, condense and differentiate into the cartilage and bone required to form the vertebral column. By an analogous process of migration, condensation and differentiation, mesenchymal cells contribute to the formation of somites, the extremities and parenchymal organs. A large number of differentiated mesenchymal cell types result from these processes.

The molecular events that control the EMT process are incompletely delineated. However, a key feature of epithelial cells is the expression of the adhesion molecule E-cadherin [3]. This molecule participates in the organization of the adherens junctions that characterize epithelia. It also binds and segregates free β -catenin [1]. If present, free β -catenin can bind to and activate the transcription factor LEF-1 which activates genes causing epithelial cells to lose epithelial features and acquire a mesenchymal phenotype.

Interestingly, in epithelial cells transfected with a LEF-1 expressing adenoviral vector, which induces EMT, this process is reversible with loss of the lymphocyte effector function-1 (LEF-1) activity, suggesting plasticity between epithelial and mesenchymal cells [4]. A variety of other factors including transforming growth factor β (TGF- β), Wnt, Hedgehog and Notch can also modulate EMT, possibly via their interaction with β -catenin and modulation of LEF-1 activity.

Mesenchymal cells express a number of characteristic genes including vimentin, several forms of actin and produce fibronectin. However, none of these are specific for mesenchymal cells. A consensus conference therefore, has suggested a definition of a mesenchymal cell (in the context of the EMT) that includes:

- 1 front-back end polarity;
- 2 elongate morphology;
- 3 filopodia; and
- 4 invasive motility (reviewed by Hay [1]).

As pointed out in the same review, a frequently used definition of myofibroblasts, the presence of stress fibres, is not appropriate because stress fibres are often an artefact that results from *in vitro* adhesion of mesenchymal cells to rigid substrates [1]. The difficulties with this definition is confounded by artefacts generated by *in vitro* studies recapitulated in attempts to define subsets of mesenchymal cells, particularly fibroblasts and myofibroblasts, cells likely to have important roles in COPD pathogenesis (see below). The lack of definitive biochemical and histochemical markers has also confounded studies of mesenchymal cell ontogeny.

All mesenchymal cells originate from primitive epithelia. However, it is likely that there are specific populations of mesenchymal cell stem precursors/stem cells that maintain mesenchymal cell populations. In this context, a stem cell is a cell that has the capability of dividing to maintain its own population (i.e. self-renewal) and of forming at least one type of differentiated cell. If a stem cell can give rise to several cell types it is pluripotent. If it can give rise to all cell types including whole organisms (i.e. it has all the capability of a fertilized egg) it is totipotent. For a variety of reasons, mesenchymal stem cells (MSCs) have attracted much recent interest [5].

MSCs have been isolated and defined based on *in vitro* characteristics [5]. For example, when bone marrow cells are isolated and plated on a rigid surface, a subpopulation of cells will adhere and proliferate to form colonies of spindle-shaped fibroblast-like cells. When subcultured under various specific conditions, these cells can differentiate into a number of lineages. The cells present in the original marrow isolate that formed the original colonies have been defined as MSCs. Unfortunately, no unique markers have been established that specifically identify MSCs, although they characteristically express the surface markers STRO-1,

SH2, SH3 and SH4 and lack the haematopoietic markers CD45, CD34 and CD14. It is likely, moreover, that MSCs are heterogeneous. In this context, a number of methods have been developed to isolate and culture MSCs. These have resulted in varied results together with a number of sometimes confusing names [5–7]. It seems quite likely that the differences among studies are in part caused by isolation of subpopulations of cells from within the MSC population [8].

MSCs have been reported to lack telomerase and to have a considerable, but limited, potential for self-renewal. However, subpopulations of cells from the MSC population have been reported to undergo more extensive population doublings [7]. Similarly, the addition of specific growth factors (e.g. fibroblast growth factor 2 (FGF2)) can result in extended population doublings [9], consistent with the selective expansion of a subpopulation of cells from within the MSC population.

MSCs have the potential to differentiate into a number of cell types. This includes a variety of mesenchymal cell types: cartilage, bone, adipocytes, smooth muscle, cardiac muscle [10], skeletal muscle [11] and stromal cells [5]. In addition, MSCs have been reported to give rise to neural cells [12] and epithelial cells [13]. On the other hand, isolated clones of MSCs have been reported to have limited potential for differentiation. Thus, some clones can give rise to chondrocytes, bone cells and adipocytes, while other clones can give rise to only two types or one type of cell, supporting the concept of heterogeneity in the MSC population [5]. These findings are also consistent with a model in which MSC 'differentiation' is accompanied by a progressive restriction in self-renewal and differentiation potential. However, Song and Tuan [14] have reported that differentiated cells derived from MSCs can be induced to dedifferentiate, replicate and subsequently redifferentiate into other types of cells. This 'trans-differentiation' suggests considerable plasticity exists within mesenchymal cell populations.

In addition to bone marrow, cells with the functional characteristics of MSCs have been isolated from many other tissues [5]. However, neither the *in vivo* role of MSCs, nor even their location within tissues has been defined. Nevertheless, it is clear that populations of cells are present within many tissues that have considerable potential for proliferation and differentiation. Interestingly, circulating pools of stem/precursor cells are also present. A population of circulating mononuclear cells that express collagen type I and can form fibroblast-like cells, termed fibrocytes, has been suggested to be a precursor for mesenchymal cells and to participate in wound healing [15]. These cells have been suggested to contribute to myofibroblast populations in the airway in asthma [16], to the development of pulmonary fibrosis [17] and may contribute to vascular remodelling in pulmonary hypertension [18].

At the present time, the precursor–progeny relationship among the various mesenchymal cell populations in the lung remains undefined. Similarly, it is unclear what the roles of the various potential precursor/stem cell populations are *in vivo*. However, as methods for tracking cell lineages advance, and as methods for identifying differentiated cell populations improve, enhanced understanding of mesenchymal cell lineages and of the molecular events that control differentiation and proliferation of specific cell types can be anticipated.

Cell types

Chondrocytes

Chondrocytes are present in the bronchial cartilages where they produce the collagenous and proteoglycan components of cartilage [19]. Like other cartilage, it is likely that airway cartilage responds to mechanical stimuli [20,21], a feature that is characteristic of other mesenchymal cells (see below). Abnormalities in bronchial cartilage are present in airway disease. Degeneration of bronchial cartilage occurs in COPD, particularly when chronic bronchitis is present, and in asthma [22,23]. Perichondrial fibrosis and neutrophilic inflammation are often associated with this degeneration. Interestingly, evidence of chondrocyte activation is also often present, suggesting that chondrocytes may contribute to cartilage degeneration, perhaps by producing MMPs. Functional alterations in airway cartilage may contribute to abnormalities in the trachea and large airways, such as collapse during cough or forced exhalations and to the structural alterations present in ‘saber sheath trachea’ [24].

Smooth muscle cells

In the lung, smooth muscle cells (SMC) are present in the airways, and in the arterial, venous and lymphatic vessels. SMC are elongated, surrounded by a basement membrane and are connected to each other by gap junctions. They characteristically contain desmin, smooth muscle myosin and α -smooth muscle actin (α -SMA) [25]. Because these markers may also be present in myofibroblasts, they are not specific markers for SMCs. Smoothelin, however, is a cytoskeletal protein that may be specific for SMCs [26]. Because SMCs can reversibly contract in response to a number of stimuli, they are crucial in regulating the luminal diameter of the vessels they surround.

SMCs from different sites vary in important ways; for example, in their response to contractile and relaxant stimuli and in their response to growth factors. Qualitative and quantitative alterations in SMCs have key roles in

many lung diseases including asthma [27], pulmonary hypertension [28,29] and lymphangioliomyomatosis [30]. It is likely that alterations in airway and vascular smooth muscle also contribute to the pathogenesis of COPD. Recognition of the role of the *TSC2* gene in lymphangioliomyomatosis [31] and of the bone morphogenic protein receptor 2 gene in primary pulmonary hypertension [32] has not only aided understanding of these diseases, but promises to clarify the mechanisms that control SMC biology in general.

Pericytes

Pericytes are smooth muscle like cells that partially surround the endothelial cells of small vessels. They are present in the lung in postcapillary venules and in alveolar capillaries. They are surrounded by a basement membrane that fuses with that of the vascular endothelial cell. Pericytes, which express α -SMA and are assumed to be contractile, have been suggested to regulate alveolar capillary blood flow [25]. Mice deficient in platelet derived growth factor-B (PDGF-B) fail to develop pericytes and develop microaneurysms, suggesting a role for pericytes in maintenance of microvascular structure [33]. MSCs from bone marrow appear to be closely related to pericytes [34].

Fibroblasts and myofibroblasts

Fibroblasts and myofibroblasts are spindle-shaped interstitial cells that are believed to be the major cells responsible for the synthesis and organization of structural extracellular matrix macromolecules, including collagen and elastin [25,35]. These two types of cells are themselves heterogeneous. For example, the dense collagen bundles present in tendon are believed to be synthesized and organized by highly specialized fibroblasts [36,37]. Similarly, the loose but highly organized extracellular matrix of organs such as the lung is believed to be synthesized primarily by local fibroblasts [38]. The observation that fibroblasts cultured from different tissues are functionally distinct supports the concept that fibroblasts in different tissues represent committed populations of distinct differentiated cells [39–42]. Even within a tissue, it is likely that myofibroblasts and fibroblasts at different sites can be functionally different. In the gut, for example, two morphologically distinct types of myofibroblasts are present [43,44]. These cells differ in their responses to cytokines and in their ability to induce responses in gut epithelial cells.

Myofibroblasts are distinguished from fibroblasts in having more highly developed cytoskeletal structures together with gap junctions [25,35]. This suggests coordinated contractile function for myofibroblasts, making them a cell intermediate between a fibroblast and an SMC. The most

commonly used feature to characterize myofibroblasts is the presence of α -SMA. However, expression of α -SMA is not a universal feature of myofibroblasts. A more characteristic feature that can distinguish myofibroblasts from fibroblasts is the presence of stress fibres. These are intracellular bundles of actin together with other contractile proteins. They insert into the cell membrane at the fibronexus, a specialized structure that links the intracellular fibre bundle with cell surface integrins and through this structure with extracellular matrix fibres. The fibronexus can mediate both outside-in and inside-out signalling. Thus, the fibronexus is believed to provide a means for the cell to exert mechanical force on the components of the surrounding matrix and to respond to external mechanical stress. While fibroblasts may express stress fibres when cultured *in vitro*, this is believed to be an artefact of the culture conditions [1,35]. *In vivo*, fibroblasts are thought to lack well-defined stress fibres. Myofibroblasts, in contrast, contain stress fibres. Consistent with this, they respond to mechanical loading and are thought to generate tension within tissue.

The distinction between fibroblasts and myofibroblasts is complicated by the fact that a large and rapidly expanding group of mediators can induce α -SMA expression in fibroblasts. This has often been used as a demonstration of myofibroblast differentiation from fibroblasts. TGF- β , for example, is a particularly effective inducer of this phenotype in fibroblasts [45]. Together with the acquisition of α -SMA expression, TGF- β induces fibroblasts to produce more collagen and fibronectin and to more vigorously contract three-dimensional collagen gels. After removal of the TGF- β , however, the original functional phenotype is gradually restored [46]. Thus, is it unclear if TGF- β induces a 'differentiation' of fibroblasts or causes a change in functional status.

TGF- β induction of α -SMA and collagen type I expression in fibroblasts, but not of plasminogen activator-1 expression, is dependent on extracellular fibronectin containing the ED-A splice variant [47]. This is also induced by TGF- β , but indicates that the differentiation (or functional regulation) of fibroblasts into myofibroblasts requires a set of signals that include specific signals from the extracellular matrix. In contrast, α -SMA expression by rat myofibroblasts does not depend on CaRG elements [48], unlike murine smooth muscle cells where these elements are required [49]. Although species differences may account for this difference, the results are also consistent with distinct regulatory pathways acting to control similar phenotypes in different populations of mesenchymal cells and therefore support the functional heterogeneity of these cells.

Fibroblasts and myofibroblasts also have key roles in embryologic development and in the regulation of other

cells within tissues. The development of many-branched parenchymal organs, including the lung, liver, pancreas, salivary gland and kidney, depends on interactions between the epithelial cells and the subjacent mesenchymal cells (epithelial-mesenchymal interactions) [50-54]. In addition, in the lung, a specialized population of lipid-containing fibroblasts has been described that has been suggested to play a key part in alveolar wall formation [55]. The signals that provide specificity for the site and structure of these organs during embryogenesis are, in large part, a function of the mesenchymal cells. Mesenchymal stromal cells also have a critical role in the maintenance of haematopoietic stem cells [56-58] and mesenchymal cell derived niches are likely important in supporting other stem/progenitor cells as well [59-63]. In the crypt of the small intestine, for example, bone marrow derived sub-epithelial fibroblasts have been shown to have a regulatory role over epithelial stem cells [64,65]. Whether fibroblasts or myofibroblasts provide similar regulatory functions in the stem cell niches present in the lung remains to be defined.

The ability of fibroblasts and myofibroblasts to provide regulatory functions likely extends beyond the role in development and in maintaining stem cell niches. These cells are active producers of inflammatory mediators, as are SMC [66]. It is likely, therefore, that mesenchymal cells play an active part in driving inflammatory processes in the lung and in modulating their resolution.

Alveolar myofibroblasts are specialized cells that differ from many other myofibroblasts in lacking α -SMA [1,35]. Alveolar myofibroblasts are relatively numerous, with up to 20 surrounding an alveolus. The nuclei are generally located at the junction of three alveolar septa into which the cell extends processes. Alveolar myofibroblasts are distinguished from pericytes by lack of a basement membrane and lack of α -SMA expression. However, like other myofibroblasts, they have gap junctions and stress fibres and are believed to account for the contractility of excised lung parenchyma. It has been suggested that the alveolar myofibroblasts, by virtue of their contractile function, have an important role in normal lung physiology [25]. Specifically, the contraction of these cells can be modified by a variety of factors including hypoxia [67], supporting a role in ventilation-perfusion matching. A role for these cells in the altered physiology of COPD, particularly altered lung volumes, is appealing.

Myofibroblasts are also thought to have key roles in the pathophysiology of several lung diseases. The cells that accumulate in fibroblastic foci and adjacent areas of fibrosis in idiopathic pulmonary fibrosis (IPF) are α -SMA positive myofibroblasts [68,69]. Similar cells are present in Masson bodies at sites of fibrosis in bronchiolitis obliterans [68] and are present in animal models of fibrosis induced by

bleomycin [70]. Myofibroblasts are increased in the airway wall in asthma [71], where the number of myofibroblasts is related to the thickness of the basal lamina [72], consistent with a role in airway wall remodelling. These disease-related myofibroblasts could potentially be derived locally, for example from TGF- β induced differentiation of resident fibroblasts. Alternatively, cells with the features of circulating fibrocytes have been described in the airway wall in asthma, suggesting a role for circulating precursors [16]. A circulating source has been suggested for the myofibroblasts present in the pulmonary parenchyma in lung fibrosis [17,73]. Similarly, a circulating source has been suggested to contribute to the remodelling that occurs in pulmonary vascular disease [18]. These studies have used different species and different experimental models and the phenotype of the circulating mesenchymal cell precursors has shown some differences. Whether these represent true heterogeneity or reflects species differences remains to be determined.

A role for myofibroblasts in the peribronchial fibrosis that characterizes many patients with COPD is appealing [74,75]. However, the precise origin and functional contribution of these cells to COPD pathogenesis remains to be determined. Experimental evidence suggests alveolar myofibroblasts, or rather their lack, can contribute to the development of emphysema. Mice that are deficient for PDGF-A fail to develop alveolar myofibroblasts and also develop emphysema, likely because of failed development of alveolar wall [76]. Whether a similar process contributes to human emphysema is not defined.

Altered populations of cells versus altered functional states

A major unanswered question is to what degree the alterations in mesenchymal cells present in COPD represent changes in populations of differentiated cells or changes in the functional state of cells in response to the cytokines and mediators present in the local milieu. This is an important issue, as the two different models should lead to different therapeutic approaches. While the latter would suggest pharmacotherapy to block specific mediator pathways, the former would require treatments that would alter structural cell populations.

Fibroblasts from different tissues are functionally distinct. These differences are preserved during extended *in vitro* cultures, suggesting they represent a true differentiated commitment rather than a response to a local mediator. This supports the concept of distinct populations of mesenchymal cells. Similarly, cells cultured from the lungs of patients with IPF show a persistently abnormal phenotype, including altered growth characteristics, increased expression of α -SMA, increased production of TGF- β 1, increased

contractility and reduced production of prostaglandin E₂ (PGE₂) [77,78]. The persistence of similar abnormalities in culture is also observed in fibroblasts cultured from other fibrotic tissues [79–81] and in animal models of lung fibrosis [82,83]. These observations support the concept that the fibroblasts in fibrotic lung tissue represent a unique, distinct, differentiated phenotype, different from that of fibroblasts present in normal lung.

Consistent with this concept, mesenchymal cells cultured from the airways of asthmatics show persistent differences from normal cells in culture including increased contraction of collagen gels [84], increased production of the protease matrix metalloprotease-2 (MMP-2) [85] and increased cytokine responsiveness [86]. These observations, together with the persistence of structural abnormalities in the airway, despite adequate anti-inflammatory therapy [87,88], have suggested the possibility that a primary abnormality of structural cells may be present in asthma [89].

Mesenchymal cells cultured from the lungs of COPD patients have also been assessed. Holz *et al.* [90] have reported reduced proliferation of fibroblasts derived from emphysematous tissues. Noordhoek *et al.* [91], however, found no difference in proliferation under ‘control’ conditions, but found altered response to interleukin 1 (IL-1) and TGF- β . Nobukuni *et al.* [92] also found reduced proliferation of emphysema fibroblasts and noted that they were more inhibited than control fibroblasts by cigarette smoke. It is unclear if differences in methodology or if heterogeneity in the patient populations studied contribute to these experimental differences. Nevertheless, while the properties of mesenchymal cells cultured from the lungs in emphysema remain to be fully delineated, a functional alteration consistent with a change in the differentiated population is possible.

The deficient proliferation observed in mesenchymal cells cultured from emphysematous lung suggests deficient repair function and contrasts markedly with the augmented function discussed above for fibroblasts isolated from fibrotic tissues. In this context, deficient repair could lead to net loss of lung tissue and could be a mechanism for the development of emphysema [93]. Interestingly, fibroblasts from aged animals have a phenotype characterized by deficient ‘repair’ type functions including migration [94], cytoskeletal organization, integrin expression [95] and proliferation [96,97]. This could provide a mechanism for the development of senile emphysema.

Mesenchymal cells may also be targets for cigarette smoke toxicity that leads to COPD. In this context, *in vitro* cigarette smoke can inhibit lung fibroblast chemotaxis, proliferation [98], production of extracellular matrix and contraction of three-dimensional collagen gels [99]. Inhibition of these ‘repair’ functions could contribute to the development of emphysema. Inhibition of collagen gel

contraction is mediated by smoke-induced inhibition of fibronectin production and can be reversed by the addition of exogenous fibronectin [99]. This effect, however, is observed in cells cultured at low density. In high-density cultures, smoke can cause activation of TGF- β and can augment gel contraction [100]. This variability with cell density suggests that the *in vivo* effect of cigarette smoke on mesenchymal cell repair functions may vary with local conditions.

Therapeutic implications

Mesenchymal cells are already major targets for therapeutic intervention in lung disease. Inhibition of airway smooth muscle contraction by anticholinergic drugs that block contraction and by β -adrenergic agonists that directly relax smooth muscle are mainstays in the treatment of COPD and asthma. Similarly, the vasodilator effects of prostacyclin and its analogues and of endothelin antagonists on vascular smooth muscle are key in treating pulmonary hypertension. A greatly expanded role for mesenchymal cells in the treatment of lung diseases in general and COPD specifically seems likely in the future for several reasons.

First, mesenchymal cells, particularly alveolar myofibroblasts, may be key in regulating ventilation–perfusion matching [25]. The ability of these cells to modulate alveolar volume offers an opportunity to alter the hyperinflation that compromises function in COPD at rest and with exercise [101].

Secondly, COPD is characterized by structural alterations of the lung that result, likely in large part, from the activity of mesenchymal cells [74,75]. It is reasonable therefore that therapy directed at mesenchymal cells could prevent or, possibly, reverse these changes.

Thirdly, several lines of evidence suggest that the lung, like many tissues, can substantially repair following injury. Retinoic acid, for example, has been demonstrated to facilitate regeneration of alveolar wall in rodent lungs following the development of emphysema [102]. Collaborative interactions among a variety of cell types, including mesenchymal cells, are required for alveolar wall formation. It is likely therefore that mesenchymal cells could be targets of treatments designed to restore lung structure.

Finally, it is possible that therapy designed to restore lung function will require replacing a population of cells. In this context, engraftment of circulating stem/precursor cells may not only contribute to disease, but could also be therapeutic. Ortiz *et al.* [103], for example, were able to block the development of bleomycin-induced fibrosis in a sensitive animal by transplanting cells from a resistant strain. This occurred even though a very small number of donor cells were engrafted, consistent with a regulatory role for the transplanted mesenchymal cells.

MSCs, and a number of similarly derived cells, which can be expanded *in vitro*, infused into living recipients and subsequently differentiate into functional tissues are being widely investigated for a variety of therapeutic applications [5]. Interestingly, MSCs appear to have a low risk for inducing graft-versus-host disease (GVHD) and may actually suppress active GVHD [104,105]. These characteristics have suggested that MSCs may be ideal carriers to introduce novel genetic material for gene-based therapy.

Conclusions

Mesenchymal cells are a heterogeneous population of cells that mediate a diverse set of functions in the lung. These include lung development, responses to injury and regulation of functions of the normal lung. As understanding of the part that mesenchymal cells play in health and disease advances, these cells are likely to become increasingly important in the therapy of lung diseases including COPD.

SECTION 4

Pathogenesis

CHAPTER 29

Lung development

Cheng Chen, David Warburton and Wei Shi

Lung developmental process

The functional mammalian lung has a honeycomb-like structure, containing extensively branched, perfectly matched conduits for air and blood. This configuration maximizes the gas exchange surface area, supports effective gas ventilation and exchange between air and blood, and facilitates maximally efficient packing within the chest cavity. In humans, the gas exchange membrane (approximately 0.1 μm thick) consists of alveolar epithelial cells, basement membrane and endothelial cells, and the total surface area is approximately 70 m^2 . This complex structure is developed sequentially by early epithelial tube branching and by late septation of terminal air sacs. Perturbation of this developmental process results in abnormal lung structure and hence deficiency of respiratory gas exchange function. Therefore fundamental knowledge about this basic developmental process and the underlying molecular regulatory mechanisms that drive it is essential to understand the pathogenesis of many respiratory diseases and, more importantly, to design novel therapeutic strategies to prevent and treat related pulmonary diseases, such as bronchopulmonary dysplasia, and their chronic sequelae.

The origin of lung

The lung originates from the ventral surface of the primitive foregut at 5 weeks' gestation in humans. The lung anlage emerges as the laryngo-tracheal groove, located in the ventral foregut endoderm, which invaginates into the surrounding splanchnic mesenchyme (Fig. 29.1). A pair of primary buds then evaginate from the laryngo-tracheal groove and the respiratory tree develops by branching morphogenesis, in which reiterated outgrowth, elongation and subdivision of epithelial buds occurs in a bilaterally asymmetrical pattern. Three lobes on the right side and two

lobes on the left side are formed in human lung. There are 23 generations of airway branching in humans. The first 16 generations branching is stereotypically reproducible and is completed by 16 weeks, while the remaining seven generations are random and are completed by approximately 24 weeks. Alveolization begins at around 20 weeks' gestation in the human lung, and is completed postnatally at approximately 7 years of age.

Lung organogenesis is under the control of many gene products that act cooperatively to define precisely the location of the laryngo-tracheal groove formation and specify proximal–distal, dorsal–ventral and left–right axes of the developing lung. The earliest endodermal signal essential for gut morphogenesis are the GATA (zinc finger proteins that recognize GATA DNA sequence) and hepatocyte nuclear factor (HNF) transcription factors. GATA-6 is required for activation of the lung developmental programme in the foregut endoderm. *Hnf-3 β* is a survival factor for the endoderm, and expression of *Hnf-3 β* is induced by Sonic Hedgehog (*Shh*) signalling. Also, *Tbx4* can induce ectopic bud formation in the oesophagus by activating the expression of *Egf10* [1]. In addition, left–right asymmetry is controlled by several gene products, including *nodal*, *Lefty-1,2* and *Pitx-2*. For example, single-lobed lungs are found bilaterally in *Lefty-1* mice, and isomerism of lung is found in *Pitx-2* null mutants. The exact molecular mechanisms responsible for primary lung bud induction are as yet only incompletely understood.

Histology and cytology of lung development

Histological stages of lung development

Histologically, lung development and maturation has been divided into four stages: the pseudoglandular stage, the canalicular stage, the terminal sac stage and the alveolar stage (see Plate 29.1; colour plate section falls between pp. 354 and 355).

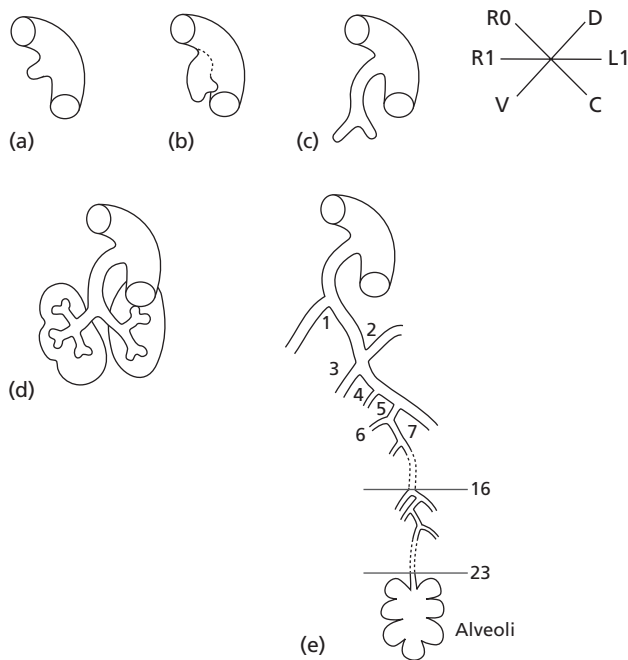

Figure 29.1 Diagrams showing key events in human lung morphogenesis. (a) The primitive lung anlage emerging as the laryngo-tracheal groove from the ventral surface of the primitive foregut at 5 weeks' gestation in humans. (b) The primitive trachea separating dorso-ventrally from the primitive oesophagus as the two primary bronchial branches arise from the lateral aspects of the laryngo-tracheal groove at 5 ± 6 weeks' gestation in humans. (c) The embryonic larynx and trachea with the two primary bronchial branches separated dorso-ventrally from the embryonic oesophagus at 6 weeks' gestation in humans. (d) The primitive lobar bronchi branching from the primary bronchi at 7 weeks' gestation in humans. (e) A schematic rendering of the term fetal airway in humans. The stereotypically reproducible first 16 airway generations are complete by 16 weeks' gestation in humans. Between 16 and 23 weeks, the branching pattern is random and this is completed by approximately 24 weeks in humans. Alveolization begins after about 28 ± 30 weeks in humans and is complete by 7 years of age at the earliest.

Pseudoglandular stage (5–17 weeks' human gestation, E9.5–16.6 days in mouse embryo)

This is the earliest stage of lung development, in which the embryonic lung undergoes branching morphogenesis, developing epithelial tubular structures with lining cuboidal epithelial cells that resemble an exocrine gland. This fluid containing respiratory tree structure cannot support gas exchange.

Canalicular stage (16–25 weeks' human gestation, E16.6–17.4 days in mouse embryo)

The cranial part of the lung develops relatively faster than the caudal part, resulting in partial overlap between this

stage and the previous stage. During the canalicular stage, the respiratory tree is further expanded in diameter and length, accompanied by vascularization and angiogenesis along the airway. A massive increase in the number of capillaries occurs. The terminal bronchioles are then divided into respiratory bronchioles and alveolar ducts, and the airway epithelial cells are differentiated into peripheral squamous cells and proximal cuboidal cells.

Terminal sac stage (24 weeks' to late fetal period in humans, E17.4 to postnatal day 5 (P5) in mouse)

There is substantial thinning of the interstitium during the terminal sac stage. This results from apoptosis as well as ongoing differentiation of mesenchymal cells [2,3]. Additionally, at this stage, the alveolar epithelial cells are more clearly differentiated into mature squamous type I pneumocytes and secretory rounded type II pneumocytes. The capillaries also grow rapidly in the mesenchyme surrounding the alveoli to form a complex network. The lymphatic network in lung tissue becomes well developed during this stage. Towards the end of this stage, the fetal lung can support gas exchange to maintain the life of prematurely born neonates. Although human premature infants can breathe with the lung that has developed towards the end of terminal sac stage, the immature lung is nevertheless vulnerable to hyperoxic injury and barotrauma, resulting in the alveolar hypoplasia phenotypes progressing toward bronchopulmonary dysplasia. Maturation of surfactant synthesis and secretion is a key factor in determining whether the newborn lung can sustain gas exchange without collapsing. Another key factor is the rapid switch from chloride ion driven fluid secretion into the airway to sodium driven uptake of fluid out of the airway. This latter is driven by the response of the adrenergic system to cord cutting at birth.

How lung development is controlled at this stage is still incompletely known. The hydrostatic pressure inside the lumen of the airway, which results from chloride ion and hence liquid secretion from epithelium in the developing lung [4–6], integrated with chemotactic signals from the mesenchyme such as FGF10 have important roles in forming terminal sacs. Mechanical factors also play an important part. Diaphragm muscle in *MyoD(-/-)* mice is significantly thinned and cannot support fetal breathing movements. As a result, lung is hypoplastic, and the number of proliferating lung cells is decreased in *MyoD(-/-)* lungs at E18.5. Therefore, mechanical forces generated by contractile activity of the diaphragm muscle have an important role in normal lung growth at this stage [7].

Alveolar stage (late fetal period to childhood in humans, P5–P30 in mouse)

Alveolization is the last step of lung development. The

majority of the gas exchange surface is formed during this stage. Alveolarization can be positively and negatively influenced by many exogenous factors including oxygen concentration, stretch in fetal airway, dexamethasone and retinoic acid.

Forming new septa within terminal sacs is the key step for differentiation of the sacculi into alveoli. This involves a complex interaction between myofibroblasts in the mesenchyme, adjacent airway epithelial cells and vascular endothelial cells. Controlled multiplication and differentiation as well as migration of the myofibroblast progenitors cells within terminal sac walls are important for new septa formation. Myofibroblasts, smooth muscle precursor cells having the morphology of fibroblasts, migrate to the proper position within nascent alveolar septa, and synthesize and deposit elastin [8,9]. This is the first step of new secondary septa development [9]. PDGF-A and its receptor PDGF- α have important roles in forming new septa. *Pdgf-A(-/-)* or *Pdgf- α (-/-)* show a phenotype comprising loss of alveolar myofibroblasts and elastin, failure of alveolar septation, and this develops into emphysema resulting from alveolar hypoplasia [8,10]. Besides PDGF-A, there are other key proteins that mediate cell-cell interaction within terminal sac walls. For example, Roundabout (ROBO) is a receptor known to be involved in repellent signalling controlling axonal extension in the developing neuronal system. ROBO and its ligand SLIT are also involved in the regulation of non-neuronal cell migration [11]. In E18, 1 day before birth, *Slit-2* is expressed in the saccular mesenchyme surrounding the airways. At the same time, *Robo* is expressed on the apical aspects of the airway epithelium adjacent to the ligand *Slit-2*, suggesting interactive roles in pulmonary bronchiolar development [12]. A *Robo* knock-out mouse has been shown to have loss of septation and thickened mesenchyme [13].

Two additional processes are necessary in septum differentiation to form a septum with final mature morphology and function: the thinning out of the septal mesenchyme and maturation of the capillary bed. Thinning of the mesenchymal tissue involves apoptosis of 'unwanted' cells in the postnatal lung. There is a substantial reduction in the number of interstitial myofibroblasts resulting from increased apoptosis during this phase of rapid alveolarization [14,15]. The immature lung contains at least two morphologically distinct fibroblast populations: lipid-filled interstitial fibroblasts (LFIF) and non-LIF (NLFIF). After alveolarization, apoptosis occurs preferentially in only one of these fibroblast populations, the LFIF. Apoptosis was correlated with down-regulation of insulin-like growth factor I receptor (Igf-IR) mRNA and cell surface protein expression [16]. This thinning of the previously thickened immature interstitium occurs simultaneously with the ongoing expansion of the epithelial, blood vessel and airspace compartments in

the rapidly developing septa. A mature capillary bed is also vital for the proper function of alveoli, but the mechanism is still incompletely known. In developing lungs, vascular endothelial growth factor (VEGF) isoforms and its receptors have been identified as being important for endothelial survival and proliferation in the alveolar wall. Inhibition of VEGF signalling results in abnormal lung vascular growth and reduced alveolarization [17]. Finally, the new septum differentiates into a functional respiratory membrane that consists of type I alveolar epithelial cells, basement membrane and capillary endothelial cells. The respiratory membrane provides a short distance for gas diffusion and thus facilitates optimal gas exchange. It is estimated that approximately 50 million alveoli are present in neonatal human lung. However, by age 7–8 years, when alveolarization is substantially complete, the number of alveolar units in the human lung has grown about six times to approximately 300 million alveoli.

Retinoid acid (RA) has been shown to increase the number of alveoli [18] and partially rescue a block in alveolar formation induced by dexamethasone [19]. In adult rats, RA has also been reported to reverse the anatomical features of elastase-induced emphysema in which there is destruction of septa [18]. In the *RAR- γ* gene deletion mouse, there is a developmental defect in alveolar formation most consistent with a defect in elastin deposition. The additional deletion of one retinoid X receptor (*RXR- α*) allele results in a decrease in alveolar surface area and alveolar number [20]. Retinoids affect multiple cellular functions that are involved in alveolar septal formation such as proliferation, migration and temporal differentiation of cells [21]. RA is an active metabolite of vitamin A. Vitamin A deficiency has long been known to injure lung and impair function of rat type II pneumocytes [20]. Taken together, the evidence suggests that RA may have an important role in alveolar development.

Specific cell types in lung

More than 40 specific types of cells are differentiated during embryonic lung development. The epithelial cell lineages are arranged in a distinct proximal–distal spatial pattern in the airways.

Cartilage lies outside the submucosa and decreases in amount as the calibre of the bronchi decreases. Cartilage is present in the bronchi, but is not present in the bronchioles. Two major cell components of the proximal bronchial epithelium are identified: pseudostratified ciliated columnar cells and mucous (goblet) cells. Both of them may derive from basal cells, but ciliated cells predominate in number. Goblet cells release mucus granules into the bronchial lumen to prevent drying of the walls and trap particulate matter. Mucous cells begin to mature around 13 weeks' gestation in humans, when the mature ciliated columnar cells are already present. The most widely used molecular

markers for mucous cells are mucins (MUC5B, -5A, -5C). The beating of cilia results in a cephalad movement of the mucus blanket, thereby cleaning and protecting the airway. In the case of cystic fibrosis, cilia movement is disabled because of the thick mucous layer that is caused by mutation of *CFTR* gene, which encodes a transmembrane Na^+ ion transporter protein. This phenotype also makes the airway surface vulnerable to microbial infection. In chronic airway injury, repair or experimental exposure of the epithelium to cytokines can result in goblet cell hyperplasia. Exposure to interleukin 9 (IL-9) resulted in increased lysozyme and mucus production by the epithelia [22]. IL-4, IL-13 and allergens enhance the release of transforming growth factor α (TGF- α), which is a ligand for the epidermal growth factor receptor that also stimulates fibroblast proliferation and goblet cell differentiation [23].

There are three different types of cells in bronchial submucosal glands: myoepithelial cells surround the gland, while mucous cells (pale cytoplasm) and serous cells (basophilic cytoplasm) produce mucins. These secreted mucins mix with lysozyme and immunoglobulin A (IgA) on the airway surface.

Kulchitsky cells are also found on the airway surface next to bronchial glands. Their finger-like cytoplasmic extensions usually reach the airway lumen. Their precise function is unclear. It is believed that they are pulmonary neuroendocrine cells (PNEC) that produce a variety of peptide hormones such as serotonin and calcitonin. PNEC differentiate by 10 weeks' gestation in humans. Kulchitsky cells expressing the markers gastrin-related peptide (GRP), calcitonin gene-related peptide (CGRP) and chromogranin may be related to certain lung neoplasms (i.e. small cell carcinoma and carcinoid tumours).

Clara cells are found in the distal bronchiolar airway epithelium which normally lacks mucous cells. They produce a mucus-poor, watery proteinaceous secretion. They assist with clearance and detoxification, as well as reduction of surface tension in small airways. The most important cellular marker of Clara cell is Clara cell-specific protein (CCSP). Cytochrome p450 reductase and uteroglobulin can also be used as cellular markers for Clara cells. Clara cells begin to mature during the 19th week in humans.

The majority of the alveolar surface is normally covered by type I epithelial cells. These flat cells are believed to be terminally differentiated cells, expressing several specific molecular markers, such as T1 α and aquaporin 5. T1 α is a differentiation marker gene of lung alveolar epithelial type I cells. It is developmentally regulated and encodes an apical membrane protein of unknown function. In the absence of T1 α protein, type I cell differentiation is blocked. Homozygous T1 α null mice die at birth of respiratory failure, and their lungs cannot be inflated to normal volumes [24]. Aquaporin 5 is a water channel in type I epithelial cells.

Type I epithelial cells only account for 40% of the total airway epithelial cells, even though 95% of the surface area of the alveolar wall is covered by this type of cells. The other 60% of the epithelial cells, named type II pneumocytes, are rounded cells that cover only 3% of the alveolar surface. Type II pneumocytes are plump or cubical and have a finely stippled cytoplasm and surface microvilli. They manufacture surfactant phospholipids and proteins that reduce the surface tension in the lung. This equalizes pressures, stabilizes and maintains all the alveoli in an open position despite variations in alveolar size. Type II cells are capable of regeneration and replacement of type I cells after injury. A commonly used cellular marker of type II cell is surfactant protein C (SPC).

Alveolar macrophages constitute a small percentage of the cells in alveoli, but they represent a major cellular sentinel of the host defence mechanism in the alveolar space. They are part of the mononuclear phagocyte system and are derived primarily from blood monocytes.

Stem and progenitor cells in the respiratory system

Respiratory stem and progenitor cells have important functions in repairing damaged trachea, bronchi, bronchioles or alveoli. However, the precise identification of lung stem or progenitor cells remains uncertain. The large surface area and highly branched and folded geography of the lung dictates that there must be several kinds of stem or progenitor cells in the respiratory system. In the trachea and bronchi, certain basal cells and mucus-gland duct cells are believed to be stem or progenitor cells. Clara-like cells and type II pneumocytes are also thought to function as stem/progenitor cells in bronchioles and alveoli, respectively.

It has recently been reported that bone marrow derived mesenchymal stem cells can differentiate into airway epithelial cells in airway and type I pneumocytes in alveoli, particularly following injury. In contrast, *in vitro* cell culture indicates that Syrian hamster fetal lung epithelial M3E3/C3 cells can differentiate into Clara cells and type II pneumocytes under different culture conditions. Whether CCSP-expressing cells with pre-Clara cell phenotypes are stem cells for the entire respiratory tract remains to be determined. In addition, the concept of a pluripotent stem cell for the whole lung needs to be further investigated because of the great differences between identified stem cell or progenitor candidates in proximal bronchi and distal alveoli. Recently, we have discovered that lung contains a population of cells with stem or progenitor cell characteristics that can be sorted by fluorescence-activated cell sorting (FACS) from adult rat lung. This population is relatively resistant to apoptosis and may possibly be responsible for repopulation of the damaged alveolar surface. Another such population of stem or progenitor cells sorted as 'side cells' on FACS has been identified to possibly repopulate several different

tissues, including the bone marrow. Research on both systemically derived as well as resident lung stem or progenitor cells may hold the key to understanding lung morphogenesis, lung regeneration and pathogenesis of lung cancer.

Molecular mechanisms of lung development

Normal embryonic lung development is controlled by many coordinated factors, including:

- 1 Transcription factors that directly modulate gene expression in the cell nucleus.
 - 2 Peptide growth factors and cytokines as well as their related intracellular signalling components that mediate cell–cell interaction.
 - 3 Extracellular matrix that provides important environmental cues for developing lung cells to differentiate.
- The specific integrated regulatory mechanisms are still largely unknown, but the interaction between epithelial and mesenchymal compartments has long been known to have a critical role during airway branching morphogenesis and lung maturation.

Transcription factors

Lung growth is initiated and developed through changes in specific gene expression. The activity and expression level of the relevant transcription factors determines gene expression profiles in the developing lung, and consequently the morphogenetic process in a particular temporospatial manner. Recent advances in mouse genetic technology allow us to evaluate each factor by either overexpressing or knocking out a specific gene [25]. Some of the pulmonary phenotypes in mice that resulted from a loss or gain of gene function are listed in Table 29.1 [25–63]. Therefore, three groups of transcription factors, forkhead box transcription factors, Nkx homoeodomain transcription factors, and *Gli*, have important roles in ciliated epithelial cell differentiation and airway branching.

Forkhead box transcription factor family

Many members of the forkhead box family transcription factors, such as HNF-3 α , HNF-3 β , HFH8 and HFH4, are important regulatory factors involved in lung development. These transcription factors share homology in the winged helix DNA binding domain, and have important roles in pulmonary cellular proliferation and differentiation.

HNF-3 α (*Foxa1*) and HNF-3 β (*Foxa2*) share 93% homology in their amino acid sequences, and were first identified as essential factors in hepatocyte differentiation [64]. However, *Hnf-3 β* is also expressed in developing lung, with

higher levels in proximal airway lining epithelial cells and lower levels in the distal type II epithelial cells [65]. Overexpression of *Hnf-3 β* under the control of the lung epithelial specific *SP-C* promoter *in vivo* inhibits lung branching morphogenesis and vasculogenesis [35]. Also, HNF-3 α and HNF-3 β have important functions in regulating expression of CCSP as well as surfactant proteins in both bronchiolar and type II epithelial cells [66–68]. *Hnf-3 β* is inducible by interferon, and regulates in turn the expression of the Nkx homoeodomain transcription factor *Nkx2.1* (also termed *Ttf-1* and *Cebp1*), which in turn regulates transcription of the surfactant protein genes in lung peripheral epithelium [69,70].

HFH8 is another important member of this family of proteins that contribute to lung development. At E9.5, *Hfh-8* expression is restricted to the splanchnic mesoderm contacting the embryonic gut and presumptive lung bud, suggesting that *Hfh-8* may participate in the mesenchymal–epithelial induction of lung and gut morphogenesis. *Hfh-8* expression continues in lateral mesoderm-derived tissue during development. By day E18.5, *Hfh-8* expression is restricted to the distal lung mesenchyme and the muscular layer of the bronchi [71]. One important regulated target of *Hfh-8* is *Pdgf* receptor that is also expressed in mesenchyme [8,72,73]. The level of *Hfh-8* expression is important for normal lung development, as an alveolar hemorrhage phenotype is observed in *Hfh-8(+/-)* mice, while *Hfh-8(-/-)* mice died *in utero*. In addition, reduction of *Hfh-8* expression in *Hfh-8(+/-)* mutants is accompanied by decreased expression of VEGF and its receptor 2 (Flk-1), bone morphogenetic protein 4 (BMP-4), and the transcription factors of the Brachyury T-Box family (Tbx2–Tbx5) and lung Kruppel-like factor [74]. HFH-8 binding sites are also found in the promoter region of genes, such as *Bmp4*, *Hgf* and *Hoxa5* which are very important in controlling lung morphogenesis [75,76].

Hfh-4 (*Foxj1*) is the key factor controlling ciliated epithelial cell differentiation. *Hfh-4* is expressed in E15.5 airway epithelium just before the appearance of ciliated epithelial cells [77]. Defective ciliogenesis in airway epithelial cells and randomized left–right asymmetry are observed in *Hfh-4(-/-)* null mutant mice, mimicking Kartagener syndrome in humans. This congenital syndrome can result in perinatal lethality, but in low penetrance gives rise to situs inversus, sinusitis, bronchiectasis and sterility, all resulting from defects in ciliary beat [28,29]. Interestingly, in mesenchyme-free airway epithelial culture, inhibition of endogenous BMP-4 signalling by adding exogenous BMP antagonist Noggin results in increased expression of the proximal lung markers CCSP and HFH-4 [78].

Foxp1, *Foxp2* and *Foxp3* are newly discovered members of the forkhead box family of transcription factors that are expressed at a high level in mouse lung and gut tissues. All

Table 29.1 Pulmonary phenotypes of mice with a specific gene null mutation or with a transgenic (TG) overexpression in lungs.

Gene	Pulmonary phenotype	Reference
<i>Transcription factors</i>		
<i>Gli2</i> (-/-) mice	Perinatal lethal phenotypes with severe skeletal and neuronal defects, and hypoplastic trachea and oesophagus are observed in <i>Gli2</i> knockout fetuses. Also, only one right lung lobe instead of the normal four lobes is formed in the knockout mice. Other <i>Shh</i> signalling pathway components, such as <i>Patch</i> and <i>Gli1</i> , less expressed in the knockout lungs	25
<i>Gli2</i> (-/-), <i>Gli3</i> (-/-) mice	Complete absence of lung, trachea and oesophagus is observed in this double knockout	26,27
<i>Gli2</i> (-/-), <i>Gli3</i> (+/-) mice	Oesophageal atresia with tracheoesophageal fistula and a severe lung phenotype occur in this mutant mouse. A single tracheoesophageal tube connects pharynx to the stomach. Hypoplastic embryonic lung fails to separate into left and right lobes	25
<i>Hfh4</i> (-/-) mice	Loss of <i>Hfh4</i> function results in retarded growth and perinatal lethality, as well as randomized left-right asymmetry of internal organs (50% situs inversus). Defective ciliogenesis in airway epithelial cells and absence of left-right dynein expression in the embryonic lungs are observed in <i>Hfh4</i> null mutant lung. Motile cilia (9 + 2 microtubules) are absent	28,29
<i>Hoxa5</i> (-/-) mice	Homozygous <i>Hoxa5</i> knockout mice die during perinatal stages with improper tracheal and lung morphogenesis leading to tracheal occlusion and diminished surfactant expression. Reduction in lung branching morphogenesis and thickening of the alveolar walls, as well as disorganization of proximal and distal respiratory airways are observed in <i>Hoxa5</i> null mutants. Reduced expression of surfactant protein, TTF-1, HNF-3 β and c-Myc was detected in the knockout lungs	30,31
<i>Pod1</i> (-/-) mice	Lung branching morphogenesis and alveolarization are dramatically reduced. Airway epithelial cell differentiation is perturbed as shown by abnormal <i>SP-C</i> and <i>CCSP</i> expression pattern	32
<i>Smad3</i> (-/-) mice	<i>Smad3</i> (-/-) mice exhibit centrilobular emphysema-like pathology	33
<i>SP-C</i> -driven <i>Hfh4</i> TG mice	Overexpression of <i>Hfh4</i> in lung epithelial cells results in abnormal lung development with altered epithelial cell differentiation and inhibited branching morphogenesis. Atypical cuboidal or columnar epithelial cells line the lung periphery of <i>SP-C/Hfh-4</i> transgenic mice. These atypical cells express <i>Ttf1</i> and <i>Hnf3β</i> , as well as ciliated cell marker <i>β-tubulin IV</i> , but not <i>SP-B</i> , <i>SP-C</i> and <i>CCSP</i>	34
<i>SP-C</i> -driven <i>Hnf3β</i> TG mice	Overexpression of <i>Hnf3β</i> (<i>Foxa2</i>) in lung epithelial cells arrests distal airway epithelial cell differentiation in the early pseudoglandular stage. Branching morphogenesis and vasculogenesis were markedly disrupted in association with decreased E-cadherin and vascular endothelial growth factor expression	35
<i>Ttf1</i> (-/-) mice	Null mutant mice of <i>Ttf1</i> are perinatal lethal with abnormal lung branching morphogenesis and missing thymus and pituitary gland. Failure in septum formation between trachea and the oesophagus in the knockout fetuses mimics the pathology of tracheo-oesophageal fistula. Furthermore, peripheral lung development is arrested at early pseudoglandular stage with a large airway sac, in which distal airway epithelial cells fail to express surfactant proteins and <i>CCSP</i>	36–38
<i>Growth factors and their signalling pathways</i>		
β -catenin (conditional knockout)	When β -catenin was conditionally excised in epithelial cells of the developing mouse lung prior to E14.5, the proximal lung tubules grew and differentiated appropriately. The mice died at birth because of respiratory failure. Lungs were composed primarily of proximal airways	39

(Continued . . .)

Table 29.1 (Continued . . .)

Gene	Pulmonary phenotype	Reference
<i>Egfr(-/-)</i> mice	<i>Egfr(-/-)</i> mice show abnormal branching and poor alveolization of lung. The severity of phenotypes depend on genetic background	40–42
<i>Fgf10(-/-)</i> mice	Tracheal development is present, but main-stem bronchial formation and all subsequent pulmonary branching morphogenesis, as well as vasculogenesis are completely disrupted	43,44
<i>Fgf9(-/-)</i> mice	<i>Fgf9(-/-)</i> mice die in the early postnatal period as a result of lung hypoplasia, particularly in mesenchyme. Lung branching morphogenesis is also inhibited, but proximal and distal airway cell differentiation is normal	45
<i>Fgfr2(IIIb)(-/-)</i> mice	Lung agenesis as in <i>Fgf10</i> null mutant	44,46
<i>Igfr(-/-)</i> mice	Severe growth deficiency and died at birth with respiratory failure	47
<i>Pdgf-A(-/-)</i> mice	<i>Pdgf-A(-/-)</i> mice survive postnatally, but develop lung emphysema secondary to the failure of alveolar septation	8
<i>Pdgfr-α(-/-)</i> mice	Failure of alveolar septation in postnatal lungs results in development of emphysema	10
Doxycycline-inducible <i>SP-C</i> -driven <i>mSpry4</i> TG mice	Continuous expression of <i>Spry4</i> caused severe lung hypoplasia. Expression of <i>Spry4</i> from E16.5 to 18.5 reduced lung growth and resulted in perinatal death from respiratory failure. Expression of <i>Spry4</i> from E18.5 to postnatal day 21, caused mild emphysema	48
<i>Shh(-/-)</i> mice	In <i>Shh</i> null mutant mice, embryo trachea and oesophagus do not separate properly and the lungs form a rudimentary sac because of failure of branching and growth after formation of the primary lung buds, but normal proximo-distal differentiation of the airway epithelium occurred	49–51
<i>TGF-β1(-/-)</i> mice	Develop normally but die within the first 2 months as a result of aggressive pulmonary inflammation. When raised under strict condition, they do not develop lung inflammation	52
<i>TGF-β2(-/-)</i> mice	Lung of E18.5 <i>TGF-β2(-/-)</i> mice shows dilated conducting airways and collapsed terminal and respiratory bronchioles	53,54
<i>TGF-β3(-/-)</i> mice	The hypoplastic lungs have thick mesenchyme between terminal airspaces. The number of C-positive cells is decreased and certain extracellular matrix protein expression is also reduced in <i>TGF-β3</i> -null mutant lungs	55,56
<i>Extracellular matrix and others</i>		
<i>Elastin(-/-)</i> mice	Terminal airway development is arrested, resulting in fewer and dilated distal air sac formation at birth	57
<i>Fibrillin(-/-)</i> mice	Lung abnormalities are evident in the immediate postnatal period and manifest as a developmental impairment of distal alveolar septation. Emphysema-like phenotype occurs in aged mice	58
<i>Integrin β6(-/-)</i> mice	Spontaneous, progressive pulmonary emphysema is developed in the adult null mutant mice, attributed to failure of activation of <i>TGF-β1</i>	59
<i>LTBP4</i>	Mice with homozygous disruption of <i>LTBP4</i> gene develop severe pulmonary emphysema with abnormal elastic fibre structure and reduced deposition of <i>TGF-β</i> in the extracellular space	60
<i>SP-D(-/-)</i> mice	Progressive development of pulmonary emphysema occurs from 3 weeks of age	61
<i>TACE(-/-)</i> mice	Lungs fail to form normal saccular structure with deficient septation and thick mesenchyme	62
<i>TIMP3(-/-)</i> mice	Progressive airspace enlargement is observed at 2 weeks. Aged animals have enhanced collagen degradation in the peribronchiolar space, and disorganization of collagen fibrils in the alveolar interstitium	63

three proteins are expressed in lung epithelium. *Foxp1* and *Foxp4* are expressed in both proximal and distal airway epithelium while *Foxp2* is expressed primarily in distal epithelium. *Foxp1* protein expression is also observed in the mesenchyme and vascular endothelial cells of the lung [3].

Nkx and Hox homeodomain transcription factors

One of the most important homeodomain transcription factors in lung development is NKX2.1, also called TTF-1 (thyroid-specific transcription factor) or CEBP-1. *Nkx2.1* is expressed in foregut endoderm-derived epithelial cells including developing lungs, thyroid and pituitary, as well as in some restricted regions of fetal brain [79,80]. *Nkx2.1(-/-)* mice suffer severe impairment in branching morphogenesis of the lung and tracheo-oesophageal septum formation. The distal airway branches are totally absent, while only the two main bronchial stems are formed in *Nkx2.1* knockout mice, which indicates that lung development is arrested at a very early stage [36,37]. In developing mouse lung, *Nkx2.1* is expressed in the proximal and distal airway epithelia and, at later stages of lung development, in the distal alveolar epithelial cells [65]. *Nkx2.1* expression is strictly controlled, and increased expression of *Nkx2.1* causes dose-dependent morphological alterations in postnatal lung. Modest overexpression of *Nkx2.1* causes type II pneumocyte hyperplasia and increased levels of SP-B. Higher expression level of *Nkx2.1* disrupts alveolar septation, causing emphysema brought about by alveolar hypoplasia. The highest overexpression of *Nkx2.1* in transgenic mice causes severe pulmonary inflammation, fibrosis and respiratory failure, associated with eosinophil infiltration as well as increased expression of eotaxin and IL-6 [81]. *Nkx2.1* is critical for surfactant protein, *Tl α* , and *CCSP* gene expression [79,82–87]. *Nkx2.1*-deficient pulmonary epithelial cells fail to express non-ciliated marker genes, including differentiated *SP-B*, *SP-C* and *CCSP*. *Bmp4* expression in these cells is also reduced. Phosphorylation of NKX2.1 is important. Mice with point mutation of seven serine phosphorylation sites of NKX2.1 died immediately following birth with malformation of acinar tubules and pulmonary hypoplasia. Meanwhile, expression of surfactant proteins, secretoglobulin 1A, and VEGF was decreased [88]. *Nkx2.1* expression can be activated by HNF-3 β [69] and GATA-6 [89] transcription factors during lung morphogenesis.

The expression of Hox transcription factors shows a proximal to distal polarity in developing lung. *Hoxa5*, *Hoxb2* and *Hoxb5* expression is restricted to distal lung mesenchyme. *Hoxb3* and *Hoxb4* genes are expressed in the mesenchyme of both proximal airway and distal lung [30,90,91]. The importance of these genes during lung development is well illustrated in gene targeting experiments in mice.

Hoxa5(-/-) null mutant mice display defects of tracheal formation and impaired lung branching morphogenesis, with tracheal occlusions, diminished surfactant protein expression and thickening of alveolar walls [30].

GLI family of zinc finger transcription factors

GLI 1–3 are very important zinc finger transcription factors, which are activated by the SHH pathway. All of them are expressed in lung mesoderm rather than endoderm, particularly in the distal portion [92]. Null mutation of *Gli2* plus *Gli3* genes results in total absence of lung. Mice with *Gli3* single deficiency are viable, but the size of the lung is smaller and the shape of the lung is also altered [92]. In *Gli2(-/-)* null mutant mice, the right and left lung are not separated but exist as a single lobe with a reduced size, and the primary branching in the right lung is defective. Also, both the trachea and oesophagus are hypoplastic, although they are separated from each other. However, proximal–distal differentiation is normal [27]. Therefore, *Gli2* has an important role in the asymmetric patterning of the lung.

Peptide growth factors that mediate cell–cell interaction

E11 mouse embryo lung can grow and branch spontaneously in serum-free medium *in vitro*. A variety of growth factors added into the culture medium can influence lung growth in the culture system [93,94]. Such experiments indicate that the embryonic lung mesenchymal and epithelial cells can communicate through autocrine or paracrine factors. In this way, different signalling pathways are coordinated to control lung growth at the right time and right place. Many of those factors are peptide growth factors, including FGF, EGF, TGF, IGF, PDGF and SHH. The expression and modification of these proteins and their downstream signalling components are strictly controlled during normal lung development. Loss of these gene function perturb normal lung development and function in mice (see Table 29.1).

FGF

FGF family members can be found in all vertebrate and invertebrate animals. Their regulatory functions during respiratory organogenesis are very well conserved from *Drosophila* [95,96] to mammals. Based on their protein sequence homology, FGFs have been divided into several subgroups. Similarly, their cognate transmembrane protein tyrosine kinase receptors are classified into several different types, contributing to the specificity of FGF ligand binding [97]. Heparin or heparan sulphate proteoglycan, an extracellular matrix protein, has been reported to be essential for FGF ligand–receptor binding and activation

[98–100]. FGFs have important roles in cell proliferation, migration and differentiation during embryo development. Inhibition of fibroblast growth factor receptor (FGFR) signalling at different stages of embryo development shows that FGF signalling is required for branching morphogenesis early in lung development. Later inhibition of FGFR signalling in E14.5 lung decreased lung tubule formation before birth and caused severe emphysema at maturity. In E16.5, FGFR inhibition caused mild focal emphysema. Inhibition of FGFR signalling after birth did not alter alveolarization [101].

One of the best-studied FGF family members during embryonic lung development is FGF10. Despite the formation of larynx and trachea, the distal embryonic lung is completely missing in *Fgf10*($-/-$) null mice [43]. *Fgf10* is expressed in the mesenchyme of E11–12 mouse lungs, adjacent to distal epithelial tubules. These sites of expression change dynamically in a pattern that is compatible with the idea that FGF10 appears in the mesenchyme at prospective sites of bud formation [102]. Culture experiments have shown that FGF10 has a chemotactic effect on nearby epithelium, so that the nearby epithelial tips proliferate and migrate toward FGF10 expressing mesenchyme or FGF10 beads [103,104]. FGF10 also controls the differentiation of the epithelium by inducing *SP-C* expression and by down-regulating the expression of *Bmp4* [78]. Several other regulatory molecules such as SHH, BMP and TGF- β may cross-talk with FGF10 to coordinate control of embryonic lung morphogenesis. These interactions will be further discussed below.

FGF7 (KGF) is found in the developing lung mesenchyme during late stages [105]. In early cultured mouse embryonic lung, addition of FGF7 promotes epithelium growth, and formation of a cyst-like structure with extensive cell proliferation. FGF7 can also contribute to distal airway epithelial cell differentiation [106,107]. *Erm* and *Pea3* are ETS domain transcription factors known to be downstream of FGF signalling. FGF7 can induce *Erm/Pea3* expression more effectively than FGF10. *Erm* is transcribed exclusively in the epithelium, while *Pea3* is expressed in both epithelium and mesenchyme. When examined at E18.5, transgenic expression of a repressor form of *Erm* specifically in the embryonic lung epithelium shows that the distal epithelium of *SP-C-Erm* transgenic lungs is composed predominantly of immature type II cells, while no mature type I cells are observed. In contrast, the differentiation of proximal epithelial cells, including ciliated cells and Clara cells, appears to be unaffected [108,109]. FGF7 does not seem to protect against hyperoxic inhibition of normal postnatal alveoli formation and early pulmonary fibrosis, but FGF7 consistently had a significant protective and/or preventive effect against the development of pulmonary

hypertension during hyperoxia [110]. However, *Fgf7*($-/-$) mutant mice have apparently no gross abnormalities in the lung [111], suggesting a redundant function of FGF7 with other factors during lung development.

Another FGF family member, FGF9, also regulates branching morphogenesis. In E10.5 lung, *Fgf9* is expressed in the visceral pleura lining the outside of the lung bud as well as in the epithelium of the developing bronchi. At E12.5 and E14.5, *Fgf9* expression persists in the mesothelium of the visceral pleura, but is no longer detected in airway epithelium [112]. *Fgf9* null mice exhibit reduced mesenchyme and decreased branching of the airways, but show significant distal airspace formation and pneumocyte differentiation. The reduction in the amount of mesenchyme in *Fgf9*($-/-$) lungs limits expression of mesenchymal *Fgf10* [44]. Recombinant FGF9 protein inhibits the differentiation response of the mesenchyme to N-SHH, but does not affect proliferation [113].

The signalling cascade activated by FGF10 and FGF9 involves Raf, MAP ERK kinase (MEK), and extracellular-regulated kinases (ERK) 1 and 2 as signal transducers. MEK inhibition has been shown to reduce lung branching and epithelial cell proliferation, but to increase mesenchymal cell apoptosis in fetal lung explants [6]. FGF signalling is regulated at several levels. One of the key negative regulators is the sprouty family. There are four sprouty (*Spry*) genes in mouse (*mSpry1–4*) and human (*hSpry1–4*). Murine *Spry2* is expressed in the distal tip of embryonic lung epithelial branches, but is down-regulated between the sites of new bud formation. Murine *Spry4* is predominantly expressed in the distal mesenchyme of the embryonic lung [114], and may play a part in branching morphogenesis. Sprouties (SPRY1, -2, -4) act as suppressors of Ras-MAP kinase signalling [115–117]. Overexpression of *mSpry2* or *mSpry4* can inhibit lung branching morphogenesis through reducing epithelial cell proliferation [48,118,119]. SPRED-1 and SPRED-2 are two sprouty-related proteins, which contain EVH-1 domains. *Spreads* are predominantly expressed in mesenchymal cells. Expression of *Spreads* is especially strong in the peripheral mesenchyme and epithelium of new bud formation. After birth, *Spreads* expression decreases, while the expression of *Sprouties* expression is still high. Both *Sprouties* and *spreads* have important roles in mesenchyme–epithelium interaction during lung development [2].

TGF- β family growth factor

The transforming growth factor- β (TGF- β) superfamily comprises a large number of structurally related polypeptide growth factors including TGF- β , bone morphogenetic protein (BMP) and activin subfamilies. TGF- β ligands bind to their cognate receptors on the cell surface, and activate

downstream Smad proteins, which translocate into the nucleus and modulate target gene expression [120,121].

TGF- β subfamily

TGF- β is well known for its inhibitory effects on embryonic lung branching morphogenesis. There are distinct expression patterns for the three isoforms of TGF- β : TGF- β 1–3. In early mouse embryonic lung (E11.5), TGF- β 1 is expressed in the mesenchyme, particularly in the mesenchyme underlying distal epithelial branching points, while TGF- β 2 is localized in distal epithelium. TGF- β 3 is mainly expressed in proximal mesenchyme and mesothelium [122–126]. Each isoform of TGF- β plays a unique and non-redundant role during embryonic development. Mice lacking TGF- β 1 develop normally but die within the first 2 months of life as a result of aggressive pulmonary inflammation [52]. A TGF- β 2(–/–) null mutation results in embryonic lethality around E14.5 in mice, and one of the abnormally developed organs is lung [53]. TGF- β 3(–/–) null mutant mice display cleft palate, retarded lung development and neonatal lethality [55,56]. Misexpression of TGF- β 1, leading to excessive TGF- β 1 activation, always results in an adverse phenotype, which depends on the developmental stages at which TGF- β 1 is expressed. Overexpression of TGF- β 1 in early mouse embryonic lung epithelium inhibits lung branching morphogenesis *in vitro* [127], while misexpression of *SP-C* promoter controlled TGF- β 1 in embryonic lung epithelium results in arrest of embryonic lung growth and epithelial cell differentiation, as well as inhibition of pulmonary vasculogenesis [128,129]. Clinically, the presence of excess TGF- β 1 activity in tracheal aspirates of human premature infants who develop more severe bronchopulmonary dysplasia (BPD) suggests a crucial role for TGF- β 1 in lung maturation [130,131]. On the other hand, misexpression of TGF- β 1 in adult rats results in a chronic, progressive interstitial pulmonary fibrosis with increased proliferation and matrix secretion by the mesenchyme [132,133]. Misexpression of TGF- β 1 in neonatal rat lung using recombinant adenoviral vectors results in neonatal alveolar hypoplasia and interstitial fibrosis that phenocopies BPD [134]. In addition, TGF- β 1 may be one of the most important factors involved in the pulmonary inflammation response to exogenous factors, such as infection, bleomycin or endotoxin. Blockade of the TGF- β –Smad3 pathway in Smad3(–/–) null mutant mice strongly attenuates bleomycin-induced pulmonary fibrosis [133]. TGF- β activated kinase-1 binding protein-1 (TAB1) was identified as a molecule that activates TGF- β activated kinase-1 (TAK1). *Tab1* mutant embryonic fibroblast cells displayed drastically reduced TAK1 kinase activities and decreased sensitivity to TGF- β stimulation. *Tab1* mutant mice died due to cardiovascular and lung dysmorphogenesis [135].

The activity of TGF- β signalling can be regulated precisely at multiple levels. For example, β 6 integrin, LTBPs and thrombospondin are involved in regulating the release of TGF- β mature peptide, while betaglycan, endoglin or decorin influence the affinity of TGF- β receptor binding. Mutation of the above genes displays phenotypes related to malfunction of TGF- β . For example, loss of function mutation both in the human and mouse endoglin gene, whose protein product binds to both TGF- β ligand and its type I receptor (Alk1), causes hereditary haemorrhagic telangiectasia [136–139].

BMP

Expression of *Bmp3*, *4*, *5* and *7* are detected in embryonic lung [140–142]. The expression of *Bmp5* and *Bmp7* has been detected in the mesenchyme and endoderm of developing embryonic lung, respectively, while *Bmp4* is expressed in a dynamic pattern that is restricted to the distal epithelial cells at high levels and adjacent mesenchyme at low level [140,141]. Misexpression of *Bmp4* under the control of the *SP-C* promoter in transgenic mice results in lungs that are smaller than normal with grossly dilated terminal sacs, which do not support gas exchange at birth [140]. BMP signalling also regulates proximal–distal differentiation of endoderm in mouse lung development. Inhibiting BMP signalling with BMP antagonist Xnoggin or overexpressed negative BMP receptor results in a severe reduction in distal epithelial cell types and a concurrent increase in proximal cell types [76]. The effect of BMP4 on embryonic lung development is still unclear. Addition of exogenous BMP4 into whole lung explant culture stimulates lung branching morphogenesis, while addition of BMP4 into isolated lung epithelial culture inhibits FGF10-induced epithelial growth [104,122,143]. In addition, BMP signalling is also important in lung vasculogenesis and angiogenesis. Mutations of BMP type II receptor (BMPRII) are associated with primary pulmonary hypertension (PPH) [144].

Sonic hedgehog (Shh) pathway

Sonic hedgehog is a vertebrate homologue of *hedgehog* (Hh) that patterns the segment, leg, wing, eye and brain in *Drosophila*. Hh binds to patched (Ptc), a transmembrane protein, and releases its inhibitory effect on downstream smoothed (Smo), which is a G protein-coupled 7-span transmembrane protein. This leads to the activation of cubitus interruptus (Ci), a 155-kD transcription factor that is usually cleaved to form a 75-kD transcription inhibitor in the cytosol. Elements of the *Drosophila* Hh signalling pathway and their general functions in the pathway are highly conserved in vertebrates, albeit with increased levels of complexity. Gli1, -2 and -3 are the three vertebrate Ci gene orthologues [145].

The SHH signal transduction pathway has important

roles in mesenchyme–epithelium interaction, which is very important in morphogenesis. In developing mouse lung, *Shh* is detected in the tracheal diverticulum, the oesophagus and later in the trachea and lung endoderm. *Shh* is expressed at low levels throughout the epithelium, while at higher level in the growing distal buds [146,147]. Null mutation of *Shh* produces profound hypoplasia of the lung and failure of trachea–oesophageal septation. Mesenchymal expression of *Ptc*, *Gli1* and *Gli3* is down-regulated. However, proximal–distal differentiation of epithelial airway is preserved [50,51]. Also, *Fgf10* expression is widespread in the epithelium in *Shh* null mutant lung, instead of the precisely location-restricted expression seen in wild-type controls. Lung-specific *Shh* overexpression results in severe alveolar hypoplasia and a significant increase in interstitial tissue caused by an increased proliferation of epithelium and mesenchyme [146]. Defective hedgehog signalling may lead to oesophageal atresia and tracheoesophageal fistula [148].

HIP1, a membrane-bound protein, directly binds all mammalian Hedgehog (HH) proteins and attenuates HH signalling [149]. *Hip1* is transcriptionally activated in response to Hh signalling, overlapping the expression domains of *Ptc1* [149,150]. Targeted disruption of *Hip1* results in neonatal lethality with respiratory failure. Although asymmetry in their growth was conserved, the initial stereotyped branching from the two primary buds was absent in *Hip1*($-/-$) lungs. Hedgehog signalling is up-regulated in *Hip1* mutants. *Fgf10* expression was slightly down-regulated at the distal tips of the primary lung buds in *Hip1*($-/-$) lungs at E10.5, but completely absent from the mesenchyme where secondary branching normally initiates [150]. Attenuated PTC1 activity in a *Hip1*($-/-$) mutant lungs leads to an accelerated lethality. *Hip1* and *Ptc1* have redundant roles in lung branching control [150]. Both of them can attenuate SHH signal in lung and pancreas development [150,151].

Wnt– β -catenin pathway

Wnt signals are transduced through seven transmembrane-type Wnt receptors encoded by *Frizzled* (*Fzd*) genes to activate the β -catenin–TCF pathway, the JNK pathway or the Ca^{2+} -releasing pathway. The Wnt– β -catenin pathway has a critical role in many developmental and tumorigenesis processes. Following Wnt binding to the receptor, β -catenin is dephosphorylated and translocates to the nucleus to activate downstream gene expression [152].

Interestingly, all members of *Fzd* gene family are expressed in embryonic and neonatal lung, albeit at different levels. *Fzd* genes are differentially expressed in the epithelium and mesenchyme. Expression of *Fzd2*, *Fzd5*, *Fzd6* and *Fzd8* was observed predominantly in the epithelium, while *Fzd4* and *Fzd10* were expressed in the

mesenchyme. Expression of *Fzd1* and *Fzd7* was observed both in the epithelium and mesenchyme, while *Fzd3* and *Fzd9* were only marginally expressed. This spatial distribution suggests differential roles for different *Fzd* receptor genes in the Wnt signalling pathway during the development of the lung [39].

In mouse lung development, between embryonic days 10.5 and 17.5 (E10.5–E17.5), β -catenin was localized in the cytoplasm, and often also in the nucleus of the undifferentiated primordial epithelium, differentiating alveolar epithelium, and adjacent mesenchyme. Other Wnt– β -catenin pathway members, *Tcf1*, *Lef1*, *Tcf3*, *Tcf4*, *sFrp1*, *sFrp2* and *sFrp4*, are also expressed in the primordial epithelium, alveolar epithelium and adjacent mesenchyme in specific spatiotemporal patterns [153]. In human fetal lung, nuclear β -catenin is present in pulmonary acinar buds [154]. Null mutation of β -catenin in mice results in abnormal, cystic structure formation in the lung and prenatal lethality. Based on molecular marker detection, the lungs are composed primarily of proximal airways, suggesting that β -catenin is one of the essential components to specify proximal–distal axis of the lung [39].

EGF family growth factors

EGF, transforming growth factor- α (TGF- α) and amphiregulin are all epidermal growth factor receptor (EGFR) ligands. Loss or gain of function experiments in mice, rat or other animal models proves that EGF ligands can positively modulate early mouse embryonic lung branching morphogenesis and cytodifferentiation through EGFR [94,155, 156]. EGF is also expressed in mature alveolar epithelial cells and regulates type II cell proliferation through an autocrine mechanism both *in vitro* and *in vivo* [157]. However, respiratory epithelial cell overexpression of TGF- α under the control of the *SP-C* promoter of transgenic mice induces postnatal lung fibrosis [158]. Overexpression of TGF- α caused severe pulmonary vascular disease, which was mediated through EGFR signalling in distal epithelial cells. Reductions in VEGF may contribute to the pathogenesis of pulmonary vascular disease in TGF- α overexpressing mice [159].

EGFR is a tyrosine kinase receptor that transfers EGF signals into the cell. Abnormal branching and poor alveolization are observed in mice deficient in epidermal growth factor receptor (*Egfr*($-/-$)). Mechanical stretch stimulated EGFR phosphorylation at least in part, induces differentiation of fetal epithelial cells via EGFR activation of the ERK pathway. Blockade of the EGFR or ERK pathway by specific inhibitors decreased stretch-inducible *SP-C* mRNA expression, suggesting EGFR may be part of a mechanical stimulus signal sensor during fetal lung development [160]. Aberrant expression of matrix metalloprotease proteins (MMPs) is also detected in *Egfr*($-/-$) null mutant mice,

which suggests MMPs may be involved in EGFR-regulated lung growth [40].

Tumour necrosis factor- α converting enzyme (TACE) is a transmembrane metalloprotease-disintegrin that functions as a membrane sheddase to release the ectodomain portions of many transmembrane proteins, including the precursors of TNF- α and several other cytokines, as well as the receptors for TNF- α , and neuregulin (ErbB4) [161]. Neonatal TACE-deficient mice had visible respiratory distress and their lungs failed to form normal saccular structures resulting in a reduction of normal air exchange surface. In mouse embryonic lung explant cultures, TGF- α and EGF can rescue lung development in the presence of TACE deficiency [62].

PDGF

There are four types of PDGF peptides. PDGF-A and PDGF-B can form homodimers (AA or BB) or heterodimers (AB). Two types of PDGF receptors, α and β , are present in embryonic mouse lung, and are differentially regulated in fetal rat lung epithelial cells and fibroblasts [162]. PDGF-A regulates both DNA synthesis and early branching in early mouse embryonic lung epithelium *in vitro* [163]. *Pdgf-A* homozygous null mutant mice die perinatally. The pulmonary phenotypes include lack of lung alveolar smooth muscle cells (SMC), reduced deposition of elastin fibres in the lung parenchyma, and development of lung emphysema because of complete failure of alveogenesis [8,10]. Abrogation of PDGF-B chain expression with antisense oligodeoxynucleotides reduces the size of the epithelial component of early embryonic mouse lung explants, but does not reduce the number of branches [164]. PDGF-B and its receptor are crucial for vascular growth and integrity during the alveolar phase [9]. PDGF-C and PDGF-D also dimerize and bind to PDGF α or β receptor [165,166]. PDGF-C mRNA expression shows a significant increase in lung fibrosis induced by bleomycin [167].

IGF

The insulin-like growth factors (IGFs) and their receptors are expressed in both rodent and human fetal lung [168–172]. Null mutant mice for the cognate type 1 IGF receptor (*Igf1r*) gene always die at birth with respiratory failure and severe growth deficiency (45% of normal birth weight). Dwarfism is further exacerbated (70% of size reduction) in either *Igf1* and *Igf2* double null mutants or in *Igf1r* and *Igf2* double null mutants. There does not appear to be a gross defect in primary branching morphogenesis per se; the lungs merely appear hypoplastic [47]. IGF signalling may have a role in facilitating other peptide growth factor pathways during lung morphogenesis. IGF1R signalling function is required for both the mitogenic and transforming activities of the EGF receptor [173]. The lungs display reduced airspace in *Igf1*-deficient embryos and neonates,

and the phenotype is exacerbated in additionally leukaemia inhibitory factor (*Lif*) null mutant mice, which showed abnormal epithelial cells and decreased SP-B expression. In addition, *Nkx2.1* and *SP-B* expression is reduced in the lung of these double null mutant neonates. Thus, LIF and IGF-I have cooperative and distinct tissue functions during lung development [174]. IGF1 is also a potent trophic factor for fetal lung endothelial cells. In human fetal lung explants, inactivation of IGF-IR results in a loss of endothelial cells, attenuates time-dependent increase in budding of distal airway and increases mesenchymal cell apoptosis [175].

VEGF isoforms and cognate receptors

Lung development must form a fine alignment between the alveolar surface and the surrounding pulmonary capillary system for effective gas exchange. Vascular endothelial growth factors (VEGF) are potent effectors of vascular development in lung morphogenesis. VEGF signals through the cognate receptors Flk-1 (fetal liver kinase-1, VEGFR2) and Flt-1 (fetal liver tyrosinase-1, VEGFR1) [176]. VEGF is diffusely distributed in pulmonary epithelial and mesenchymal cells, and is involved in controlling endothelial proliferation and the maintenance of vascular structure [177]. VEGF can be regulated by hypoxia-inducible transcription factor-2 α [178].

Vasculogenesis is initiated as soon as the lung evaginates from the foregut epithelium [179]. Development of the vascular system influences branching morphogenesis of the airway as well as alveolarization. In transgenic mice, where the *Vegf* transgene is misexpressed under the control of the *SP-C* promoter, gross abnormalities in lung morphogenesis are associated with a decrease in acinar tubules and mesenchyme [180]. VEGF has also been demonstrated to have a role in maintaining alveolar structure [17]. Lungs from newborn mice treated with antibodies to Flt-1 were reduced in size and displayed significant immaturity with a less complex alveolar pattern [181].

Extracellular matrix and lung development

The protein components of extracellular basement membrane, laminins, entactin/nidogen, type IV collagen, perlecan, SPARC and fibromodulin, are important in mediating cell–cell and cell–extracellular matrix (ECM) interaction during fetal lung morphogenesis. Basement membrane components are differentially expressed, and have a specific cell distribution during lung morphogenesis. ECM components may not only provide the support for tissue architecture, but may also have an active role in modulation of cell proliferation and differentiation [182]. For example, basement membrane components may serve as a barrier and reservoir of growth factors, which in turn regulate epithelial and mesenchymal cell proliferation.

Absence or inhibition of the interaction of epithelial cells with the basement membrane results in failure of normal lung development [183,184].

Laminins (LNs) are glycoproteins involved in cell adhesion, migration, proliferation and differentiation during tissue development and remodelling. LNs are composed of three chains, one central (α) and two laterals (β and γ) that are linked by disulphide bonds to form a cross-shaped molecule [185]. To date, five α , three β and three γ chain isoforms have been identified, which suggests that their combination can lead to approximately 30 variants of LN [186–195]. The $\alpha 1$ chain has been found principally localized in the basement membrane at the epithelial–mesenchymal interface, with a predominant distribution in specific zones. The LN $\alpha 1$ chain has also been identified around some mesenchymal cells. Molecular analysis dissecting the $\alpha 1$ chain isoform has shown that a domain in the cross-region of the $\alpha 1$ chain is involved in the regulation of lung epithelial cell proliferation [196]. The $\alpha 4$ chain, found in LN8 and LN9 variants, has been reported to be highly expressed in lung and heart tissues during mouse development [189–191,197]. The LN $\alpha 4$ chain, localized principally around vessels in fetal lung, may have a role in the organization of lung mesenchyme [194,198]. The $\alpha 5$ chain, found in LN10 and LN11, has been found to be abundantly expressed during fetal lung morphogenesis [194,199,200]. Mouse embryos bearing mutated LN $\alpha 5$ chain isoform display poor lobar septation and bronchiolar branching, suggesting that the LN $\alpha 5$ chain isoform might be the most indispensable LN variant for lung branching morphogenesis.

A constant expression of $\beta 1$ and $\gamma 1$ is observed during fetal lung development [201]. These two chains also have a role in cell adhesion. The globular domains near the N-terminal of $\beta 1$ and $\gamma 1$ chains participate in the regulation of cell polarization [202,203]. Immunohistochemistry studies have demonstrated that the LN $\beta 2$ chain isoform is localized in the basement membrane of prealveolar ducts, airways, smooth muscle cells of airways, and arterial blood vessels, as well as type II pneumocytes.

Nidogen (150 kDa) is a constituent of the basement membranes. Nidogen binds to the $\gamma 1$ and $\gamma 3$ chains of LN, and forms a link between LN and collagen IV [193, 204,205]. Nidogen is actively synthesized by mesenchymal cells during fetal lung development, which suggests that nidogen has a key role in the organization of the basement membrane during lung morphogenesis [206]. Blocking the interaction of nidogen with LN affects the progression of lung development [204,206,207]. Susceptibility of nidogen to degradation by matrix metalloproteinases may contribute to the remodelling and degradation of the basement membrane [208].

Proteoglycans (PGs) contain a core protein with sulphated carbohydrate side chains. They function as flexible

structures in the organization of the basement membrane and may also have an important role as a reservoir for growth factors, water and ions. Perlecan is a predominant proteoglycan in the basement membrane. It is composed of an approximately 450-kDa core protein with three heparan sulphate chains. Perlecan is involved in the control of smooth cell proliferation and differentiation because increased cell proliferation of fetal lung smooth muscle cells is accompanied by a highly increased synthesis of perlecan [209]. Growth and branching of E13 mouse lung explants can be disrupted by inhibiting PG sulphation. The migration of epithelial cells towards invading lung mesenchyme as well as towards beads soaked in FGF10 is inhibited and branching morphogenesis in lung mesenchymal and epithelial tissue recombinants is severely decreased when PG sulphation is inhibited by chlorate.

Fibronectin also has an important role in lung development. In branching morphogenesis, repetitive epithelial cleft and bud formation creates the complex three-dimensional branching structure characteristic of many organs. Fibronectin is essential for cleft formation during the initiation of epithelial branching in salivary gland. Immunofluorescence comparisons of fibronectin localization during early branching of lung and kidney also showed an accumulation of fibronectin at sites of epithelial constriction and indentation [210], supporting a possible role for fibronectin in branching morphogenesis of the lung [211]. Direct tests for the role of fibronectin, by treatment of developing lung rudiments with antifibronectin antibody or siRNA, inhibited branching morphogenesis, while fibronectin supplementation promoted branching of lung [210]. The EIIIA segment of fibronectin is one of the major alternatively spliced segments and modulates the cell proliferative potential of fibronectin *in vitro*. The EIIIA-containing fibronectin isoform localized in both the epithelial cells and the mesenchyme. Its expression gradually decreased from the pseudoglandular stage to the saccular stage and then slightly increased from the saccular stage to the alveolar stage. This change in expression pattern of EIIIA-containing fibronectin seemed to be in accord with the change in the number of proliferating cell nuclear antigen (PCNA)-positive cells in the distal pulmonary cells throughout lung development [212].

Extracellular matrix is under dynamic control during lung development. The matrix metalloproteinases (MMPs) are a large family of ECM-degrading enzymes. They are inhibited by the family of tissue inhibitors of metalloproteinases (TIMPs). Activity of MMPs may be required during development and normal physiology in several ways:

- 1 to degrade ECM molecules and allow cell migration;
- 2 to alter the ECM microenvironment and result in alteration in cellular behaviour;
- 3 to modulate the activity of biologically active molecules

by direct cleavage, release from bound stores, or by modulating of activity of their inhibitors [213].

In *Timp3* null mutant mouse lung, airway branching is inhibited. Compared with wild type, in the *Timp3* null mouse the number of bronchioles is reduced and alveologenesis is attenuated [214]. The *Timp3* null animals spontaneously develop progressive alveolar airspace enlargement similar to that seen in human emphysema [215]. Early postnatal exposure to dexamethasone (Dex) influences MMP2 and MMP9, as well as their tissue inhibitors (TIMP1 and TIMP2) in the developing rat lung; the expression of *Timp2* is reduced and *Mmp9* expression increases. These changes may be responsible, in part, for some of the known adverse maturational effects of steroids on lung structure in the newborn [216]. MT1-MMP, which acts as a potent activator of MMP2, is a major downstream target of EGFR signalling in lung. *Egfr*($-/-$) mice had low expression of *MT1-Mmp*. Extracts from lungs of *Egfr*($-/-$) mice showed a 10-fold reduction in active MMP-2. At birth, the abnormal lung alveolization phenotype of *Mmp2*($-/-$) mice is similar to that of *Egfr*($-/-$) mice, albeit somewhat less severe [40]. The balance between the activity of MMPs and TIMPs is important to normal lung development.

Retinoic acid and lung morphogenesis

Retinoids (all-*trans*, 9-*cis*, 13-*cis*) are fundamental for normal development and homeostasis of a number of biological systems including the lung. There is a precisely controlled RA synthesis and degradation system in mammals [217]. Retinaldehyde dehydrogenase-2 (RALDH-2) has a prominent role in generating RA during organogenesis [218–220]. RA signalling is mediated by its nuclear receptors of the steroid hormone receptor superfamily: RAR (α , β , γ) and retinoid RXR (α , β , γ), [217]. RAR/RXR heterodimers have also been shown to transduce RA signalling *in vivo* [221]. Within the E13.5 lung, *Rar β* isoform transcripts are specifically localized to the proximal airway epithelium and immediately adjacent mesenchyme, whereas *Rar α* , *Rar α 2* and *Rar γ 2* isoforms are ubiquitously expressed [222].

RA signalling is required for lung bud initiation. Acute vitamin A deprivation in pregnant rats at the onset of lung development results in blunt-end tracheae and lung agenesis in some embryos, which is similar to *Fgf10*($-/-$) null mutant mice [223,224]. Disruption of RA signalling in *Rar α / β 2* knockout mice leads to agenesis of the left lung and hypoplasia of the right lung [225]. Interestingly, lung branching morphogenesis is characterized by a dramatic down-regulation of RA signalling in the lung. Treating embryonic lung explants with high concentrations of RA (10^{-6} – 10^{-5} mol) results in dramatic disruption of distal budding and formation of proximal-like immature airways

[226,227]. Continued RA activation by overexpression of constitutively activated *Rar α* chimeric receptors also resulted in lung immaturity, and lungs did not expand to form saccules or morphologically identifiable type I cells. High levels of *SP-C*, *Nkx2.1* and *Gata6*, but not *SP-A* or *SP-B*, in the epithelium at birth suggested that in these lungs differentiation was arrested at an early stage. Down-regulation of RA signalling, however, is required to allow completion of later steps of this differentiation programme that ultimately forms mature type I and II cells [228]. RA inhibits expression and alters distribution of *Fgf10* and *Bmp4*, which are required for distal lung formation [226,227]. Pan-RAR antagonism alters the expression of *Tgf- β 3*, *Hnf-3 β* and *Cftr* in proximal tubules and alters expression of *Bmp4*, *Fgf10* and *Shh* within the distal buds [222].

It is also noteworthy that during early stages of lung branching (days 11–12.5), *Raldh-2* expression is concentrated in trachea (mesenchyme) and proximal lung (mesothelium) at sites of low branching activity. The *Raldh-2* pattern is not overlapping with that of *Fgf10*, supporting the idea that RA signalling restricts *Fgf10* expression and helps to define the proximal–distal axis of the developing lung. However, during later postnatal stages of lung development, RA has been shown to increase the number of alveoli and therefore partially rescue dexamethasone-induced suppression of alveolarization. In adult rats, RA has also been reported to reverse the anatomical features of elastase-induced emphysema in which there is destruction of septal structures [18,19,229]. In the *Rary* gene deletion mouse, there is a developmental defect in alveolar formation, consistent with a defect in elastin deposition [21]. This combined evidence suggests that RA may have an important but rather complex role in alveolar development during late lung development.

Lung development and COPD

Chronic obstructive pulmonary disease (COPD) is defined as airflow obstruction that does not change appreciably over a period of several months. It is a syndrome comprised of chronic bronchitis, small airways disease (bronchiolitis) and emphysema, which vary in proportion between affected individuals [230]. There is some structural remodelling inappropriate to maintaining normal lung function, and chronic inflammation characterized by infiltration of airways, pulmonary vessels and lung parenchyma by CD8⁺ T-cytotoxic lymphocytes. Small airways mucous metaplasia, increased small airways smooth muscle mass, airway wall fibrosis, and emphysema are specific features of structural remodelling in COPD [231].

COPD results from a complex interaction between

genetic and environmental factors. The normal interactions between mesenchymal and epithelial cells that maintains proper structure and function of the airways and gas exchange surface, as described herein, are dramatically perturbed. The structural damage of lung in COPD cannot be repaired or regenerated properly, suggesting that stem or progenitor cell reparative functions are overwhelmed and some important signal transduction pathways that control lung development have been perturbed, leading to abnormal airway remodelling in COPD. It is likely that developmental processes have a role in abnormal tissue remodelling in COPD. For example, *Shh* is up-regulated in epithelial cells at sites of fibrotic disease and the Shh receptor Patched was detected in infiltrating mononuclear cells and alveolar macrophages, as well as normal resting peripheral blood T lymphocytes [232]. On the other hand, RA, which has an important role in lung morphogenesis and alveolarization, can induce the complete regeneration of alveoli that have been destroyed by various noxious treatments in some experimental systems [229]. Therefore, continued elucidation of the molecular mechanisms of lung development may identify novel rationally based therapeutic targets in the quest to prevent and even cure COPD.

CHAPTER 30

Animal models

**Piero A. Martorana, Monica Lucattelli, Barbara Bartalesi
and Giuseppe Lungarella**

The main purpose of studying animal models of human disease is to gain insight into the underlying mechanisms of the disease. The recognition that chronic obstructive pulmonary disease (COPD) is a global health problem with no effective treatment has resulted in recent years in an explosion of new animal models of emphysema, a major component of COPD. Bronchial pathological changes were also described in some of these models. A very comprehensive review of these models has recently been published [1].

This chapter reviews some selected animal models developed in recent years that, in the eyes of the authors, may provide new insight into the pathogenesis of emphysema and COPD.

Genetic models

Strains of mice that spontaneously develop emphysema have been reported. Here we present only those strains of mice where the genetic mutation has been described and/or the mechanism leading to the lung changes investigated. Strains with developmental lung changes (i.e. a defect in alveolar formation) are not presented.

Tight-skin mouse

This mutant is commercially available on a C57Bl/6J background. The tight-skin (*Tsk*) gene on chromosome 2 is associated with a tandem duplication of the fibrillin-1 gene, which results in a larger-than-normal protein [2]. A potential effect of the incorporation of Tsk fibrillin-1 into microfibrils is increased proteolytic susceptibility.

In these mice, massive emphysema develops early, at approximately 2–4 weeks of age, and progresses thereafter [3]. Biochemical analysis reveals a decrease in lung elastin

content that coincides in time with parenchymal destruction [4]. In fact, these mice also have abnormally high levels of elastase and cathepsin G in their neutrophils, coupled with low serum α_1 -antitrypsin (AAT) levels and serum elastase inhibitory capacity (EIC) [5].

This is, to our knowledge, the only strain of mice with spontaneous emphysema in which the development of the lung disease is followed by the development of right-ventricular hypertrophy. This begins between 8 and 16 months of age and progresses thereafter [6].

Pallid mouse

This is commercially available on a C57Bl/6J background. The pallid (*pa*) gene is situated on chromosome 2 and encodes a novel syntaxin-13-interacting protein [7].

The serum of pallid mice has lower AAT levels (–55%) and EIC values (–71%) than those of other strains and spontaneous emphysema develops late in life between 8 and 12 months of age [8]. This is the first animal model in which emphysema has been shown to develop as a result of the following sequence of events [5,9]:

- deficient activity of serum antielastase screen;
- increased lung elastase burden; and
- decreased lung elastin content.

These results give an experimental basis for the protease-antiprotease theory of emphysema and indicate the pallid mouse as the mouse counterpart of the human AAT-deficient MZ phenotype.

Klotho mouse

This is a mutant that resulted as a consequence of a transgenic experiment. Insertion-mutation of several copies of the transgene in the 5'-flanking region of the *klotho* gene yielded a null mutation in the klotho mouse. The

klotho gene encodes a membrane protein homologous to β -glucosidase enzymes.

In *klotho*($-/-$) mice, emphysema starts to develop at 4 weeks of age with a gradual progression with increasing age. The heterozygous ($+/-$) mutant develops emphysema late in life at approximately 120 weeks of age. The *klotho* gene may be important for maintaining pulmonary integrity [10].

Models of cytokine expression

Some cytokines that are known to orchestrate the inflammatory response in asthma and in other inflammatory diseases may also have a major role in the pathogenesis of COPD. Transgenic and gene deletion technology has been used to explore the temporal role of cytokines in the development of COPD animal models. Models with developmental defects are not presented.

γ -Interferon

When γ -interferon (IFN- γ) is targeted in a transgenic fashion to the adult murine lung using the reverse tetracycline transactivator system and a promoter active in Clara cells, the response is emphysema and a macrophage- and neutrophil-rich inflammation.

Significant protease and antiprotease alterations are also found, such as:

- 1 induction and activation of matrix metalloproteinases (MMPs) MMP-12, MMP-9 and cathepsins B, H, D, S; and
- 2 selective inhibition of secretory leucocyte protease inhibitor (SLPI) [11].

Additionally, it has been found that IFN- γ *in vivo* is a potent stimulator of alveolar epithelial cell apoptosis. This response is associated with both the death receptor and the mitochondrial apoptotic pathways. Treatment with Z-VAD abrogates the apoptotic response and causes an impressive decrease in IFN- γ -induced emphysema. IFN- γ also stimulates the expression of pulmonary cathepsins and treatment with leupeptin or E-64 abrogates IFN- γ -induced apoptosis and emphysema. Cathepsin S (14150) and cathepsin B (CA 074) inhibitors have similar effects. Interestingly, Z-VAD and leupeptin also decrease IFN- γ -induced inflammation and the induction of MMPs and cathepsins. These studies demonstrate that a cathepsin-dependent alveolar apoptotic response is a critical event in the pathogenesis of IFN- γ -induced emphysema. They also highlight a potential positive feedback loop in which IFN- γ -induced apoptosis contributes to local inflammation and tissue protease degradation. These findings integrate existing hypotheses of the pathogenesis of emphysema (see also Models of apoptosis) [12].

Interleukin 13

Overexpression of interleukin 13 (IL-13) in the airway epithelium of adult mice results in emphysema, goblet cell metaplasia and inflammation. MMP-2, -9, -12, -13 and -14 and cathepsin B, S, L, H and K are also induced. Inhibition of MMPs substantially prevents the development of emphysema and reduces the influx of inflammatory cells by more than 90%. Inhibitors of thiol proteinases also reduce emphysema and inflammation. Neither class of proteinase inhibitors blocked goblet cell metaplasia.

Thus, IL-13 is a potent stimulator of MMP- and cathepsin-based proteolytic pathways in the lung and may cause emphysema via an MMP- and cathepsin-dependent mechanism [13].

Tumour necrosis factor- α

Overexpression of tumour necrosis factor- α (TNF- α) in alveolar type II cells of mice under the control of the human surfactant protein C promoter results in bronchiolitis, chronic inflammation and emphysema. Limited fibrosis can be seen only in the subpleural, peribronchial and perivascular regions. Physiological assessment shows an increase in lung volumes and a decrease in elastic recoil. Gelatinase activity is increased in bronchoalveolar lavage (BAL) fluids [14].

Mice with knocked-out TNF- α or IL-1 β receptors have significantly less emphysema than wild type mice, following an intratracheal instillation of porcine pancreatic elastase. It was suggested that elastase-induced emphysema might be driven in large measure through ongoing TNF- α and IL-1 β -induced inflammation, and possibly through TNF- α and IL-1 β -mediated inhibition of elastin and collagen repair (see also Models of cigarette smoke exposure) [15].

Transforming growth factor- β

In an elegant study it has been recently demonstrated that mice lacking the $\beta 6$ subunit of the integrin $\alpha v \beta 6$ (which occurs only in epithelial cells such as those the line the lungs) are protected against pulmonary fibrosis but develop pulmonary emphysema with age.

The mechanism is based on the knowledge that integrin $\alpha v \beta 6$ binds and activates latent transforming growth factor- β (TGF- β). In mice lacking the subunit $\beta 6$, this binding and activation does not take place and results in increased expression of the extracellular macrophage MMP-12 in the lungs and the development with time of spontaneous emphysema. MMP-12 is clearly necessary for disease onset, because mice lacking both MMP-12 and the integrin subunit $\beta 6$ do not develop emphysema. Also, when $\beta 6$ -deficient mice are genetically manipulated to produce

permanently active TGF- β , emphysema does not develop [16]. These results broaden the spectrum of factors involved in emphysema to those that activate latent TGF- β in the lung and, by inference, to TGF- β -triggered signalling molecules.

Models of apoptosis

Recent clinical studies have shown elevated levels of apoptosis in alveolar walls of emphysematous lungs. Accordingly, animal models have been developed in an attempt to investigate if apoptosis may have a role in the mechanism of emphysema. The following is a review of some of these models.

Vascular endothelial growth factor receptor blockade

In rats, chronic inhibition of vascular endothelial growth factor (VEGF) R2, which is responsible for endothelial cell growth, migration and differentiation, by the VEGF receptor blocker and angiogenesis inhibitor SU5416 results in emphysema. The emphysema is characterized by alveolar septal cell death, as assessed by TUNEL, activated caspase-3 immunostaining and DNA oligonucleosomal laddering. There is no lung infiltration by inflammatory cells or fibrosis. Treatment with the caspase inhibitor Z-Asp-CH2 prevents SU5416-induced septal cell apoptosis and emphysema development [17].

Also, when compared with control animals, rats treated with the VEGF receptor blocker show expression of markers of oxidative stress, all of which are prevented by the superoxide dismutase mimetic M40419. The preservation of lung structure in SU5416+M40419-treated lungs is associated with increased septal cell proliferation, and enhanced phosphorylation of the prosurvival and anti-apoptotic Akt, when compared with SU5416-treated lungs. Consistently with a positive feedback interaction between oxidative stress and apoptosis, it was found that apoptosis predominates in areas of oxidative stress, and that apoptosis blockade by a broad-spectrum caspase inhibitor markedly reduces the expression of markers of oxidative stress induced by the SU5416 treatment [18].

Active caspase-3

A single intratracheal instillation of active caspase-3 and Chariot, a new protein transfection reagent, causes alveolar cell apoptosis and significant emphysema. Elastica and van Gieson-stained lung tissue sections demonstrate loss of elastin layers within the alveolar walls. There is no alveolar

or airway inflammation or fibrosis. In mice killed at different time points, emphysema is evident as early as 2 h after treatment and is maintained for at least 15 days. However, the increase in mean linear intercept (Lm) is reduced by 60% from 6 h to 15 days, suggesting that the lesion may be partially reversible. In mice instilled with the combination active caspase-3 and Chariot plus the caspase inhibitor DEVD-CHO, the lungs have a normal appearance.

Airspace enlargement, alveolar wall destruction and loss of elastin layers are also noted in lungs of mice instilled with nodularin, a serine/threonine kinase inhibitor that induces caspase-dependent apoptosis [19].

Calorie restriction

In adult mice, calorie restriction (two-thirds reduction for 2 weeks) diminishes alveolar number by 55%, alveolar volume increases 1.9-fold and alveolar surface area decreases by 25%; however, lung volume is not affected. Within 72 h of calorie restriction, alveolar wall cell apoptosis is increased and lung DNA diminished (-20%). Refeeding fully reverses these changes. Thus, according to this study, adult mice have endogenous programmes to destroy (apoptosis) and regenerate alveoli [20].

It may be important to determine if calorie restriction-related alveolar loss and progressive alveolar loss of COPD are mediated by the same signalling pathways. Also, the observation that alveolar cell apoptosis is a major factor in the pathogenesis of emphysema in many different animal models will probably result in the focusing of future research on the molecular and cellular requirements of the alveolar wall for its maintenance throughout a lifetime.

Models of cigarette smoke exposure

Cigarette smoke is the greatest risk factor of COPD. However, only approximately 15–20% of cigarette smokers develop COPD. The fact that these susceptible individuals are generally clustered into families hints that there may be certain genes that predispose people to smoking-induced COPD. In recent years there has been a great effort to develop animal models of cigarette smoke-induced lung lesions with the goal of detecting the mechanism(s) that may be responsible for the greater sensitivity of responders. Both acute and chronic animal models of cigarette smoke exposure have been used. These models are here presented separately.

Acute smoke exposure

Obviously, in the acute animal models the end-points

are not the physiological, biochemical or morphological changes classical of COPD but rather represent changes that reflect the occurrence either of an acute inflammatory process or of an acute oxidative stress. This model is also used to assess the efficacy of compounds on markers of inflammation or oxidation.

Role of an oxidative stress

Acute exposure of C57Bl/6J mice to cigarette smoke causes a significant decrease in total antioxidant capacity (Trolox equivalent antioxidant capacity, TEAC) and significant changes in oxidized glutathione, ascorbic acid, protein thiols and 8-epi-PGF-2 α in bronchoalveolar lavage fluids (BALF).

Because the major mouse trypsin inhibitor is not sensitive to oxidation, and the mouse SLPI does not inhibit trypsin while human recombinant (hr) SLPI is sensitive to oxidants and inhibits trypsin, this model has been used to investigate the oxidative inactivation of hrSLPI. Intratracheal hrSLPI significantly increases BALF antitryptic activity *in vivo* in the mouse. Acute cigarette smoke exposure induces a 50% drop in the antitryptic activity of hrSLPI. Pretreatment with *N*-acetylcysteine prevents this fall of activity as well as the decrease of the BALF antioxidant capacity and the elevation of 8-epi-PGF-2 α [21]. Thus, this is a model for investigating the effects of cigarette smoke oxidative stress on human protease inhibitors with antitrypsin activity *in vivo*.

In the same model of acute oxidative stress, mice of the inbred strains DBA/2 and C57Bl/6J respond to acute cigarette smoke exposure with a decrease of the TEAC of their BALF, while mice of the strain ICR increase their BALF TEAC. These results may have predictive value on the outcome of chronic exposure to cigarette smoke in these strains of mice [22].

Role of proteases in the acute inflammatory process

In C57Bl/6J mice, acute exposure to cigarette smoke causes a dose-response increase in BALF in neutrophils, desmosine (DES, a marker of elastin breakdown) and hydroxyproline (HP, a marker of collagen breakdown) but not of alveolar macrophages. Pretreatment with an antibody against neutrophils reduces after smoke exposure BALF neutrophils to undetectable levels, prevents increases in BALF DES and HP and does not affect alveolar macrophages. Intraperitoneal injection of human AAT before cigarette smoke exposure increases serum level of AAT threefold and completely abolishes smoke-induced connective tissue breakdown by-products as well as the increase in neutrophils without affecting alveolar macrophages in BALF. These results indicate that in this model, cigarette smoke acutely induces connective tissue break-

down, an effect probably brought about by neutrophil-derived proteases. Exogenous AAT is protective and inhibits both matrix degradation and neutrophil influx [23].

In a subsequent study, macrophage metalloelastase knockout mice (MME(-/-)), as well as MME(+/+) mice, were acutely exposed to cigarette smoke. In MME(+/+) mice, the acute smoke exposure results in an elevation in neutrophils, DES and HP in BALF but no elevation in MME-deficient mice. Both neutrophil influx and increased level of DES and HP are restored by administering alveolar macrophages from MME(+/+) mice to MME(-/-) mice and then exposing them to cigarette smoke.

These studies show that acute smoke-induced connective tissue breakdown, the precursor to emphysema, requires both neutrophils and macrophage metalloelastase (MME or MMP-12) [24]. Thus, these studies together underline the importance of both classes of proteases (serine elastases and MMPs) in the pathogenesis of lung matrix degradation.

Role of TNF- α in the acute inflammatory process

Mice with knocked out p55/p75 TNF- α receptors (TNF- α RKO) and control mice were exposed acutely to cigarette smoke. Two hours after smoke exposure, increases in gene expression of TNF- α , neutrophil chemoattractant macrophage inflammatory protein-2 and macrophage chemoattractant protein-1 are seen in control mice. By 6 h, TNF- α , macrophage inflammatory protein-2 and macrophage chemoattractant protein-1 gene expression levels are back to control values. In TNF- α RKO mice, no changes in gene expression of these mediators are seen at any time. At 24 h, control mice show increases in BALF neutrophils, DES and HP, whereas no elevation in these parameters are seen in TNF- α RKO mice.

In a separate experiment, mice of the strain 129, which produce low levels of TNF- α , show no inflammatory response to smoke either at 24 h or 7 days. These results indicate that TNF- α is central to acute cigarette smoke-induced tissue breakdown [25].

In another study, both mice lacking MMP-12 (MMP-12(-/-)) and wild type mice (MMP-12(+/+)) demonstrate rapid increases in whole-lung nuclear factor- κ B activation and gene expression of proinflammatory cytokines after acute cigarette smoke exposure. This indicates that lack of MMP-12 does not produce a global failure to up-regulate inflammatory mediators. However, only MMP-12(+/+) mice demonstrate an increase in whole-lung TNF- α protein. Similarly, levels of whole-lung E-selectin, a marker of endothelial activation, are increased only in MMP-12(+/+) mice. These findings suggest that MMP-12 mediates cigarette smoke-induced inflammation acutely by releasing TNF- α , from macrophages, with subsequent endothelial activation, neutrophil influx and proteolytic matrix breakdown caused by neutrophil-derived proteases.

TNF- α release may be a general mechanism whereby metalloproteases drive cigarette smoke-induced inflammation [26].

Taken together these data support the idea that in humans TNF- α promoter polymorphism may be of importance in determining the individual responders who develop cigarette smoke-induced COPD (see also Models of cytokine expression).

Pharmacological studies

The effects of compounds on markers of inflammation can be investigated in acute models of cigarette smoke exposure. These studies may also serve as a relatively quick test for the activity of these compounds in the lung prior to their investigation in a time-consuming chronic model.

The serine elastase inhibitor ZD0892 (AstraZeneca, Lund, Sweden), an agent that selectively inhibits human neutrophil elastase and has an additional anti-inflammatory activity, was investigated in two acute models: the guinea pig and the mouse.

In the guinea pig model, animals given ZD0892 orally at doses of 10 and 30 mg/kg prior to smoke exposure, lowers the smoke-induced increases in total cell number and neutrophil number, as well as the increases in DES and HP content in BALF compared with untreated animals [27].

In the mouse model, ZD0892 administered orally at a dose of 30 mg/kg before cigarette smoke exposure, reduces the smoke-induced gene expression of macrophage inflammatory protein-2 and macrophage chemoattractant protein-1 in lung tissue but not of TNF- α . However, ZD0892 completely prevents the smoke-induced increase in plasma TNF- α [27].

Thus, compounds with antielastase and anti-inflammatory activities are effective in models of acute exposure to cigarette smoke.

Chronic smoke exposure

These models have been used to investigate the sensitivity of various strains of inbred mice to the effects of chronic smoke exposure, the role played by proteases in causing the lesions, the potentiating effects of viral infections and the potential therapeutic effects of compounds.

Mouse strain sensitivity

As a follow-up to the study of the model of acute smoke exposure, mice of the strains ICR, DBA/2 and C57Bl/6J have been chronically exposed to cigarette smoke for 7 months.

Mice of the strain ICR are not sensitive to oxidants and have normal levels of serum AAT, DBA/2 mice also have normal levels of serum AAT but are sensitive to oxidants while C57Bl/6J mice are both sensitive to oxidant and have a moderate deficit (-25%) of serum AAT. After the chronic

exposure to cigarette smoke, ICR mice have normal levels of lung elastin content and no emphysema. On the other hand, both DBA/2 and C57Bl/6J mice show a significant drop in lung elastin content as well as emphysema assessed by three different methods. Histologically, emphysema was patchy and of the panlobular type (Fig. 30.1a,b).

In a separate experiment, pallid mice with a severe serum AAT deficiency and that develop spontaneous emphysema were exposed to cigarette smoke for 4 months. This resulted in an acceleration of the development of spontaneous emphysema assessed by morphometrical and biochemical (lung elastin content) methods [22]. In a recent study it was found that the lack of sensitivity of the ICR mice to the effects of chronic smoke exposure, is probably due to the activation of the nuclear factor erythroid-derived 2, like 2 (Nrf2) in this strain. Nrf2 is a redox-sensitive basic leucine zipper protein transcription factor that is involved in the regulation of many detoxification and antioxidant genes. The disruption of the Nrf2 gene in the ICR mice led to extensive emphysema in these mice following chronic cigarette smoke exposure [28].

Recently, a study was carried out in an attempt to differentiate the pattern of emphysema induced by chronic cigarette smoke exposure in C57Bl/6J and pallid mice. After 6 months of smoking, pallid mice, but not C57Bl/6J mice, show a T-cell inflammation in the alveolar wall and an increase in lung compliance. Also, in pallid mice the emphysematous lesion is more diffuse than in C57 mice, affecting all airspaces [29].

These studies together indicate that the response to cigarette smoke exposure in mice is strain-dependent and suggest further investigations of the genetic differences in the susceptibility to cigarette smoke-induced lesions that may have implications for human disease.

Role of MMPs in chronic cigarette smoke exposure

In this study, macrophage elastase deficient mice (MME(-/-)) were subjected to cigarette smoke exposure for 6 months. In contrast to their littermates (MME(+/+)), these mice do not show an increased number of macrophages in their lungs and do not develop emphysema in response to cigarette smoke.

Smoke-exposed MME(-/-) mice that received monthly intratracheal instillations of macrophage chemoattractant protein-1 show accumulation of macrophages but not emphysema [30].

In another study, it was found that the development of emphysema in smoke-exposed guinea pigs correlates with alveolar macrophage numbers and alveolar macrophage-derived proteolytic activity but not with neutrophil numbers [31]. Furthermore, depletion of alveolar macrophages prevents smoke-induced emphysema, whereas depletion of neutrophils is not protective [32].

(a)

(b)

Figure 30.1 (a) Well-fixed normal lung of a C57B1/6J control mouse exposed to room air for 7 months. (b) Lung of a C57B1/6J mouse exposed to the smoke of three cigarettes/day for 7 months showing emphysematous changes. The emphysema is patchy and of the panlobular type. HE, original magnification $\times 32$.

Thus, these studies taken together indicate that macrophage elastases have an important role in the pathogenesis of chronic cigarette smoke-induced emphysema.

Role of neutrophil elastase in chronic cigarette smoke exposure

Mice lacking neutrophil elastase are approximately 60% protected against cigarette smoke-induced emphysema [33].

In another investigation, groups of mice were exposed daily to cigarette smoke for up to 6 months. One group of mice received human AAT every 48 h. In mice receiving AAT there was an approximately twofold increase in serum AAT levels and elastase inhibitory capacity. Treated mice, contrary to untreated ones, did not show elevations in BALF neutrophil numbers and matrix breakdown products measured from 2 to 30 days of smoke exposure. After 6 months exposure to cigarette smoke the AAT-treated mice show a 63% protection against emphysema and full protection against the smoke-mediated increase in plasma TNF- α .

There is thus direct as well as indirect evidence that neutrophil elastase also has a role in chronic cigarette smoke-induced emphysema. The latter study also suggests an anti-inflammatory activity for AAT [34].

Potentiating effects of viral infections

This study was designed to test the hypothesis that cigarette smoke-induced inflammation and emphysema are amplified by the presence of latent adenoviral infection. The results confirm that in guinea pigs, chronic cigarette-smoke exposure causes lesions similar to human centrilobular emphysema. They also show that latent adenoviral infection combined with cigarette-smoke exposure causes a greater increase in lung volume, air-space volume and lung weight, and a further decrease in surface : volume ratio compared with smoke exposure alone.

Analysis of inflammatory response in parenchymal and airway tissue shows that smoking causes an increase of polymorphonuclear leucocytes, macrophages and CD4 cells and that latent adenoviral infection independently increases polymorphonuclear leucocytes (PMN), macrophages and CD8 cells.

Thus, latent adenoviral infection amplifies the emphysematous lung destruction and increases the inflammatory response produced by cigarette-smoke exposure. In this study, the increase in CD4 is associated with cigarette smoke and the increase in CD8 cells with latent adenoviral infection [35].

Table 30.1 Theories and hypotheses of the pathogenesis of emphysema and/or COPD that have been either confirmed or put forward in animal models.

Theories/hypotheses	Animal model	References
NE/AAT	Pallid mouse, knocked out, acute smoke, chronic smoke	8, 9, 23, 33, 34
MMPs	Acute smoke, knocked out, chronic smoke	24, 30, 31, 32
Apoptosis	Transgenic, specific models, feed restriction	12, 17, 18, 19, 20
IFN- γ	Transgenic	11, 12
TGF- β	Knocked out	16
TNF- α	Transgenic, knocked out, acute smoke	14, 15, 25
Integrative hypothesis:		
CS \rightarrow Mac \rightarrow MMP-12 \rightarrow TNF- α \rightarrow ENDO \rightarrow NE	Acute smoke	26
AAT, alpha-1 antitrypsin; CS, cigarette smoke; ENDO, endothelial activation; IFN- γ , interferon- γ ; Mac, macrophage activation; MMP, matrix metalloprotease; NE, neutrophil elastase; TGF- β , transforming growth factor β ; TNF- α , tumour necrosis factor α .		

Pharmacological studies

The compound ZD0892 was investigated in a model of chronic cigarette smoke exposure in guinea pigs. Long-term (6 months) cigarette smoke exposure results in emphysema, an increase in neutrophils, DES and HP in BALF, and in an increase in TNF- α in plasma. ZD0892 treatment abolishes the BALF changes, reduces the plasma increase in TNF- α by 30% and emphysema by 45%. Thus, the positive results obtained with ZD0892 in the model of acute smoke exposure have a predictive value for the effects of ZD0892 in the model of chronic smoke exposure [27].

In a recent study groups of C57Bl/6J mice were dosed daily with the phosphodiesterase 4 inhibitor roflumilast at two dose levels (1 and 5 mg/kg p.o.) and were exposed to cigarette smoke for 7 months. In control animals chronic smoke exposure caused a 1.8-fold increase in lung macrophage density, emphysema, an increase of the mean linear intercept (+21%), a decrease of the internal surface area (-13%), and a drop (-13%) in lung desmosine content. The low dose of roflumilast did not have any effect, whereas the high dose prevented the increase in lung macrophage density by 70% and fully prevented the other changes [36]. This study supports the role of an inflammatory process in the development of cigarette smoke-induced matrix destruction and emphysema.

In another study the 3-hydroxy-3-methyl-glutaryl-coenzyme-A reductase inhibitor simvastatin was given daily at the dose of 5 mg/kg p.o. to Sprague-Dawley rats and the animals were exposed to cigarette smoke for 4 months. Simvastatin inhibited lung parenchymal destruction and development of pulmonary hypertension, and also inhibited peribronchial and perivascular infiltration of inflammatory cells and induction of matrix metalloproteinase-9 activity in lung tissue [37]. The amelioration by simvastatin of the structural derangements caused by cigarette smoking was attributed to an anti-inflammatory effect of this compound.

In conclusion, the investigation of novel pharmacological approaches in the amelioration of emphysema in animal models has provided new leads for the treatment of this disease. Additionally, the study of the pathogenesis of emphysema and/or COPD in animal models of this disease has been very intense in recent years and novel hypotheses have been put forward. The theories and hypotheses that have been confirmed in animal models are summarized in Table 30.1.

CHAPTER 31

Proteinases and COPD

Anita L. Sullivan and Robert A. Stockley

Proteinases are believed to have an important role in the pathogenesis of COPD. The proteinase–antiproteinase hypothesis states that the lung damage of COPD arises when the action of proteinases is no longer controlled by antiproteinases. This may occur when there is a genetic abnormality of antiproteinases, as in α_1 -antitrypsin (α_1 -AT) deficiency, or a functional loss of antiproteinases through proteolytic or oxidative damage. Alternatively, the same imbalance can arise because of excessive recruitment or activation of proteinases.

Proteinases are classified as serine or cysteine proteinases, depending on the amino acid at their active site, and a third major group, the matrix metalloproteinases (MMPs), which require a metal ion in their structure for their extracellular matrix protein-degrading activity. Proteinases are able to degrade structural lung proteins giving them their capacity as elastases, collagenases or gelatinases (Fig. 31.1 a–c; for c also see Plate 31.1; colour plate section falls between pp. 354 and 355). In addition, many proteinases have roles in post-translational processing of other enzymes, cytokines and receptors. Over the years, a large body of work has accumulated showing important roles for proteinases and antiproteinases from all three of the major groups in the pathogenesis of COPD. However, it is difficult to assess the relative importance of each from the results of studies of individual proteinases, as they are often conflicting. This chapter provides an overview following discussion of the likely contributions from enzymes of each biochemical group.

Serine proteinases

These comprise neutrophil elastase (NE), cathepsin G (CG) and proteinase-3 (PR3), which are stored with myeloperoxidase (MPO) in the azurophil granules of neutrophils [1]. They are made early during neutrophil development

in the bone marrow, with gene expression ceasing at the metamyelocyte stage [2] and are produced as pre-proenzymes, activated by a lysosomal cysteine proteinase, dipeptidyl peptidase I (cathepsin C) [3]. Although these enzymes are often considered to be neutrophilic in origin, they are also produced by a subgroup of circulating monocytes. Furthermore, these monocytes are also migratory and release the enzymes on activation [4]. The potential importance of these enzymes is underlined by their ability to induce the pathological changes seen in COPD and the increased risk of emphysema in patients deficient in their main inhibitor, α_1 -AT [5]. A list of the serine proteinase inhibitors relevant to the lungs is given in Table 31.1.

NE was the first of these enzymes to be shown to produce emphysema in animal models and hence has been the subject of most study. It is believed that the main physiological function of NE is bacterial killing, which takes place after ingestion of opsonized bacteria into a phagosome. Granules are released into a lysosome, which fuses with the phagosome, and the combination of proteinases and oxidants results in bacterial killing [6]. Deficiency of azurophil granule serine proteinases, Chédiak–Higashi syndrome, leads to immunodeficiency [7]. The major role of NE in health is thus probably within the neutrophil.

NE has the capacity to be intensely destructive. It is believed to be a key effector of lung damage in both emphysema and chronic bronchitis [8]. This concept is supported by a number of animal studies, in which instillation of NE and other elastases have reproduced the morphological changes of emphysema and bronchitis (Table 31.2). The development of emphysema is specific to elastase activity [9], and the severity of the ensuing emphysema relates to the elastolytic potency of the enzyme used [10]. Lung damage by NE can be prevented by specific elastase inhibitors [11,12]. NE can degrade matrix proteins such as elastin, fibronectin [13] and collagen [14], and weakens immunity by attacking immunoglobulins [15]

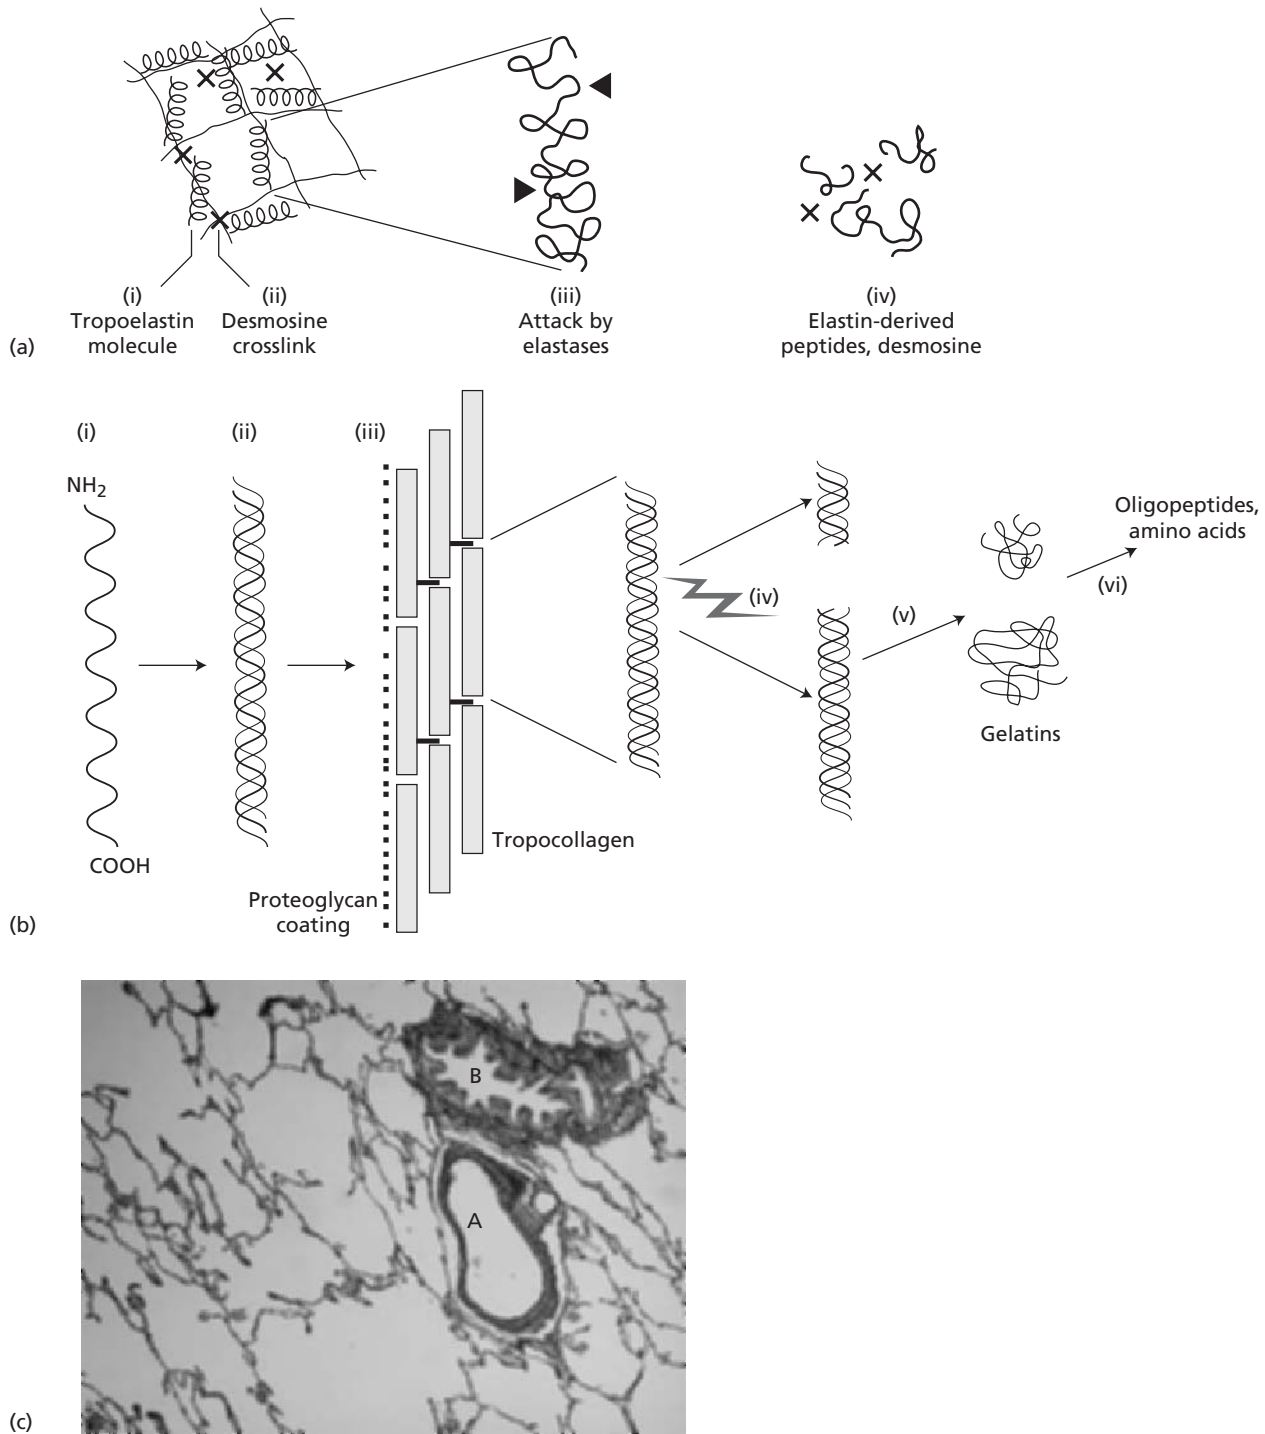

Figure 31.1 (a) Elastin and its degradation. Tropoelastin molecules associate on a framework of fibrillin molecules (i), and are cross-linked between lysine residues. Four lysine residues form a desmosine cross-link (ii). Elastases hydrolyse bonds between amino acids according to their active site specificity (iii), producing characteristic elastin-derived peptides and desmosine cross-links which are specific markers of elastin degradation (iv). (b) The α -helical procollagen strands (i) associate into a triple helix to form a tropocollagen molecule (ii). These molecules then associate into collagen fibres (iii), with cross-links between the telopeptides of each tropocollagen molecule and the hydroxyproline and hydroxylysine residues in the helical area. The fibre is coated with proteoglycans and glycopeptides, which may help to stabilize it or to protect it from collagenolytic attack. Serine and cysteine proteinases can destabilize the fibre by degrading intra- or intertropocollagen bonds, and some can also cleave within the

Table 31.1 Serine proteinase inhibitors in the lungs. Individual references not given for reasons of space.

Inhibitor	Source	Molecular weight (kDa)	Target proteinase	Inhibition
α_1 -AT	Serum	54	NE, CG, PR3, mast cell chymase	Irreversible

NE, neutrophil elastase; PR3, proteinase 3.

and components of the complement system [16,17]. It may also slow wound healing, possibly by its effect on transforming growth factor β [18] or epithelins [19].

In order to reach the lungs, neutrophils must be activated, adhere to endothelium and then migrate through to the airways. Neutrophils may degranulate, releasing enzymes, or may cause tissue damage by close contact with cells and matrix. During neutrophil activation, azurophil granule proteinases are expressed on the neutrophil membrane [20]. *In vitro* studies have shown that approximately 2% of the azurophil granule proteinases are released

into the media on activation of the neutrophil by pro-inflammatory stimuli, the rest remaining associated with the cell by a charge-dependent mechanism [21,22]. While NE bound to the neutrophil membrane exhibits partial resistance to the effects of native inhibitors such as α_1 -AT [20], free NE can be readily inhibited by both serum- and tissue-based inhibitors [23], thereby preventing tissue damage at a distance from the cell.

Although the majority of serine proteinase activity remains associated with the neutrophil even after activation, free NE activity can be detected in secretions from

helical region. ‘True’ collagenases (matrix metalloproteinases [MMPs]-1, -8 and -13) cleave the tropocollagen molecule at three-quarters of the length of the helix, producing characteristic one-quarter and three-quarter length fragments (iv). Collagen fragments spontaneously denature into gelatin at body temperature (v), which can then be further degraded into oligopeptides and amino acids, predominantly hydroxyproline, which thus acts as a marker for collagen breakdown (vi). (c) Section of normal human lung $\times 100$, stained with Elastic van Gieson, which highlights elastic fibres as black (see Plate 31.1; colour plate section falls between pp. 354 and 355). Collagen stains crimson red with this stain (see Plate 31.1; colour plate section falls between pp. 354 and 355). Distinct elastin laminae can be seen within the walls of a bronchiole (B) and its accompanying nutrient artery (A). Collagen is best seen surrounding blood vessels in this photomicrograph (see Plate 31.1; colour plate section falls between pp. 354 and 355). Note the predominance of elastin staining in alveolar tissue. Sections kindly prepared by Dr Simon Trotter, Department of Histopathology, Birmingham Heartlands Hospital, UK.

patients with COPD [24]. This may be the result solely of neutrophil degranulation, but there are several other possibilities. First, when neutrophils die by apoptosis, they are cleared by macrophages [25], which can also scavenge free NE [26], whereas necrotic neutrophils release their contents into the extracellular space [27]. Secondly, the process of phagocytosis may involve release of significant amounts of both NE and PR3 into the media [28]. This might occur when neutrophils attempt to ingest large extracellular structures ('frustrated phagocytosis'), or as a by-product of normal phagocytosis ('sloppy eating'), demonstrated in studies comparing activation by lipopolysaccharide (LPS) alone with ingestion of opsonized yeast cells, which showed that free NE activity was only detected in the media with the latter [29]. Thirdly, studies of macrophages isolated from the lungs of patients with COPD showed that their *in vitro* elastolytic effect depended largely on serine proteinases within the first 24 h of culture, but MMPs over the next 48 h, suggesting that the early serine proteinase activity was attributable to endocytosed enzymes rather than constitutively secreted enzymes [30]. Earlier studies showed that alveolar macrophages could release active NE that was endocytosed up to 5 days previously [31]. Finally, monocytes can express and secrete serine proteinases, although they lose this capacity on differentiation to macrophages [32].

The majority of NE-related parenchymal tissue destruction may occur in association with the passage of neutrophils from the circulation to the airway. This suggests that NE inhibitors might mediate their protective effect at least in part by reducing neutrophil migration, but studies examining this concept have produced conflicting results. Using the multiple blind well assay system, chemotaxis in response to formyl-methionyl-leucyl-phenylalanine (fMLP) was inhibited by α_1 -AT [33], specific antibody against CG and physiological concentrations of mutant forms of α_1 -AT and α_1 -antichymotrypsin [34]. Synthetic inhibitors of CG were shown to reduce the leading front response in the under agarose assay. Interestingly, the same study suggested that a mutant form of α_1 -AT with greater antichymotrypsin activity was effective in reducing migration, implying that CG has a greater role in this activity than NE [34]. Serine proteinase inhibitors have been shown to prevent degradation of basement membrane components by cell-free NE [23]. However, examination of neutrophil migration across fibrinogen or Matrigel barriers has shown conflicting results using NE and MMP-9 inhibitors [23,35,36]. In rats, inhibition of NE could prevent neutrophil migration *in vivo*, but migration across endothelial monolayers *in vitro* was not prevented [37]. Studies using a combination of endothelial cells and basement membrane have consistently shown that proteinase inhibitors do not prevent neutrophil migration [38,39]. Furthermore, *in vitro*

neutrophil migration across endothelium was not impaired in mice deficient in NE or MMP-9 [40]. The variability in the results of these studies demonstrate the difficulties of assessing the importance of proteinases in neutrophil migration, either by using antiproteinases, which may not be able to inhibit cell-associated enzymes in contact with matrix structures, or by eliminating only one proteinase from neutrophils that retain two other potent serine proteinases.

In support of this concept, neutrophils from mice whose genes for NE and CG had been 'knocked out' showed normal migration *in vitro*, and these mice exhibited normal neutrophil infiltration into tissue in response to fungal infection and lipopolysaccharide, although pathogen clearance was severely impaired [41]. In humans, patients with Papillon-Lefèvre syndrome have deficient dipeptidyl peptidase I [42], causing a functional deficiency of NE and CG through impaired processing of the pre-proenzyme, and neutrophil migration is also impaired *in vitro* [43]. The main phenotype, however, is severe periodontitis, with no systemic immunodeficiency – which may imply physiological redundancy, or that another enzyme activates these proteinases after secretion *in vivo*. On the other hand, neutrophils from patients with Chédiak-Higashi syndrome, in which all three neutrophil serine proteinases are deficient, do not migrate towards chemoattractants [44].

Animal studies using proteinase inhibitors often show reduced neutrophil influx to the lungs. For example, studies in guinea pigs demonstrated an acute response to cigarette smoke, consisting of airway neutrophilia and increased connective tissue breakdown products in bronchoalveolar lavage fluid (BALF), which could be inhibited by pre-treatment with a synthetic NE inhibitor [45]. In rats, instillation of NE to the airways induced neutrophil influx, which was inhibited by intratracheal but not intravenous administration of a synthetic NE inhibitor. On the other hand, intratracheal instillation of sputum from cystic fibrosis patients (in whom there is intense neutrophilic inflammation) induced a massive neutrophil influx, which could be prevented by the same inhibitor only when it was administered intravenously rather than intratracheally [46]. This suggests that the effect was related to inhibition of proteinases in the circulation (prior to neutrophil migration) rather than the airway. These studies support the concept that the type of stimulus for neutrophil migration influences the role of proteinases in neutrophil migration, and that the proteinase-dependent process may occur while the neutrophil is still within the circulation.

The mechanisms of neutrophil migration are not well understood. Even if serine proteinases are required, their function is not necessarily degradation of extracellular matrix substrates to allow cell passage, as they may process other important proteins such as adhesion factors [37],

Figure 31.2 Quantum proteolytic events associated with PMNs bathed in serum from donors with various AAT phenotypes. PMNs were allowed to migrate for 30 min at 37°C on opsonized fluoresceinated fibronectin while bathed in serum from phenotypes with (a) Pi M, (b) Pi MZ, (c) Pi SZ and (d) Pi Z. Cells were fixed and then examined by incident-light fluorescence microscopy. Note the discrete, rounded, dark areas associated with migrating cells, which are very localized areas of degraded fibronectin (short arrows in (a) identify selected areas of quantum proteolysis). Note also the coalescent areas of degradation that are related to release of two or more azurophil granules. PMNs remaining on the surface are fluorescent because of ingested fibronectin fragments (broad arrows). The quantum proteolytic events are visually similar in size in a–c. Note also that cell-associated proteolytic events are strikingly larger in cells bathed in Pi Z serum (long arrow in d) when compared with those bathed in serum from the other donors. Scale bar: 10 μm . (From Campbell *et al.* [49] with permission.)

or stimulate intracellular signalling [47]. However, tissue degradation might occur as a side-effect of neutrophil passage without being necessary for migration. The failure of serine proteinase inhibitors to prevent this process might relate to the phenomenon of quantum proteolysis, in which the concentration of NE falls exponentially with the distance from the site of enzyme release [48]. Thus, although the concentration of free NE in the lung is lower than the concentration of its inhibitors, there would be an imbalance between proteinase and inhibitor close to the

site of release of the enzyme, which enables breakdown of elastin to occur. This concept was proved in a series of experiments with serum from patients with normal or deficient α_1 -AT (Figure 31.2) [49]. A similar local imbalance, closer in proximity to the neutrophil, could occur without release of free enzyme, as native inhibitors are functionally less effective against membrane-bound proteinases [20]. *In vivo* therefore, neutrophil activation and migration may be sufficient to cause some tissue destruction despite the presence of inhibitors, and the true contribution of serine

proteinases to this process may not be determined until development of animal models in which all three enzymes are absent only in the postnatal period.

The mechanism by which neutrophil serine proteinases cause lung damage may be modified by their interaction with proteinase inhibitors, the presence of the neutrophil itself, epithelial cells and the extracellular matrix. For example, NE, once bound to elastin, is poorly inhibited by α_1 -AT, while the activity of secretory leucoproteinase inhibitor (SLPI) is unaffected [50]. NE bound to α_2 -macroglobulin is prevented from degrading elastin, but can still degrade small substrates [51]. Studies using intra-tracheal interleukin 8 (IL-8; a neutrophil chemoattractant) in guinea pigs showed that goblet cell degranulation could be prevented by IL-8 blockade or specific inhibitors of NE. Further *in vitro* studies incubating explanted tracheal tissue with neutrophils showed that inhibition of neutrophil adhesion factors also prevented degranulation. The authors speculated that adhesion of neutrophils to goblet cells altered the neutrophil membrane, facilitating release of membrane-bound NE into the intercellular space and triggering goblet cell degranulation [52].

There seems little doubt that NE is the critical proteinase in the mucus hypersecretory phenotype of COPD. Animal models have demonstrated induction of secretory cell metaplasia in direct response to NE (see Table 31.2) and prevention of secretory cell metaplasia with inhibitors of NE [52], while inhibition of other classes of proteinase is not effective [53,54]. The mechanism for these changes is not fully understood, however, and may involve an effect on the epidermal growth factor receptor [55], with NE acting as part of a signalling cascade.

Serine proteinases also have many deleterious effects on respiratory epithelium. In chronic bronchitis, secretions contain a toxic component that influences ciliary beating, which is abrogated by inhibitors of NE [56]. Purified NE *in vitro* reduces ciliary function and damages respiratory epithelial cells [57]. Serine proteinases trigger a state of oxidative stress in respiratory epithelial cells [58], which may contribute to the effect of NE on mucin secretion [59]. NE can also induce the detachment of bronchial epithelial cells from extracellular matrix [60] and apoptosis of epithelial cells [61], while both NE and PR3 induce detachment and apoptosis of endothelial cells [62,63]. This may be important in the pathogenesis of COPD. Serine proteinases, especially NE, are therefore likely to have many effects on the airway epithelium in COPD as well as the connective tissue matrix. Most of this concept, however, has been hypothetical but recent work has shown more clearly that the purulence of sputum relates to the activity of NE in secretions [64], which is in direct contact with the epithelium and results from neutrophil migration. This is particularly important during exacerbations when neutrophil

influx and elastase activity increase [64]. The frequency of these episodes relates to the progressive decline in lung function, suggesting a causal relationship [65,66].

The central role of NE in human emphysema has been called into question by animal models showing that NE knockout mice are only partially protected against the development of emphysema [67]. However, these models may be limited by the persisting presence of CG and PR3 in azurophil granules – the former can cause secretory cell metaplasia [68] and the latter can cause both emphysema and secretory cell metaplasia [69]. Nevertheless, indirect data from human studies support the concept that neutrophils and neutrophil enzymes are important in emphysema. Studies have shown that smokers have increased numbers of neutrophils in lung tissue [70], sputum [71,72] and BALF [73], and that neutrophils isolated from patients with emphysema exhibit increased elastolytic and chemotactic activity compared with those from controls [74], and express more adhesion factors [75]. Even at an early stage with subclinical emphysema on high-resolution CT scan, there is an increase in NE and other neutrophil proteins in BALF [76,77]. Studies on patients with established emphysema indicate that NE activity in BALF correlates with the severity of emphysema in smokers [78] and falls when they stop smoking [79], and cessation of smoking is the only intervention shown to affect progression of COPD to date. On the other hand, although the neutrophil count in lung interstitium correlated with the severity of emphysema in one study [80], it showed an inverse relationship in other studies [81–83]. However, before any conclusions can be drawn from these studies, it should be remembered that the neutrophil is a migratory cell and its residence in the interstitium is short. It is likely that any interstitial damage leading to emphysema relates to the cells that have passed as much as the ones seen while migrating through the tissues.

NE may also have an indirect role as it has the ability to amplify the inflammatory process in the lungs. Leukotriene (LT) B_4 released from lung macrophages is important as a chemoattractant bringing neutrophils to the lungs in COPD [84,85], and release of LTB_4 by macrophages is stimulated by free NE [86]. In addition, NE may stimulate bronchial epithelial cells to release IL-8. Finally, neutrophils themselves release LTB_4 and IL-8, leading to further cell recruitment. In this way, NE released by neutrophils contributes to positive feedback recruiting more neutrophils and amplifying inflammation. This amplification will be greater in patients deficient in α_1 -AT, who have greater concentrations of LTB_4 and elastase, and more neutrophilic inflammation in their lung secretions than have non-deficient COPD patients [87].

The overall evidence from *in vitro* work, animal models and human studies suggests that NE is important in

pathogenesis of COPD and is therefore a potential target for therapeutic intervention. Caution will be needed, however, in suppressing a critical antibacterial defence [88]. Although serine proteinases may have an important role in migration of neutrophils from blood to lung, either they are not essential for this activity, or it is not possible to achieve sufficiently high inhibitor concentrations to inactivate the proteinases in the immediate vicinity of the neutrophil. Reassuringly, studies using LPS as the stimulus for lung damage showed that neutrophil influx was not inhibited by α_1 -AT [89], suggesting that the therapeutic use of serine proteinase inhibitors should not affect lung immunity adversely, while limiting the severity of elastase-induced damage.

Animal models have indicated that both synthetic [11] and natural [12,90–92] NE inhibitors are useful when given at the time of administration of the insult causing emphysema. The only animal study examining the effect of NE inhibition on progression of established cigarette smoke-associated disease showed that inflammation and connective tissue breakdown can be reduced by a synthetic NE inhibitor from the time of onset of treatment [45]. More recently, the same group has shown that α_1 -AT augmentation has the same effect and prevents the development of emphysema, although this may not be a direct antiproteolytic effect [93]. The relevance of these studies to human disease remains to be determined. Certainly, some animal models have suggested that neutrophil influx is greatest at the onset of lung disease, while macrophage accumulation may be more important later on [94,95]. In human disease, the use of α_1 -AT has been confined to patients with deficiency, with some anti-inflammatory effect [96], and indirect studies suggest a reduction in progressive decline in lung function [97,98]. Whether this antiproteinase benefit is of relevance to patients with usual COPD remains unknown.

Other serine proteinases

A subset of mast cells synthesizes cathepsin G together with chymase, while the most important serine proteinase in mast cells as a whole is tryptase. Mast cells may also produce NE and PR3 [99]. There is some evidence that mast cells may be important during exacerbations of COPD [100] and, if so, their proteinases may have a role in tissue damage [101]. Clearly, further studies with these cells are indicated.

Cysteine proteinases

These include cathepsins B, H, K, L and S, inhibited by the cystatins A, C and S and α_2 -macroglobulin. This group of proteinases has received less attention, but they have sim-

ilar properties to the serine proteinases and there are imbalances between cysteine proteinases and cystatins in COPD.

Cathepsin B secretion by epithelial cells has been demonstrated *in vitro* [102], but it is not known if this is the major source *in vivo*. This elastinolytic and collagenolytic enzyme is found in sputum from patients with COPD, the amount increases during exacerbations [103] and can be reduced by oral corticosteroids [104]. In patients with bronchiectasis, cathepsin B activity is reduced by antibiotics [104], suggesting it is a feature of inflammation caused by bacteria in this condition. Cathepsin B activity is higher in BALF from smokers than non-smokers [105], although smokers with emphysema had similar cathepsin B levels in BALF to smokers without emphysema [106]. Although cathepsin B is produced by macrophages, not neutrophils [107], its activity in BALF from patients with bronchiectasis correlates with neutrophil but not macrophage counts. Cathepsin B levels also correlate positively with MPO and NE activities, and negatively with cystatin C in these patients [108]. These interrelationships suggest that neutrophilic inflammation and cathepsin B activity are intimately related. It is known that NE generates cathepsin B activity in sputum by activating the pro-enzyme [109]. Cystatin C, which inhibits cathepsin B, is present in mucoid sputum, but in purulent sputum (when NE and cathepsin B activities are detectable), it is only found in a form similar to that produced by NE cleavage *in vitro* [109]. In this form, it inhibits cathepsin B poorly [110]. It therefore seems that NE can play a major part in the activation of cathepsin B, and this may be further amplified because cathepsin B can also inactivate SLPI, the local NE inhibitor (Fig. 31.3) [111]. This amplification and synergy may be of major importance

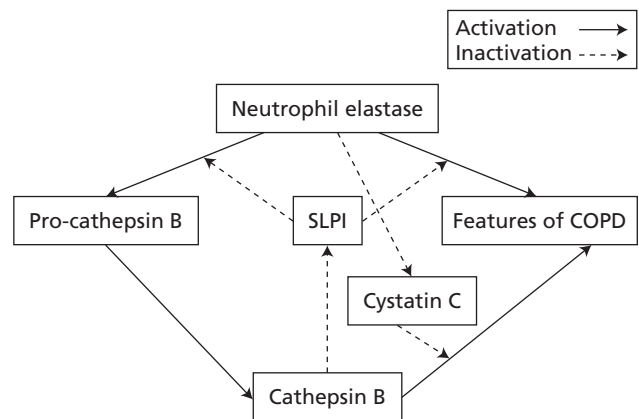

Figure 31.3 Neutrophil elastase (NE) and cathepsin B have synergistic effects. NE can activate pro-cathepsin B while inactivating its inhibitor, cystatin C. Cathepsin B can inactivate an inhibitor of NE, secretory leucoproteinase inhibitor (SLPI), and both NE and cathepsin B degrade connective tissue matrix proteins.

because both NE [68] and cathepsin B [112] can reproduce many of the pathological features of COPD *in vivo*.

Cathepsin K is expressed and synthesized by bronchial and alveolar epithelial cells [113]. It has collagenolytic, gelatinolytic and elastinolytic activity, but its role in the pathogenesis of lung disease is unclear.

Cathepsin L, another elastinolytic proteinase [114], has been studied in COPD, and found in higher concentrations in BALF from smokers with emphysema compared with both non-smokers and smokers without emphysema. Cathepsin L levels did not correlate with NE- α_1 -AT complex. In the same study, levels of cystatin C (its natural inhibitor) were found to be elevated in smokers with emphysema [106]. It is unknown whether cathepsin L can directly cause the pathological features of COPD, but it has been shown to degrade α_1 -AT *in vitro* [115].

There are few animal models of COPD examining cysteine proteinases and their inhibitors. A study of IL-13-induced emphysema [53] demonstrated an increase in the expression and secretion of cathepsins B, H, K, L and S in the lung. Cysteine proteinase inhibitors E-64 and leupeptin were able to reduce the severity of emphysema by approximately 65% and inflammatory cell infiltrate by approximately 60% when administered alone, and similar results were obtained with a broad-spectrum MMP inhibitor, but even combined administration of both cysteine proteinase and MMP inhibitors did not confer total protection. Interestingly, IL-13 also induced a decrease in pulmonary expression of α_1 -AT of approximately 80%, which may induce a critical NE- α_1 -AT imbalance.

Matrix metalloproteinases

There has been a major expansion of knowledge of the potential role of MMPs in COPD in recent years. They have

important cell signalling functions, as well as the ability to break down extracellular matrix during the remodelling process. They are secreted as pro-enzymes and usually activated by another MMP, often as part of a proteinase cascade. They have the ability to form complexes with inhibitors, dimerize in homologous or heterologous fashion, and remain associated with the cell membrane, sometimes in complexed form. This makes interpretation of activity levels of MMPs in biological fluids difficult. Neutrophils and macrophages each secrete large quantities of MMPs and their inhibitors, the tissue inhibitors of metalloproteinases (TIMPs), although other cells also produce both MMPs and TIMPs in variable amounts.

The potential role of MMPs in COPD is far-reaching, because they not only degrade matrix proteins, but also degrade antiproteinases such as α_1 -AT and α_1 -antichymotrypsin, activate other enzymes such as those in the clotting cascade, modify cytokines and degrade a number of other miscellaneous proteins such as adhesion factors and substance P. Upwards of 24 mammalian MMPs have now been described, generally grouped as collagenases, gelatinases, etc., according to their primary extracellular matrix (ECM) substrate, but it should be noted that many of these enzymes can degrade all constituents of ECM. Studies in COPD have generally concentrated on those listed in Table 31.3. The main serum inhibitor is α_2 -macroglobulin, while all four of the mammalian secreted TIMPs described to date inhibit all of the relevant MMPs (for detailed reviews see [116,117]).

Examination of BALF in patients with emphysema compared with healthy smokers confirmed the presence of metalloelastase activity [118], and studies on isolated macrophages have demonstrated that their elastinolytic activity, while less potent than that of neutrophils, is better preserved in the presence of proteinase inhibitors [119]. The absolute number of macrophages in the lungs of COPD

Table 31.3 Matrix metalloproteinases (MMPs). (Adapted from Sternlicht and Werb [117], additional references not given for reasons of space.)

MMP	Other names	Source	Substrates include
MMP-1	Interstitial collagenase, human collagenase-1	Macrophages, fibroblasts and other stromal cells	Collagens I-III, VII, VIII, X, XI, gelatin
MMP-2	Gelatinase A (72 kDa)	Macrophage, stromal cells	Collagens I, III-V, VII, X, XI, elastin, gelatin
MMP-3	Stromelysin-1	Macrophages, stromal cells	Collagens III-V, VII, IX-XI, elastin, gelatin
MMP-7	Matrilysin	Monocytes	Collagens I, IV, elastin, gelatin
MMP-8	Neutrophil collagenase, collagenase-2	Neutrophils	Collagens I-III
MMP-9	Gelatinase B (92 kDa)	Neutrophils, eosinophils, macrophages, stromal cells	Collagens IV, V, XI, XIV, elastin, gelatin
MMP-12	Macrophage metalloelastase	Macrophages	Collagens I, IV, elastin, gelatin
MMP-13	Collagenase 3	Macrophages, stromal cells	Collagens I-IV, IX, X, XIV
MMP-14	Membrane type (MT) 1-MMP	Macrophages	Collagens I-III, gelatin

patients is always greater than the number of neutrophils, and macrophages are resident cells that have the capacity to continue producing and secreting MMPs throughout their lifetime. For these reasons, it is suspected that they may play a major part in connective tissue degradation in emphysema. Their contribution was demonstrated in histological studies of elastase-induced emphysema in dogs, where alveolar macrophages were seen at the sites of alveolar gaps, although it was unclear whether they had caused the tissue damage, or were part of the repair process [120].

Various studies have produced conflicting results as to the correlation between the numbers of macrophages or neutrophils and the elastolytic activity in the lung, but it is likely that these cells and the enzymes that they produce also act cooperatively. A number of macrophage enzymes can degrade inhibitors of NE including α_1 -AT [121–123] and monocyte–neutrophil elastase inhibitor (M-NEI) [124], and NE degrades TIMPs [125], thereby facilitating MMP activity. Furthermore, NE can activate several of the MMPs [126–128], and MMP-9 is thought to degrade some neutrophil chemoattractants, at least in mice [54], which would potentially decrease PMN recruitment and hence lung NE load. Thus, it is clear that a complex interaction also exists between NE, its inhibitors and the MMPs and TIMPs in a similar way to that for the cysteine proteinases and cystatins. This interaction is evident in animal models of emphysema, which only show partial protection with inhibition of serine, cysteine or MMPs [45,53]. The exceptions to this include the MMP-12 knockout mouse, and the studies by Ofulue *et al.* discussed below.

Animal studies

Macrophage metalloelastase (MMP-12) is the main elastolytic enzyme of macrophages. A mouse model of cigarette smoke-induced emphysema has demonstrated a critical role for MMP-12 in pathogenesis. Line 129 mice deficient for MMP-12 did not develop emphysema in response to cigarette smoke, and inflammation in the lungs was reduced. The only elastolytic activity found in whole lung homogenates in wild type mice was derived from MMP-12, and this was absent in the knockout mice. Macrophages from the knockout mice were able to migrate to the lungs in response to instillation of MCP-1, but failed to cause emphysema, while in wild type mice, administration of MCP-1 increased the severity of emphysema [129]. This study suggested that MMP-12 might be the critical proteinase causing lung destruction in emphysema.

Further support for this concept came from studies examining the time course of smoking-induced emphysema in Sprague–Dawley rats over 6 months. While both neutrophil and macrophage numbers increased in response

to cigarette smoke, the elevation in neutrophil count and neutrophil elastolytic activity (defined as that inhibited by a specific NE inhibitor) was greatest in the first month. Connective tissue breakdown and the development of emphysema occurred later, correlating with macrophage count and macrophage elastolytic activity (defined as that inhibited by ethylenediaminetetraacetic acid [EDTA], i.e. MMP activity), which steadily increased throughout the duration of the study [94]. A second series of studies in the same model examined the effect of depleting either neutrophils or circulating monocytes and macrophages. Monocyte–macrophage depletion was protective against emphysema although the smoke-induced neutrophil influx and associated neutrophil elastolytic activity was not reduced. Neutrophil depletion was not protective against emphysema, although neutrophil elastolytic activity was markedly reduced [130]. These studies suggest that macrophages are required for the development of emphysema, while neutrophils play no part. It should be noted, however, that neutrophil versus macrophage elastolytic activity does not, strictly speaking, equate to serine proteinase versus MMP activity. Neutrophils produce MMP-9, and macrophages can at least take up and release NE, while immature macrophages may not yet have lost their serine proteinase producing capacity, a situation more likely to arise when large numbers of monocytes migrate into the lungs in response to an acute insult.

The role of macrophages and neutrophils was also examined in animal studies using coal and silica to induce lung damage. In C57Bl/6 mice, intratracheal instillation of coal or silica induced early neutrophil influx and an increase in elastase activity and elastin breakdown products at 24 h. Elevation of α_1 -AT levels also occurred, although some of the α_1 -AT was oxidized or degraded. Macrophage numbers did not rise until 7 days after exposure and, after coal but not silica, the macrophage numbers correlated with collagen breakdown products. Depletion of neutrophils reduced the quantity of elastin breakdown products in BALF at 24 h but not 7 days. The studies showed that mineral dust induces lung damage, which is only driven by neutrophil-derived proteinases in the early stages, and also showed that high levels of α_1 -AT do not prevent lung tissue breakdown mediated by neutrophil serine proteinases, supporting the concept of quantum proteolysis [95].

Because this was not an animal model of emphysema, the nature of the challenge and other features of the neutrophilic influx may have influenced the results. The same investigators therefore studied cigarette smoke-induced disease in C57Bl/6 mice, to investigate the mechanisms of damage arising in the first 48 h after smoke inhalation. BALF at 6 and 24 h showed an acute influx of neutrophils with evidence of both elastin and collagen degradation, all related to smoke exposure in a dose-dependent fashion

and resolving by 48 h. Macrophage numbers were not affected. Both neutrophil depletion and administration of α_1 -AT reduced neutrophilia and release of desmosine and hydroxyproline. Cigarette smoke increased both serine and metalloelastase activity in BALF, but only the former was reduced by α_1 -AT. In a model using LPS instead of cigarette smoke, exogenous α_1 -AT inhibited elastin breakdown without reducing neutrophil influx, suggesting that it was the direct antiproteolytic effect that was protective [89]. In these studies, progression after 48 h was not assessed, which may explain why the results conflict with the longer-term studies of Ofulue *et al.* [94,130].

Similar studies in guinea pigs also demonstrated acute responses to cigarette smoke, with neutrophilia and increased desmosine and hydroxyproline in BALF, which could be inhibited by pre-treatment with a synthetic NE inhibitor [45]. In the same study, guinea pigs were exposed to cigarette smoke over 6 months, causing airspace enlargement, elevation of desmosine, hydroxyproline and neutrophil count in BALF, and elevation of tumour necrosis factor α (TNF- α) in plasma. Inhibition of NE reduced plasma TNF- α by 30%, reduced neutrophils, desmosine and hydroxyproline in BALF to control levels, and reduced the severity of emphysema by 45%. This degree of protection is consistent with that found with the NE knockout mouse [67], and suggests that neutrophils and NE have a role in the development of at least some of the emphysema. However, when the NE inhibitor was given after 4 months instead of from the start of the 6 months smoking period, there was no protection against emphysema and TNF- α levels remained elevated, although neutrophils, desmosine and hydroxyproline in BALF were normalized, suggesting that the early changes are critical.

The interaction between TNF- α and neutrophil proteinases was further explored in animal models. A TNF- α receptor knockout mouse was protected against acute neutrophil infiltrate, connective tissue breakdown and up-regulation of neutrophil chemoattractants induced by cigarette smoke. Furthermore, mice from a strain producing lower than usual levels of TNF- α (line 129) were similarly protected [131]. (Because these mice were used to generate the original MMP-12 knockout mouse, this may help to explain why the disease in these mice was predominantly macrophage-dependent [129].) Partial protection against elastase-induced emphysema has been shown in mice deficient in the TNF- α receptor or the IL-1 β receptor [132] and more detailed studies of the role of TNF- α showed that this cytokine orchestrates up to 70% of the tissue destruction in cigarette smoke-induced emphysema, probably via neutrophil influx [133]. Taken together, these studies suggest that inhibitors of NE may also have an anti-inflammatory effect, possibly by modulating cytokine expression rather than directly preventing neutrophil migration.

Using MMP-12 knockout mice bred back into strain C57Bl/6, the relationship between neutrophils and macrophage proteinases was re-examined. Cigarette smoke induced a neutrophilic infiltrate and the release of desmosine and hydroxyproline in the wild type mice only. Macrophage numbers increased in both, albeit less in the MMP-12 knockout mice. The wild type response to smoke could be reconstituted in the knockout mice by intratracheal instillation of macrophages obtained by lavage in wild type mice. Use of a MMP inhibitor prevented the smoke-induced increase in neutrophils and the release of desmosine and hydroxyproline, while macrophage numbers were unaffected. These studies suggest that MMP-12 is required to elicit the neutrophil response to cigarette smoke. It was noted that α_1 -AT increased after smoke, and inhibition of MMPs reduced this effect, suggesting that MMPs do not contribute to NE activity by degradation of α_1 -AT in this model [134]. Subsequently the relationship of MMP-12 to TNF- α was examined. Stimulation with cigarette smoke elicited production of TNF- α by alveolar macrophages isolated from wild type mice, but this response was not seen in macrophages from MMP-12 knockout mice, despite normal levels of expression of TNF- α mRNA. It was determined that MMP-12 processes TNF- α after secretion, and without this, expression of endothelial adhesion factors fails, so that neutrophil recruitment does not occur [135].

Gelatinase B (MMP-9) makes up approximately 50% of the elastolytic activity of macrophages, the rest being attributable to MMP-12 [32]. It is synthesized in neutrophils during maturation [136], stored in the specific and gelatinase granules [137] and released with a proportion bound to neutrophil gelatinase-associated lipocalin (NGAL) [138]. In order to examine the role of MMP-9 in COPD, mice deficient for MMP-9 were exposed to intratracheal LPS. The knockout and wild type mice exhibited the same levels of myeloperoxidase activity (used as a surrogate for neutrophil infiltration) and histological tissue damage, with no difference in the basement membrane breakdown products and total protein in BALF (a surrogate measurement of neutrophil migration) [139]. Other investigators however used a cigarette smoke-induced emphysema model in guinea pigs to examine the effect of a broad-spectrum MMP inhibitor. MMP inhibition reduced the severity of emphysema, inflammatory cell infiltrate and MMP-9 activity in BALF, when measured at 2 or 4 months [140]. An MMP inhibitor was also able to reduce the severity of porcine pancreatic elastase-induced emphysema in hamsters [141], showing that MMPs are involved in the pathological process induced by a serine proteinase.

The complex animal model of emphysema using mice transgenic for human IL-13 was extended to study the role of MMPs [54]. When expression of IL-13 was induced, the animals exhibited infiltration of the lung by macro-

phages, eosinophils, lymphocytes and neutrophils, and airspace enlargement developed. Combining this model with deletion of the genes for MMP-12 and MMP-9 enabled assessment of the contribution of these MMPs to the pathogenesis of IL-13-induced lung disease in mice. IL-13-mediated secretory cell metaplasia was not inhibited with either cysteine proteinase inhibitors or a broad-spectrum MMP inhibitor, and MMP-9 and MMP-12 knockout mice were not protected either. Furthermore, MMP-9 knockout mice actually exhibited greater neutrophil infiltration, possibly related to the ability of MMP-9 to degrade mouse neutrophil chemoattractants. Airspace enlargement was significantly reduced, but not to control levels, suggesting that the residual tissue damage may be mediated by neutrophil serine proteinases.

Animal models have also been developed to investigate the role of collagenases. Application of the results from these models to human disease should be cautious because there is wide variation in the amount of collagen found in lungs of different species of animals [142]. In a transgenic mouse expressing human MMP-1, enlarged airspaces were seen consistent with emphysema [143]. A developmental abnormality could not be excluded, because the expression of MMP-1 is constitutional. For this reason, further studies were performed [144] which demonstrated that lung histology was normal until expression of the gene was seen. This occurred at variable points after birth in different strains of mice (emphasizing the difficulties of extrapolating results in mouse experiments to humans) and was more severe in homozygous than heterozygous mice. A loss of type III collagen was found, together with deposition of type I collagen, implying increased collagenolysis and increased but disordered collagen deposition, which is consistent with findings in human emphysema [145].

These extensive animal studies suggest a number of conclusions. First, it is difficult to harmonize the conflicting results obtained from different species of animals and even different strains of the same species. The marked disparity between the results of the studies on rats [130] and those on mice and guinea pigs [45,134,140] may indicate an important difference in the pathology of COPD in different species and strains, or simply methodological issues of inhibitors versus cell depletion. Secondly, neutrophil influx appears to be an early event in both single insult and continued insult models, and lavage neutrophils and neutrophil elastolytic activity relate well to lung damage at this stage. In most models, an acute neutrophil response appears to be the precursor to progressive lung damage. Thirdly, macrophages appear to be necessary, either to initiate the acute neutrophilic response, or to convert acute neutrophil-mediated tissue damage into established progressive emphysema. Fourthly, because these studies generally examine limited exposure to a single type of

insult, they do not enable us to predict the relative importance of individual proteinases once the insult has been withdrawn, as in ex-smokers, or after repeated and varied insults, as in patients having exacerbations of COPD. Fifthly, proteinases have a number of pathological functions beyond destruction of extracellular matrix proteins, and there is a wide functional overlap between proteinases from different biochemical groups and cell populations (Fig. 31.4). Complex interactions between neutrophils, macrophages and their respective proteinase armamentaria may make interpretation of single measurements unreliable or even irrelevant.

Human studies

A number of clinical studies have identified MMPs in patients with COPD, although not consistently. Studies by Segura-Valdez *et al.* [146] showed increased tissue staining for collagenases (MMP-1, MMP-8) and gelatinases (MMP-2, MMP-9) in patients compared with controls. Ohnishi *et al.* [147] found no tissue staining for MMP-1, MMP-8 or MMP-9 protein in emphysematous lung, although mRNA for MMP-1, MMP-2 and MMP-9 was present. MMP-2 and MMP-14 protein were present, and both collagenolytic and gelatinolytic activities were increased in tissue homogenates from patients compared with controls. In this study, neither MMP-12 nor NE-related activity was elevated in patients compared with controls. Another study found MMP-1 mRNA and protein in lung tissue in patients with COPD [146].

Besides these immunohistochemical techniques, cells isolated from patients have been studied. Several studies have shown that macrophages harvested by BAL from COPD patients showed greater expression of MMP-1 and MMP-9 compared with controls [30,149,150]. The study by Finlay *et al.* [150] also showed greater proteinase activity of MMP-1 and MMP-9 associated with these macrophages, and MMP-9 localized on gel electrophoresis at the same place as neutrophil-derived MMP-9 (i.e. complexed with NGAL), suggesting that macrophages from patients with COPD might have internalized either free NGAL or NGAL-MMP-9 complexes, released by neutrophils. Additional NE activity was also detected from macrophages from patients. An alternative explanation to that of internalization is that some of the macrophages in the patients were immature and retained the ability of monocytes to secrete neutrophil enzymes. Interestingly, expression of MMP-2 and MMP-12 was the same in patients and controls, and macrophages did not appear to secrete these enzymes. Collagenase activity was the same in active versus ex-smokers, suggesting that it was a consequence of the emphysematous process rather than an initiating factor [150]. In a study of induced

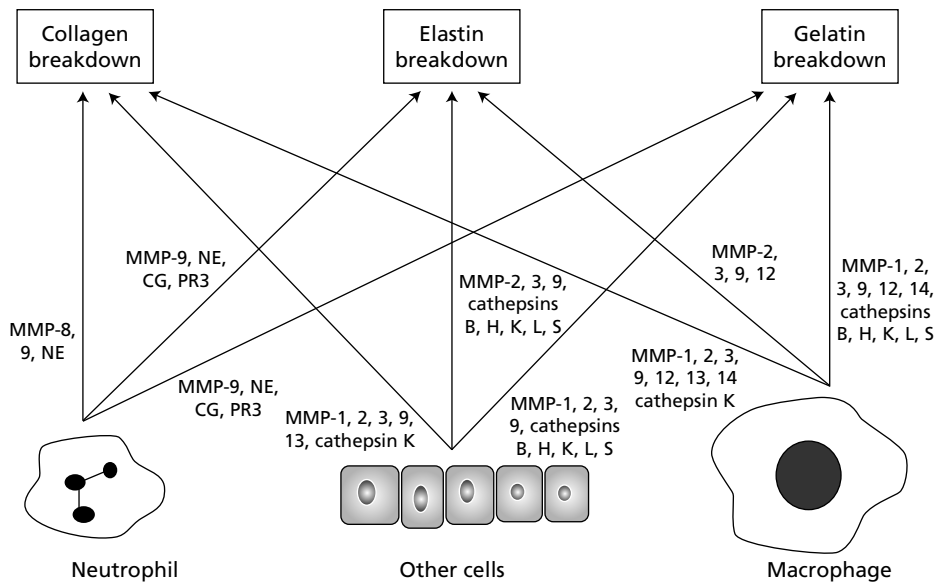

Figure 31.4 This figure demonstrates the overlapping proteinase complement of the cells present in the lung in COPD. Neutrophils produce directly collagenolytic enzymes (matrix metalloproteinase-8 [MMP-8], neutrophil elastase [NE]) and enzymes which can degrade both gelatin and elastin (MMP-9, NE, cathepsin G [CG], proteinase 3 [PR3]). Macrophages produce a large number of proteinases which share collagenolytic and gelatinolytic activities, and in some cases, elastinolytic activity also (MMP-2, MMP-9 and MMP-12). In addition, other cells such as alveolar and bronchial epithelial cells, endothelial cells and fibroblasts between them can produce almost all of the enzymes released by macrophages. Few enzymes are confined to one cell type or one substrate only.

sputum from patients with COPD and healthy smokers, MMP activity was measured according to gelatinase or true collagenase function. Both gelatinase (MMP-9) and collagenase (MMP-8) activity were elevated in COPD compared with controls, and the activity of these two enzymes correlated with each other and with the number of neutrophils, suggesting neutrophilic origin. This was confirmed by immunohistochemistry of sputum cells, showing MMP-8 only in neutrophils, and MMP-9 in both neutrophils and macrophages [151]. In another study, sputum levels of MMP-9 and TIMP-1 were increased in patients with COPD and asthma and correlated with the numbers of neutrophils in sputum [152], while there was no difference in the amount of MMP-9 expressed or secreted by circulating neutrophils from patients or healthy controls [153]. Interestingly, these *in vitro* studies showed release of both the pro-enzyme and the activated form by neutrophils, and the activated form was probably the result of activation of pro-MMP-9 by NE. Thus, it can be predicted that inhibitors of NE may also inhibit MMP-9 activity [36]. In a further study [77], BALF from smokers with emphysema was compared with BALF from healthy smokers. MMP-9 and MMP-8 levels were elevated in emphysema, and MMP-9 was again complexed to NGAL, suggesting neutrophil derivation. NGAL was also elevated in emphysema, although neutrophil numbers were not appreciably increased. Alveolar macrophages were isolated and cultured, but in this study only produced latent MMP-9 with no difference in MMP-9 level between the subjects with

and without emphysema. Finally, induced sputum from patients with COPD has been shown to contain increased MMP-22 activity compared to that from controls [154]. Overall these data indicate that COPD is associated with activation of the MMP class, but this activity appears related to neutrophils rather than macrophages, suggesting that this class of proteinases may be activated as a consequence of neutrophilic inflammation. The contribution of MMPs to the pathology of COPD is likely to be substantial given their broad spectrum of activity. This is supported by genetic studies which have shown that polymorphisms of the MMP-1, MMP-9, MMP-12 and TIMP-2 genes are more common in patients with emphysema [155–157], suggesting their products in some way have a role. However, the effects of these polymorphisms on gene function have yet to be determined.

Conclusions

There is strong evidence linking serine proteinases and matrix metalloproteinases with the pathogenesis of COPD, despite wide discrepancies between studies of individual proteinases. The observation that NE can activate MMPs [36,125] may indicate that NE is an early step in a proteinase cascade that leads to proteinase–antiproteinase imbalance and degradation of lung tissue. Although the absence of α_1 -AT in humans predisposes to severe early-onset emphysema, implying a major role for NE in the pathogenesis of emphysema, this could still be a modulatory

role rather than as the chief agent of matrix destruction. It seems likely that macrophage-derived MMPs are also critical mediators of lung damage but it is far from clear whether this is related to their ability to break down lung tissue per se, or their other abilities including disordered repair, modulation of cytokine function and degradation of inhibitors of other proteinases.

The therapeutic approach to the role of proteinase inhibitors in COPD should be a pragmatic one. It may be that the critical proteinase in the pathogenic process is not the one causing the tissue destruction, but rather one that activates the destructive enzymes, inactivates endogenous inhibitors or enables recruitment and activation of inflammatory cells. Further complexities that arise when considering the interactions between proteinases and their inhibitors in the lungs include oxidants, which impair the function of inhibitors of NE and activate the inflammatory cascade, and infections. In patients with COPD related to smoking therefore, the proteinase cascade may be different to that arising in patients whose COPD is related to chronic asthma, and different again to that associated with bronchiectasis, where bacterial products can also stimulate neutrophil influx to the lungs, and stimulate a different profile of macrophage cytokine secretion. Equally, smoking-related COPD may have a different proteinase-antiproteinase profile in active smokers versus ex-smokers. Finally, the biochemical and cytokine profile may differ in individuals with advanced disease compared with those with early disease, and in those with pure emphysema versus the bronchiolitis or chronic bronchitis phenotypes. The fact that different rates of progression and different disease phenotypes exist may reflect the polymorphisms of various MMPs and cytokine receptors that have been linked with rate of progression, and this in turn may alter the clinical effect of proteinases and response to proteinase inhibitors. For these reasons, we should continue to try to elucidate the pathogenetic mechanisms related to proteinases, in order to identify patient groups in whom inhibitors can be tested with the best chance of eliciting a clinically significant therapeutic response and thereby clarifying the central processes.

CHAPTER 32

Oxidants

William MacNee

The toxicity of oxygen in the lungs has been recognized for over 100 years; however, the mechanism of this toxicity was not determined until the importance of oxygen radicals, unstable compounds with an unpaired electron and other non-radical reactive pro-oxidants capable of initiating oxidation, were identified (referred to as reactive oxygen species, ROS). It is now recognized that ROS are not only relevant to oxygen toxicity, but that oxidant reactions occur in a broad spectrum of conditions involving tissue inflammation and injury [1,2]. Every compound, including oxygen, that can accept electrons is an oxidant and a substance that donates electrons is a reductant. A chemical reaction in which a substance gains electrons is defined as a reduction, whereas oxidation is a process in which loss of electrons occurs [2]. Thus, when a reductant donates electrons, it causes another substance to be reduced and, when an oxidant accepts electrons, it causes another substance to be oxidized. Physiologically relevant ROS include superoxide radicals and non-radical pro-oxidants (Table 32.1). To minimize oxidative damage the lungs are equipped with multiple enzymatic and non-enzymatic antioxidant systems (see below).

Reactive oxygen species are found diffusely throughout the lungs and are by-products of normal metabolism. The mitochondria are the largest producers of ROS as a result of the leak of electrons from the electron transfer chain onto oxygen to form superoxide anions [2]. It is estimated that 23% of oxygen produced in cells forms superoxide in this way. Other sources of superoxide include cytosolic xanthine oxidase [3], mitochondrial respiration, membrane nicotinamide adenine dinucleotide phosphate (NADPH) oxidases and the endoplasmic reticulum [4].

Hydrogen peroxide is formed from the dismutation of superoxide, but also by glycolate oxidase in peroxisomes. In the presence of metals, hydrogen peroxide in the Fenton reaction forms the hydroxyl radical. Hydroxy radicals are also produced in the metal-mediated Haber–Weiss reaction

Table 32.1 Radical and non-radical oxygen metabolites.

Name	Symbol
<i>Oxygen radicals</i>	
Oxygen (bi-radical)	O ₂
Superoxide	O ₂ ⁻
Hydroxyl	OH
Peroxyl	ROO
Alkoxy	RO
Nitric oxide	NO
<i>Non-radical oxygen derivatives</i>	
Hydrogen peroxide	H ₂ O ₂
Organic peroxide	ROOH
Hypochlorous acid	HOCl
Ozone	O ₃
Aldehydes	HCOR
Singlet oxygen	¹ O ₂
Peroxynitrite	ONOOH

in which ferric ions are reduced by superoxide radicals to ferrous ions (Fig. 32.1) [5].

Reactive nitrogen species (RNS) are primarily derived from nitric oxide, which is produced by the action of the three nitric oxide synthases (NOSs) on arginine (Fig. 32.2):

- 1 constitutive NOS, which is found in respiratory epithelium, blood vessels and nerve endings;
- 2 inducible NOS, which is found in respiratory epithelium and activated macrophages [6]; and
- 3 neuronal NOS, which is found in the nerve plexus of the trachea [7].

Antioxidants are the primary defence against ROS/RNS. Antioxidants can be broadly divided into enzymatic or non-enzymatic antioxidants. The antioxidant enzymes include the families of superoxide dismutase (SODs), catalase, glutathione peroxidase, glutathione S-transferase and thiorodoxin (Fig. 32.3) [8,9].

Figure 32.1 The role of iron in oxidant reactions in smokers and COPD patients. Macrophages release more iron which is also mobilized from ferritin by reducing agents and by cleavage and decreased synthesis of transferrin. Free iron in the ferrous form takes part in both the Fenton reaction and Haber–Weiss reaction with H_2O_2 and superoxide anion to produce hydroxyl radicals.

The non-enzymatic antioxidants include low molecular weight compounds such as glutathione (GSH), ascorbate, urate, α -tocopherol and bilirubin. Other high molecular weight molecules that might be considered to be antioxidants include proteins that have oxidizable thiol groups such as albumin, or proteins that bind free metals such as transferrin. The concentrations of these antioxidants vary depending on both the anatomical and the subcellular location. For example, GSH is 100-fold more concentrated in airway epithelial lining fluid, compared with plasma, and as such is considered to be a very important antioxidant in the lungs; whereas albumin and transferrin are found in high concentrations in serum, but in much lower concentrations in airway epithelial lining fluid [1,10].

Figure 32.2 Synthesis of nitric oxide (NO) and NO-related products. NO is produced from L-arginine under the influence of NO synthases. NO reacts with thiols to produce nitrosothiols, nitrotyrosine to peroxynitrite. Nitrotyrosine or nitrosothiols can be measured as markers of oxidative stress. FAD, flavin-adenine dinucleotide; FMN, flavin-mononucleotide; H_2O_2 , hydrogen peroxide; NADP, the oxidized form of nicotinamide adenine dinucleotide phosphate; NADPH, the reduced form of nicotinamide adenine dinucleotide phosphate; O_2 , oxygen; S-GSNO, S nitrosothiols.

Oxidative stress

In the lungs, as in all organs, there is a delicate balance between ROS/RNS and antioxidants. If this balance is in disequilibrium, either because of an excess amount of ROS/RNS and/or depletion of antioxidants, then oxidative stress is said to occur.

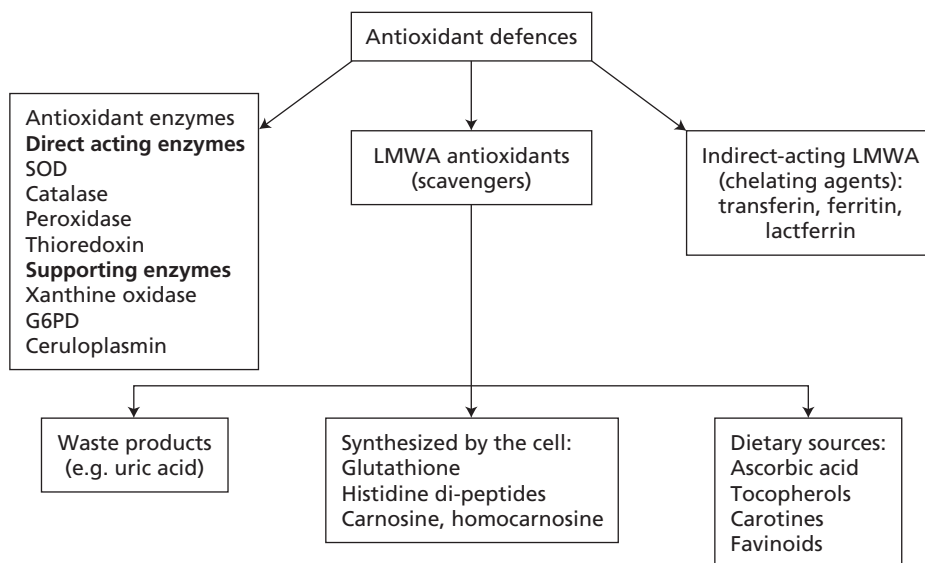

Figure 32.3 Antioxidant defences in the lungs. G6PD, glucose-6-phosphate dehydrogenase; LMWA, low-molecular weight; SOD, superoxide dismutase.

Measuring oxidative stress

Oxidative stress can be assessed by direct measurement of the oxidant burden (e.g. hydrogen peroxide in exhaled breath condensate) or the response to oxidative stress, such as activation of the heme-oxygenase system, assessed by measurements of CO in exhaled breath. Another way to measure oxidative stress is to measure the effects of oxidative stress on target molecules in the lungs, such as the nitration of tyrosine producing nitrotyrosine or the peroxidation of cell membrane lipids which results in products of lipid peroxidation.

Oxidants in cigarette smoke

Cigarette smoke is the main aetiological factor in the pathogenesis of COPD. It is a complex mixture of over 5000 different chemical compounds, including free radicals and other oxidants that are present in high concentrations [11,12]. Both the gas and the tar phase of cigarette smoke contain large amounts of ROS [11]. Each puff of cigarette smoke contains approximately 10^{15} radical molecules, primarily of the alkyl and peroxy types. Nitric oxide is another oxidant present in the gas phase of cigarette smoke in concentrations of 500–1000 ppm (550–100 mg/L) [12]. The gas phase of cigarette smoke also contains organic carbon and oxygen centred radicals, which can react with unsaturated compounds to form carbon centred organic radicals [12].

In the tar phase of cigarette smoke, there are more stable radicals such as the semi-quinone radical, which can reduce oxygen to produce superoxide anion (O_2^-) and the hydroxyl radical ($\cdot OH$). The tar phase also contains ROS that are not radicals such as hydrogen peroxide (H_2O_2) [12]. The tar from cigarette smoke contains over 5000 different organic compounds from which the water-soluble components, such as aldehydes, catechol and hydroquinone are extracted out into the epithelial lining fluid [12]. Cigarette smoke condensate, which may form in the epithelial lining fluid, continues to produce ROS for a considerable time.

Cell-derived oxidants

A characteristic feature of COPD is an abnormal inflammatory response in the lungs to inhaled particles or gases [13]. Recent studies, which have characterized the inflammatory response in lung tissue, bronchial biopsies and sputum, have clearly shown increased numbers of leucocytes in the airway and distal airspace walls in patients who develop COPD, compared with smokers with a similar smoking history but who have not developed the disease [14–16].

The increased oxidative burden produced by inhaling cigarette smoke is therefore further enhanced by the release of ROS from inflammatory leucocytes, both neutrophils and macrophages, which migrate in increased numbers

into the lungs of cigarette smokers, particularly in those who develop COPD [17]. In addition, the lungs of smokers who have airway obstruction have more neutrophils than smokers without airway obstruction, with the potential for a further increase in the oxidant burden [18].

Alveolar macrophages from the lungs of smokers are more activated than those from non-smokers [19,20] and release increased amounts of ROS such as O_2^- and H_2O_2 , [21–24]. *In vitro* smoke exposure of alveolar macrophages has been shown to increase the oxidative metabolism of alveolar macrophages [25]. Subpopulations of alveolar macrophages with a higher density are more prevalent in the lungs of smokers and are thought to be the source of the increased O_2^- production in smokers [26].

The xanthine/xanthine oxidase (X/XO) system can generate O_2^- and H_2O_2 and XO activity is increased in cell free bronchoalveolar lavage fluid from COPD patients, compared with normal subjects, associated with increased O_2^- and uric acid production [27].

Iron is a critical element in many oxidative reactions [28]. Free iron in the ferrous form catalyses the Fenton reaction and the superoxide-driven Haber–Weiss reaction, which generate the extremely reactive hydroxyl radical (see Fig. 32.1). The lung lining fluid of smokers contains more iron than non-smokers [29,30] and alveolar macrophages from smokers, particularly those who develop chronic bronchitis, both contain [30] and release more iron than those of non-smokers [31,32]. The presence of increased amounts of free iron in the airspaces will therefore enhance the generation of oxidants in the lungs of smokers [33]. Airway epithelial cells are another source of ROS. Type II alveolar epithelial cells can release both H_2O_2 and O_2^- in similar amounts to alveolar macrophages [34] and the release of ROS from these cells is able, in the presence of myeloperoxidase, to inactivate α_1 -antitrypsin *in vitro* [35] thereby reducing the protective antiprotease screen.

Tumour necrosis factor α (TNF- α) and lipopolysaccharide (LPS), which are relevant mediators in the inflammatory response in COPD, can stimulate airway epithelial cells to produce increased amounts of ROS and RNS [34]. ROS and RNS can also be generated intracellularly from several sources as described above. Depending on the relative amounts of O_2^- and NO, which are almost invariably produced simultaneously at sites of inflammation, these can react together to produce the powerful oxidant peroxynitrite ($ONOO^-$). Because this reaction occurs at a nearly diffusion-limited rate, it is thought that NO can out-compete SOD for reaction with O_2^- and thus $ONOO^-$ will be generated [1]:

Peroxynitrite is directly toxic to cells or may decompose to produce the hydroxyl radical:

The reaction of free radicals with polyunsaturated fatty acid side-chains in membranes or lipoproteins results in lipid peroxidation. This reaction is self-perpetuating, continuing as a chain reaction [36]. Lipid peroxides also have a role in the signalling events and in the molecular mechanisms involved in inflammation (see below).

Evidence for oxidative stress in COPD

Direct measurements of oxidative stress are difficult as free radicals and ROS are highly reactive and thus short lived. Numerous studies have measured a range of surrogate markers of oxidative stress in smokers and in patients with COPD. These surrogate markers measure oxidants directly (Table 32.2) [37–40], measure the stress responses to an increased oxidant burden or measure the effects of radicals on biomolecules such as lipids, protein or nucleic acids. Measurements of these markers of oxidative stress have been made in blood, exhaled breath or breath condensate and in induced or spontaneously produced sputum. Markers of oxidative stress have also been measured in bronchoalveolar lavage fluid and in lung tissue in patients with COPD.

A valid biomarker of oxidative stress in COPD should be:

- 1 implicated in the disease;
- 2 stable;
- 3 representative of the balance between oxidative damage generation and clearance;
- 4 determined by an assay that is specific, sensitive, reproducible and robust;
- 5 free of confounding factors from dietary intake; and
- 6 present at a detectable level [37–40].

Table 32.2 Measurements of oxidative stress.

<i>Direct measurements of the oxidative burden</i>
Hydrogen peroxide in breath condensate
BAL/peripheral blood leucocyte ROS production
Nitric oxide in exhaled breath
<i>Responses to oxidative stress</i>
CO in breath (haemoxymetabolism)
Antioxidants, antioxidant enzymes in blood, sputum, BAL and lung tissue
<i>Effects of oxidative stress on target molecules</i>
Nitrotyrosine (peroxynitrite)
Oxidized proteins (orthotyrosine, nitrotyrosine, chlorotyrosine)
Lipid peroxidation products (isoprostanes, 4-hydroxynonenol, hydrocarbons) in breath condensate, sputum, BAL, blood, lung tissue

BAL, bronchoalveolar lavage; CO, carbon monoxide; ROS, reactive oxygen species.

Measurements of oxidative stress in breath, breath condensate and sputum

Exhaled breath condensate is collected by cooling or freezing exhaled air. The content of breath condensate reflects the composition of the airway and airspace epithelial lining fluid, although large molecules may not aerosolize as well as small molecules. Measurement of biomarkers in breath condensate reflects molecules derived from the oral cavity and oral pharynx, tracheal bronchial tree and alveoli. However, their proportional contribution is not fully established. It is assumed that turbulent airflow aerosolizes airway and airspace lining fluid.

Hydrogen peroxide, measured in exhaled breath condensate, is a direct measurement of this oxidant in the airspaces. Smokers and patients with COPD have higher levels of exhaled H_2O_2 than non-smokers [41,42], and levels are even higher during exacerbations of COPD [43]. The source of the increased H_2O_2 is not fully determined but may derive in part from increased release of O_2^- from alveolar macrophages in smokers [44]. However, there is one study that did not show that smoking increased the levels of exhaled H_2O_2 [41], although in this study the levels of exhaled H_2O_2 correlated with the degree of airflow obstruction as measured by forced expiratory volume in 1 s (FEV_1).

Exhaled *nitric oxide* (NO) has been considered to be both a marker of airway inflammation and indirectly as a measure of oxidative stress. Increased levels of NO have been reported in exhaled breath in some studies of patients with COPD [45,46], but not in others [47]. However, the reported levels are not as high in COPD as in asthmatics [48]. Smoking increases NO levels in breath [49], and the reaction of NO with O_2^- and with thiol groups limits the usefulness of this marker in COPD, except perhaps to help to differentiate from asthma [50].

Neutrophils and macrophages are known to migrate in increased numbers into the lungs of cigarette smokers, compared with non-smokers [51]. Moreover, the lungs of smokers with airway obstruction have more neutrophils than smokers without airway obstruction [52]. Neutrophils from cigarette smokers have been shown to have an increased myeloperoxidase content [53] and the levels of myeloperoxidase correlate negatively with the FEV_1 in patients with COPD [43,54], suggesting a role for neutrophil myeloperoxidase-mediated oxidative stress in the pathogenesis of airways obstruction in COPD.

An increased oxidative burden in smokers is also shown by increased release of ROS such as O_2^- and H_2O_2 from smoker's macrophages [55] and peripheral blood neutrophils [56] compared with non-smokers.

Thus, direct measurements of the oxidant burden in the airspaces indicate an enhanced oxidant burden in cigarette

Figure 32.4 The heme-oxygenase system is activated by oxidative stress and converts heme to bilirubin producing carbon monoxide (CO) which can be measured as an indirect marker of oxidative stress. Fe, iron.

smokers in most studies, with even greater oxidant burden in those who have COPD.

Markers of the responses to oxidative stress have also been measured in COPD patients. Carbon monoxide (CO) is produced endogenously as a result of oxidant-mediated induction of the stress protein heme-oxygenase 1 (HO-1) in a variety of cell types [57]. HO-1 converts heme and hemin to biliverdin with the formation of CO (Fig. 32.4). Biliverdin itself is rapidly converted to bilirubin which acts as an antioxidant. Cigarette smoking causes an acute increase in exhaled CO making this measurement less useful in smokers. However, high levels of exhaled CO have been found in ex-smoker COPD patients [57,58]. It is presumed that the high levels of exhaled CO in COPD patients are caused by inflammatory cytokines or ROS inducing HO-1 expression and therefore the high levels of CO may reflect both oxidative stress and inflammation.

A further response to oxidative stress in the lungs is a change in antioxidants. Glutathione (GSH) is an important antioxidant in lung lining fluids. Reduced GSH is elevated in bronchoalveolar lavage fluid (BALF) in chronic smokers [59–61]. However, the twofold increase in BALF GSH in chronic smokers may be insufficient to deal with the excessive oxidant burden *during* smoking, when acute depletion of GSH may occur [62]. The depletion of GSH in epithelial lining fluid following cigarette smoking is likely to result from direct interaction of GSH with oxidants and electrophilic compounds in cigarette smoke to form oxidized GSH or GSH conjugates [63,64]. The increase in GSH in chronic cigarette smokers is likely a response to oxidative stress by up-regulating γ -glutamylcysteine synthetase, the main synthesizing enzyme for GSH [63,64].

Changes in other antioxidants and antioxidant enzymes in response to cigarette smoke have been variable. Reduced levels of vitamin E have been found in the BALF of smokers compared with non-smokers [65], whereas increased activity of antioxidant enzymes (SOD and catalase) have been reported in alveolar macrophages from young smokers [66]. Others have found that the increased superoxide

generation by alveolar macrophages in elderly smokers compared with non-smokers is associated with decreased antioxidant enzyme activities [67]. There is therefore no consistent change in antioxidant defences in the epithelial lining fluid in smokers and no information in COPD patients.

The effects of oxidative stress on target molecules in the lungs have been assessed. Ethane, pentane and hydrocarbons are released during lipid peroxidation in biological tissues. Ethane derives from the peroxidation of N-6 polyunsaturated acids. Ethane levels in exhaled breath are elevated in COPD patients and correlate with the degree of airflow limitation [68]. Isoprostanes are lipid peroxidation products formed from the peroxidation of arachidonic acid independent of the cyclo-oxygenase enzyme pathway [69,70]. Their presence is therefore an indication not only of oxidative stress, but also that oxidative stress has affected important target molecules to produce a lipid peroxidation product. These compounds may also have an important role in pulmonary pathophysiology [71]. Isoprostanes cause constriction of the pulmonary vasculature and airway smooth muscle cells [72] and have been shown to induce various second messenger systems that result in vaso- and bronchoconstriction [73,74]. Isoprostanes have also been shown to activate inflammatory cells such as neutrophils and to enhance their adhesion [75].

8-Isoprostane levels in exhaled breath condensate are elevated in patients with stable COPD [76,77] and correlate with the degree of airway inflammation as measured by sputum neutrophil numbers [78]. The levels of 8-isoprostane are increased further in exacerbations of COPD [79].

Lipid peroxidation products have been found in increased amounts in lung tissue from cigarette smokers and the levels relate to the length of smoking [80]. BALF from cigarette smokers also contains increased products of lipid peroxidation, such as malondialdehyde [21].

4-hydroxy-2-nonenal (4-HNE) is a highly reactive aldehyde lipid peroxidation product which has been shown to enter cells and activate mitogen-activated protein (MAP) kinase signalling pathways [81]. It also acts as a chemoattractant for neutrophils [81]. Increased levels of 4-HNE-modified proteins have been found in airway, alveolar epithelial cells, endothelial cells and in neutrophils in subjects with airway obstruction compared with subjects without airway obstruction but who have had similar smoking histories. This suggests not only the presence of this lipid peroxidation product but that this product modifies proteins in lung cells to a greater extent in patients with COPD. In addition, the levels of 4-HNE-adducts in alveolar and airway epithelium have been shown to be inversely related to the FEV_1 , suggesting a role for 4-HNE in the pathogenesis of COPD (Fig. 32.5) [82].

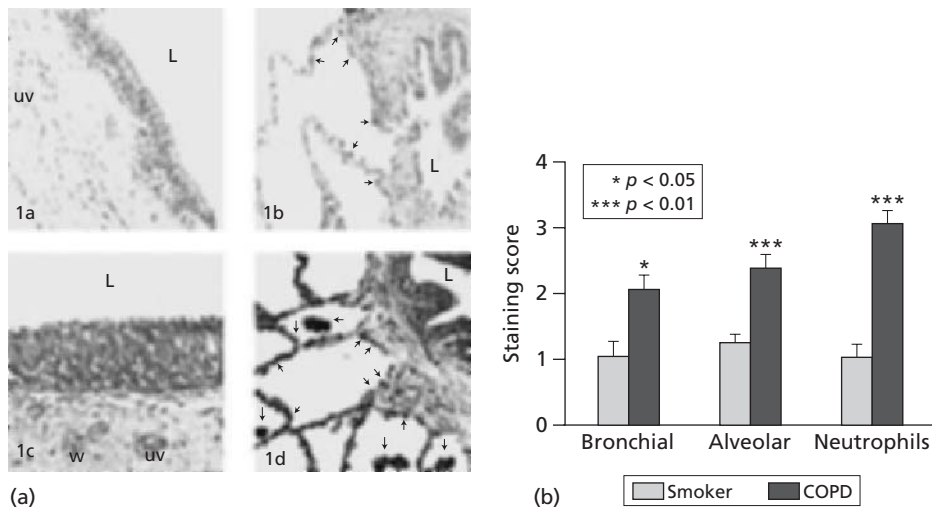

Figure 32.5 Immunostaining for 4-hydroxy-2-nonenal adducts in lungs of smokers and COPD patients. (a) Immunostaining in bronchi and alveoli are shown for smokers with the same smoking history as a group of patients with COPD. There is increased immunostaining for 4-hydroxy-2-nonenal in COPD patients. (b) The staining scores for 4-hydroxy-2-nonenal in bronchial and alveolar cells and in neutrophils from both smokers and COPD patients. (From Rahman *et al.* [82] with permission.)

Systemic oxidative stress in COPD

COPD is now considered not only to produce local effects in lungs but also to have systemic manifestations [83,84]. Examples of these systemic effects are the skeletal muscle dysfunction and weight loss that occurs in some patients and are a predictor of reduced survival [85].

There is evidence of an increased systemic oxidative burden in COPD, as shown by the greater ability of circulating neutrophils from patients with COPD to release ROS [56]. The lipid peroxidation products thiobarbituric acid reactive substances have been found in plasma in greater amounts in healthy smokers and in patients with acute exacerbations of COPD, compared with healthy non-smokers [83]. Other products of lipid peroxidation such as conjugated dienes of linoleic acid are also elevated in the plasma in chronic smokers [86]. Similarly, levels of the lipid peroxidation product F_2 -isoprostane are elevated in the urine in smokers [87]. Measurements of the antioxidant capacity in the blood can be used as a marker of systemic oxidative stress. Smoking causes a transient decrease in antioxidant capacity which also occurs during exacerbations of COPD [55,83]. The reaction of nitric oxide with superoxide anion leads to the formation of peroxynitrite which has been shown to decrease plasma antioxidant capacity rapidly by oxidation of ascorbic acid, uric acid and plasma sulphhydryls [88]. Increased plasma peroxynitrite levels have been demonstrated in cigarette smokers [89] and increased immunoreactivity for nitrotyrosine has been shown in sputum leucocytes in patients with COPD. Nitration of tyrosine residues or proteins in plasma leads to the production of 3-nitrotyrosine. Higher levels of 3-nitrotyrosine have been found in the plasma in smokers compared with non-smokers, which correlated negatively with the plasma antioxidant capacity in smokers [89].

Consequences of oxidative stress in the pathogenesis of COPD

Airspace epithelial injury and permeability

The epithelial surface of the lung airspaces, by virtue of its direct contact with the environment, is particularly vulnerable to the effects of oxidative stress produced by cigarette smoke. Oxidants in cigarette smoke can directly damage components of the lung matrix (such as elastin and collagen) [90]. The synthesis and repair of elastin can also be impaired by cigarette smoke [91], which may augment the proteolytic damage to matrix components and thus enhance the development of emphysema.

One of the earliest injurious events in smokers is increased airspace epithelial permeability [92]. Cigarette smoke produces direct injury to human alveolar epithelial cell monolayers *in vitro* as shown by increased epithelial cell detachment, decreased cell adherence and increased cell lysis [93]. These effects are in part oxidant mediated because they are abrogated by the antioxidant GSH in concentrations (500 $\mu\text{mol/L}$) that are present in the epithelial lining fluid.

Studies in humans show increased epithelial permeability in chronic smokers compared with non-smokers, as measured by increased $^{99\text{m}}\text{Tc}$ -diethylenetriamine-pentacetate ($^{99\text{m}}\text{Tc}$ -DTPA) lung clearance, with a further increase in $^{99\text{m}}\text{Tc}$ -DTPA clearance following acute smoking [59].

Both extra- and intracellular GSH appear to be critical to the maintenance of epithelial integrity following exposure to cigarette smoke. Studies of increased permeability of epithelial cell monolayers *in vitro* [62,94] and in rat lungs *in vivo* [64] show that smoke exposure is associated with profound changes in the antioxidant GSH. Concentrations of GSH are consistently decreased following smoke

exposure, concomitant with a decrease in the activities the enzymes are involved in the GSH redox cycle such as GSH peroxidase and glucose-6-phosphate dehydrogenase. Depletion of lung GSH alone induces increased airspace epithelial permeability both *in vitro* and *in vivo* [64,94,95].

Oxidative stress and apoptosis

Apoptosis or programmed cell death of leucocytes constitutes an important mechanism in the resolution of inflammation [96]. It is now recognized that structural cells in the lungs also undergo apoptosis and oxidant-mediated mechanisms may be involved. Hydrogen peroxide can induce apoptosis in airway epithelial cells [97]. Studies both *in vitro* and *in vivo* in animals and in humans have shown that apoptosis can occur in smoke-exposed macrophages [98]. However, studies *in vitro* in both endothelial cells and airspace epithelial cells indicate that smoke exposure may induce necrosis rather than apoptosis and necrosis itself may be a further stimulus to inflammation in the lungs [99].

It has been suggested that pulmonary capillary epithelial cell apoptosis, induced by cigarette smoking, may be an early event in the process that leads to alveolar wall destruction and emphysema. Studies of human lungs indicate that pulmonary vascular endothelial apoptosis is present in emphysematous lungs [100]. Mechanisms involving transcription factors AP-1 and NF- κ B and the down-regulation of the vascular endothelial growth factor receptor KDR (VEGF-KDR) have been proposed as part of the mechanism. Down-regulation of the VEGF-KDR receptor in an animal model can induce both apoptosis and emphysema [101]. It has also been proposed that oxidant-mediated mechanisms are involved in this process, because the apoptosis in emphysematous lungs is also associated with markers of oxidative stress, specifically lipid peroxidation products such as 4-hydroxy-nonenal [102]. Furthermore, the emphysema induced by inhibiting VEGF-KDR can be prevented by antioxidant treatment [102].

Protease–antiprotease imbalance

The development of a proteinase–antiproteinase imbalance in the lungs is thought to be a critical event in the pathogenesis of emphysema. The hypothesis is that increased recruitment of leucocytes to the lungs will increase the protease burden in the lungs and at the same time the antiprotease screen, particularly α_1 -antitrypsin (α_1 -AT), may be inactivated by oxidation resulting in a relative deficiency of antiproteases in the presence of an excess of proteases, leading to a proteinase–antiproteinase imbalance.

However, this simple hypothesis of an imbalance between an increased elastase burden in the lungs and a functional ‘deficiency’ of α_1 -AT because of its inactivation by oxidants is an oversimplification, not least because

other proteinases and antiproteinases are likely to have a role. Early studies showed that the function of α_1 -AT in bronchoalveolar lavage was decreased by approximately 40% in smokers compared with non-smokers [103]. This ‘functional α_1 -AT deficiency’ is thought to be caused by oxidative inactivation by cigarette smoke of the methionine residue of α_1 -AT at its active site [104,105]. Oxidation of the methionine residue in α_1 -AT has been confirmed in the lungs of healthy smokers [106]. *In vitro* studies show that oxidants [107], including cigarette smoke [108], reduce the inhibitory capacity of α_1 -AT. Other studies have shown that macrophages from the lungs of smokers release increased amounts of ROS which can inactivate α_1 -AT *in vitro* [105]. However, it has been shown that the α_1 -AT in the airspaces in cigarette smokers remains active and is still capable of protecting against the increased protease burden. There are also conflicting data on whether α_1 -AT function is altered in cigarette smokers [109], and the original observation that oxidation of α_1 -AT occurs in bronchoalveolar lavage in smokers has not been confirmed [110]. Studies of the effects of acute cigarette smoking have only shown a transient but non-significant fall in the antiprotease activity of bronchoalveolar lavage fluid (BALF) 1 h after smoking [111]. Thus, studies assessing the function of α_1 -AT in either chronic or acute cigarette smoking have failed to produce a clear picture that oxidative stress inactivates antiproteases.

Neutrophil sequestration and migration in the lungs

The enhanced inflammation that is thought to characterize COPD is associated with the influx of leucocytes of which polymorphonuclear leukocytes are a prominent cell. Neutrophil recruitment into the airspaces is initiated by the sequestration of these cells in the lung microcirculation [112]. Initial sequestration of neutrophils in the pulmonary microcirculation results from the size differential between neutrophils (average diameter 7 μ mol) and pulmonary capillary segments (average diameter 5 μ mol). Thus, under normal circumstances, a proportion of the circulating neutrophils have to deform in order to negotiate the smaller capillary segments, which delays their transit through the microcirculation. Radiolabelled neutrophil studies in healthy subjects indicate that a proportion of neutrophils are normally delayed in the pulmonary circulation [113]. It has also been shown that there is a correlation between neutrophil deformability measured *in vitro* and the subsequent sequestration of these cells in the pulmonary microcirculation following their re-injection in normal subjects – the less deformable the cells the greater the sequestration of these cells in the pulmonary circulation [112]. Sequestration of neutrophils in the pulmonary capillaries allows time for the neutrophils to interact with

the pulmonary capillary endothelium, resulting in their adherence to the endothelium and thereafter their transmigration across the alveolar capillary membrane to the interstitium and airspaces of the lungs in response to inflammation or infection.

Neutrophils in transit in the pulmonary microcirculation can be activated by a number of mediators, including cytokines released from alveolar macrophages, epithelial and endothelial cells. Inhaled oxidants such as those contained in cigarette smoke and other air pollutants can influence the transit of cells in the pulmonary capillary bed. Studies using radiolabelled neutrophils and red cells in healthy smokers show a transient increase in neutrophil sequestration in the lungs during smoking [114], which is associated with an acute decrease in cell neutrophil deformability [115,116], an effect that is likely to be oxidant mediated. Support for this comes from *in vitro* studies that show decreased neutrophil deformability induced by cigarette smoke is abolished by antioxidants [115]. There is also evidence of systemic oxidative stress following cigarette smoking, which may affect neutrophils and increase their sequestration in the pulmonary microcirculation [116].

Cigarette smoke has also been shown to cause the release of neutrophils from the bone marrow with decreased deformability, which may preferentially sequester in the pulmonary microcirculation [117]. The mechanism for release of bone marrow neutrophils in response to smoke is as yet unclear, but oxidants may have a role.

Thus, cigarette smoking increases neutrophil sequestration in the pulmonary microcirculation, at least in part, by decreasing neutrophil deformability, an effect that may be oxidant mediated. Once sequestered in the pulmonary microcirculation, components of cigarette smoke can alter neutrophil adhesion to endothelium by up-regulating CD18 integrins [118,119]. Inhalation of cigarette smoke in hamsters increases neutrophil adhesion to the endothelium of both arterioles and venules [118], an event that may be mediated by superoxide anion derived from cigarette smoke, because it is inhibited by pretreatment with CuZn-SOD [118]. Neutrophils sequestered in the pulmonary circulation of the rabbit following cigarette smoke inhalation also show increased expression of CD18 integrins [119].

Oxidant-mediated mechanisms may also result in increased sequestration of neutrophils, which occurs in the pulmonary microcirculation during exacerbations of COPD [55,113]. Studies in animal models of smoke exposure [120] have shown increased neutrophil sequestration in the pulmonary microcirculation, associated with up-regulation of adhesion molecules on the surface of these cells [119]. Activation of neutrophils sequestered in the pulmonary microvasculature could induce the release of reactive oxygen intermediates and proteases within the microenvironment, with limited access for free radical

scavengers and antiproteases. Thus, destruction of the alveolar wall, as occurs in emphysema, could result from a proteolytic or oxidant insult from the intravascular space, without the need for the neutrophils to migrate into the airspaces [121].

Mucus hypersecretion

Mucins are complex glycoproteins that are an essential protective mechanism in the upper airways. The regulation of mucus production and clearance is altered in the lungs of COPD patients. The airways of smokers contain more goblet cells than do those of non-smokers and goblet-cell activation results in mucus hypersecretion leading to airway plugging. Cigarette smoke has been shown to activate epidermal growth factor (EGF) receptors, resulting in the induction of mucin (*mucin5ac* gene expression) synthesis in epithelial cells and in lungs *in vitro* and *in vivo* [122]. Oxidants appear to be involved in these events because cigarette smoke-mediated *MUC5ac* gene expression is inhibited by antioxidants [122].

Oxidative stress and muscle dysfunction

COPD is now considered to have important systemic consequences including weight loss and muscle dysfunction. The cause of the muscle dysfunction in COPD is not well understood, but mechanisms involving oxidative stress may be involved. Skeletal muscles can generate ROS at rest and ROS production increases during contractile activity. Increased oxidative stress also occurs in skeletal muscle during skeletal muscle fatigue [123]. This may result from hypoxia, impaired mitochondrial metabolism and increased cytochrome C oxidase activity in skeletal muscle in patients with COPD [124]. Reduced muscle glutamate (a precursor of GSH) occurs in patients with severe COPD, associated with increased muscle glycolytic metabolism [125]. In association with lowered levels of glutamate, GSH levels were also decreased in muscles, suggesting an oxidant-antioxidant imbalance is involved in the skeletal muscle dysfunction in patients with COPD. A causal relationship between abnormally low muscle redox potential at rest and alteration of protein metabolism observed in patients with emphysema has been suggested. This is supported by a study that showed decreased muscle redox capacity, probably as a result of a reduced ability of muscles to synthesize GSH during endurance training in patients with COPD [126]. Several lines of evidence therefore suggest that oxidative stress has a role in mediating muscle mass wasting in susceptible subsets of patients with COPD.

Inflammation, oxidative stress and gene expression

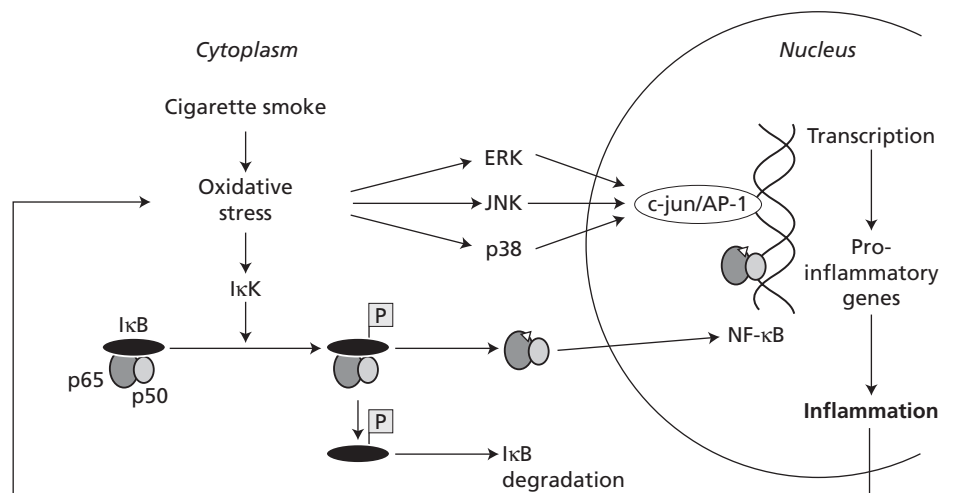

A characteristic feature of COPD is an abnormal inflammatory response in the lungs to inhaled particles or gases [13,127]. The mechanism of this enhanced inflammatory response is the subject of intensive study. Gene expression for many inflammatory mediators, such as those for the cytokines, interleukin 8 (IL-8) and TNF- α , and nitric oxide, are regulated by transcription factors, such as NF- κ B. In quiescent cells, NF- κ B is present in the cytosol in an inactive form linked to an inhibitory protein I κ B. Oxidants are one of the mediators that can activate NF- κ B by activating I- κ B kinase, which phosphorylates the inhibitory protein I κ B resulting in cleaving of I κ B from NF- κ B and its destruction in the proteasome [128]. Oxidants also activate other signal transduction pathways involved in inflammation, such as the ~ERK and JNK and P₃₈ MAP kinase pathways, which may signal through other transcription factors such as C-jun-AP-1. Activation of these transcription factors and their binding to their consensus sites in the nucleus increases transcription of many proinflammatory genes leading to inflammatory cytokine release from lung cells. Inflammation itself will generate further oxidative stress and this may lead to a vicious circle which enhances the inflammatory response (Fig. 32.6).

Studies *in vitro* show that treatment of macrophages, alveolar, bronchial epithelial cells with oxidants result in increased mRNA expression and the release of inflammatory mediators such as IL-8, IL-1 and nitric oxide, associated with increased nuclear binding and activation of NF- κ B [129,130]. In addition, a stimulus relevant to exacerbations of COPD, such as particulate air pollution, which has oxidant properties, also activates NF- κ B in alveolar epithelial cells and causes the release of IL-8 [131].

Thiol antioxidants such as *N*-acetylcysteine and *N*-acetylcystein, which are potential therapies in COPD, have been shown in *in vitro* experiments to block the release of these inflammatory mediators from epithelial cells and macrophages in response to oxidants by a mechanism involving increasing intracellular GSH and decreasing NF- κ B activation [129,131]. The intracellular GSH redox status in cells is affected by cigarette smoke and may have a critical role in the regulation of transcription factors such as NF- κ B and AP-1 [132–134]. Interaction may also occur between oxidants and TNF, which are both relevant mediators in COPD, producing synergistic activation of NF- κ B [135].

A further mechanism that may enhance the inflammatory response in COPD is the remodelling of chromatin which involves histone acetylation–deacetylation [128]. In the nucleus, DNA is normally tightly wound around a core of histone residues. This configuration of the chromatin results in gene silencing by preventing access of transcription factors and RNA polymerase to the transcriptional machinery. Under the influence of enzymes known as histone acetyl transferases (HATs), core histone residues are acetylated, which results in the unwinding of DNA around the core histones and allows access for transcription factors and RNA polymerase to the transcriptional machinery, resulting in transcription. This process is regulated by other enzymes known as histone deacetylases (HDAC), which deacetylate histone residues and cause the rewinding of DNA and gene suppression (Fig. 32.7). Thus, an increase in histone acetylation and/or a decrease in HDAC will alter the balance between acetylation and deacetylation in favour of enhanced gene expression. Oxidants such as H₂O₂ and oxidants derived from cigarette smoke or particulate air pollution alter chromatin remodelling, producing increased acetylation and decreased HDAC expression [136,137]. Cigarette smoke exposure has also been shown to produce decreased HDAC protein expression and increased histone

Figure 32.6 Effects of oxidative stress on signalling pathways involving transcription factors NF- κ B and AP-1 and the up-regulation of proinflammatory genes.

Figure 32.7 Histone acetylation and deacetylation. In resting cells DNA is tightly wound around a core of histones. This configuration results in gene silencing (left). Under the influence of histone acetyltransferase histone residues are acetylated, changing their charge and resulting in unwinding of DNA allowing access for transcription factors such as NF- κ B and RNA polymerase II producing increase transcription. The process is reversed by histone deacetylases which deacetylate histone residues and result in the rewinding of DNA and gene silencing.

acetylation in the lungs of animals exposed to cigarette smoke associated with enhanced lung inflammation and increased oxidative stress [138].

Oxidative stress and the development of airways obstruction

Relatively few studies have assessed the relationship between markers of inflammation or oxidative stress and the progression of disease in COPD. The neutrophil appears to be an important cell in the pathogenesis of COPD and one study has shown a relationship between blood neutrophil counts and FEV_1 [139]. Moreover, a relationship has also been shown between the change in peripheral blood neutrophil count and the change in airflow limitation over time [140]. A relationship has also been demonstrated between the release of ROS by neutrophils and measurements of airflow limitation in young cigarette smokers [141]. Neutrophil counts in sputum have also been shown to relate to the decline in FEV_1 : the greater the neutrophil count in sputum the more rapid the decline in FEV_1 [142]. Oxidative stress, measured as lipid peroxidation products in plasma, has also been shown to correlate inversely with the percentage predicted FEV_1 in a population study [143], but not in a COPD population [144].

General population studies have shown an association between dietary intake of antioxidant vitamins and lung function. In a population of 2633 subjects, an association was demonstrated between dietary intake of the antioxidant vitamin E and lung function [145], supporting the hypothesis that antioxidants may have a role in protecting against the development of COPD. A further study suggested that antioxidant levels in the diet may explain the

differences in COPD mortality in different populations [146]. Dietary polyunsaturated fatty acids have also been suggested as being protective in cigarette smokers against the development of COPD [147,148]. However, intervention studies of dietary antioxidant supplementation have not been able to demonstrate a positive effect in the development of COPD.

Only 15–20% of smokers appear to be very susceptible to the effect of cigarette smoke and have a rapid decline in FEV_1 and develop COPD [149]. There has been considerable interest in identifying those who are susceptible and the mechanisms underlying that susceptibility [149–151] because this would provide an important insight into the pathogenesis of COPD.

Association studies of polymorphisms of various genes have been performed and a number of polymorphisms have been shown to be more prevalent in smokers who develop COPD [150]. Some of these polymorphisms have functional significance, such as the TNF- α gene polymorphism (TNF2), which is associated with increased TNF levels in response to inflammation and the development of chronic bronchitis [152]. Microsomal epoxide hydrolase is an enzyme involved in the metabolism of highly reactive epoxide intermediates which are present in cigarette smoke [153]. The proportion of individuals with slow microsomal epoxide hydrolase activity (homozygotes) is significantly higher in patients with COPD and a subgroup of patients shown to have emphysema (COPD 22%; emphysema 19%), compared with control subjects (6%) [153]. These data, however, have not been reproduced in other patient populations [154]. Although the results of association studies with polymorphisms have shown inconsistent results, there does seem to be more evidence to support abnormal polymorphisms in the oxidant–antioxidant pathways with

Table 32.3 Genetic association studies of COPD and related phenotypes.

the development of COPD than with other pathways (Table 32.3) [153–163]. It may be that a panel of ‘susceptibility’ polymorphisms, of functional significance in enzymes involved in xenobiotic metabolism or antioxidant enzyme genes, may allow individuals to be identified as being susceptible to the effects of cigarette smoke.

Therapy to be targeted at oxidative stress

There is now convincing evidence for an oxidant–antioxidant imbalance in smokers and a probable role for this imbalance in the pathogenesis of COPD. However, proof of concept of the role of oxidative stress in the pathogenesis of COPD will only come with studies of effective antioxidant therapy.

Various approaches have been tried to redress the oxidant–antioxidant imbalance. One approach is to target the inflammatory response by reducing the sequestration or migration of leucocytes from the pulmonary circulation into the airspaces. Possible therapeutic options for this are drugs that alter cell deformability, so preventing neutrophil sequestration or the migration of neutrophils, either by interfering with the adhesion molecules necessary for migration, or preventing the release of inflammatory

cytokines such as IL-8 or leukotriene B₄ which result in neutrophil migration. Agents are available that may in part be effective by preventing activation of leucocytes and in particular the release of ROS. Preliminary results of phosphodiesterase 4 inhibitors have shown some therapeutic benefit in patients with COPD [164]. The mechanism by which such drugs act is by increasing cellular cyclic adenosine monophosphate (cAMP), which decreases neutrophil activation. In particular, the release of ROS by neutrophils may be decreased, because cAMP blocks the assembly of NADPH oxidase [165,166].

Various strategies are available to enhance the lung antioxidant screen in order to quench oxidants. One approach is to use specific spin traps such as α -phenyl-*N*-tert-butyl nitron to react directly with reactive oxygen and ROS at the site of inflammation. However, considerable work is needed to demonstrate the efficacy of such drugs *in vivo*. Antioxidants that have a double action, such as inhibition of lipid peroxidation and quenching of ROS, may be developed [167]. A further approach might be the manipulation of antioxidant genes, such as GSH peroxidase or the genes involved in the synthesis of GSH, such as γ GCS, or by developing molecules with activity similar to these antioxidant enzymes.

Effective oxidant therapy has been shown, at least in animal models, to reduce inflammation. Recombinant

Figure 32.8 The effect of recombinant superoxide dismutase (rhSOD) on cigarette smoke (CS) induced neutrophils, interleukin 8 (IL-8) gene expression and NF-κB binding in guinea pigs lungs. (From Nishikawa *et al.* [168] with permission.)

SOD treatment can prevent neutrophil influx into the airspaces induced by cigarette smoke. IL-8 release from air-space leucocytes induced by cigarette smoking is also decreased by SOD through a mechanism involving down-regulation of NF-κB (Fig. 32.8) [168]. This holds great promise if compounds can be developed with antioxidant enzyme properties that may be able to act as novel anti-inflammatory drugs by regulating the molecular events in lung inflammation.

A further therapeutic approach would be to administer antioxidant agents. This has been attempted in cigarette smokers using various antioxidants such as vitamins C and E. In general, the results have been rather disappointing, although the antioxidant vitamin E has been shown to decrease markers of oxidative stress in patients with COPD [169].

Attempts to supplement lung GSH have been made using GSH or its precursors [170]. GSH itself is not efficiently transported into most animal cells and an excess of GSH may be a source of the thiyl radical under conditions of oxidative stress [171]. Nebulized GSH has also been used therapeutically, but this has been shown to induce bronchial hyperreactivity [172]. The thiol cysteine is the rate-limiting amino acid in GSH synthesis [173]. Cysteine administration is not possible because it is oxidized to cystine, which is neurotoxic. The cysteine-donating compound *N*-acetylcysteine (NAC) acts as a cellular precursor of GSH and is deacetylated in the gut following oral administration to cysteine. This compound reduces disulphide bonds and has the potential to interact directly with oxidants. NAC also has mucolytic properties by reducing disulphide bonds in mucus. The use of NAC in an attempt to enhance GSH in patients with COPD has met with varying success [174,175]. NAC given orally in low doses of 600 mg/day to normal subjects results in very low levels of NAC in the plasma up to 2 h after administration [175].

NAC given in a higher dose of 600 mg three times daily for 5 days produced a significant increase in plasma GSH levels [174]. However, there was no associated significant rise in BAL GSH or in lung tissue [175]. These data may imply that producing a sustained increase in lung GSH is difficult using NAC in subjects who are not already depleted of GSH. In spite of this, several studies have shown that NAC reduces the number of exacerbation days in patients with COPD [176,177], although these results have not been confirmed in all studies [178].

Very recently, preliminary results of a large randomized controlled trial of NAC, 600 mg/day, in patients with COPD has been presented [179]. This study assessed the effect of NAC compared with placebo on the rate of decline in FEV_1 , on exacerbation rates and pulmonary function. Unfortunately, the design of this study resulted in a group of patients with mild to moderate COPD being studied with an FEV_1 of approximately 57% predicted. Indeed, 75% of the patients in this study had an FEV_1 greater than 50% predicted. In addition, 75% of the patients were already taking inhaled corticosteroids. The study did not show any significant effect of NAC on the rate of decline in FEV_1 , although there were significant improvements in FEV_1 , vital capacity and a reduction in functional residual capacity (FRC) as a measure of overinflation in severe COPD patients treated with NAC compared with placebo. There was no overall effect on exacerbation rates when the result of the whole group was analysed. However, in those patients who were not taking inhaled corticosteroids there was a significant fall in exacerbations rates from 1.33 to 0.99 per year (22% reduction), which was similar to the effects of inhaled corticosteroids on exacerbation rates in a moderate to severe group of COPD patients. These data suggest that there may be an effect of NAC on exacerbations rates and pulmonary function, at least in patients with severe COPD who are not already taking inhaled corticosteroids.

Nacystelyn (NAL) is a lysine salt of *N*-acetylcysteine. It is thiol antioxidant compound and a mucolytic that has a neutral pH in contrast to NAC, which is acidic. NAL can therefore be aerosolized into the lung without causing bronchial hyperreactivity [180]. Studies comparing the effects of NAL and NAC found that both drugs enhanced intracellular GSH in alveolar epithelial cells and inhibited hydrogen peroxide and superoxide anion release from neutrophils harvested from peripheral blood from both smokers and patients with COPD [181].

Molecular regulation of GSH synthesis, by targeting γ GCS, has great promise as a means of treating oxidant-mediated injury in the lungs. Recent work has shown that recombinant γ GCS in rat hepatoma cells completely protected against the TNF- α -induced activation of NF- κ B, AP-1 and apoptosis as well as inflammation [182]. Cellular GSH may be increased by increasing γ GCS activity, which may be possible by gene transfer techniques, although this would be an expensive treatment which may not be considered for a condition such as COPD. However, knowledge of how γ GCS is regulated may allow the development of other compounds that may act to enhance GSH.

Future perspectives

There is now good evidence for an oxidant-antioxidant imbalance in COPD, and increasing evidence that this imbalance is important in the pathogenesis of this condition. A major effect of oxidative stress is its role in the inflammatory response to cigarette smoke in the lungs through up-regulation of redox-sensitive transcription factors and hence proinflammatory gene expression. Inflammation itself induces oxidative stress in the lungs, and polymorphisms in genes for inflammatory mediators or antioxidant genes may have a role in the susceptibility to the effects of cigarette smoke. Knowledge of the mechanisms of the effects of oxidative stress should allow the development of potent antioxidant therapies which can be used to support the hypothesis that oxidative stress is involved in the pathogenesis of COPD, not only by direct injury to cells, but also as a fundamental factor in the inflammation in smoking-related lung disease.

CHAPTER 33

Cigarette smoke-induced disease

Stephen I. Rennard and Lisa M. Hepp

Cigarette smoking is the major cause of preventable mortality in the developed world, contributing to death from cardiac disease, stroke, pulmonary and extrapulmonary malignancy and chronic obstructive pulmonary disease (COPD) as well as other causes (Table 33.1) [1]. In addition, cigarette smoking contributes to a large number of other disorders that result in significant morbidity (see Table 33.1). Because cigarette smoking is the most important risk factor for the development of COPD, many smokers with COPD suffer from these allied conditions as comorbidities.

The mechanisms by which cigarette smoke causes disease are not fully delineated. It is likely, however, that overlapping mechanisms contribute to the multiple pathologies caused by cigarette smoking. Thus, for example, smokers with COPD are at increased risk for cardiac disease [2] and lung cancer [3] compared with similar smokers without COPD. This suggests a mechanistic connection among these conditions. The current chapter provides an overview of current thinking relating to the mechanisms by which cigarette smoke causes disease.

Cigarette smoke toxins

Several factors contribute to the complex mixture of chemicals present in cigarette smoke including the starting materials, the complex chemistry that results from the burning and heating of the cigarette and the individual way in which each cigarette is smoked [4]. A cigarette contains a blend of tobaccos that are wrapped in a paper. 'American blend' cigarettes include a mixture of burley, flue cured and oriental tobaccos, the composition of which depends on both their source and their processing. In addition, a variety of additives are included that influence the taste, aroma and potentially the delivery of nicotine [5]. When the cigarette is lit, the tip burns at a temperature of approximately 800°C. When air is inhaled through the cigarette the

temperature increases by an additional 100–120°C. As the heated air, mixed with the combustion products, is inhaled over the unburned tobacco, it rapidly cools, causing the nicotine and many other substances in the unburned tobacco to volatilize. These substances subsequently condense forming the smoke, which is an aerosol of liquid particles. One millilitre of fresh mainstream smoke contains approximately 4×10^9 particles with a mean diameter of approximately 0.2 μmol [6,7]. For analytical purposes, the components of smoke are divided into the 'particulate phase', which can be retained on a glass fibre filter, and the 'vapour phase', which is not. In general, approximately 90% of the mass of smoke is contained in the vapour phase [8].

The smoke breathed in during active smoking is mainstream smoke. The smoke that is produced by the burning of the cigarette that occurs between puffs is sidestream smoke. The constituents of sidestream smoke are generally similar to that of mainstream smoke, but the relative amounts can differ substantially. Environmental tobacco smoke (ETS) is a mixture of sidestream smoke and the components of mainstream smoke that are exhaled. The composition of ETS will be further modified as the components of smoke age and as they react with other components in the ambient air.

The particles present in mainstream smoke change in size and composition. Coagulation occurs as a function of density and time, resulting in a three- to fourfold increase in diameter over 2 s [4]. In addition, smoke particles can absorb water, resulting in a rapid twofold expansion in size in a completely humid environment. Even with these size increases, however, smoke particles are of the range likely to reach and be deposited in the alveoli [9]. The fraction of the various smoke constituents that is absorbed varies with their chemistry. For example, nicotine, which in the free base form is highly lipophilic, is essentially completely absorbed, while approximately 30% of inhaled solanesol may be exhaled [10].

Table 33.1 Diseases associated with cigarette smoking.

Lung disease	<i>Other tissues</i>	Febrile seizures
<i>COPD</i>	Oesophagus	Reduced intelligence
Emphysema	Pancreas	Behavioural disorders
Chronic bronchitis	Bladder	Atopic disease/asthma
Asthma	Uterine cervix	Effects on children of parental smoking
<i>Other lung diseases</i>	Kidney	Asthma
Idiopathic pulmonary fibrosis	Anus	Rhinitis
Histiocytosis X	Penis	Otitis
Respiratory bronchiolitis	Stomach	Pneumonia
Goodpasture's syndrome	Liver	Increased risk to smoke
Sleep apnoea	Leukaemia	Rheumatological disease
Pneumothorax	Gastrointestinal disease	Osteoporosis
Cardiovascular	<i>Peptic ulcer disease</i>	Rheumatoid arthritis
<i>Atherosclerotic vascular disease</i>	Gastric	Psychiatric
Coronary artery disease	Duodenal	Depression
Carotid vascular disease	<i>Gastro-oesophageal reflux</i>	Schizophrenia
Mesenteric, renal, iliac	<i>Chronic pancreatitis</i>	Oral disease
Abdominal aortic aneurysm	<i>Crohn's disease</i>	Periodontal disease
<i>Peripheral vascular disease</i>	<i>Colonic adenomas</i>	Loss of taste
Thromboangiitis obliterans (Berger's)	Dermatological disease	Loss of olfaction
Deep venous thrombosis	Skin wrinkling	Infectious disease
Pulmonary embolus	Psoriasis	Tuberculosis
<i>Cardiac disease</i>	Reproductive disease	Pneumococcal infection
Angina pectoris	<i>Ovarian failure</i>	Meningococcal infection
Coronary artery spasm	<i>Pregnancy related</i>	Endocrine disease
Arrhythmia	Prematurity	Altered hormonal secretion
Malignancy	Premature rupture of membranes	Graves' disease
<i>Respiratory tract</i>	Spontaneous abortion	Antidiuresis
Lung cancer	<i>Decreased sperm quality</i>	Goiter
squamous cell	<i>Fetal effects</i>	Renal
adenocarcinoma	Low birthweight	Glomerulonephritis
large cell	Impaired lung growth	Benign prostatic hypertrophy
small cell	Sudden infant death syndrome	Cataracts
Laryngeal cancer		
Oral cancer		

Smoke contains an estimated 4000–6000 chemical moieties in a large number of chemical classes (Table 33.2). The precise number is difficult to determine, as many of the most reactive, and potentially most toxic, components of cigarette smoke are very short lived. These compounds may be extracted from the unburned tobacco, as nicotine is, or may be generated from the burning of the tobacco, or from reactions that occur in the complex chemical milieu of the hot and cooling smoke. For example, nitric oxide is present in smoke, but quickly reacts to form nitrogen dioxide. These oxides can then react with methanol to form methyl-nitrite, which could be absorbed by a smoker, although it is not a component of 'fresh' mainstream smoke [4].

The compounds present in smoke depend on a large number of factors [11]. The puff volume and intensity [12], which will affect the temperature, the tobacco composition [13], the presence of additives [5] and the deposition of compounds that condense in the unburned tobacco from portions of the cigarette that are previously burned, can all contribute [4]. In addition, many cigarettes, particularly light and ultralight cigarettes, contain a filter with air vents. These air vents, if unblocked, will dilute the smoke stream with air. Partially blocking the vents, which a smoker can easily do by holding the cigarette by the filter, changes the mix and also the yield of compounds [14]. Several standard machine-based smoking methods have been developed to

Table 33.2 Classes of compounds present in fresh tobacco smoke. (From Borgerding & Klus [4] with permission.)

Class	Number
Neutral gases	> 5
Carbon oxides	2
Nitrogen oxides	1 (2)
Amides, imides, lactames	~ 240
Carboxylic acids	~ 230
Lactones	~ 150
Esters	~ 470
Aldehydes	~ 110
Ketones	~ 520
Alcohols	~ 380
Phenols	~ 280
Amines	~ 200
Volatile <i>N</i> -nitrosamines	4
Tobacco specific nitrosamines	4
<i>N</i> -heterocyclics	~ 920
Hydrocarbons, aliphatic, acyclic, aromatic	~ 760
Nitriles	~ 100
Anhydrides	~ 10
Carbohydrates	~ 40
Ethers	~ 310
Nitro-compounds	> 10
Metals	~ 30
Short- and long-living radicals	???

estimate cigarette yields. The Federal Trade Commission (FTC) method, which uses 2-s puffs of 35 mL volume every minute until a final butt length is reached and in which vents are not blocked, has been widely used to estimate yields [15,16]. However, many smokers smoke more intensely and/or block vents, resulting in potentially greater yields. Thus, while standard machine-smoking regimes may have utility for comparing cigarettes, they are limited in providing estimates of exposure for a smoker.

Laboratory methods that attempt to recapitulate 'real' smoking topography are also problematic for several reasons. First, the instruments required to monitor puff behaviour likely change the way smokers smoke. In addition, smokers will vary their smoking behaviour during a single cigarette [17] and from cigarette to cigarette [18]. Because these factors change the composition and yield of smoke constituents, it becomes very difficult to estimate real exposures to smoke. The same issues apply to the smoke used in animal and *in vitro* testing. The lack of standardized and validated smoking regimes complicates comparison of results, as differences in smoking regimes can influence the composition and likely the toxicity of the smoke.

Determining the constituents responsible for the toxicity of cigarette smoke has been a major research goal for

Figure 33.1 Direct and indirect injury due to smoke-derived toxins. Cigarette smoke contains multiple toxins that can directly damage tissues by a variety of mechanisms. Smoke can also activate cells that can result in indirect tissue damage. Mediators produced by inflammatory cells, in particular, are believed to have a major role in causing COPD.

many years. Compounds that have been suggested to contribute are listed (Table 33.3). As additional components are studied, it is likely this list will grow.

Oxidants

Many of the components present in cigarette smoke are potent oxidants, and oxidant injury is believed to be a major mechanism for cigarette smoke-induced toxicity [19]. It has been estimated that cigarette smoke contains approximately 10^{14} free radical oxidants per puff [4]. Most of these are expected to have half-lives of fractions of a second. Despite this, cigarette smoke contains some free radicals that have lifetimes of several minutes [20]. A steady state chemical model, involving the reaction of nitrogen dioxide and polymers containing semi-quinones [21], has been suggested to be responsible for the long-lived oxidants present in smoke. In addition, the inflammatory cells that are recruited and activated by cigarette smoke also produce oxidants [19]. Thus, cigarette smoke may be able to cause oxidant injury both as a direct toxicity and indirectly through the inflammatory response (Fig. 33.1).

It is likely that there are many important targets for oxidant-mediated damage in the lung including lipids, proteins and nucleic acids. Oxidation of arachidonic acid containing lipids, for example, can lead to the generation of isoprostanes that can, in turn, function as proinflammatory molecules [22,23]. Increased levels of isoprostane are present in the urine of smokers and can be reduced by oral antioxidants [24]. Cigarette smoke also can induce oxidation of low-density lipoproteins [25], which is believed to be a major pathogenic mechanism in the development of atherosclerotic vascular disease [26]. Smoke-induced oxidation of methionyl residues in α_1 -protease inhibitor can

reduce its ability to inhibit neutrophil elastase and could shift the protease–antiprotease balance in favour of tissue destruction [27,28]. In addition, smoke-derived oxidants can activate nuclear factor $\kappa\beta$ (NF- $\kappa\beta$) [29] and activator protein-1 (AP-1) [30], thus activating inflammatory pathways. Finally, cigarette smoke-derived oxidants can also lead to DNA damage [31,32].

A variety of oxidants are present in cigarette smoke, and they can react with target molecules in a number of ways. For example, reactive nitrogen species, particularly peroxy-nitrite, which is formed from nitric oxide and superoxide, can oxidatively nitrate proteins at tyrosine residues [33]. Because tyrosyl residues are important in regulating the function of many proteins, either directly or by serving as substrates for phosphorylation, their nitration is likely to greatly alter function. Consistent with this, reactive nitrogen species inactivation of a variety of proteins has been reported [34,35]. Because oxidants are not the only components in smoke that can damage lipids, proteins and DNA, it is likely that the molecular injury that results from oxidants is compounded and potentially amplified synergistically by other toxins.

Aldehydes

Smoke contains a large number of reactive aldehydes that can also adduct proteins and nucleic acids, thus leading to potentially complex toxicities. For example, both acetaldehyde [36] and acrolein [37] have been demonstrated to have direct genotoxic effects. In addition, acetaldehyde can form adducts with tubulin and dynein and can lead to inactivation of cilia beating in airway epithelial cells [38]. Acetaldehyde can also form adducts with the lipid peroxidation product malondialdehyde leading to complex adducted proteins [39], which can potentiate inflammatory responses through protein kinase C mediated mechanisms [40]. Acrolein, in contrast, has been reported to inhibit inflammatory [41] and immune responses [42]. Finally, both acrolein and acetaldehyde have been reported to inhibit lung fibroblast and airway epithelial cell chemotaxis and proliferation [43–45]. Smoke, which contains relatively large concentrations not only of acetaldehyde and acrolein, but other reactive aldehydes as well, is likely to exert toxic effects through these moieties.

Metals

Smoke contains a number of metals, and it is likely they contribute to smoke-induced disease. Iron contained in smoke, for example, can potentiate the generation of reactive oxygen species by catalysing the Haber–Weiss reaction [46]. Because the availability of iron may be limiting, the increased iron burden that is reported in the lungs of

smokers [47] may be a means for persistent generation of excess oxidants.

Among the other metals contained in smoke, evidence supports a role for cadmium in the pathogenesis of COPD. In this context, increased cadmium levels have been associated with reduced lung function in the National Health and Nutrition Examination Survey (NHANES) study [48]. In animal studies, cadmium can cause emphysema [49] and emphysema has been associated with industrial cadmium exposures [50,51]. Although the mechanisms by which cadmium can cause emphysema are undefined, cadmium has been reported to impair several fibroblast-mediated repair responses including proliferation [52], matrix macromolecule production [53] and matrix contraction [54]. Cadmium can activate a number of genes that influence not only inflammation, but potentially repair as well [55]. This suggests that cadmium may cause emphysema, at least in part by altering both tissue injury and repair. An oxidant-dependent mechanism for cadmium toxicity has also been suggested [56], further supporting the notion that cigarette smoke-derived toxins can interact in causing their toxic effects.

Mutagens

Cigarette smoke can also cause a variety of types of DNA damage including point mutations, strand breaks and chromosomal alterations [57]. Smoking is a major cause of cancer, and DNA damage has been most widely studied in the context of carcinogenesis. In this regard, whole smoke and both the particulate and the vapour phases are reported to contribute to carcinogenesis. Smoke, moreover, contains more than 60 compounds that are identified as carcinogens in at least some systems [58]. It is likely that this list will grow as additional compounds are studied. Some, such as the polycyclic aromatic hydrocarbon benzo[a]pyrene (BaP), the tobacco-specific nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) and 1,3-butadiene have been relatively extensively studied. The first two cause lung tumours in rats and mice, but the last in only mice [59]. This difference likely arises from species differences in xenobiotic metabolism and underlies a major issue in the assessment of carcinogens in smoke; metabolic differences greatly influence the carcinogenic potential. This results in marked species differences and likely also contributes to differences in human sensitivity to specific compounds [57].

The mechanisms that lead to DNA mutations are incompletely defined. Oxidants can damage DNA and reactive aldehydes can form adducts with DNA, and both processes can lead to mutations. Many of the other chemical carcinogens are also able to form adducts with DNA [59]. It is likely that formation of chemical adducts leads to activation of

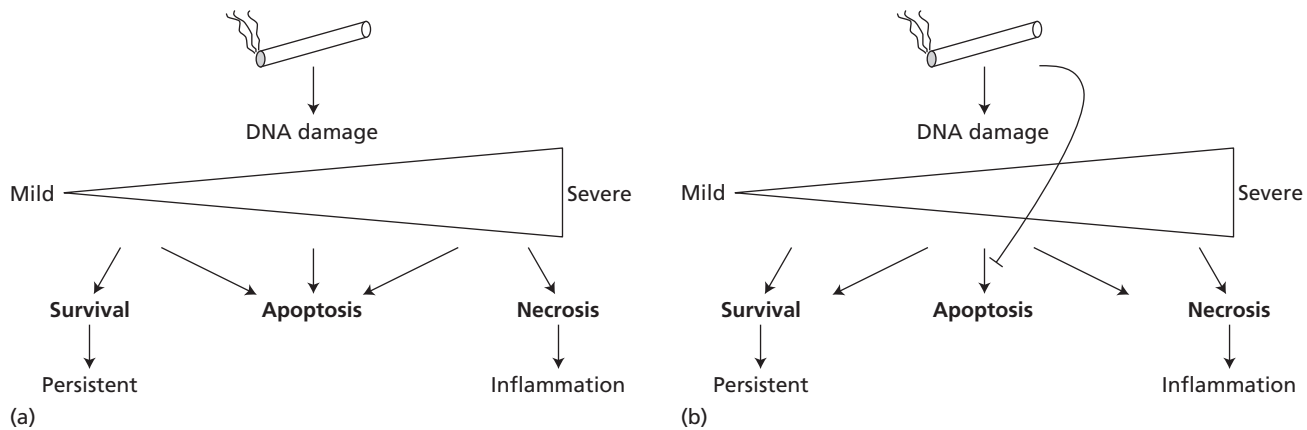

Figure 33.2 Smoke induced DNA damage: consequences. (a) Cigarette smoke can damage DNA by several mechanisms. If mild, this damage can be repaired and cells can survive, although with a risk of persistent DNA mutation. If moderate, apoptotic mechanisms are activated. These lead to cell death, which prevents mutations from persisting and, moreover, results in clearance of the cells without activation of inflammatory mechanisms. If severe, DNA damage can lead to necrosis which can activate inflammation. (b) Smoke also inhibits apoptosis. In so doing, some cells that would have been cleared by apoptosis will survive, leading to persistent mutations. Others will die by necrosis leading to increased inflammation.

DNA repair mechanisms and, if incomplete or incorrect repair results, mutations arise. Specific adducts are thought to lead preferentially to certain specific types of mutations. For example, BaP and NNK produce GC to TA mutations. BaP has been suggested to bind preferentially to sites in the DNA that contain endogenously methylated cytosine-guanine (CpG) dinucleotides [60]. These sites, therefore, represent potential 'hot spots' for BaP-induced mutagenesis. In this context, the *p53* gene is an important regulator of cell survival and replication. It is frequently mutated in lung and other types of cancer. GC to TA mutations are present more commonly in smokers with lung cancer than in non-smokers with lung cancer [57] and these *p53* mutations, moreover, occur selectively at 'hot spots' in the gene that contain methylated CpG sites [60], supporting the concept of sequence sensitivity to individual cigarette smoke component-induced mutagenesis. Interestingly, bladder cancers, which are also associated with cigarette smoking but are believed to result from aromatic amines, are associated with a distinct but different pattern of *p53* mutations, suggesting sequence selectivity in carcinogen induced DNA damage.

Acquired somatic cell mutations, which are likely to occur throughout the lung epithelium, are widely accepted as a likely mechanism for cigarette smoke-induced lung cancer. The suggestion has recently been made that similar somatic cell mutations may also contribute to the pathogenesis of COPD [61]. In support of this concept, microsatellite instability, which is believed to result from mismatch repair, is more frequent in patients with COPD [62]. When DNA damage occurs, repair mechanisms may attempt to correct the defect. Alternatively, in the face of excessive damage, apoptotic mechanisms are activated that

lead to cell death, but are thought to protect the genome of the organism. The DNA damage induced by cigarette smoke can, under some conditions, lead to apoptosis [63,64]. However, smoke can also initiate antiapoptotic mechanisms. These may lead to cellular necrosis [65], which could initiate inflammation or, alternatively, may result in DNA repair and cell survival [66,67] (Fig. 33.2). Through such mechanisms, smoke exposure may be a particularly effective means to damage DNA and lead to the subsequent survival of cells with acquired mutations.

Smoke-induced inflammation

Cigarette smokers characteristically have a prominent inflammatory response. This includes the accumulation of pigment-laden macrophages within the lower respiratory tract, a condition termed 'small airways disease' [68,69]. Bronchoalveolar lavage studies reliably demonstrate a marked increase in the number and state of activation of alveolar macrophages obtained from smokers [70,71]. In addition, there are more modest increases in neutrophils in the lower respiratory tract together with an alteration in the distribution of lymphocytes. Specifically, CD8 lymphocytes are increased relative to CD4 lymphocytes, resulting in an increase in the CD8 : CD4 ratio [72]. This alteration resulting from smoking is of particular interest as an increase in CD8 cells is a feature of COPD that increases with disease severity [73,74].

In addition to an inflammatory response in the lung, cigarette smokers have a characteristic systemic inflammatory response. A 20–25% increase in peripheral blood

neutrophils is observed in smokers, which correlates with the degree of loss of lung function [75,76]. Activation of the bone marrow leading to increased production of neutrophils has been suggested as a mechanism to account for neutrophilia in smokers [77]. Smoke exposure also leads to neutrophil priming that can occur even at levels encountered with environmental tobacco smoke exposure [78]. Neutrophils of smokers are less deformable than control neutrophils [79] and smoking results in selective retention of neutrophils within the lung where they may cause damage from an intravascular site [80]. Other evidence supporting systemic inflammatory response in smokers includes elevated C-reactive protein and fibrinogen [81] as well as evidence of endothelial cell dysfunction [82]. The ability of cigarette smoke to stimulate local pulmonary and systemic inflammation is believed to be a major pathogenetic mechanism in leading to pulmonary and extrapulmonary disease. Of interest is the fact that the vast majority of smokers have evidence of augmented inflammation although smaller numbers manifest clinically significant disease.

The mechanisms by which cigarette smoke induces inflammation are also multiple (Fig. 33.3). Cigarette smoke can activate complement through the alternate pathway leading to the generation of C5a, which can serve as a chemotactic factor driving the recruitment of inflammatory

Figure 33.3 Activation of inflammation by cigarette smoke. Cigarette smoke can induce inflammation by a variety of mechanisms. Smoke activates several cells in the lungs. Resident macrophages and epithelial cells are believed to be most prominent as initial responders to smoke. Both can directly release chemotactic factors that can recruit and activate other inflammatory cells. They can also activate each other. Smoke also activates the cell independent complement system. This leads to generation of C5a, which can recruit inflammatory cells and can synergistically augment the activation of epithelial cells. Smoke also blocks part of the down-regulatory mechanisms that serve to control complement activation. (See text for details.)

cells [83]. In addition, the activity of C5a can be potentiated by the vitamin D binding protein Gc globulin, the activity of which can itself be inhibited by a molecule termed chemotactic factor inactivator (CFI) [84]. Cigarette smoke can inactivate CFI, thus leading to potentially augmented activity of C5a [85]. In addition to its direct chemotactic activity, C5a can also interact with receptors located on airway epithelial cells and, by this mechanism, can further potentiate inflammation [86].

Cigarette smoke is also able to directly activate a variety of cells to release proinflammatory molecules. Although it is likely that several mechanisms could account for such activity, evidence has been provided in support of an oxidant-mediated mechanism [87]. Specifically, it has been suggested that cigarette smoke-derived oxidants can activate NF- κ B [88], although the importance of this mechanism has also been questioned [89]. However, the presence of oxidants is thought to lead to or to facilitate the degradation of inhibitor κ B (I κ B), which ordinarily inhibits the activity of the transcription factor NF- κ B. In the absence of its inhibitor, NF- κ B binds to DNA leading to the activation of a number of proinflammatory genes. Through this mechanism cigarette smoke is believed to induce the production of a variety of proinflammatory molecules including, for example, the chemotactic factor interleukin 8 (IL-8) from airway epithelial cells. Oxidant-dependent activation of AP-1 has also been reported to activate cells to produce proinflammatory mediators [87,90]. Interestingly, C5a interacts synergistically with cigarette smoke in inducing epithelial cell release of IL-8 [91–93]. This suggests that cigarette smoke, by acting through multiple pathways, can lead to dramatically augmented proinflammatory signalling.

Several cell types within the lung can be activated to produce inflammatory mediators in response to cigarette smoke. Smoke can activate both alveolar macrophages and airway epithelial cells [94–96] to release a variety of chemotactic factors and inflammatory mediators. Inhibitory effects of cigarette smoke have also been reported [97,98]. It seems likely that the effects of smoke will depend on the experimental design used and, very likely, on the methods used to prepare the cigarette smoke. As these can vary considerably, depending on methodology, it is not surprising that there are some differences between studies reported. Because differences in smoke composition are likely among smokers, these results suggest that cigarette smoking may lead to heterogeneous inflammatory responses that may depend on differences in specific exposures. Undoubtedly, these variations will be further increased by genetic and other differences among smokers.

The inflammatory cells recruited and activated by cigarette smoke are capable of inducing tissue damage through a number of mechanisms. Inflammatory cells are potent sources of oxidants, and the oxidant burden caused

by inflammatory cells can damage protein, lipid and nucleic acid components within the lung. At present, it is difficult to determine if oxidant-induced damage results directly from cigarette smoke-derived oxidants or indirectly from cigarette smoke-induced inflammatory cell generation of oxidants. However, as the capacity of inflammatory cells to produce oxidants greatly exceeds the oxidants contained in cigarette smoke, it is likely that inflammatory cell amplification has a significant role [19].

Inflammatory cells also produce proteases and toxic peptides that can damage cells and tissues within the lung. The production of proteolytic enzymes in excess of the antiprotease defences is believed to have a major role in the pathogenesis of emphysema, the so-called 'protease-antiprotease' hypothesis (see Chapter 31). This concept, which originated with the observations that individuals with deficiency in the α_1 -protease inhibitor developed emphysema [99] and that neutrophil elastase, a serine protease inhibited by α_1 -protease inhibitor, induced emphysema when instilled in the lungs of animals [100], has now been extended to include a number of other serine, metallo and cysteine proteases and their respective inhibitors [101, 102]. Interestingly, these inhibitors interact in a complex network. Many are released as precursors that can be activated by other proteases. In addition, metalloproteases and serine proteases are capable of inactivating each other's inhibitors. Cigarette smoke can affect this complex network in several ways. By inducing the recruitment in activation of inflammatory cells, the protease burden can be increased. In addition, cigarette smoke can oxidatively inactivate α_1 -protease inhibitor resulting in an acquired deficiency of antiprotease [28]. Because α_1 -protease inhibitor may also

play a key part in inactivating toxic peptides such as defensins [103], the ability of cigarette smoke to inactivate α_1 -protease inhibitor can have several effects leading to augmented tissue damage in the face of an inflammatory burden.

Tissue repair

Cigarette smoke not only leads to tissue damage, but it can also compromise tissue repair mechanisms (Fig. 33.4) [104]. In this context, the lung, like most tissues, has considerable capacity to repair following injury. Mechanical injury of the airways, for example, is followed by migration of epithelial cells to cover the epithelial defect, a process that is initiated within minutes [105,106]. This is followed by an orderly recruitment, proliferation and differentiation of cells within the epithelium. A similar process of recruitment proliferation, production of provisional matrix and eventual resolution takes place in the subjacent mesenchyme [107]. If these processes proceed effectively, tissue structure and function can be completely restored. Cigarette smoke is capable of inhibiting both epithelial cell [45,108] and mesenchymal cell [44] recruitment, proliferation, matrix production, matrix remodelling and apoptosis [66,67]. It is likely therefore that the altered tissue structure that is characteristic of the lungs of smokers results not only from smoke-induced tissue damage, but also from smoke-induced alterations in tissue repair mechanisms. Altered tissue repair likely contributes not only to the lesions present in the airways of smokers, but also to emphysematous changes within alveolar structures and to the vascular changes present within both the pulmonary parenchyma and the airways.

Figure 33.4 Injury of the airway epithelium is followed by an orderly sequence of events that can restore structure and function. These include epithelial cell recruitment, proliferation and differentiation. Similar events take place somewhat later in the subjacent mesenchymal tissues. Cigarette smoke has been demonstrated to inhibit many of these processes, indicated by the 'cigarette' in the figure. It is likely that cigarette smoke will alter epithelial cell differentiation as well. By altering repair, smoke could contribute to the structural changes that take place in the airway or in the alveolar walls in COPD. Smoke can also alter vascular repair (not shown).

Conclusions: common disease mechanisms

Cigarette smoke is a major causative factor for many conditions (see Table 33.1). As a result, individuals who have cigarette smoke-induced COPD frequently also have other smoke-related conditions as comorbidities. Individuals with COPD are more likely to have atherosclerotic vascular disease [2], lung cancer [3] and osteoporosis [109] than are individuals with similar smoking histories who do not have COPD. There are a number of mechanisms that could explain the increased comorbidity present in COPD patients. One mechanism is that systemic inflammatory consequences of COPD contribute to these allied conditions. An alternative mechanism is that COPD and its allied conditions result from similar toxic effects of cigarette smoke. As variations in individual susceptibility to the toxic effects of smoke are likely, individuals at increased risk for the development of COPD may also be at increased risk for other conditions. Understanding the mechanisms by which cigarette smoke toxicity leads to the panoply of diseases associated with smoking offers the opportunity to develop new strategies to address these diverse conditions.

CHAPTER 34

COPD and air pollution

Kenneth Donaldson, Andrew Churg and William MacNee

Although cigarette smoking is clearly the major cause of COPD, the lungs of those with COPD are, like everyone's, exposed to such polluting particles and gases as are present in their general environment. There is evidence that levels of harmful air pollutants in the general environment can reach levels high enough to both cause and exacerbate disease, in many instances through mechanisms that are well understood [1]. The predominant mechanism that initiates proinflammatory gene expression in COPD is oxidative stress [2]. The gases and particles in air pollution are also known to cause oxidative stress and inflammation and so some additive impact of air pollution in smokers is to be anticipated. Substantial epidemiologic research has confirmed that there is increased incidence of COPD in more polluted areas, suggesting a chronic effect of pollution. There are clear links between short-term increases in pollution levels and exacerbations of COPD, suggesting an acute effect in some individuals. Air pollution also affects the cardiovascular system in ways that are not well understood, but it has been hypothesized that the mechanisms may involve oxidative stress and inflammation. This chapter outlines the evidence in support of the above, especially relating to the underlying mechanisms.

Air pollutants

The principal types of air pollution found in urban atmospheres are shown in Table 34.1. The impacts of air pollution are best described in conurbations where the levels of air pollutants are higher than in rural settings and where there are more people exposed and so the effects are more likely to be detected.

The major components of modern air pollution monitored by most agencies are particles (PM_{10}), ozone, SO_2 and NO_2 , although there are others. Of these, particulate material (PM), and ozone are present at levels where they

Table 34.1 The principal types of air pollution found in urban atmospheres.

Pollutant	Sources
Particles	Motor vehicles, industry, burning of fossil fuels, atmospheric chemistry, biomass cooking
Ozone	Photochemical reaction of nitrogen oxides and hydrocarbons released by motor vehicles and industry
Nitrogen dioxide	Automobile fuel combustion; fossil fuel combustion
Sulphur dioxide	Domestic homes and power stations burning fossil fuels; industry
Other air pollutants less likely to be involved in COPD	Volatile organic compounds, heavy metals, polycyclic aromatic hydrocarbons, fungal products; but note that some of these can be associated with the particle fraction and so may have a role in the effects of PM_{10}

are likely to cause harm as identified in epidemiological and chamber studies, although other components could be relevant in some situations. Both particles and ozone are powerful oxidative stressors although they operate by different pathways to generate harmful free radicals. The other gaseous components of the air pollution mix are also capable of producing oxidative stress either directly or indirectly. PM has received special research attention because of the fact that in several epidemiologic studies there is no threshold for its adverse effects suggesting that, even at the 'normal' levels experienced in cities these adverse effects are occurring. For these reasons and because of the experience of the authors, this review is confined

to the effects of PM in COPD. However, the mechanisms described are likely to be relevant to any oxidizing pollutant.

Particulate material

Sources

Particles such as sea salt and windblown and re-entrained dust from natural attrition processes in the Earth's crust arise naturally, and become part of the air pollution particle cloud. Anthropogenic particles, arising from motor vehicles industry and other human activities, add substantially to the concentration of particles in the cloud especially in cities. In addition, complex environmental chemistry gives rise to particles and, no doubt, modifies existing ones. Therefore the ambient particle cloud is a complex mixture comprising organic matter, elemental carbon or soot, metals, chlorides, sulphates, nitrates and geologically derived crustal dust [3]. Particles can be classified as *primary*, formed immediately (e.g. diesel particles), or *secondary*, those particles that form from atmospheric chemistry (e.g. ammonium nitrate) [4]. Not all of the different particles present in the ambient cloud are considered to have equal potency in causing adverse effects. Secondary particles and crustal particles are generally considered to be less potentially harmful than primary combustion-derived particles. Combustion particles, such as diesel particles, can be heterogeneous, with a carbon core plus associated metals and organics derived from the incomplete combustion of fuel or engine oil. Particles may be agglomerated, with individual particles adhering together more or less tightly.

Particle measurement and deposition in the lungs

Particles deposit in the different parts of the bronchial tree depending on their aerodynamic diameter [5] and this forms the basis of health-related size-based sampling of PM in the air, which forms the regulatory basis for control of ambient particles. The PM_{10} sampling convention is a mass measure where particles of $10\ \mu\text{m}$ are collected with 50% efficiency and is increasingly efficient for smaller particles and less efficient for larger particles; it roughly corresponds to the thoracic fraction of particles as defined by the International Organization for Standardization (ISO) [5]. The $PM_{2.5}$ convention captures particles of $2.5\ \mu\text{m}$ with 50% efficiency and roughly corresponds to the respirable fraction of particles as defined by ISO [5]. Therefore, PM_{10} describes the mass of particles that deposit throughout the airways, while $PM_{2.5}$ more accurately describes the mass penetrating beyond the ciliated airways to the sensitive centriacinar region; both conventions are expressed as $\mu\text{g}/\text{m}^3$. The European (EC) standard for PM_{10} is currently $50\ \mu\text{g}/\text{m}^3$ (24 h daily average) allowing 35 exceedences per year, but is under review. Deposition depends on aero-

dynamic diameter and is independent of composition, except that it depends on density, but once deposited the fate and effects of the particle depends on its composition. Salts such as nitrates and sulphates may dissolve and be relatively invisible to the lungs, but if the particles, for example, release transition metals that undergo Fenton chemistry, then hydroxyl radicals may be produced. If the ubiquitous bacterial product endotoxin is present in association with the particles, then lung cells may be stimulated to produce inflammation. All of these effects may lead to oxidative stress.

Epidemiologic studies of PM and COPD

PM and the incidence of COPD

There is evidence to suggest that chronic exposure to high levels of PM may not only exacerbate pre-existing COPD, but may also cause chronic airflow obstruction, although the number of reports examining this issue is limited [6]. Abbey *et al.* [7–10] studied a cohort of nearly 4000 non-smoking Seventh Day Adventists in Southern California and found significantly increased risks for the development of new cases of chronic bronchitis and COPD that were associated with increased levels of exposure to ambient PM_{10} and $PM_{2.5}$ [7,8]. Symptom severity correlated with $PM_{2.5}$ and PM_{10} levels. Long-term increases in PM_{10} concentrations were also found to be associated with greater forced expiratory volume in 1 s (FEV_1) decrements [9] as were increases in mortality from non-malignant lung disease [10]. However, one of the peculiarities of these results was that they largely applied to males, with little or no effect observed in females.

Somewhat similar results were obtained in the UCLA-CORD study [11,12], which examined lung function changes over time in three areas of Southern California. In men, FEV_1 declines were found to be significantly greater in both smokers and non-smokers in the region with the highest levels of particulate pollutants (Long Beach), nitrogen oxides and sulphates, but smoking appeared to account for the majority (approximately 70%) of the decline. In women, effects were only seen in never-smokers. Of interest, no chronic effects were seen in the UCLA-CORD study in the region in association with high levels of ozone (Glendora).

A number of other, largely cross-sectional, studies have been performed, consistently reporting that increased levels of air pollutants are associated with greater apparent declines in FEV_1 and/or forced vital capacity (FVC). However, there are differences in the pollutants that seem to be most important; some studies report associations with PM_{10} or total suspended particulates whereas others only find associations with levels of sulphates or acid [6].

All of these studies suffer from a number of methodological

problems [6] and, as noted, there is no consistent correlation with a specific type of pollutant. Nonetheless, there do seem to be reasonably good data to suggest that chronically elevated levels of air pollutants, including PM, can produce COPD.

Similar results have been found in women in developing countries who are exposed to the very high levels of PM emitted from cooking with biomass fuels. Perez-Padilla *et al.* [13] performed a case-control study of Mexican women and reported an increased risk of chronic bronchitis and chronic airflow obstruction associated with cooking with wood; the risk of chronic bronchitis was linearly associated with hours/year of cooking with biomass fuels. Dennis *et al.* [14] came to a similar conclusion examining women in Colombia who cooked with biomass fuels. Cooking with biomass fuels, particularly indoors, produces very high PM exposures [15,16].

PM and COPD mortality

Schwartz [17] noted that the relative risk of death from COPD increased by 1.25 on days when the PM₁₀ averaged 141 µg/m³ compared with low pollution days when the pollution averaged 47 µg/m³. Both PM₁₀ and total suspended particulate (TSP) were associated significantly with respiratory mortality, including COPD, in Detroit, Michigan for the 1985–90 period. Relative risk (RR) estimates of 1.123 were reported for PM₁₀ and 1.109 for TSP per 5–95th percentile increment [18]. In Barcelona, levels of PM₁₀ but not gaseous pollutants were associated with mortality in COPD patients after adjusting for meteorologic variables and influenza epidemics, with an odds ratio of 1.11 for the interquartile difference [6]. The RRs of death in COPD patients in Hong Kong were 1.017 for an increase of 10 µg/m³ PM₁₀ and 1.034 for ozone and a dose-response effect was evident [19]. In the Netherlands, statistically significant associations between air pollution and mortality in COPD patients were found in the age category of 65 years and above. Significant associations with ozone were found for COPD mortality in those less than 65 years [20].

PM and exacerbations of COPD

Hospital emergency room visits for COPD were studied in Barcelona [21] in relation to temporal trends in air pollution, and a reduction of 50 µg/m³ in particles was accompanied by a reduction of approximately 6% in emergency room visits for COPD. Morgan *et al.* [22] studied hospital admissions in Sydney, Australia, 1990–94 and demonstrated that an increase in daily maximum 1-h particulate concentration from 10th to 90th percentile was associated with an increase of 3.01% (95% confidence interval, 0.38–6.52) in COPD admissions. In a prospective study [23], 40 subjects with COPD, who lived within a 5-km radius of the regional council's air pollution monitoring site, com-

pleted symptom diaries twice daily for 3 months during the winter of 1994. Although the pollution levels were low in that year, a rise in the PM₁₀ concentration equivalent to the interquartile range was associated with an increase in night-time chest symptoms. The association between air pollution and hospital admissions for COPD was investigated in Minneapolis-St. Paul and Birmingham, Alabama for the period 1986–91 [24]. PM₁₀ was associated with hospital admissions but could not be singled out as being more important than SO₂ and NO₂ in this regard.

In the APHEA study [25], admissions for COPD in six European cities were examined. For all ages, the relative risk of admission to hospital for COPD for a 50-µg/m³ increase in black smoke was 1.04 (1.01–1.06) and for total suspended particulate was 1.02 (1.00–1.05). Wordley *et al.* [26] reported on hospital admissions in Birmingham, UK in relation to particulate air pollution and described a 10-µg/m³ rise in PM₁₀ as being associated with a 2.4% increase in respiratory admissions; while low, this risk was linear and without evidence of a threshold. Dab *et al.* [27] reported on the relationship between air pollution and hospital admissions in Paris, 1987–92. PM₁₀ and black smoke were associated with hospital admissions for all respiratory causes when the black smoke level exceeded its 5th percentile value by 100 µg/m³. Schwartz [28] related hospital admissions for the elderly in Birmingham, Alabama with air pollution levels. Inhalable particles were a risk factor for admission for COPD (RR 1.27; 95% confidence interval, 1.08–1.50). An increase of 25 µg/m³ black smoke produced adjusted changes of 6% and 9% in emergency room admissions for COPD in Barcelona during winter, although the change was smaller in the summer [29]. A study was carried out in Delhi, one of the 10 most polluted cities in the world, relating emergency room visits for exacerbations of COPD and air pollution. Over a 2-year period, the daily air pollution often exceeded national air quality standards and emergency room visits for COPD increased by one-quarter when the air pollution was significantly increased. The presence of air conditioning, resulting in lower pollution levels in homes, was reported to be a factor in reducing hospital admissions for COPD in the study of Janssen *et al.* [30].

Inflammatory effects of PM

There are many studies demonstrating acute proinflammatory effects of PM. The initiating mechanism for the proinflammatory effects of PM appears to involve the ability of the particles to generate oxidative stress as a result of various components such as transition metals, particle surfaces and organics. These cellular and molecular mechanisms are detailed in Donaldson *et al.* [31] and examples of the proinflammatory effects of PM are outlined in Table 34.2.

Table 34.2 Proinflammatory effects of particulate material (PM).

Effect	References
PM ₁₀ particles can generate oxidative stress in cell-free systems	32
PM ₁₀ causes oxidative stress and activation of oxidative stress-responsive signalling pathways in epithelial cells	33
PM ₁₀ causes synthesis and release of proinflammatory cytokines	34
PM ₁₀ causes pulmonary inflammation in laboratory animals	35
PM ₁₀ causes inflammation in humans exposed to CAPS by inhalation or instilled with soluble components	36

CAPS, concentrated ambient particles.

Mechanism of inflammatory effects

The cellular signalling pathways leading to proinflammatory gene expression that are activated following the encounter between lung target cells and PM are partially understood and involve oxidative-stress responsive mechanisms; these pathways are shown in diagrammatic form in Figure 34.1. There have been a number of studies into the effects of PM₁₀ on the mitogen-activated protein kinase (MAPK)

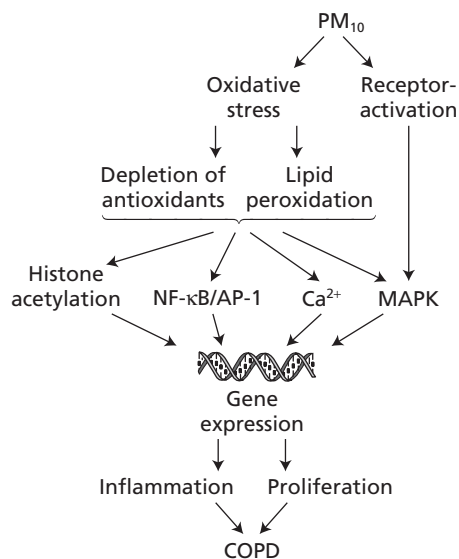

Figure 34.1 Diagrammatic representation of the hypothetical signalling pathways involved in the transcription of proinflammatory genes following exposure to PM₁₀. MAPK, mitogen-activated protein kinase; NF-κB, nuclear factor κB.

pathway. Timblin *et al.* [37] demonstrated increases in Jun N-terminal kinase (JNK) activity in alveolar epithelial cells exposed to PM and this was accompanied by increases in phosphorylated cJun and transcriptional activation of elements of the AP-1 transcription factor complex. These changes were accompanied by increased incorporation of 5'-bromodeoxyuridine, a marker of cell proliferation. Utah Valley PM caused increases in ERK1/2 phosphorylation via activation of the epidermal growth factor receptor (EGFR) [38]. Treatment of alveolar macrophages with residual oil fly ash (ROFA) demonstrated that JNK and p38, but not extracellular signal regulated kinase (ERK), were activated [39] while diesel exhaust particulates (DEP) activated p38 MAPK and induced interleukin 8 (IL-8) production in human bronchial epithelial cells [40]. The importance of transition metals in PM₁₀-induced nuclear factor κB (NF-κB) activation has been demonstrated by Jimenez *et al.* [33], who showed that PM₁₀ collected in the UK induced nuclear translocation, DNA-binding and transcriptional activation of NF-κB, which occurred in the absence of IκB degradation in human alveolar epithelial (A549) cells. Treatment of PM₁₀ with both deferoxamine and ferrozine, transition metal chelators with high affinities for Fe²⁺ and Fe³⁺, respectively, completely inhibited NF-κB activation. Furthermore, exposure of A549 cells to soluble fractions from phosphate-buffered saline-treated PM₁₀ activated NF-κB, indicating that soluble components such as metals or organic materials present on the surface of PM₁₀ are themselves capable of activating NF-κB. Kennedy *et al.* [41] reported that Utah Valley PM₁₀ enhanced NF-κB binding to DNA and IL-6 release from the bronchial cell line BEAS 2B by a copper-driven mechanism. Shukla *et al.* [42] reported that inhalation of PM_{2.5} in mice up-regulated several NF-κB-mediated genes including tumour necrosis factor α (TNF-α), IL-6 and transforming growth factor β. PM_{2.5} also enhanced transcriptional activation of a NF-κB-luciferase reporter in murine alveolar type II epithelial cells, which was attenuated in the presence of catalase. In the same study, ultrafine carbon black, a surrogate for the ultrafine fraction of PM₁₀ known to cause oxidative stress in lung cells [43] stimulated transcriptional activation of NF-κB.

DEP, an important constituent of air pollution, increased NF-κB activity and caused IκB degradation in human bronchial epithelial (16HBE) cells, responses abrogated by the hydroxyl scavenger dimethyl thiourea [44,45]. Benzene-extracted organic components of DEP and benzo[a]pyrene induced NF-κB activity in BEAS-2B cells concomitant with expression of proinflammatory genes [46].

Quay *et al.* [47], using ROFA, showed a time and dose-dependent increase in IL-6 mRNA which was preceded by NF-κB activation. ROFA particles also induced transcriptional activation of the IL-6 promoter, a response that was attenuated by transition metal chelation. Vanadium, a

transition metal component of ROFA, triggered both EGFR activation and Ras-dependent activation of NF- κ B [48,49]. In addition, the vanadium-induced NF- κ B activation was ameliorated by overexpression of the dominant negative Ras (N17), suggesting that vanadium stimulates NF- κ B through cross-talk with the EGFR signalling pathway at the level of Ras.

The AP-1 pathway is also stimulated by PM₁₀ via oxidative stress leading to proinflammatory and proliferative gene transcription [34].

We have demonstrated that PM₁₀ stimulates the activity of histone acetyltransferase as well as the level of acetylated histone 4 (H4), resulting in chromatin remodelling that allows transcription [50]. The enhanced acetylation of H4 was mediated by oxidative stress as shown by its inhibition with a thiol antioxidant. The acetylation of H4 mediated by PM₁₀ was associated with the promoter region of the IL-8 gene. PM₁₀- and trichostatin A (TSA)-mediated increases in IL-8 and histone acetylation were associated with increases in NF- κ B activation. These data suggest that the remodelling of chromatin by histone acetylation has a role in the PM₁₀-mediated proinflammatory responses in the lungs [50].
